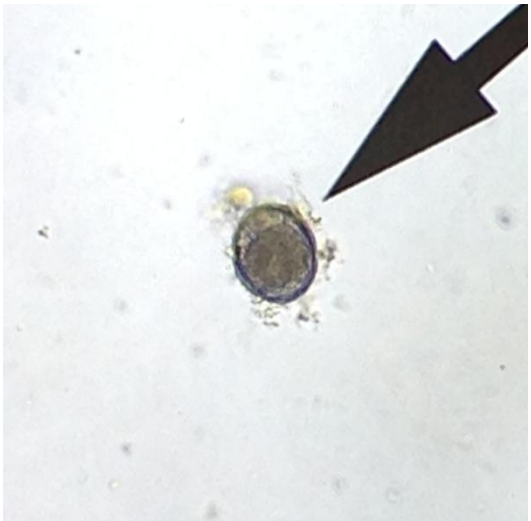
Appendix II: Parasite Eggs

Photographs of eggs found in feces through fecal flotation, as described in Chapter 2.



Three Large strongyle eggs in different stages of development; small strongyles were common but not photographed

Worm, most likely a hatched strongyle (Chacha, 6/30/13)

Possible *Strongyloides westeri* egg (Anastasia, 7/15/13)

Possible tapeworm egg (*Anoplocephala sp*) (Hedvig, 7/2/13)

Parascaris equorum eggs were also found, but not photographed.

Appendix III: Body Condition Scoring

As described in Chapter 2, each mare was given a body condition score from 1 to 5 based on the amount of fat in her rump. Commonly assigned scores are described below, with examples given.

Score	Description	Mare	Photograph
2	The rump takes on a concave shape from the spine to the point of the hip, which appears pointed above the rump.	Carrot	
3	There is a flat line of fat between the spine and the point of a hip, as if a book could be balanced on the surface of the rump.	Hiphop	

Score	Description	Mare	Photograph
3.5	In between a score of 3 and 4, the rump is longer a flat line but is not all the way rounded across the spine.	Keller	
4	The rump is rounded across the spine, like a dome.	Donoma	

Score	Description	Mare	Photograph
4.5	Above a score of 4, the rump begins to bulge above the spine on either side, shaped like an apple.	Shag	

Appendix IV: Recovery Based on Contraception Intensity

Numbers in parentheses designate the last year in the sequence of consecutive treatments. Mares that have more than one entry in the table are marked with *.

Consecutive years of treatment	Foaled after treatment period	Did not foal after treatment period
1	Carrot (2009) Hedvig (2009) Keller (2009) Wallace (2009)	Biff (2009) Bo (2005) Julikmi (2009) Kelty (2009) Noir (2009)

Received 7 February 2011; received in revised form 13 June 2011; accepted 16 June 2011

Abstract

The uncontrolled reproduction of free-roaming feral cats contributes to overpopulation and associated concerns regarding their welfare and impact on public health and the environment. Nonsurgical fertility control that could be administered to feral cats in the field would be a powerful tool for cat population control. The objective was to test the efficacy and duration of activity of a single-dose GnRH immunocontraceptive vaccine (GonaCon™) on the fertility of adult female laboratory cats. Vaccinated cats (n = 15) received a single injection of vaccine containing a GnRH-KLH conjugate (200 μg) emulsified in a mycobacterial and oil adjuvant on study Day 0. Sham-treated cats (n = 5) received a single injection containing all vaccine components except the GnRH-KLH conjugate. A breeding trial started on study Day 120. Vaccinated cats had a longer time to conception (median 39.7 mo) compared to sham-treated cats (4.4 mo; $P < 0.001$). A total of 93% of vaccinated cats remained infertile for the first year following vaccination, whereas 73, 53, and 40% were infertile for 2, 3, and 4 y, respectively. At study termination (5 y after a single GnRH vaccine was administered), four cats (27%) remained infertile. The GnRH antibody titers declined more rapidly in short-term responding cats with < 2 y of infertility (n = 4), compared to long-term responding cats that experienced fertility control for >2 y (n = 11) ($P < 0.05$). Non-painful but persistent late-onset granulomatous injection site masses appeared 2 y after initial vaccination in five cats. We concluded that GnRH immunocontraception is an ideal candidate for further development for feral cat control.

1. Introduction

Unowned free-roaming (feral) cats number in the millions nationally and exist throughout the world [1]. Their uncontrolled reproduction contributes to cat overpopulation and associated concerns regarding their impact on public health and the environment [2]. In parts of the world where progressive animal control resources are not available, measures such as poisoning and shooting are still used to control cats [3]. Surgical sterilization followed by return to the colony is an increasingly popular method of controlling feral cat populations, but is expensive, labor-intensive, highly technical, and limited in scale [4,5].

Nonsurgical fertility control that could be administered to feral cats in the field would be a powerful tool

doi:10.1016/j.theriogenology.2011.06.022

for cat population control. Control of free-roaming species is often aimed at the level of the population, rather than at specific individual animals. Treatment must be efficacious in a high proportion of the population, but it is not essential that every treated animal be rendered infertile. Feral cats are wary of humans, and once trapped and released, are unlikely to return for repeated trapping episodes. A practical fertility control technique for feral cats would induce permanent or multiyear duration of action following a single treatment in the majority of animals treated.

Vaccines aimed at reproductive targets are one approach to nonlethal control of overabundant free-roaming species. Overcoming tolerance to self antigens and induction of durable immunity without the use of repeated booster vaccines are substantial challenges for the development of immunocontraceptive vaccines. A commonly used contraceptive antigen in wildlife is the zona pellucida. In previous studies, we demonstrated that vaccinating against the zona pellucida was ineffective in preventing pregnancy in cats [6,7]. Subsequently, we showed in a short-term study that a single dose of GnRH vaccine in a mycobacterial and oil emulsion (GonaCon™) effectively blocked testosterone production and spermatogenesis for at least 6 mo in a majority of vaccinated adult male cats [8]. This was apparently the first report to suggest that fertility control may be achievable in cats following a single vaccination against a reproductive self antigen.

We hypothesized that long-term fertility control in cats can be induced by immunological blockade of GnRH activity. The purpose of this study was to test the efficacy and duration of activity of single-dose GnRH immunocontraception on the fertility of adult female cats.

2. Materials and methods

2.1. Cats

Twenty-four 8- to 14-mo-old specific-pathogen-free female domestic shorthair cats were acquired from a commercial vendor (Liberty Research, Waverly, NY, USA). Cats were group-housed in one large enriched room with raised resting benches, maintained at ambient temperatures between 21 and 23 °C, and exposed to controlled lighting (explained later). Food and water were available *ad libitum*. The experimental design was approved by the University of Florida Institutional Animal Care and Use Committee, and facilities were accredited by the Association for Assessment and Accreditation of Laboratory Animal Care. All cats and their offspring underwent surgical sterilization and were adopted to private homes at the conclusion of the study.

Upon arrival, the 24 cats were housed for 30 d in a photoperiod regimen (8 h light: 16 h dark) that is inhibitory for estrous cyclicity. Forty-six days prior to treatment (Day −46), the photoperiod regimen was reversed to 16 h light: 8 h dark, which is permissive for estrous cyclicity within 15 d in most cats [9,10]. In cats, behavioral estrus occurs in conjunction with elevated concentrations of estradiol-17β secreted by developing follicles. Progesterone concentrations rise significantly within 4 d after ovulation, regardless of whether or not fertilization has occurred [9,10]. Serum progesterone and estradiol-17β concentrations were measured on Day −64, and then every other day from Day −46 to Day −26. The magnitude and duration (Day > 20 pg/mL) of elevated estradiol-17β concentrations in each cat were used to confirm normal photoperiod sensitivity and estrous cyclicity in cats selected for this study.

2.2. Vaccine construction

A GnRH vaccine was constructed using a synthetic GnRH peptide with the sequence [pEHWSYGLRPGGC-SH] produced by the Fmoc/tBU protection method (Global Peptide Services, Fort Collins, CO, USA). Immunogenicity was enhanced by coupling GnRH peptides to a protein carrier, keyhole limpet hemocyanin (KLH; Pierce Biotechnology, Rockford, IL, USA), in a 1:3 GnRH:KLH mass ratio. The first 10 amino acids represent the native GnRH molecule and "pE" signifies pyroglutamate. One glycine was added at the C-terminus as a spacer and a cysteine was added to ensure consistent alignment of the peptide to the maleimide-activated KLH. The aqueous-based GnRH-KLH conjugate (200 μg) was combined in a 1:1 ratio by volume with an emulsifying adjuvant, AdjuVac™, which was produced by modifying a USDA-licensed Johne's disease vaccine containing inactivated *Mycobacterium avium* in mineral oil (Mycopar®; Fort Dodge Animal Health, Fort Dodge, IA, USA). This GnRH vaccine (GonaCon™, USDA, Pacarello, ID, USA) is licensed as a "restricted-use pesticide" for prevention of estrous cyclicity in white-tail deer.

2.3. Treatment

Twenty cats were selected for use in the GnRH vaccination study based upon estrus induction following an increase in light to 16 h per day. These 20 cats were randomized based upon a similar peak estradiol-

17β concentrations in response to long-day photoperiod into a sham treatment group (n = 5) and a vaccination group (n = 15). The sham-treated group received placebo injections containing all components except the GnRH-KLH conjugate. The treatment group received vaccines containing 200 μg GnRH-KLH. Vaccines were administered intramuscularly under general anesthesia. Brief anesthesia was induced by administration of isoflurane (IsoFlo®; Abbott Laboratories, North Chicago, IL, USA) by face mask. The hair of the right cranial thigh was clipped, and the injection site was cleaned with 70% isopropyl alcohol. The vaccine (0.5 mL) was injected into the quadriceps muscle group. This site was selected to avoid critical structures such as the sciatic nerve in the event of a vaccine reaction. This site is also accessible when cats are resting in a crouched position, making it one of the likely injection targets in nonsedated cats in the field. The right pinna was tattooed with a treatment code for permanent identification.

Potential reactions to vaccination were evaluated by daily physical examination, including inspection of the injection site, and measurement of body temperature for 1 wk following treatment. The injection site was inspected at the time of each monthly blood sample collection throughout the study.

2.4. Breeding trial

The effects of treatment on fertility were evaluated in a breeding trial beginning 4 mo after treatment and continuing until each cat became pregnant or until 60 mo post-treatment, whichever came first. The daily photoperiod was alternated between the estrus-inhibiting short-day regimen (16 h dark:8 h light) and the estrus-inducing long-day regimen (8 h dark:16 h light). The cats were exposed to short-day photoperiod from Days 0 to 120, and from Days 330 to 360 (8% of post-treatment time). For the remainder of the study, the cats were exposed to long-day photoperiod. The switch from short-day photoperiod to long-day photoperiod was intended to induce estrus in any of the cats that were capable of an estrous response. A breeding male was housed continuously with the females during the long-day photoperiods beginning on Day 120. Four breeding males were alternated, to reduce the chance that inter-cat behavioral incompatibility would affect breeding success. Time-lapse videography was used to monitor breeding activity during lighted hours. The recordings were reviewed daily and the number of attempted and successful breedings was recorded.

Time to conception was defined as the interval between treatment Day 0 and fertilization date, which was estimated by subtracting the average length of cat gestation (63 d) from parturition date. Fertility was defined as full-term pregnancy. Litter size was defined as the number of total births (live and stillborn). Fecundity was defined as the number of live births. Pregnancy was scored as a treatment failure, and the cats were removed from the study after parturition. Short-term response to GnRH immunocontraception was defined as fertility control for two y or less, whereas a long-term response was defined as fertility control lasting more than 2 y after the single vaccination.

2.5. Blood collection

Blood (4 mL) was collected by jugular venipuncture monthly into serum separator tubes for determination of GnRH antibody titer and progesterone concentration. In addition, blood was collected every other day during an interval of 20 d following change from short-day photoperiod to long-day photoperiod beginning on Days 120 and 360 (for determination of serum concentrations of estradiol-17β and progesterone). Serum was separated by centrifugation and stored at −20 °C pending analysis.

2.6. Detection of GnRH antibodies

Serum was tested for GnRH antibodies using an enzyme-linked immunoabsorbant assay (ELISA). The 96-well plates (Thermo Electron Corporation, Waltham, MA, USA) were coated with BSA-GnRH and blocked with PBS buffer containing steelhead salmon serum (SEA BLOCK; Pierce Biotechnology, Rockford, IL, USA). Cat serum was added to wells in two-fold dilutions starting at 1:1,000. Two negative controls (buffer without cat serum and pre-vaccination cat serum) and one positive control (serum from a cat with a known high antibody titer) were included on each plate. The GnRH antibodies were detected with goat anti-cat IgG (Sigma Chemical Co., St. Louis, MO, USA) followed by rabbit anti-goat IgG conjugated with horseradish peroxidase (Sigma Chemical Co.), and color development with tetramethylbenzidine/phosphate-citrate buffer (Sigma Chemical Co.). Sulfuric acid (2M) was added to each well to stop the reaction. Absorbance was read at 450 nm with a Dynatech MR 5000 ELISA plate reader (Dynatech Laboratories Inc., Alexandria, VA, USA). The endpoint titers were defined as the dilution at which the absorbance was twice the absorbance of the pre-vaccination cat serum.

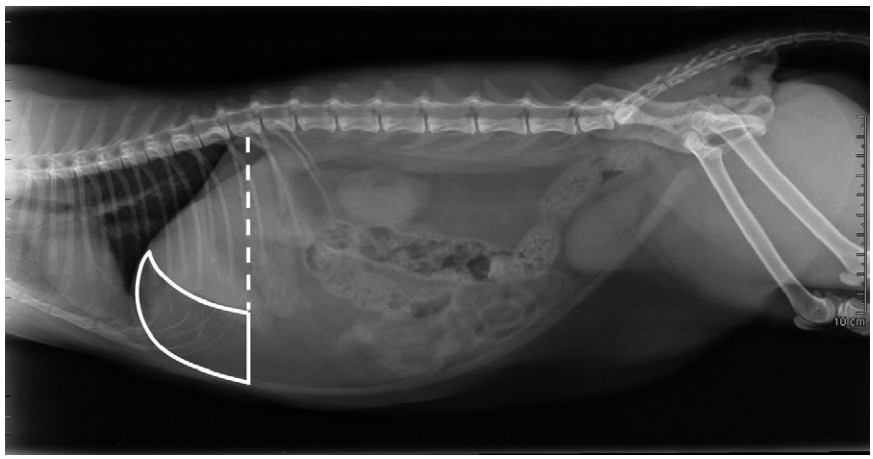

Fig. 1. The size of the falciform fat pad in female cats was assessed radiographically as an estimate of body fat content. The depth of the fat pad was measured at the level of the center of the T12 vertebral body (dashed line) from the ventral border of the liver to the ventral abdominal wall. The area of the fat pad was measured as the area confined by the ventral border of the liver, the caudal surface of the diaphragm, the ventral abdominal wall, and the line used for the depth of the fat pad measurement. The solid line shows the boundaries for measuring the area of the fat pad.

2.7. Determination of serum concentrations of estradiol-17β and progesterone

Serum samples were analyzed for total estradiol-17β and progesterone by radio-immunoassay (Coat-A-Count®; Diagnostic Products Corporation, Los Angeles, CA, USA) according to the manufacturer's instructions. In each run, controls included human serum with three concentrations of estradiol-17β (57, 127, and 934 pg/mL) and progesterone (1.78, 3.4, and 18.3 ng/mL).The manufacturer reports an assay sensitivity for estradiol-17β of 8 pg/mL with inter-assay CV (coefficient of variation) of 4 to 8% and intra-assay CV of 4 to 7%. Progesterone assay sensitivity was reported to be 0.02 ng/mL with inter-assay CV of 4 to 10% and intra-assay CV of 2 to 9%.

2.8. Body weight and composition

It has been well-documented that cats gain weight and percent body fat after ovariectomy [11,12], but it is unknown if immunocontraception has the same effect. To evaluate for this effect, an estimation of body fat was made by radiographic evaluation of the abdominal falciform fat pad on Day 420. Cats were sedated with medetomidine 40 mcg/kg IM (Domitor; Pfizer Animal Health, New York, NY, USA) and imaged in right lateral recumbency using computed radiography (Kodak, Rochester, New York, USA). The depth (mm) of the falciform fat pad was measured by dropping a perpendicular line from the center of the body of the 12th thoracic vertebra to the ventral body wall and measuring the distance between the caudoventral angle of the liver and the ventral body wall. The area (mm^2) of the fat pad was defined as the area outlined by the line used for the depth measurement, the ventral border of the liver, the caudal aspect of the diaphragm, and the ventral body wall (Fig. 1).

2.9. Statistical analysis

Differences in the median time to conception between the sham-treated group and the GnRH-vaccinated group were determined by the Kaplan-Meier survival analysis log rank test. Mean ± SEM were calculated for normally distributed data (monthly titers, body weight, fat pad measurements, litter size), and groups were compared with the Kruskal-Wallis one way ANOVA. Median and interquartile range (IQR) were calculated for non-normally distributed data (peak titer, titer at conception), and groups were compared with the Mann-Whitney rank sum test. Differences were considered significant when $P < 0.05$. All tests were performed using SigmaStat® statistical software, version 3.1 (SPSS Inc., Chicago, IL, USA).

3. Results

3.1. Reactions to treatment

Body temperature in all of the cats remained normal after treatment, and there was no inflammation or tenderness at the injection sites. One vaccinated cat died

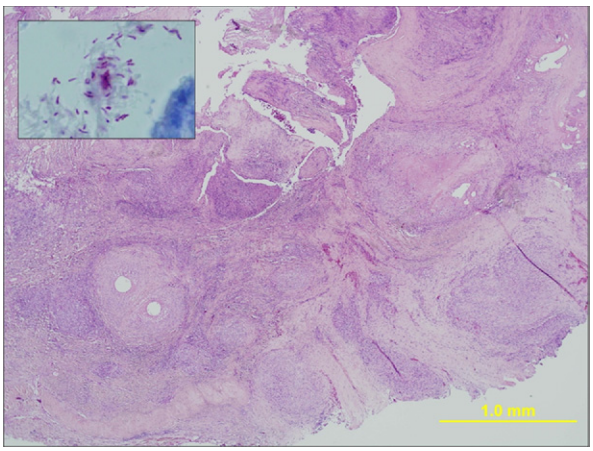

Fig. 2. Biopsy (stained with hematoxylin and eosin) of a subcutaneous injection-site nodule in a cat which appeared 24 mo following a single vaccination against GnRH. There was granulomatous inflammation, with acid fast bacilli evident within the lesion (inset). Five cats developed persistent late-onset, non-painful, injection-site nodules.

suddenly 45 d after treatment; necropsy revealed no gross or histological abnormalities to explain the death. This cat was replaced with a 2 y old cat of proven fertility from the colony and vaccinated with the GnRH vaccine according to the standard protocol.

Twenty-four months after immunization, it was discovered that one of the cats had a firm 4 cm × 5 cm mass at the vaccination site. No pain reaction was elicited on palpation of the mass. A biopsy revealed granulomatous inflammation with interlesional acid-fast bacteria (Fig. 2). Aerobic, anaerobic, and mycobacterial cultures were negative. Smaller single or multiple masses < 1 cm in diameter developed at the injection site of four other cats. The size of the masses in all five cats waxed and waned for the duration of the study, but the cats never appeared painful and the lesions never drained. Three of the cats with masses never became pregnant, and the other two became pregnant at 863 and 1212 d, respectively. No masses were observed in the sham-treated cats.

3.2. Breeding trial

All four breeding male cats sired litters during the study. The first male cat was introduced on Day 120 post-treatment at the beginning of a second long-day photoperiod. All sham-treated cats displayed behavioral signs of estrus and were receptive to breeding attempts by the male within 10 days of the change to long-day photoperiod. Time-lapse videography revealed that the male bred each of the sham-treated cats at least 15 times between Days 122 and 155. One sham-treated cat was observed breeding in two intervals during gestation (Days 7 to 11 and Days 25 to 26 of gestation). Four (27%) vaccinated cats that displayed estrous behavior and began breeding on Days 128, 418, 469, and 504 were classified as having a short-term response to GnRH vaccination.

Based on an average gestation period of 63 d, parturition date was used to estimate the date of conception. The GnRH-vaccinated group had a longer median time ($P < 0.001$) to conception following treatment (39.7 mo) compared to the sham-treated group (4.4 mo; Fig 3). All five sham-treated cats became pregnant 7–28 d (study Days 127–148) after the male cat was introduced. One short-term responder cat was bred in three successive periods of estrus between Days 129–164, before becoming pregnant on Day 164, whereas the other three short-term responder cats became pregnant during their first estrus following a prolonged vaccine-induced anestrous period (Days 418, 469, and 504, respectively).

Eleven (73%) cats were classified as long-term responders with fertility control lasting greater than two y following a single GnRH vaccination. A total of 93% of vaccinated cats remained infertile for the first year following vaccination, 73% for 2 y, 53% for 3 y, and 40% for 4 y (Fig. 3). At the time the study was terminated (5 y after a single GnRH vaccine was administered), four cats (27%) had never become pregnant.

There was a small but significant difference in fecundity (live births) in the GnRH-vaccinated group (2.6 ±

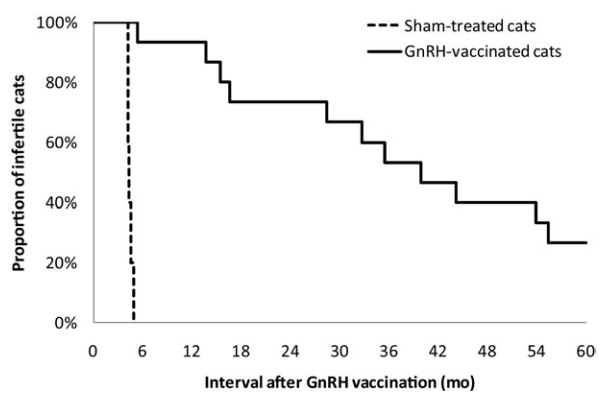

Fig. 3. Fertility control in cats. Vaccinated cats (n = 15) received a single injection of vaccine containing a GnRH-KLH conjugate (200 μg) in a mycobacterial and oil emulsion on study Day 0. Sham-treated cats (n = 5) received a single injection containing all vaccine components except the GnRH-KLH conjugate (n = 5). A breeding trial was commenced on study Day 120. Vaccinated cats had longer time to conception (median 39.7 mo) compared to sham-treated cats (4.4 mo; $P < 0.001$).

Table 1
Time to conception, litter size, and GnRH antibody titers in individual sham-treated cats (n = 5), short-term responding cats (n = 4), and long-term responding cats (n = 11). Four cats remained infertile for the entire duration of the 5 y study.

Cat	Conception (Day)	Peak GnRH titer	GnRH titer at conception	Live births	Still births	Injection-site reaction
Sham 1	127	0	0	3	0	No
Sham 2	128	1000	1000	3	1	No
Sham 3	131	0	0	4	0	No

Long-term 11	NA	256,000	NA	NA	NA	Yes

0.3) compared to the sham-treated group (3.8 ± 0.4; P = 0.04; Table 1). There was no difference in the number of stillborn kittens between the groups (P = 0.9).

3.3. GnRH antibody titers

All vaccinated cats developed detectable GnRH antibodies (Table 1). The magnitude of GnRH antibody titers 1 mo after vaccination was similar in cats that responded to vaccination for < 2 y (short-term responding group) and those that responded for > 2 y (long-term responding group; Fig. 4). However, antibody titers decreased more quickly in the short-term responding group and remained lower at each monthly point beginning 5 mo post-vaccination (P < 0.05). Peak

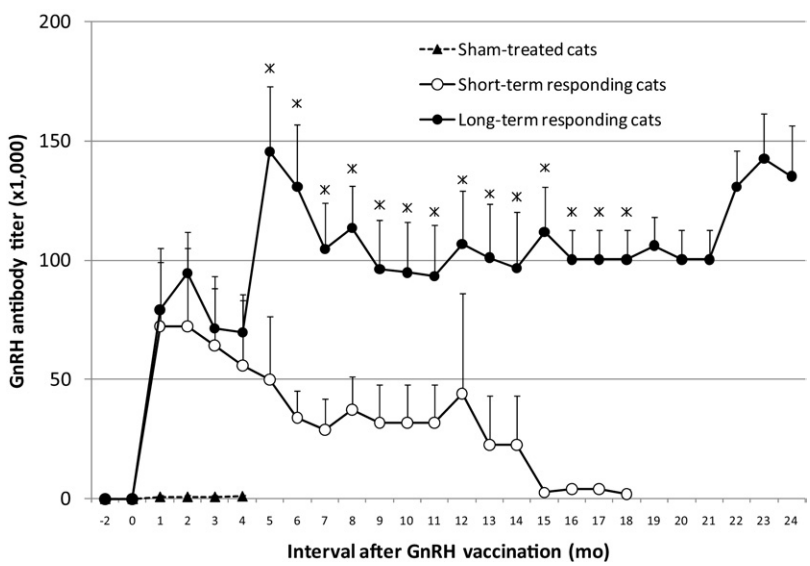

Fig. 4. GnRH antibody titers (mean ± SEM) in sham-treated cats (n = 5), short-term responding cats (n = 4), and long-term responding cats (n = 11) during the first 2 y following treatment with a single sham or GnRH vaccine. The GnRH antibody titers declined more rapidly in short-term responding cats with < 2 y of infertility compared to long-term responding cats that experienced fertility control for >2 y (*P < 0.05).

GnRH antibody titers were higher in the long-term responding group (median 256,000, IQR 128,000–256,000) than in the short-term responding group (median 80,000, IQR 32,000–128,000; P = 0.02; Table 1). Most cats that became pregnant had antibody titers of 16,000 or less at the time of conception, but four cats had antibody titers of 64,000–128,000. Antibody titers in the four cats that never became pregnant were 128,000–256,000 at the end of the study, 5 y after the single GnRH vaccination.

3.4. Hormone concentrations

Nineteen of the cats selected for the study responded to long-day photoperiod prior to treatment, with a surge in estradiol-17β > 20 pg/mL for at least four consecutive days and peak estradiol-17β > 40 pg/mL for at least 1 d. The remaining cat responded to long-day photoperiod with elevation of estradiol-17β from baseline, but exceeded 20 pg/mL on 1 d only. Six of 20 cats had an increase in serum progesterone > 2 ng/mL following the change to long-day photoperiod prior to treatment, indicating pseudopregnancy following estrus, even though the male cat had not yet been admitted to the colony. A cycle of 1 mo of short-photoperiod followed by return to long-day photoperiod on Day 360 failed to trigger behavioral estrus, breeding attempts, or increases in serum progesterone in any of the 14 vaccinated cats that remained in the study at that time.

The first elevation of progesterone > 2 ng/mL during monthly testing was associated with pregnancy in 14 of the cats (5 sham-treated cats and 9 vaccinated cats). In two other cats, both long-term responders, episodic non-fertile progesterone increases were detected during Days 1500 to 1590 and Days 1410 to 1650 before conception followed by term pregnancy occurred on Days 1640 and 1684, respectively. Progesterone elevation was also observed on Days 1230, 1650 to 1680, and 1830, respectively, in three of the cats that never became pregnant during the 5 y study period. Elevated progesterone was never detected in one of the cats that never became pregnant.

3.5. Body weight and composition

At the time of treatment on Day 0, there were no significant differences (P = 0.5) in body weight among the sham-treated (3.5 ± 0.2 kg), short-term responder (3.2 ± 0.2 kg), and long-term responder (3.3 ± 0.1 kg) groups. Similar to cats undergoing surgical sterilization, long-term responder cats had a higher percentage gain in body weight than sham-treated cats and short-term responder cats (P = 0.02; Table 2). Weight gain was also reflected in abdominal fat content. The mean falciform fat pad depth for the long-term responder group was greater than the mean for the sham-treated group (P = 0.02) and the short-term responder group (P = 0.03). The area of the falciform ligament was not significantly different among groups (P = 0.1).

Table 2
Body weight gain and abdominal fat (mean ± SEM) in cats as a function of response to GnRH vaccination. Body weight was measured at the time of treatment on Day 0 and again on Day 420 and the percentage change in weight calculated. Abdominal falciform fat pad depth and area were measured from lateral radiographs made on Day 420. Long-term responding cats (n = 11) gained more weight and had greater fat pad depth than sham-treated (n = 5) and short-term responding cats (n = 4).

Response group	Body weight gain (%)	Fat pad depth (mm)	Fat pad area (mm^2)
Sham (n = 5)	15 ± 7	19 ± 2	728 ± 145
Short-term responses (n = 4)	4 ± 10	19 ± 2	839 ± 172
Long-term responses (n = 11)	40 ± 6*	28 ± 3*	1193 ± 148

* P ≤ 0.02.

4. Discussion

The vaccine used in this study induced fertility control in 100% of cats following a single injection, but duration of contraception varied from 5 mo to > 5 y. Infertility was maintained for 3 y in approximately half of the cats and for more than 5 y in a quarter of the cats. Response to vaccination was accompanied by a cessation in estrous cyclicity and with weight gain, similar to cats undergoing surgical sterilization via ovariectomy.

This is apparently the first study to demonstrate multi-year fertility control following a single vaccination in cats. Although permanent sterilization is ideal, the relatively short life-span of many free-roaming feral cats suggests that a contraceptive that blocks fertility for several years in a high proportion of cats may be successful in reducing the population. Most models propose that more than 70% of the female cats in a population must be rendered infertile to trigger a negative population growth rate [13–15], but one model found that focusing a control program on juvenile cats and utilizing a contraceptive having 3 y duration of activity would stop population growth when just 60% of the female cats were treated [16].

Duration of infertility was associated with persistence of high GnRH antibody titers. Most cats with an antibody titer > 16,000 remained infertile. However, several cats, all long-term responders, successfully re-

produced in the presence of antibody titers as high as 256,000. We inferred that there is no absolute contraceptive antibody titer that is predictive of infertility and that other factors also influence the contraceptive effect of GnRH immunization in female cats. In a previous study in male cats, antibody titers of $> 32{,}000$ were associated with suppression of serum testosterone concentrations and spermatogenesis consistent with immunocastration [8]. Immunocontraception targeting GnRH appeared to be more effective in female cats than in male cats. All female cats in the current study experienced a delay in conception compared to sham-treated cats, whereas only 67% of male cats demonstrated infertility as determined by semen analysis in the previous study [8]. Higher efficacy in females has been observed in other species including feral swine [17], white-tailed deer [18], and domestic dogs (L. Miller, unpublished).

In addition to suppression of estrus, GnRH immunocontraception may have additional effects on reproduction. In this study, litter sizes in cats that recovered fertility were slightly smaller than litter sizes in sham-treated cats. Whether this is a transient phenomenon in the first pregnancy following recovery of fertility, is related to the older age of the vaccinated cats at the time of pregnancy, or is a persistent effect possibly related to the continued presence of GnRH antibodies is unknown, as cats were removed from the study following delivery of their first litter.

Granulomatous injection-site reactions containing acid fast bacteria, presumably from the adjuvant, were identified in five long-term responding cats. This evidence of an ongoing immune response may explain the ability of this depot vaccine to create durable immunity against a self antigen in a large proportion of cats in the absence of a booster vaccination protocol. Granulomatous and neoplastic masses at the injection site and systemic inflammatory responses have been previously reported in cats receiving zona pellucida antigens in the presence of mycobacteria and oil (Freund's complete or incomplete adjuvants) [6,19]. The production of durable immunity using non-replicating vaccines is a great challenge, particularly against a small self antigen such as GnRH [20]. Adjuvants and carrier proteins with T-cell epitopes that stimulate the immune system to react against the target antigen do so in the context of inducing a local inflammatory response. As a species, cats are at increased risk for development of life-threatening sarcomas at the site of inflammation resulting from vaccination and other injections [21]. In another study of GnRH immunocontraception in cats, all kittens vaccinated with a GnRH vaccine or placebo containing oil developed acute transient injection-site masses [22]. The initial reactions resolved, but examination of injection sites following booster vaccines up to 20 mo later was not reported. Consideration should be given to the development of vaccine formulations that reduce the risk of injection-site reactions and possible sarcoma formation in cats. However this concern should be balanced against the very real threats to the welfare of cats associated with their uncontrolled reproduction and with control programs that rely on long-term confinement or culling. Risk assessments associated with non-surgical fertility control should also include a comparison with the known morbidity and mortality associated with surgical sterilization, particularly in owned cats in which the benefit to the individual is a higher priority than population control.

GnRH has many of the characteristics of an ideal contraceptive target. Hypothalamic GnRH is a decapeptide "master hormone" that controls downstream pituitary and gonadal responses in both male and female mammals. In the absence of GnRH stimulation, the gonadal hormones estrogen, progesterone, and testosterone are suppressed and gamete maturation does not occur [8,22,23]. This results in infertility, elimination of repeated estrous cycles that can lead to uterine disease and mammary carcinoma, and reduction of undesirable nuisance behaviors such as fighting, roaming, spraying, and estrous calling. This is an advantage over contraceptive targets (such as zona pellucida) that block fertility, but not necessarily estrous cyclicity. The availability of a single product effective in both males and females following a single dose is also an advantage, because it eliminates the need to re-trap animals for repeat treatments, to maintain an inventory of multiple different products, to target trapping campaigns to one sex, or even to determine what sex a trapped cat is. The vaccine used in this study was approved in September 2009 for control of white-tail deer by the Environmental Protection Agency, which regulates the use of "pesticides," including nonlethal products for use in feral and "pest" species [24]. The vaccine has not been approved for use in any other species at this time, including feral cats.

Many feral cats are too unsocialized for safe handling. In contrast to surgical sterilization, the GnRH vaccine used in this study could possibly be administered without sedation to cats confined in a humane trap. This obviates the need for veterinarians to be directly involved with each cat targeted in a population control campaign, a distinct advantage in parts of the

world where veterinary services for companion animal species are not universally available. These findings suggest that GnRH immunocontraception is an ideal candidate for further development for the control of feral cats.

Contraception in mares heteroimmunized with pig zonae pellucidae

I. K. M. Liu, M. Bernoco and M. Feldman

Department of Reproduction, School of Veterinary Medicine, University of California, Davis 95616, U.S.A.

Summary. Ten fertile feral mares and 6 domestic horses (4 fertile mares, 1 infertile mare, 1 gelding) were immunized with heat-solubilized pig zonae pellucidae by 4 injections equivalent to 2000 or 5000 zonae each at 2–4-week intervals and a booster injection of 20 000 zonae 6–10 months after the last of the initial inoculations. The immune response was reflected by high antibody levels as measured by an enzyme-linked immunosorbent assay (ELISA) using immobilized pig zona antigen. In-vivo inhibition of fertility occurred in 12 (86%) of the 14 fertile mares studied and persisted for a minimum of 7 months. Repeated mating of the fertile domestic mares resulted in conception when anti-pig zona antibody concentrations had decreased from initial peak absorbance ratios (>1·0) to relatively lower levels (0·64 or less with one exception). An indirect immunofluorescence assay, revealed a considerably lower cross-reactive antibody titre with horse oocytes as compared to pig oocytes. Clinical, endocrinological and histological analyses of the ovaries and their function following regained fertility after immunization revealed no abnormalities. One mare remained infertile.

Keywords: horse; contraceptive vaccine; zona pellucida; antibodies; heteroimmunization.

Introduction

Attempts to reduce fertility in several mammalian species have been reported. Active immunization of female rabbits (Gwatkin *et al.*, 1980; Woods *et al.*, 1981; Skinner *et al.*, 1984), bitches (Shivers *et al.*, 1981; Mahi-Brown *et al.*, 1982) and monkeys (Sacco *et al.*, 1983) with pig zonae pellucidae has resulted in reduced fertility of the treated animals. Similarly, immunocontraception was achieved in mice (Gwatkin *et al.*, 1977) and rabbits (Gwatkin & Williams, 1978) by using hamster and cattle zonae. Other investigators have successfully inhibited fertilization *in vivo* by passive immunization, injecting rodents of several species with antisera against mouse (Shahani *et al.*, 1972; Jilek & Pavlok, 1975), rat and hamster (Tsunoda & Chang, 1976; Oikawa & Yanagimachi, 1975) ovaries.

Natural antibodies directed against the zona pellucida have been reported to occur in mares infertile for unexplained causes (Liu & Shivers, 1982). Further attempts to investigate the role of horse 'auto-antibodies' against the zona demonstrated immunological cross-reactivity of pig and horse zonae and in-vitro reduction of binding of boar spermatozoa to pig oocytes treated with horse zona-positive antiserum (Shivers & Liu, 1982).

According to several reports, however, the use of zona components as the antigen in active immunization results in altered cyclicity and ovarian malfunction. Such side effects have been described for the bitch by Mahi-Brown *et al.* (1982, 1985). A decrease in ovarian weight, marked reduction of follicular development, abnormal follicular differentiation and lack of response to induction of ovulation by human chorionic gonadotrophin were also reported for rabbits after

active immunization (Wood *et al.*, 1981; Skinner *et al.*, 1984). Sacco *et al.* (1983, 1987) have reported that fewer ovulated oocytes were recovered from monkeys after injections of purified pig zona antigen, but ovarian function was reduced only temporarily and returned to normal 7 months after the end of the treatment.

The present study was conducted to determine whether heteroimmunization of mares with crude pig zona antigen would temporarily inhibit fertilization *in vivo* and, if so, to assess the possible causes of the inhibition.

Materials and Methods

Selection of feral mares. Thirty (30) feral mares were captured at a wild horse sanctuary of $\sim 2000\ km^2$ in Northern California holding approximately 200 horses of different ages (~ 120 mares, 15 stallions and 65 geldings). After 6 months of confinement to a large area without stallions each mare was herded into a restraining chute and the reproductive tract was palpated *per rectum* to determine pregnancy status and potential abnormalities. Ten (10) presumably fertile mares were selected for this study on the basis of (1) a palpable normal reproductive tract, (2) a non-gravid uterus and (3) age (estimated to be 3–10 years old): 4 of the mares appeared to be maiden mares and the remaining 6 had foals by their sides. The individual mares were identified by their colour and markings and the group of mares treated was marked by removing their manes entirely with a pair of scissors. The 10 selected mares remained in a small corral for the period of the initial 4 immunizations, were subsequently released and recaptured 8 months later for assessment of pregnancy status and administration of booster injections.

Selection of domestic horses. These horses provided the opportunity for frequent serological analysis and continued examination of the reproductive tract for folliculogenesis, ovulation and pregnancy status. The group, housed at the Equine Research Laboratory's breeding facility of the University of California in Davis, consisted of 4 presumably fertile mares, 1 infertile mare with chromosome abnormality (63XO genotype) and 1 gelding. The 4 fertile mares were selected on the basis of (1) a palpable normal reproductive tract and speculum examination, (2) age, (3) history of pregnancy, and (4) normal cyclicity. The fertile mares were between 3 and 8 years old, had a history of never having been mated naturally or by artificial means and had normal physiological and behavioural oestrous cycles. The infertile mare and the gelding served as immunological controls.

Preparation of pig oocytes and zona antigen. Zonae pellucidae were isolated using procedures reported by Gwatkin *et al.* (1980) and Dunbar *et al.* (1980). The frozen–thawed ovaries were sliced in a ganged razor blade apparatus. The oocytes were separated by filtration through a series of screens of 210, 150 and 73 μm in the presence of phosphate-buffered saline (PBS, pH 7·2). The oocytes were counted and ground in a Potter–Elvehjem homogenizer. The zonae were trapped on a 48 μm screen, thoroughly rinsed with PBS and heat-solubilized at 70°C for 30 min in PBS for inoculation (doses of 2000 or 5000 zonae in 0·5 ml, 20 000 zonae in 2 ml), or in 0·1 M-glycine buffer (adjusted to pH 9·5 with NaOH) when used for the ELISA. The protein concentration of the heat-solubilized pig zona antigen was determined by the Automated Protein Assay (Technical Bulletin 1177: Bio-Rad Laboratories, Richmond, CA, U.S.A.) microassay procedure using bovine serum albumin as standard. Doses of 2000, 5000 and 20 000 zonae corresponded to 27·4, 68·5 and 274 μg protein, respectively.

Immunization adjuvants. The two initial inoculations used for all 16 horses consisted of a mixture of 3 parts zona antigen and one part amphogel (aluminium hydroxide gel) as adjuvant. As based on preliminary data obtained in an indirect immunofluorescence assay, this adjuvant seemed to be only moderately effective in most of the horses and was therefore substituted by Freund's adjuvant. Emulsions of equal parts of zona antigen and Freund's (complete for the initial, incomplete for the following injections) adjuvant were used for the remaining inoculations. However, serum analyses performed later by ELISA revealed more satisfactory immunization responses in 13 of the 16 horses after use of amphogel as adjuvant.

Immunization protocol. A series of 4 intramuscular injections of zona antigen was administered to each of the 16 horses at 2–4-week intervals. The doses for the 1st, 3rd and 4th injection consisted of 5000 zonae, the second injection dose consisted of 2000 zonae. At 6–9 months after the last injection, when antibody concentrations in the fertile domestic mares had decreased to levels that allowed conception at absorbance ratios of $<0{\cdot}64$ (one exception), the fertile domestic and feral mares received booster injections of 20 000 zonae each. Serum samples for antibody determination were obtained from all the horses before each inoculation and from the domestic horses monthly (with some variations) throughout the 3·5-year period of this study.

Mating of mares and pregnancy test. After the initial 4 inoculations, the feral mares were returned to their natural habitat with known fertile stallions: 8 months later they were recaptured and examined for pregnancy status by palpation *per rectum*. After immunization, the 4 fertile domestic mares were rectally palpated every other day through each oestrous cycle (every 18–21 days) of the mating season for observation of follicular development and

ovulation. (The natural mating season usually lasts from March through October and is followed by a 4-month anoestrous period.) Through each cycle and following the development of a preovulatory follicle of at least 40 mm in diameter, the mares were inseminated naturally or artificially with semen from known fertile stallions until ovulation. At 16–25 days after ovulation, ultrasonographic scanning was utilized for early pregnancy detection (embryo and heart beat). Additional pregnancy examinations by rectal palpation were performed at 45 and 60 days of gestation. The first pregnancies of the domestic mares that occurred during the study were terminated at 25 days by injection of 10 mg prostaglandin (Lutalyse: Upjohn, Kalamazoo, MI, U.S.A.). At 4 months after delivery of healthy foals in the second pregnancy, to Mares ST and GO, all 4 domestic mares were ovariectomized by colpotomy.

ELISA for determination of zona antibodies. The assay was performed essentially as described by Voller *et al.* (1980). Fox *et al.* (1981) and Drell *et al.* (1984) have measured antibody activity to pig zona antigen by the ELISA procedure. The biotin–avidin bridge method (S. Grimes, personal communication) was chosen for this study because of its low background reactivity.

Briefly, 50 µl of a 5 µg/ml zona antigen solution in 0·1 M-glycine buffer was placed in each well of a flat-bottom Microelisa Immulon 2 plate (Dynatech Laboratories, Alexandria, VA, U.S.A.) and incubated overnight at 4°C. The plate was washed once and incubated with 200 µl PBS–Tween for 30 min to block unspecific binding sites. After 2 more washes (PBS–Tween) the treatment of the plate consisted of subsequent 1-h incubations with 50 µl/well of PBS–Tween-diluted reagents used in the following order with 3 washes each in between: (1) test serum 1:1000, (2) biotinylated goat anti-horse IgG (Zymed Laboratories, San Francisco, CA, U.S.A.) 1:1000, (3) alkaline phosphatase avidin (Zymed) 1:2000. Finally, 50 µl substrate solution of 1 mg *p*-nitrophenyl phosphate/ml (5 mg tablets: Sigma Chemical Co., St Louis, MO, U.S.A.) in 10% diethanolamine buffer (pH 9·8) were added to each well, and the plate was scanned for absorbance at 405 nm (A_{405}) by an MR 580 Microelisa Auto Reader (Dynatech) when the absorbance of the positive reference serum had reached a level between 0·80 and 1·00 after incubation for 15–20 min.

Optimal concentrations of biotinylated goat anti-horse IgG and alkaline phosphatase avidin were selected after 'checkerboard' experiments in which, in an antigen–antibody (reference serum)-coated plate, doubling dilutions of one reagent are tested against doubling dilutions of the other reagent. The working dilution of the experimental sera (1:1000) was chosen from within the straight segment of the sigmoidal curve obtained after plotting various dilutions of the positive reference serum against their absorbances. Control reagents included PBS–Tween, 3 positive sera (weak, medium, strong) and 2 negative sera. The medium positive serum consisted of a pool of 8 different pre-tested serum samples and served as reference serum. The negative control pools were derived from 12 non-immunized random horses and from the pre-immunization samples of the 6 domestic horses in this study.

The experimental sera were tested in duplicate and their results are expressed as means ± s.e.m. of the ratios of the duplicate experimental absorbances divided by the mean absorbance of the reference serum tested on the same plate (EA_{405}/RA_{405}).

Indirect immunofluorescence assay with horse and pig oocytes. Frozen horse ovaries (obtained from an abattoir) were thawed and minced in ice-cold PBS and the mixture was filtered through gauze and a 73 µm screen. The oocytes were aspirated by micropipette from the cellular material trapped on the screen under a stereo microscope. The difficulty in obtaining horse ovaries and the poor recovery of oocytes from them (an average of 4 per ovary) did not permit any large scale usage as needed in the ELISA. Horse and pig (prepared as described earlier) oocytes (5 of each) were incubated for 30 min with 300 µl serum dilution in PBS on separate Boerner slides inside a humid chamber. They were washed 3 times by transfer to watchglasses holding PBS. After a 30-min incubation with 100 µl fluorescein isothiocyanate-conjugated rabbit anti-horse IgG (Miles-Yeda Ltd, Rehovot, Israel), diluted 1:10, the oocytes were washed and scored for surface zona fluorescence using an Olympus B2-2 microscope.

In-vitro assessment of sperm binding. Pig oocytes (n = 200) were incubated with 600 µl horse anti-pig zona serum dilution and washed 3 times by centrifugation. The oocyte pellet was resuspended in 30 µl PBS and transferred to a 5-ml sterile culture tube containing 0·4 ml boar sperm suspension at a concentration of 5×10^6/ml in basal medium (BM) with 0·5% bovine serum albumin (BSA) at pH 7·7. The fresh semen had been previously centrifuged on Percoll and the spermatozoa capacitated by incubation in BM with BSA and in an humidified incubator with 5% CO_2 at 39°C for at least 3 h (Berger & Horton, 1988). The oocytes were gently mixed with the spermatozoa and incubated overnight in the same incubator. The stop–fix technique of Saling *et al.* (1978) for recovering spermatozoa tightly bound to the zona was modified for treatment of the oocyte–sperm mixture. The mixture was carefully layered on discontinuous dextran (mol. wt 500 000: Sigma) gradients (1·8% over 2·25%) in BM using a 1-ml Fisher tube, and centrifuged in a Fisher microfuge at 100 *g* for 2 min. The pellet was resuspended in 25 µl 2·5% glutaraldehyde in PBS and transferred on a slide for microscopic examination. An average of 85 oocytes was counted per slide. The various degrees of sperm binding were classified as: (1) negative = no or less than 5 spermatozoa, (2) intermediate = 5–20 spermatozoa, (3) heavy = >20 spermatozoa bound per oocyte.

Enzyme immunoassay for progesterone. Luteal response was determined by progesterone analysis of plasma by an enzyme immunoassay (Munro & Stabenfeldt, 1984).

Preparation of ovarian tissue for histological examination. Ovarian tissue from the 4 fertile domestic mares was fixed in 10% formalin, embedded in paraffin wax, sectioned at 6 µm and stained with haematoxylin and eosin.

Results

Immune responses of feral mares

The anti-pig zona antibody responses of the 10 feral mares to the zona inoculations, as tested at 5 different time points, are summarized in Fig. 1. The antibody levels of all the mares were similar to one another at the first 4 test times as indicated by low standard errors. Pre-immune sera resulted in mean absorbance ratios of 0·04 and 0·05. The initial low response gradually increased with each inoculation and peaked after the 3rd, measuring a mean absorbance ratio of 1·03. Antibody responses of the feral mares to the 4th injection were not examined since the mares were released after the last inoculation. When 9 of the 10 treated feral mares were recaptured and tested 8 months later (Month 10·5) their results clearly fell into two groups: 7 mares still had remarkably high antibody levels (mean absorbance ratio = 0·82), and no antibodies could be detected in the 2 remaining mares (mean absorbance ratio = 0·06).

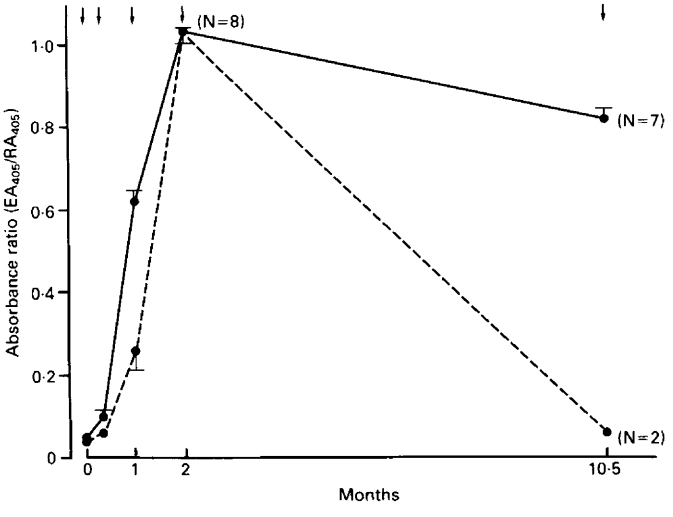

Fig. 1. Immune response to pig zona vaccinations (arrows) in 10 feral mares as measured by ELISA using pig zona antigen. Results of 7 mares (●——●), which had high antibody levels at Month 10·5 of the study, and results of 2 mares (●- - -●) with negative antibody levels at Month 10·5. One mare was not tested at Month 10·5. The mean absorbance ratios ± s.e.m. were calculated from the original duplicate absorbance ratios obtained per individual. Errors of $<0{\cdot}010$ are not shown.

Immune responses of domestic horses

The antibody responses of the 6 domestic horses to the zona inoculations were monitored over a total period of 22–41 months. The results, as found in the ELISA using pig zonae as antigen (Fig. 2), are presented individually for each horse because of treatment variability. The 4 initial inoculations gradually increased the antibody concentrations of all 6 horses to peak levels expressed by absorbance ratios between 1·00 and 1·20. When antibody levels of 3 (ST, AP, GO) of the 4 fertile mares had declined to absorbance ratios of ~0·50 at 7, 10 and 6 months (respectively) after the 4th inoculation, all 4 fertile mares received booster injections. As a result, their antibody levels peaked as before with the exception of Mare GO, which had developed an abscess at the injection site and

therefore received a second booster 4 months later. Antibody levels of the 4 fertile mares were monitored monthly for most of the period of 24–32 months following the booster injection. In 2 mares (ST, GO) antibody concentrations declined to lower levels (absorbance ratios 0·56, 0·42, respectively) 7 and 6 months after the booster. In Mare AP antibody levels remained above absorbance ratios of 0·82 for 23 months. Mare SH, however, maintained the high antibody level it had reached after the booster for 27 months (absorbance ratio at 27th month = 1·03). This originally healthy cycling mare developed bilateral blindness about 18 months after the initial vaccination. The mare's ovaries subsequently remained inactive, causing permanent acyclicity.

The infertile (XO) Mare SQ and the Gelding AL served as immunological control horses and were considered to be immunologically naive to zona components. Because they lacked antigenic exposure and subsequent antibody absorption from the circulation, higher and more persistent antibody levels were expected to result from immunization as compared to normal mares. However, the immune response actually reached by these control horses rather resembled some of the patterns observed in the healthy mares of this study and did not compare to the plateaued pattern of the Mare SH.

Antibody titre of horse versus *pig oocytes*

Because of the small numbers of available horse oocytes the indirect immunofluorescence assay was used instead of ELISA for antibody titre comparison of horse and pig oocytes. An antiserum of medium–strong reactivity against pig zona (Mare AP, after 3rd inoculation, absorbance ratio 0·94) was chosen and 2-fold dilutions were tested. The highest reactive serum dilutions were found to be 1:20 with horse oocytes and 1:800 with pig oocytes. The comparatively lower endpoint titre obtained with horse oocytes can be expected when cross-reacting antibodies are involved. The results confirm the cross-reactivity between pig and horse antigenic zona determinants as published earlier.

In-vivo block of fertilization

The 8-month period of exposure of feral mares to fertile stallions consisted of the last 2 months of the current physiological mating season, an intermediate 4-month anoestrous period and the first 2 months of the following year's mating season. Examination *per rectum* of the 9 feral mares that could be recaptured revealed one pregnancy of 21–23 days and no evidence of pregnancy in the remaining 8 mares. The pregnancy was not confirmed by ultrasonography because of the difficulty of applying this method to feral mares. Attempts to recapture the 10th mare failed, but observation from approximately 20 feet did not indicate any evidence of advanced pregnancy, and 8 months later it was seen without a foal by its side. When analysed for anti-zona antibodies, the pregnant mare's serum was negative. Among the 8 remaining non-pregnant mares, 7 demonstrated substantial antibody levels (mean absorbance ratio = 0·82) and one was found to be negative (Fig. 1).

Of the 4 fertile immunized domestic mares, 2 (AP, SH) did not conceive for an 8·5-month period after the 4th inoculation (Fig. 2). Of this 8·5-month period, 4·5 months consisted of active physiological mating period and the remaining 4 months of anoestrous and transitional phase periods. Conception occurred when antibody concentrations had decreased from peak absorbance ratios of 1·16 to 0·64 (AP) and from 1·14 to 0·91 (SH). At 25 days, the pregnancies were diagnosed by ultrasonography (embryo and heartbeat) and terminated. After subsequent booster injections, antibody concentrations regained high levels (absorbance ratios 1·11 and 1·12) and remained high for 27 months during which time continued insemination of Mare AP did not result in pregnancy. Because of persistent ovarian inactivity, possibly resulting from its blindness, Mare SH was not mated for the remaining part of the study.

How long the block of fertilization after the first immunization series lasted for the fertile domestic Mares ST and GO cannot be stated with certainty as the mares were in anoestrus with low

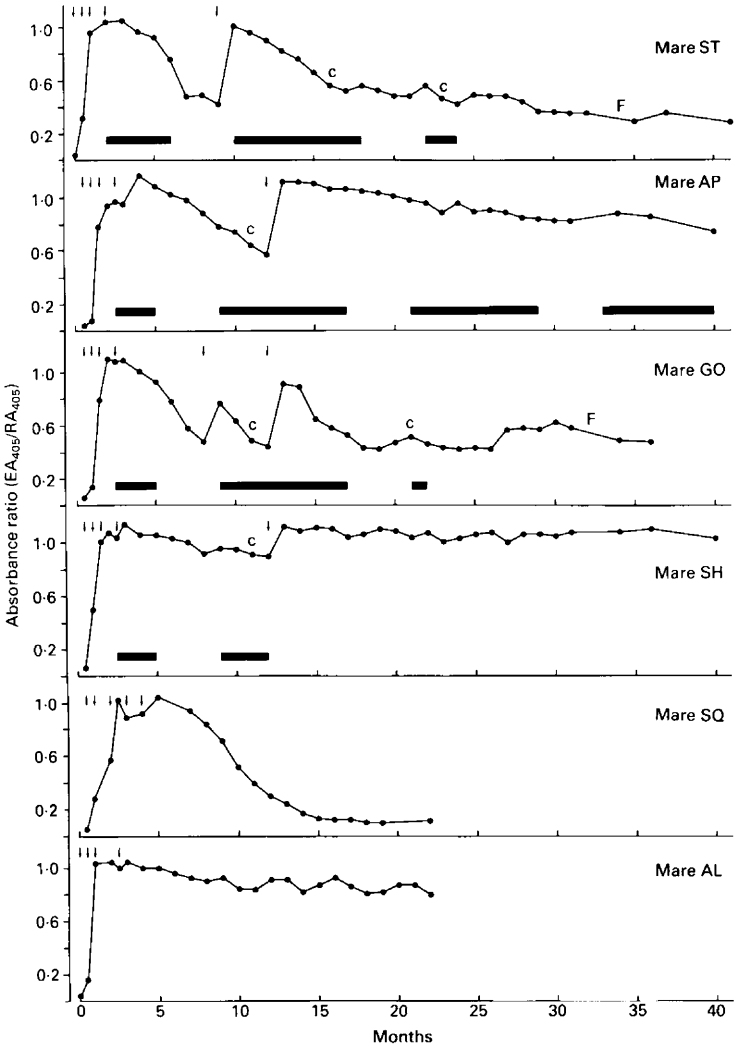

Fig. 2. Immune response to pig zona vaccinations shown individually in 6 domestic horses as measured by ELISA using pig zona antigen. Mares ST, AP, GO and SH were fertile, Mare SQ was infertile (63XO) and Horse AL was a gelding. Results are expressed as means of duplicate absorbance ratios: 57% of the standard errors (not shown) were <0·010, the mean of the remaining errors was 0·021 (range 0·010–0·052). ■, Period when inseminated; ↓, vaccination; C, conception; F, foaling.

antibody levels (0·42 and 0·49) at 5·5 and 7 months after inoculation and received booster injections before the start of the new mating season. In addition, the booster injection and subsequent immunological response of Mare GO was considered invalid because of the development of an abscess at the injection site. The injection was repeated 4 months later when a 25-day pregnancy was diagnosed (absorbance ratio 0·44) and terminated. Following the booster injection it required 7 months for Mare ST and at least 5 or at most 9 months (considering the anoestrous period) for Mare GO to regain fertility. At the time of conception the antibody levels were expressed as absorbance ratios of 0·46 and 0·51, respectively. The second pregnancies of Mares ST and GO were not interrupted and both delivered healthy foals after normal pregnancies.

Antibody-dependent in-vitro block of sperm binding

Repeated efforts to develop a binding assay for horse spermatozoa and oocytes failed because of inconsistent controls. This is consistent with the lack of reports of in-vitro fertilization or sperm binding techniques in the horse. The only alternative was to study the blocking abilities of the horse anti-zona sera using pig oocytes and boar spermatozoa. Sera collected at different periods from the same mare (AP) were selected on the basis of their different antibody levels and were tested simultaneously. The oocytes displayed normal sperm binding (95% heavy + 5% intermediate) after preincubation with pre-immune serum and similarly strong binding was found after treatment with a random non-immune serum and PBS (Fig. 3). Preincubation of the oocytes with the various antisera, however, reduced sperm binding in apparent relationship to the antibody levels of the sera. The weakest of the antisera used in this experiment (absorbance ratio = 0·57), collected in Month 12 of the study (Fig. 2), blocked sperm binding in 25% of the treated oocytes. Blocking of sperm binding gradually increased with higher antibody levels. The strongest antiserum (absorbance ratio = 1·16, Month 4) prevented sperm binding in 99% of the oocytes.

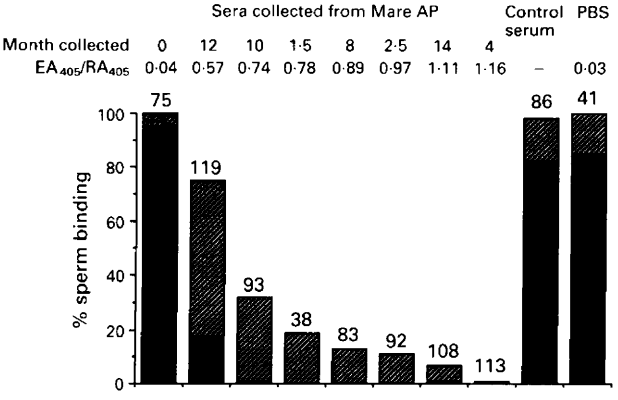

Fig. 3. In-vitro block of boar sperm binding (■, heavy; ▨, intermediate) to pig oocytes by horse anti-pig zona antibodies. Sera collected from Mare AP before (pre-immune) and at different times after immunization were selected for sperm binding experiments on the basis of their antibody level diversity. The results were placed in order of the antibody levels of the sera. The control serum originated from a non-immunized random mare. The total number of oocytes counted per test appears above each column.

Histological examination of the ovaries

The ovaries of 3 of the domestic mares appeared normal. Most of them showed severe hyalinization of the arteries in the capsules, a common finding in many ovaries of untreated mares. Graafian follicles, developing and atretic follicles, functional corpora lutea and recent ovulation sites were present in all the ovaries examined. No active inflammation was noted in the arteries. Both ovaries from Mare SH were inactive: no follicles or corpora lutea were noted in either ovary.

Progesterone profiles

Progesterone profiles obtained from the 4 domestic mares at the end of the study are shown in Fig. 4. Mare SH revealed no evidence of luteal function and remained acyclic, whereas Mares ST, GO and AP demonstrated evidence of ovulation, luteal function and normal cyclicity. Progesterone

concentrations of the 3 cycling mares peaked with a mean of 8·9 ng/ml, ranging from 5·6 to 13·1 ng/ml. Ovulation to ovulation (1 complete oestrous cycle) required a mean of 22·3 days, ranging from 21 to 25 days.

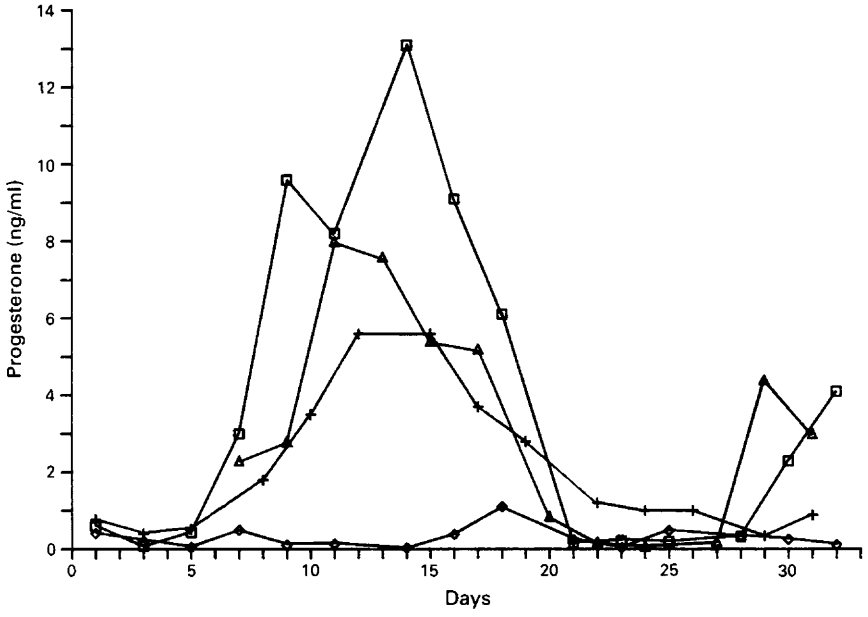

Fig. 4. Progesterone profiles of the 4 fertile domestic mares (△ = ST, + = AP, □ = GO, ◇ = SH) through one complete oestrous cycle (ovulation to ovulation, with the initial one occurring on Day 5) were obtained before ovariectomy.

Discussion

An immune response was provoked in horses by active heteroimmunization with heat-solubilized pig zonae. Other investigations confirm the effects of heteroimmunization when compared with alloimmunization (Gwatkin *et al.*, 1977; Wood *et al.*, 1981; Mahi-Brown *et al.*, 1982), whereby heteroimmunization appears to be the more immunogenic and therefore preferable method of eliciting anti-zona antibodies.

In this preliminary study, the contraceptive effect correlated with high anti-pig zona antibody concentrations, persisted for at least 8 months in most of the animals studied and the effect diminished as antibody levels declined. As in other investigations in which large quantities of zonae from the immunized species are unavailable, the horse anti-pig zona antibodies were studied by using pig and not horse antigen. Such data permit insight into the kind of immune response elicited, although correlation of the direct antibody titres with the more important cross-reactive antibody titres exists only to a certain extent within the same individual (Sacco *et al.*, 1983) and may vary between individuals, especially when the immune response is directed against different antigenic determinants of the zona. In an indirect immunofluorescent assay it was demonstrated that horse anti-pig zona antibodies cross-reacted with horse zona components at a considerably lower titre than with pig zona components. Such cross-reactivity (Shivers & Liu, 1982), as well as cross-reactivity among zona components of several mammalian species, has been reported elsewhere (Gwatkin *et al.*, 1978; Sacco *et al.*, 1981). While ELISA absorbance ratios of 0·64 or less appeared to indicate the level at which most mares became susceptible to pregnancy, one of the fertile

domestic mares conceived at an absorbance ratio of 0·91 and one feral mare had not conceived in the absence of antibody against pig zonae. It was not determined why conception occurred in Mare SH at such a high anti-pig zona antibody titre, but it is possible that the associated cross-reactivity with horse zona antigens may have had a lower titre than in the other mares. The failure of the feral mare to conceive could have been due to one or more of several reasons (e.g. uterine infections following copulation, persistence of a corpus luteum, or early embryonic loss at 40 days and over, resulting in persistence of PMSG secretion) unconnected with the immunization programme.

Binding assays with boar spermatozoa and pig oocytes pretreated with horse anti-pig zona sera demonstrated antibody-dependent interference with sperm binding. The sperm blocking ability of the horse anti-pig zona antibodies, in conjunction with the evidence of their cross-reactivity with horse zona, suggests that stallion sperm binding sites at the zona surface may be blocked by steric hindrance from cross-linked antibodies as described by Aitken *et al.* (1982). According to Ahuja & Tzartos (1981), the antibodies are interacting with structures in close proximity to the binding sites rather than directly with the less immunogenic sperm receptors. Thus, sperm attachment and subsequent penetration are prevented as long as sufficient levels of cross-reacting antibodies are present.

Unfortunately, the contraceptive effect of zona antibody injections was not evaluated during one continuous physiological mating season (March–October). Instead, the study was initiated in June and the effects on fertility were studied during the second half of one mating season and the first half of the following mating season. Because of the apparent block of in-vivo fertilization well into the second mating season and the persistence of high antibody levels, it is reasonable to assume that the contraceptive effect would have lasted through one continuous physiological mating season. Possible causes, other than immunological, for the temporary inhibition of fertility in the 4 fertile domestic mares after zona injections were investigated. Clinically, no abnormalities were found regarding follicular development, cyclicity, ovulation and duration of oestrus. After 2 mares had regained fertility they conceived normally and produced healthy foals following normal pregnancies. Endocrinological profiles and histological sections of the ovaries $\sim$3 years after the last immunization revealed no ovarian malfunction and/or abnormal effects on the oestrous cycle with the exception of Mare SH. It has not been determined whether the development of inactivity of the ovaries of Mare SH was due to the effects of zona injections or to adverse effects of bilateral blindness because the photoperiod is critical to the initiation of cyclicity in mares. Ovarian malfunction and follicular changes have been reported as resulting from approximate dose equivalents of 4000 pig zonae/kg in rabbits (Skinner *et al.*, 1984) and 4–6 monthly doses of 118 and 59 zonae/kg in dogs (Mahi-Brown *et al.*, 1985). In contrast, the horses of this study received only 4 doses of 4 or 11 zonae/kg in 3 months and a single dose of 44 zonae/kg 6–10 months later. The possible absence of ovarian side effects in this study may be attributed to the proportionately lower dose of zona antigen administered.

Preliminary data on the use of an aluminium hydroxide gel as immunization adjuvant suggested satisfactory immune responses in horses without apparent side effects. However, more information is needed before any conclusions can be drawn.

Control mares receiving sham injections were not used in this study. Instead, the conception rates of untreated feral mares at the sanctuary and untreated domestic mares at the Equine Research Laboratory's breeding facility were considered alternative controls. The normal breeding behaviour of a healthy mare in the presence of fertile stallions is to produce one foal per breeding season and year. Annual conception rates of the untreated feral mares maintained at the sanctuary are estimated at 60–70%. This is consistent with the findings reported in other feral herds throughout the northern hemisphere (Kirkpatrick & Turner, 1986). Untreated fertile domestic mares maintained at the same facility with the 4 fertile zona-immunized mares conceived at an estimated annual rate of 90% when mated to the same fertile stallions.

In the past, stallions in wild horse populations in the Northern hemisphere have been the target for temporary sterilization as a means of controlling overpopulation. These attempts have met with minimal success. Provided a mare is fertile and inhibition of fertilization can be accomplished for

one physiological mating season, a period of 2 years will yield the birth of only one foal. This represents approximately one half the normal number of foals produced annually for each mare immunized. This preliminary study suggests that the use of preparations of pig zonae pellucidae may serve as an attractive alternative for the control of wild horse populations for which management levels are desired.

Further studies are needed, however, to purify the antigen used for contraceptive purposes, minimize the number of doses required, and improve the method of its administration, before any realistic management procedures can be adopted for use in feral horse populations. Immunization of pregnant mares and its effect upon the fetus and the mare's long-term fertility also should be investigated.

This investigation was supported by grants from the Oak Tree Racing Association, Arcadia, CA, and the Public Service Research and Dissemination Program, University of California, Davis, CA. We thank Mr William Tanaka and Ms Connie Litrell for excellent technical assistance; Ms Coralie Munro for preparation of the enzyme immunoassay for progesterone; and Ms Traci Gastineau for preparation of the manuscript.

ABSTRACT

Feral horses on Shackleford Banks Island, North Carolina, are managed by the National Park Service in order to reduce their impact on the fragile barrier island ecosystem. Management techniques include removal of young horses and immunocontraception of many of the mares using Porcine Zona Pellucida immunocontraceptive. This immunocontraceptive reduces the number of horses that need to be physically removed from the island, but there is concern that the contraception may be influencing the social behavior of the contracepted mares. We investigated the effect of immunocontraception on harem stability by tracking the number of harem changes of each adult mare through the breeding season over two seasons. In both seasons the mares that had been treated with the immunocontraceptive changed harems significantly more than mares never treated (2007 $P = 0.037$ and 2008 $P = 0.016$) and visited significantly more harems (2007 $P = 0.021$ and 2008 $P = 0.011$). The number of years treated did not have a significant effect on the number of harem changes (2007 $P = 0.145$ and 2008 $P = 0.848$), nor did the number of years a mare had been off contraceptive once the contraceptive was discontinued (2007 $P = 0.443$ and 2008 $P = 0.826$). Additionally, there was no significant difference in harem changes between mares that were actively contracepted and mares that had been treated in the past but were not currently actively contracepted (2007 $P = 0.336$ and 2008 $P = 0.533$). These results indicate that the PZP immunocontraceptive has a significant effect on harem stability and that once a mare has been contracepted the behavioral effect of the contraceptive treatment may not be readily reversed.

1. Introduction

Feral horse populations are often considered to be a nuisance due to their competition with livestock and their effect on native habitats (Rubenstein, 2001). Although commonly associated with grassland habitats, feral horses also occur on barrier islands, where they have been shown to have significant effects on native flora and fauna (Turner, 1969). De Stoppelaire et al. (2004) found that feral horse grazing had a significant negative impact on dune formation and contributes to dune erosion. Overgrazing of marsh areas may result in a loss of important nursery habitat for many marine species (Levin et al., 2002). Due to the impact of feral horse populations on the environment, populations are often actively managed to reduce population size through a variety of strategies, including selective removals, adoption programs, and fertility control (Rubenstein, 2001).

Feral horses generally associate in harems or bands consisting of up to three adult males, a group of adult females,

and their offspring (Linklater et al., 2000; Rubenstein, 1981, 1986). Although these social groups are generally stable (Klingel, 1975; Linklater et al., 2000) several studies have documented harem changes by adult females (Blumenshine et al., 2002; Rubenstein, 1981; Stevens, 1990). Harem stability has been found to positively correlate with yearly (Rubenstein, 1986) and lifetime reproductive success in females (Kaseda et al., 1995), possibly because mares that are more stable are able to devote more time to grazing and thus are in better condition to support a foal (Rubenstein, 1986). Females that change harems less frequently are more likely to reproduce and produce foals that survive to independence than mares that change harems more frequently (Rubenstein and Nuñez, 2009). Linklater et al. (1999) proposed that stable relationships between females and a harem male or group of males serve to reduce intraspecific aggression and the resultant reproductive costs. Altering harem stability may therefore alter overall reproductive rate, effective population size, and patterns of genetic diversity critical to maintaining long term stable populations. Thus, successful management of feral horse populations requires an understanding of how management strategies may alter social structure.

Population management through contraceptive use may minimize disturbance to social structure by preventing reproduction without altering group size or composition (Garrott and Taylor, 1990). Porcine Zona Pellucida (PZP) immunocontraception has been proposed as a contraceptive agent because it can be administered remotely through the use of darts, is relatively inexpensive, and has been shown to be safe and effective in many animal species (Barber and Fayrer-Hosken, 2000; Martinez and Harris, 2000). Immunocontraception with PZP is also temporary, lasting approximately two years in horses when conventional dosing schedules are used (Powell and Monfort, 2001), although treatment for over seven years may not be reversible (Kirkpatrick and Turner, 2002).

However, the results of studies that have assessed PZP impact on social behavior in feral horses are inconsistent. In a study of Assateague Island horses, no impact on social behavior was noted (Kirkpatrick et al., 1995). Other studies have found no effect on aggression initiated or received, activity budgets of mares, sexual behavior, or proximity to stallions (Powell, 1999; Powell and Monfort, 2001). In contrast, Nuñez et al. (2009) documented an increase in harem changes, number of harems mares associated with, and reproductive behaviors in treated mares. This study was conducted over a span of five weeks, included a limited number of mares, and occurred during the non-breeding season (Nuñez et al., 2009). Given the potential impact of increased rate of harem change on individual fitness, additional study is clearly necessary to determine if there is a significant effect of PZP immunocontraception on harem changes.

In this study we investigated the effect of PZP immunocontraception on harem stability of the feral horse population on Shackleford Banks, North Carolina, USA, during the course of two breeding seasons. We examined the number of harem changes each mare on the island made and the number of harems each mare visited during the course of the 2007 and 2008 breeding seasons. Every mare on the island was included in the analysis and data were collected over a period of several months each year. Given the previous work conducted by Nuñez et al. (2009), we hypothesized that contracepted mares would change harems significantly more often than control mares over both seasons and that contracepted mares would visit more harems than control mares. We also analyzed the effect of foaling status on harem changes, hypothesizing that mares that foaled during the survey year would change less than non-foaling mares.

We also attempted to relate the historical record of immunocontraception with the current patterns of harem changes. We examined the relationship between number of years contracepted, number of consecutive years contracepted, or number of years off contraception and harem changes. We predicted that harem changes would increase as the number of years contracepted increased and the number of consecutive years contracepted increased. Conversely, we predicted that the number of harem changes would decrease as the number of years off contraception increased. Finally, we examined the number of harem changes made by females that were actively contracepted in comparison to those that had been contracepted in the past, but were not currently contracepted. We predicted that actively contracepted mares would change harems more than mares with lapsed contraception.

2. Materials and methods

2.1. Study area

Shackleford Banks is a small barrier island located approximately 3 km off the coast of North Carolina, USA, in Cape Lookout National Seashore. The island is approximately 17 km long and 1 km wide with a variety of habitats including beach, swale, dunes, salt and freshwater marshes and maritime forest (Rubenstein, 1981). Individual horse bands are generally distributed along the entire island but individual harems occupy home ranges within a portion of the island. These home ranges can be grouped into far-east, mid-east, and western distributions. Each area contains at least one permanent water source, although digging may be necessary to access the water. Subjects in all areas of the island were observed for this study.

2.2. Study subjects

There are currently approximately 120 horses on the island. Most horses on the island are found in harems including one to two males and a group of mature females and their immature offspring. Several harems have an alpha stallion and a beta stallion. Over the course of the study, harem sizes ranged from a single male and a single female to two males, multiple females, and multiple offspring. Both sexes disperse from their natal harems as found in other feral horse populations (Feh, 1990). Territoriality has been reported on the island in the past (Rubenstein, 1981), but does not appear to exist currently. This change may be the result of reduced water sources in the eastern end of the island where territories were found. Harems and soli-

Please cite this article in press as: Madosky, J.M., et al., The effects of immunocontraception on harem fidelity in a feral horse (*Equus caballus*) population. Appl. Anim. Behav. Sci. (2010), doi:10.1016/j.applanim.2010.09.013

tary stallions tend to be found within the same general area of the island from season to season and year to year. There is some movement between areas, especially by dispersing juveniles, but most adult horses settle into one area of the island. There are exceptions – during a particularly dry summer several harems shifted areas or expanded their home range in order to access a better water source and there is more overlap between harems occupying the mid-east and far-east areas than between those in the mid-east and the west.

The minimum population of Shackleford horses is fixed by federal law at 100 horses (Prioli, 2007), and the National Park Service limits the population to approximately 130 individuals to reduce the potential for damage to the island ecosystem. The immunocontraception program was initiated in 2000 to reduce population size and control population growth (Nuñez et al., 2009). The contraceptive is administered by dart gun by the National Park Service between February and April every year. Each dose contains 100 μg of PZP mixed with 0.5 cm^3 of either Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem, Gibbstown, NJ, USA, #344289) for initial doses, or Freund's Incomplete Adjuvant (Sigma, St. Louis, MO, USA, #F5506) for subsequent doses (S. Stuska, personal communication; Nuñez et al., 2009). Booster doses are administered at least 14 days after the initial dose. At the initiation of the program eight mares were chosen as controls, chosen from eight distinct genetic lineages present on the island. These controls have never been contracepted. One additional control was added in 2007 in order to increase the age variation in controls and is included in the data analyzed for 2007, but died before the breeding season in 2008.

We observed harem affiliations for every mare on the island. Only mares that had dispersed from their natal harems were included in the analysis: nine controls and 55 contracepted mares in 2007 and eight control mares and 57 contracepted mares in 2008. The contracepted mares consisted of any mare that had ever been treated with the contraceptive, regardless of whether they had been treated in the previous year. We included all mares ever contracepted as there is some evidence that the contraceptive effect may last longer than one year (Powell and Monfort, 2001) and it is important to determine if contraception at any point changes the mare's subsequent behavior.

2.3. Behavioral sampling

The study was conducted by multiple observers supervised and trained by the primary investigator (J M). All observations were collected during the breeding season. Observations were collected between May 22nd, 2007 and July 29th, 2007 and between May 22nd, 2008 and August 12th, 2008, totaling 2965 total sightings in 2007 and 2985 total sightings in 2008. A sighting was defined as an independent positive identification of a mare and her harem association. Each observer recorded initial sightings upon identifying individuals. Unless a mare changed harems more than 20 min after the initial sighting no additional sightings were recorded of the harem by that observer unless the harem was independently identified at a later point in the day. If two observers identified the same individuals within 20 min only one identification was included in the sightings count. Harem changes were recorded regardless of their timing during the observation session. Individual horses were identified by freeze brand, distinctive markings on the face and body, color, and sex.

Harems were located an average of five times a week during 2007 and approximately four times a week during 2008. Each mare was sighted an average of 46.3 times in 2007 (S.E. 1.70) and 45.9 times in 2008 (S.E. 1.64), or approximately every 1.2 days (2007) and every 1.6 days (2008). After examining the standardized Z score, no individuals were found to be outliers, and there was no correlation between the number of sightings and harem changes for either year (2007 $P = 1.82$ and 2008 $P = 0.502$). Each time a harem was located the harem members were all individually identified and the composition was recorded along with the GPS location of the harem. The number of harem changes for each mare on the island was quantified as a change from one harem to another over successive sightings. All sightings from all observers were compiled for each season and each move from one harem to another was counted. Absence from a harem without a sighting in a different harem was not counted as a harem change as in some rare cases mares were found without a harem stallion. The number of harems a mare visited was quantified as the number of harems a mare was affiliated with over a given season.

2.4. Statistical analysis

We analyzed the effect of contraception on the mean number of harem changes per individual per season using Mann–Whitney U tests. The Mann–Whitney U test was selected given the non-normality of the data and the large difference in sample size between the control (nine in 2007, eight in 2008) and contracepted (55 in both years) mares, which may cause problems when using t-tests (Zar, 1999). One-tailed tests were used as we predicted that contracepted mares would change harems significantly more than control mares given the previous work by Nuñez et al. (2009). Effect size provides a measure of the strength of the relationship between the variables and was calculated using G-power (Faul et al., 2007) for a one-tailed t-test, which provides a reasonably equivalent estimate for the Mann–Whitney U analysis (Zar, 1999). Data were analyzed independently for each year and statistical outliers (one per year) were eliminated from the analysis. In this study both statistical outliers were contracepted mares that changed harems repeatedly over the season. Eliminating the outlier in each year made the analysis more conservative.

We examined the effect of age on harem changes using nonparametric correlation (Spearman's rho) between age on June 1st of the survey year and number of harem changes during that survey season. We ran Mann–Whitney U tests to determine if the average age differed between control and contracepted females. We also ran Kruskal–Wallis tests to determine if mares that foaled during a given survey year changed harems less than mares that did not foal based on their contraceptive status. All mares that foaled during the survey year (not just during the data collection season)

Please cite this article in press as: Madosky, J.M., et al., The effects of immunocontraception on harem fidelity in a feral horse (*Equus caballus*) population. Appl. Anim. Behav. Sci. (2010), doi:10.1016/j.applanim.2010.09.013

were included as mares that foaled even if the foal did not survive. The mares eliminated as statistical outliers for earlier analyses were also eliminated from the age and foaling analyses.

To investigate the impact of historical contraception patterns on current behavior, we analyzed the effect of total number of years contracepted, number of years contracepted consecutively with the survey year, total number of years ever consecutively contracepted, and number of years off contraception prior to the survey year on harem changes using Kruskal–Wallis tests. Our assessment of contracepted status in a given year was based on National Park Service records, and included only contraception attempts deemed successful (solid hit with the dart and immunocontraceptive solution ejected from the dart) were included. We analyzed the effect of active versus lapsed contraception on harem changes using Mann–Whitney *U* tests. Mares were considered to be actively contracepted if contraception had been administered in the past two years (Powell and Monfort, 2001). Again, data were analyzed independently for each year and statistical outliers were eliminated from the analysis. All analyses were conducted in SPSS 15 (SPSS Inc., 2006).

3. Results

3.1. Immunocontraception and harem changes

During 2007, there were nine controls and 55 contracepted mares; of the contracepted mares 25 received PZP in the previous year and 20 had not. Sixty-six percent of mares changed harems at least once over the season, with most changing harems multiple times. One individual mare changed harems 26 times over the course of the field season (the outlier in 2007 – a contracepted mare). Additionally, 70.9% of contracepted mares (39 of 55) changed harems at least once while 33.3% of control mares (three of nine) changed harems. Contracepted mares changed harems significantly more than control mares (Mann–Whitney $U = 157.00$, one-tailed $P = 0.0415$, effect size (d) = 0.61). The mean number of harem changes for contracepted mares was 3.62 ± 0.606 S.E., while the mean number of harem changes for uncontracepted mares was only 1.44 ± 0.766 S.E. (Fig. 1). Contracepted mares also visited more harems than control mares (Mann–Whitney $U = 145.5$, one-tailed $P = 0.021$, effect size (d) = 0.80). The mean number of harems visited for contracepted mares was 2.73 ± 0.213 S.E., while the mean number of harems visited for control mares was 1.67 ± 0.333 S.E.

During 2008, there were eight controls and 55 contracepted mares; 20 contracepted mares had received PZP in the previous year and 37 had not. Seventy-three percent of mares changed harem at least once, with a maximum of 27 harem changes (the outlier for 2008 – a different contracepted mare). In 2008, 77.2% of contracepted mares (44 of 57) changed harems at least once while only 50% of control mares (four of eight) changed harems. Again, contracepted mares changed harems significantly more frequently than control mares (Mann–Whitney $u = 124.5$, one-tailed $P = 0.0205$, effect size (d) = 0.92). In 2008, the mean number of harem changes for contracepted mares was 5.47 ± 0.758 S.E., while the mean number of harem changes for control mares was only 1.50 ± 0.732 S.E. (Fig. 1). Contracepted mares visited more harems that control mares (Mann–Whitney $U = 115$, one-tailed $P = 0.011$, effect size (d) = 1.10). The mean number of harems visited for contracepted mares was 3.05 ± 0.222 S.E., while the mean number of harems visited for control mares was 1.63 ± 0.263 S.E.

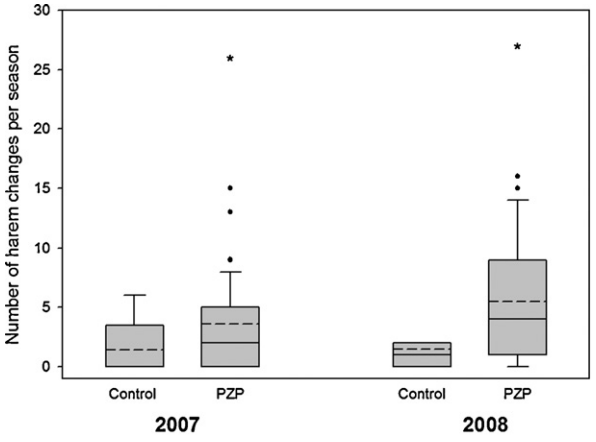

Fig. 1. Box plot showing the number of harem changes by contraceptive status for both 2007 and 2008 with median (solid line), mean (dashed line), and statistical outlier (asterisk). The statistical outlier is presented, but not included in analysis.

3.2. Age and harem changes

Age of the mare was not found to correlate with harem changes in either year (2007 rho = −0.073 (61), $P = 0.569$, 2008 rho = −0.023(62), $P = 0.854$). Additionally, average age was not significantly different between contracepted mares and control mares (2007 Mann–Whitney $U = 200.5$, $P = 0.403$, 2008 Mann–Whitney $U = 139$, $P = 0.084$).

3.3. Foaling and harem changes

In 2007, six control mares foaled and four non-control mares foaled; two non-controls had been off PZP for at least a year while two others had been contracepted the previous year. In 2008, seven control mares foaled and eight non-control mares foaled; again two mares contracepted the previous year foaled. In 2007, the 92% of treated mares did not foal while in 2008 90% of treated mares did not foal. There was a significant difference in the number of harem changes between mares that foaled and those that did not foal in 2008 (Mann–Whitney $U = 240.5$, $P = 0.042$) and a borderline significant difference in 2007 (Mann–Whitney $U = 165.0$, $P = 0.054$). In both cases mares with a foal changed harems less than mares without a foal. There was no significant difference in the number of harem changes between mares that were previously contracepted and foaled, mares that were controls and foaled, and mares that did not foal (Kruskal–Wallis 2007 $P = 0.120$, df = 2; 2008 $P = 0.112$, df = 2), but in both years mares that had previously been contracepted and foaled changed harems less

Please cite this article in press as: Madosky, J.M., et al., The effects of immunocontraception on harem fidelity in a feral horse (*Equus caballus*) population. Appl. Anim. Behav. Sci. (2010), doi:10.1016/j.applanim.2010.09.013

than contracepted mares without foals and more that control mares with foals.

3.4. Prevalence of harem changing

The distribution of harem changes each season significantly differed from the Poisson distribution (2007: Chi-square = 269.11, df = 10, $P < 0.001$; 2008: Chi-square = 761.15, df = 10, $P < 0.001$) suggesting that harem changes are not random. In general, there were more mares at the extremes and fewer mares in the center of the distribution than expected in a Poisson distribution. Prior to the immunocontraception program only 10.8% of mares changed harems in the same study area (Rubenstein, 1981) as opposed to the 66% and 73% found over the two seasons of this study. This difference was significant for both years (2007: Chi-square = 316.293, df = 1, $P < 0.001$; 2008: Chi-square = 401.599, df = 1, $P < 0.001$). In 2007, 94% of harems experienced at least one mare changing into or out of the harem and in 2008 97% of harems were affected by the harem changes.

3.5. Historical PZP treatment and harem changes

The number of years treated with PZP did not have a significant effect on the number of harem changes (Kruskal–Wallis 2007 $P = 0.199$, df = 6; 2008 $P = 0.871$, df = 7), nor did the number of years a mare had been off contraceptive after it had been discontinued (Kruskal–Wallis 2007 $P = 0.310$, df = 4; 2008 $P = 0.823$, df = 5). The number of years a mare had been treated consecutively with the survey year did not have a significant effect (Kruskal–Wallis 2007 $P = 0.273$, df = 7; 2008 $P = 0.093$, df = 4), nor did the maximum number of years a mare had ever been consecutively treated (Kruskal–Wallis 2007 $P = 0.782$, df = 6; 2008 $P = 0.889$, df = 6). There was no significant difference in harem changes between mares that were actively contracepted and mares that had been contracepted in the past but were not currently actively contracepted (2007 Mann–Whitney $U = 275.0$, $P = 0.196$, 2008 Mann–Whitney $U = 365.0$, $P = 0.751$).

4. Discussion

It is important in any management program to reduce the impacts of the management on the natural behavior of the population, though the importance of preserving behavior is often overlooked (Clemmons and Buchholz, 1997). In a highly social species such as feral horses it is critical to ensure that management strategies do not negatively impact social behavior. The results of this study indicate that the PZP immunocontraceptive used to control population numbers on Shackleford Banks Island has a significant negative effect on harem stability and that this behavioral effect is more persistent than the physiological contraceptive effect documented in previous studies (Powell and Monfort, 2001). This study demonstrates that the negative effect of the PZP immunocontraception on harem stability during the non-breeding season (Nuñez et al., 2009) was also present in the breeding season and that age was not related to number of harem changes in a given season. The significant increase in the historic rate of harem changes (from approximately 10% to approximately 66 and 73%) indicates that the overall rate of harem changes has increased since the immunocontraceptive program was initiated. Additionally, the high percentage of harems affected by harem changes indicates that the change in stable social structure after PZP immunocontraception affects the entire population, not just the mares contracepted.

Although the control sample size in this study was necessarily small due to management concerns, the replication of these results over two breeding seasons increases our confidence in the significance of differences in harem changes between contracepted and control mares. Given that mares stayed in the same general area, they frequently revisited the same harem several times during the season. The average number of harems visited for all mares was 2.58 in 2007 and 2.88 in 2008. Contracepted mares visited more harems than control mares in both years. It is important to note that some mares changed harems several times over the course of a week or even a day. High temporal resolution is critical to insure that these rapid harem changes between small numbers of harems are documented.

4.1. Impacts of historical contraceptive treatment

The fact that the number of harem changes did not differ among mares contracepted for different numbers of years, or different numbers of consecutive years, suggests that any exposure to PZP contraception may alter female behavior in fundamental ways. Additional years of contraception did not result in a higher number of harem changes, indicating that contracepting for multiple years does not decrease social stability further. However, increasing the number of years between contraception did not mitigate the behavioral effect of the contraception as expected. Surprisingly, mares that were not currently contracepted but had been in the past did not change harems less than mares that were actively contracepted. These analyses indicate that contraception schedule does not seem to mitigate the behavioral effects of the contraception and that the behavioral effects of the PZP contraception may persist long after the contraceptive should no longer be physiologically effective.

4.2. Influence of foals on harem fidelity

As seen in the non-breeding season (Nuñez et al., 2009), mares that had foals changed harems less than mares without a foal, regardless of their contraceptive status. The presence of a foal may increase mare fidelity. Unfortunately, it is difficult to separate the effect of the contraceptive itself from the result of the contraceptive – a lack of foals. If the presence of a foal is a driver of harem fidelity all contraceptive strategies may reduce social stability. Although not significantly different, the pattern of harem changes suggests that previously contracepted mares with foals may change more than controls with foals, but less than contracepted mares without foals suggesting that the contraceptive may have an effect beyond the presence of a foal. The failure to find a significant difference in this com-

Please cite this article in press as: Madosky, J.M., et al., The effects of immunocontraception on harem fidelity in a feral horse (*Equus caballus*) population. Appl. Anim. Behav. Sci. (2010), doi:10.1016/j.applanim.2010.09.013

parison may be due to low sample size. Further studies should be conducted with higher sample size to determine if contracepted mares with foals change harems at the same rate as control mares with foals.

It is possible that foaling returns mares to pre-contraceptive behavior – the sample size of this study was simply too low to conclusively answer this question. Relatively few mares that had been previously contracepted, but were not currently contracepted, foaled in either year – two out of 30 in 2007 and six out of 37 in 2008. Further studies should be conducted to determine if contracepted mares cease changing harems the season after they are reproductively successful or if they continue to change harems at a higher rate than mares that are never treated.

4.3. Potential motivations for harem infidelity

While it is clear that PZP immunocontraception causes a decrease in harem fidelity in this population regardless of season, it is unclear if this decrease is due to male or female choice. Males have been shown to discriminate between females based on female reproductive success in many taxa (Berglund et al., 1986; Berven, 1981; Johnson and Hubbell, 1984; Jones et al., 2001; Szykman et al., 2001; Verrell, 1985). This male choice may result in males defending reproductively successful mares (as evidenced by their foals) more than contracepted mares, allowing contracepted mares to change harems more often due to reduced male attentiveness. Previous studies found increased herding of mares with foals, but no difference in harem tending behaviors between currently contracepted mares and controls (Ransom et al., 2010). Alternatively, continuous cycling may lead to increased breeding attempts (Ransom et al., 2010) and male harassment of contracepted females. Contracepted females may elect to change harems more frequently to escape harassment or in an attempt to become pregnant. Future work aimed at distinguishing between male and female choice would be of particular interest.

4.4. Fitness impacts of decreased harem stability

Finally, the pervasive pattern of decreased harem stability may affect individual fitness of both males and females. In feral horses the breeding season corresponds to the foaling season (McCort, 1984) and thus a decrease in harem stability may lead to decreased grazing time while caloric demands on lactating mares are highest (Pagan, 1998; Pilliner, 1999) and decreased body condition even among mares that do not change harems. Ransom et al. (2010) found no difference in grazing time between treatment groups, but did not consider the overall effect of decreased harem stability on grazing. With decreased social stability, males may be required to spend more time guarding their harem to prevent harem changes. This increase in time spend guarding harems may lead to reduced time grazing and result in lowered body condition for the harem stallions. Future work will test if body condition of males or females has decreased since the implementation of the immunocontraception program.

4.5. Management implications

The contraception of the majority of adult females on the island may have substantially changed the social structure of the population, and it is unclear if contracepted mares will ever return to pre-contraception social stability. Immunocontraception using PZP offers many potential benefits, but managers should also consider the potential impacts PZP may have on social structure and stability. One of the key benefits of PZP immunocontraception is the temporary nature of the contraceptive affect. However, even if mares can be physiologically restored to reproductive condition; their continuing propensity to move may reduce their subsequent fitness and complicate management. The persistent behavioral effects are not reduced by manipulating the number of years treated with PZP, so reducing these behavioral effects may not be possible.

Given that PZP immunocontraceptive is administered to a wide variety of species including deer, African elephants, feral water buffalo, feral burros, elk and more than 95 species of zoo animals (ZooMontana, 2000), it is critical to further examine the behavioral effects the contraception may have on other species. Although immunocontraception does not have some of the potential physiological effects of steroidal contraceptives and while behavioral effects may vary with different social systems present in different species, this study indicates that social behavior can be changed by PZP immunocontraception. If, as is known in horses, social behavior affects reproductive success, population management may be complicated by lingering changes in social dynamics. Managers of other species treated with PZP should be cautious in assuming that PZP immunocontraception ameliorates the behavioral effects of other types of contraception.

5. Conclusions

This study, combined with previous work, demonstrates that there is a significant effect of PZP contraception on behavior in feral horses. Contracepted mares changed harems significantly more often than control mares. Further, a high percentage of mares change harems over the course of each season, indicating that this change is affecting the entire population. The duration of contraception does not have an effect on harem changes, nor does the duration of time off contraception reduce harem changes. Mare behavior is altered after contraception and this alteration appears to be long-lived. Given the pervasive behavioral effect of the PZP immunocontraception and the duration of this behavioral effect, it is especially important to investigate the potential costs of the reduction in harem stability to both sexes regardless of the direct effect of the contraceptive.

Summary The prospect for successful biocontrol using immunocontraception is threatened if there is adaptation to the vaccine through natural selection of individuals that are genetically resistant to the contraceptive agent. To assess this possibility we examined the literature and found that little relevant data are available for any species on the appropriate trait, fertility variation among immunized individuals, or about appropriate population and genetic parameters influencing the likelihood of a selection response. Some data are available on variation in antibody response to immunocontraceptives, but the relationship between antibody response and fertility levels is poorly documented. The antibody response data indicate low heritability for this trait suggesting that fertility levels of contraceptive-resistant individuals will also have a low heritability. Slow evolution of contraception resistance might therefore be anticipated. The absence of information about relevant parameters makes the construction of quantitative models premature. We discuss factors in particular need of investigation if predictions about resistance evolution are to be made. These include: 1. the genetic basis of fertility retention, 2. the proportion of the population resistant to the contraceptive agent and how this is affected by gene flow from refuge populations, 3. the genetically-based fitness tradeoffs of resistant individuals that often accompany selection, 4. cross-generation effects that can thwart the effects of selection, and 5. the efficiency of delivery of the contraceptive agent. An understanding of the above for particular species, and the development of appropriate divergently acting multiple vaccines that can be used in temporal rotation or in mixtures, should facilitate the development of management options to minimize resistance evolution.

Key words: immunocontraception, population control, resistance evolution.

Introduction

Environmental degradation and economic losses due to pest populations of native and exotic mammals are widespread problems[1,2] and immunocontraception has been heralded as a potential solution to these problems.[3–5] Immunocontraceptive vaccines are designed to target the reproductive system of pest mammals by promoting antibody production against various proteins necessary for reproduction.[6] The potential end result is a publicly acceptable and humane control over wildlife numbers. Nevertheless, the application of this method to wildlife populations is still in its infancy and several concerns have been raised regarding detrimental consequences of immunocontraception.[7] One of the most controversial issues involves selection for individuals who fail to mount a significant contraceptive response to the immunogen and hence remain fertile in the presence of the vaccine. It is possible that the progeny of these individuals will inherit this resistance in which case alleles of genes responsible will increase in frequency. Thereby biocontrol via immunocontraception will become increasingly ineffective over time due to strong selective pressures in favour of non-response to the immunocontraceptive.[8]

Received 3 July 2002; accepted 20 November 2002.

There are many examples of rapid evolutionary changes in populations faced with an environmental shift, such as the evolution of pesticide resistance in insects, resistance to anticoagulants in rodents, and resistance to heavy metals in plants and invertebrates.[9–11] Adaptation to environmental shifts, however, can also be unsuccessful. Many fossil studies suggest that species move away from stressful conditions rather than adapt to them.[12–14] There are also many documented examples of population extinction following stressful conditions.[15,16] Even in the case of pesticides and fungicides, resistance is not necessarily a foregone conclusion as there are agrichemicals that have been used for many years without resistance problems being encountered. Thus it is not clear that resistance adaptation to immunocontraceptives is inevitable.

To address the likelihood of resistance evolving a number of factors and population processes need to be considered. While extensive research has been conducted on developing immunocontraceptive vaccines, far less research has been directed towards assessing population variability in fertility response to vaccines, and towards identifying factors that might influence resistance evolution. Many such factors are intrinsic properties of the species or population, such as the degree to which contraception resistance is heritable. Other factors however, might be manipulated in ways that minimize resistance evolving, as has been done for pesticide resistance.[17]

Here we elaborate on the factors and processes that need to be understood to assess the likelihood of the evolution of

contraception resistance. We draw upon examples from other types of traits and from non-mammalian species and make suggestions for research directions to address concerns. Once relevant factors and processes are understood, strategies could be put in place that reduce the likelihood of this occurring.

Heritable variation and contraception resistance

Traits that vary are not always heritable. For any quantitative trait heritability is defined as the extent to which the phenotypic variance in a trait (V_P) is a consequence of genetically caused, as distinct from environmentally caused, variation (V_G as distinct from V_E). In the broadest sense it can be thought of as the proportion of the variance of a trait attributable to genetic causes. Note that in a 'contracepted population' fertility variation will not be all-or-none. Individuals will vary in the level of induced immunocontraception. Heritability is normally expressed as V_G/V_P, where $V_P = V_G + V_E$. The genetic variation component is normally further subdivided into three components, that due to additive effects (V_A), dominance effects (V_D) and genetic interaction (epistatic) effects (V_I). In predicting the response to selection, the additive effects are considered particularly important because they determine the similarity between parents and offspring; in other words the extent to which variation for a trait in one generation is passed to the next generation. Interaction effects can also have an impact on resemblance across generations. Because of the importance of V_A, the extent to which a trait is genetically determined is often expressed as V_A/V_P, defined as the narrow-sense heritability.[18] An important point is that if a high proportion of the population phenotypic variation is caused by environmental factors (V_E is large) then even intense selection will have little consequence in changing the phenotype of future generations. While levels of contraception resistance may vary markedly among individuals this does not mean heritability is high.

Immunocontraception research has largely ignored the heritability of fertility effects. However, there are heritability data on one component of the immune response, the antibody response, and there are some studies of associations between antibody response and resultant fertility. It is important to distinguish between heritabilities of these two measures because only effects on fertility are selected; non-response of antibodies will not be selected in the absence of associated fertility effects. Also, while antibody response to an immunocontraceptive treatment may be a primary mechanism that reduces fertility, it is unlikely to be the only mechanism since other processes such as cell-mediated immunity may be involved.

Heritabilities of antibody levels have been estimated from selection experiments. For example, selection of chickens for high and low antibody response to two different bacterial vaccines was carried out for seven generations.[19] All high response lines exhibited significant increases in antibody production to both vaccines when compared to the low lines. Unfortunately the omission of a control line means that we cannot be confident the increase was other than a response to general rearing conditions. Assuming this was not the case heritabilities for antibody response were low (ranging from –0.23–0.61). In a similar chicken experiment, selection over a period of 14 generations was the likely cause of high and low antibody titres attained and heritabilities ranged between 0.02 and 0.20.[20] In mice selected for high and low response to antigens for 15 generations, immune responses were 60 times higher in high lines compared to low lines.[21] Heritability was estimated at 0.18. Similar antibody heritabilities were estimated for pure-bred pigs immunized with two different vaccines.[22] Here low heritabilities of 0.18 ± 0.09 and 0.15 ± 0.07 were recorded for immune response to a modified-live pseudorabies vaccine and an inactivated bacterial bacterin, respectively, both measured 56 days after inoculation (however, it was 0.52 ± 0.15 for the bacterin after 119 days). Overall the data indicate that the level of an antibody response is heritable and will respond to selection, but heritabilities are not necessarily high relative to other traits.[23–25]

Immunization followed by a booster can elicit an immune response that results in reduced or zero fertility, provided antibody titres remain high.[26–28] However, in some cases a high immune response did not ensure against contraception resistance,[29–31] there was no apparent correlation between antibody titre and fertility[32] or associations between these traits were ambiguous because appropriate controls were either absent or inadequate.[29] These data indicate that high antibody titres do not ensure contraceptive efficacy. However such associations might be higher in future efforts to relate fertility to immune response levels if the efficacious epitopes are identified and quantified.

While the heritability for antibody response levels are low to intermediate, the heritability of fertility effects are likely to be even lower, since antibody levels are only one component of fertility effects and underlying components of traits have higher heritabilities than the traits themselves.[24] This might be particularly the case under field conditions where environmental variance is likely to be higher and contribute to each subcomponent of the fertility trait.[33] While most studies of heritable variation in non-response have taken place in defined laboratory situations, natural conditions will be more stressful and/or more variable, reducing the heritability of contraception resistance. Also, levels of heritable variation expressed in one environment are not necessarily the same as those in another environment.[34] Considering the above, in all likelihood contraception resistance will have a low heritability and therefore respond only slowly to selection.

Note that small sample size is an area for concern in the estimation of heritabilities for immunological responses. Heritabilities have usually been estimated using a few individuals and these estimates have little statistical power. They may be unrepresentative of a population, especially given the large amount of genetic polymorphism associated with immunological responses to contraception.[30,35] Estimates for outbred animals tend to be particularly variable (for example, natural variability in pregnancy rates of foxes after mating was between 35 and 90%).[36] Note also that heritabilities are not constant but change as selection proceeds because they depend on underlying gene frequencies that change under selection. Predictions of selection responses based on heritabilities therefore only apply for a few generations. Finally, note that heritabilities do not necessarily provide information on the extent to which a trait will shift under selection; the extent of change is also influenced by the mean of a trait.[25,37]

Genetic basis of contraception resistance and selection intensities

Heritable variation alone does not ensure the evolution of a particular phenotype. The type and level of genetic variation, and the intensity of selection are also important. If selection intensities are relatively high, a response to selection may not be successful and the population will go extinct even when there is some genetic variance in the population.[38] There are several cases in the pesticide resistance literature where resistance has not evolved or has not persisted despite the presence of genes with small effects on resistance variability and strong selection pressures.[39] Strong selection may kill all individuals unless they carry major resistance genes (although see Groeters and Tabashnik).[40] A similar situation is thought to be relevant for the evolution of resistance to other toxicants, such as heavy metals.[41] High selection intensities can favour the spread of genes having large effects on a trait, and genes that are often initially rare, particularly if the genes show some dominance. However, local populations may not be large enough to harbour such individuals and evolution does not occur. The frequency of genetic variants, the nature of the way the genes affect the phenotype and selection intensities are all important for predicting the occurrence and speed of evolutionary change.

The genetic and molecular basis of immunocontraception resistance has yet to be explored. However genetic variation in some components of the immune response, especially antibody response, has been investigated. Early research suggested that the genetic basis for antibody response is under the control of a dominant Mendelian locus.[42] Later data suggested both a dominant autosomal effect of a major gene and some polygenic influences.[43,44] The MHC complex, containing an array of tightly linked genes that are highly polymorphic, appears to be a strong candidate for a major autosomal dominant gene that affects antibody response.[45,46] However non-MHC linked genes, such as those involved with Class I antigen processing or genes that influence antibody isotope usage, may have substantial effects.[47] Therefore the genetic control of antibody non-response might be realistically modelled as two or more independent (unlinked) polymorphic genes, one with a major effect on fitness, the MHC cluster, and several with minor effects.

For contraception resistance on the other hand, where associations between antibody response and contraception resistance may not be strong, other genes again are likely to be involved. For example, genes that effect variation in cell-mediated immune responsiveness,[48] or expression of cytokines (reviewed in Reiner and Locksley).[49] A further level of complexity is introduced if the antigen is delivered using a genetically modified vector organism, in which case the target species may evolve resistance to the vector itself. The evolutionary genetics of host resistance to a virulent horizontally transmitted pathogen is well-researched and modelled[50,51] and may help our understanding of contraception resistance evolution in these situations. While single genes can be important in host-pathogen systems, this complexity makes the prediction of contraception resistance even more difficult. It may be appropriate to model contraception resistance using a small number of major genes and a large number of minor genes. Polygenic models that rely on an infinite number of loci each with small effect, or simple single gene models, are likely to be unrealistic. More information is needed if models relevant to natural populations are to be developed.

Proportion of the population that is contraceptive resistant

To predict the outcome of selection for contraception resistance it will be important to know both the initial frequency of resistant individuals and the ongoing impact of immigration from non-immunized sources, from 'refuges', that can dilute the frequency of resistant individuals. Such inward gene flow could prevent resistance evolution. The proportion of a population that retains any level of fertility after contraception treatment is likely to be highly variable.[52,53] For a given immunocontraceptive in a particular population it is this proportion that determines the initial selection response. If the initial frequency is very low resistance will build up slowly and populations may become extinct because they do not reach effective demographic population size. Data useful for predictive purposes need to be obtained from outbred animals in the field, as laboratory-reared or inbred populations will have less genetic variability affecting contraception resistance. Also, captive populations are likely to show high fertility levels, having been selected for breeding in captivity and buffered against natural stresses that decrease fertility.

Because average fertility levels of non-immunized individuals are below that of the most fertile individual, one must assume that the functional, or effective level of contraception resistance (remaining fertility) is higher than the published data indicate. For example, using data from fox,[52] the effective contraception-resistance fertility after immunization would be close to 53% (36%, of control fertility at 68%), and for the feral mares[53] the effective level of fertility would be between 8 and 51% (between 4.5 and 28.6% of about 55%). We suggest that the effective contraception resistance levels be used in any evolutionary modelling exercises. However, these levels might be overestimates since breeding failure in controls may be related to other factors (for example, lack of opportunity or poor conditions compared to treated individuals).

To predict the results of selection for contraception resistance, information on immigration from refuge populations is needed. Gene flow often limits adaptation, as has been recognized for a number of traits and organisms.[54–56] An influx of susceptible individuals into a population previously exposed to controlling treatment will dilute the frequency of resistance genes. The dilution effect is likely to be particularly significant in the case of polygenic resistance. When individuals with polygenic resistance mate to susceptible individuals, the gene combination needed for resistance will be lost in the ensuing generations because there is only a low probability of recovering offspring with polygenic resistance. This dilution effect has a much lower impact in the case of major genes. The dilution effect will depend on the species, population, and environment being considered. For example interpopulation movement level is likely to be very different between the red kangaroo[57] and the brushtail possum.[58] Clearly in captive populations gene flow will have no influence on the response rates to selection for contraception resistance.[55]

Cross generation effects, resistance tradeoffs and costs of contraception

Cross-generation effects

Cross-generation effects can have a negative impact on selection responses.[59] Cross-generation effects arise when environments experienced by the parent influence the phenotype/performance of the offspring, or when genes carried by the parent (usually the mother) influence offspring phenotype (even when the offspring has not inherited a causal gene). Often this results in a fitness cost in the F1 generation[60] that can influence selection responses. They can even lead to phenotypic changes in the direction opposite to that being selected.[61]

The potential for an immunocontraceptive vaccine to have cross-generation effects is suggested by one study on rats.[62] Both males and females were subject to vaccination against luteinizing hormone receptor (LHR), and mated with untreated individuals. For both treated sexes the number of progeny per coupling was reduced compared to control groups but was more apparent in the couplings of a treated male. A cross-generation fertility effect was evident for the F1 progeny from treated females where, in the absence of vaccine, the F1 progeny had reduced fertility. Such effects have the potential to reduce the selective intensity for contraception resistance and alter the rate of evolution of contraception resistance.

Genetic trade-offs

Much of life history theory is concerned with genetic tradeoffs and how they limit evolutionary change.[25] There is a lot of evidence that alleles favoured under one set of environmental conditions can be selected against under a different set of conditions[15,25] thus leading to tradeoffs between environments. Moreover, genetic change in one trait often has costs in terms of a different trait even when the environment does not change. There are good examples of tradeoffs associated with resistance to chemicals. For instance, while both warfarin resistance in rodents and pesticide resistance in insects lead to increased survival when these poisons are present in the environment, resistance is often selected against when the chemical is absent resulting in the loss of resistance in populations that are no longer exposed to the toxin.[60,63,64]

Subsequent fitness improvement that counteracts these deleterious effects may occur in the longer term however, when treatment persists.[9,10] This is particularly well studied in the case of sheep blowflies where resistance to the pesticide diazinon is associated with a fitness cost.[65] In this example there is no fitness cost detectable in the genetic background of a contemporary field population where the pesticide has been present for many years. In this population genes have been selected that modify the deleterious effects of the major resistance gene. If a major gene for contraception resistance was associated with fitness costs and reached high frequency in a treated pest population, modifier gene selection could nullify the cost, helping to maintain the gene in the population and thwart control efforts.

Little research has been conducted into defining or clarifying potential tradeoffs for immunocontraception resistance. This issue is pertinent given that a low level of responsiveness to some antigens could potentially influence responsiveness to others. These individuals may be more susceptible to particular categories of infectious or parasitic agents that retard selection for contraception resistance, particularly if the target population experiences intermittent applications of the vaccine. With intermittent selection, any change in contraception resistance gene frequencies could theoretically be reversed during periods when the immunocontraceptive agent is absent.

Tradeoffs will only limit adaptation if they have a genetic basis. To establish this in mammals individuals should be followed over two or more generations and sample sizes need to be large.[18] While for morphological traits there may be a good correspondence between simple phenotypic tradeoff associations and genetic correlations, this is not the case for other traits[25] making it difficult to test for genetic tradeoffs involving immunocontraception resistance.

Loss of genetic variability and immunological fitness

A possible outcome of long-term selection for contraception resistance is a general loss of genetic variability. In the laboratory, strong selection for a single trait can reduce levels of genetic variability in that trait as favoured alleles go to fixation. While in theory this would lead to a reduction in trait variance it often does not.[18] Intense selection can also lead to a general decrease in genetic variation if the number of breeding individuals in a population is small. However there is also evidence that sharp reductions in population size can increase levels of trait variability due to the 'unveiling' of nonadditive genetic variance.[66] A reduction in population size as a consequence of immunocontraception may therefore not invariably decrease phenotypic variability.

Another possible outcome of long-term selection for contraception resistance is a loss of immunocompetence.[7,8] As the fertility response to an antigen may be largely controlled by the MHC locus, individuals resistant to contraception could show reduced diversity in their immunological response. At this stage a few laboratory investigations have reported that selection for high antibody responders is associated with altered immunological fitness against other antigens/pathogens, but this is not a general finding.[21,67] If hypersensitivity to a specific infectious agent was a recognized tradeoff for a contraception resistance gene, a synergistic treatment program (treatment with both vaccine and infectious agent) could become part of a management control strategy, similar to what has been implemented for integrated insect pest management schemes.[68]

Under field conditions, the outcome of contraception-resistance selection on levels of genetic variation in target and other traits is difficult to predict. Effects are likely to be species-specific and dependent on the duration and intensity of selection. To determine the impact of such selection on levels of genetic variation and overall immuno-competence it will be necessary to undertake both field and laboratory-based experiments looking at longer term effects. Of course loss of genetic variability and immunological fitness will be less of a problem for invasive or exotic pest populations targeted for elimination.

Also note that within the lifetime of immunized individuals deleterious direct effects of immunization may occur that

lead to behavioural changes or low 'quality of life', effects that are over-and-above those that reduce fertility.[7] These changes may or may not be an undesirable outcome of the immunocontraception, however, they can effect social dynamics within the population and impact on selection for contraception resistance.

The component of the population targeted for contraception

The proportion of a population immunized will impact directly on the rate of increase of contraception resistance in a population, since the selection intensity will be reduced if not all breeding individuals are targeted. If the species to be controlled is contained within restricted habitats, it may be possible to inoculate the entire population. However in many cases this will be impossible. Several modelling and laboratory investigations have suggested that, to obtain the necessary reduction in population size, approximately 50–75% of individuals need to be targeted.[69–71] If only a small proportion of the breeding population is targeted effectively, selection intensity for increased levels of contraception resistance will be low.

The sex that is targeted can influence potential selection intensity. In most case studies female-specific contraceptive agents have been tested[27,31,72] although males have also been investigated.[62,73] When the immunogen targets the reproductive response of both sexes, there will be fewer progeny from contraception-resistant individuals. However selection for contraception resistance will be greater as all progeny will contain contraception-resistant genes from both parents, as opposed to only the treated sex.

The social and reproductive dynamics of the targeted population will influence selection intensities for resistance. For example, under a harem system where a dominant male mates many females, control programs may target the dominant male in the group. Alternatively, when reproduction occurs in distinct times of the year, it may be more effective to only target populations at these times, perhaps when climatic or nutritional stress is maximum. These approaches could more effectively reduce population size without increasing selection intensity for contraception resistance. Knowledge of a species' social and mating structure can help the design of a strategy to minimize resistance evolution.

Optimal contraception requires multiple and booster immunizations

Multiple applications of an immunogen are required to elicit the maximum level of infertility response.[28] This is generally the case for a range of laboratory and outbred species. Thus to achieve high levels of infertility individuals need to receive multiple applications, spread out over time. In addition, immunocontraceptive effects have a finite duration and booster vaccinations are required to maintain a high level of infertility.[74] This is particularly relevant for species with a long generation time and/or multiple reproductive seasons – additional factors that would impinge on the timeframe for the evolution of immunocontraception resistance. While the goal for much of the research is for a long-lasting single shot vaccination this does not yet appear to have been achieved. It is therefore likely that in natural populations it may be difficult, even impossible, to implement complete control by a single treatment or repeated regular delivery of the immunogen to many or most individuals. In large, or complex populations, a number of strong short-term selective episodes at intermittent times would be interspersed with periods of reduced selection for resistance. If there are genetic tradeoffs associated with contraception-resistance there may even be negative selection at these times, decreasing the chance of resistance evolving.

Multiple vaccines in rotation or mixtures

A multiple-vaccine approach has been advocated as a strategy to improve contraception and population control;[30] it might also minimize the chance of resistance evolving. This strategy has been successfully used to reduce the rate of insecticide resistance evolution in field situations.[17,75,76] By rotating pesticides, the number of applications of a particular chemical is reduced. This effectively reduces the selection pressure for resistance to each pesticide and also allows any fitness costs of resistance alleles to decrease resistance incidence between applications. Moreover, any influx of susceptible individuals into a target population in the intervening period can further reduce the incidence of resistance. The other strategy involves mixing pesticides. This may delay the evolution of resistance more effectively than pesticide rotation strategies,[77] however, if resistance occurs it is more likely to elicit a single cross-resistance response.[78] Pesticides with a contrasting mode of action are the best choice, whether rotating or mixing, since a common mechanism of resistance is more likely for related pesticides. The experimental and theoretical aspects of a multiple-treatment approach with respect to pesticides has been discussed by Tabashnik.[79]

Exposure to multiple antigenic determinants may therefore be effective, particularly where the mode of action of the immuno-contraceptives varies and the same genes are unlikely to confer cross-resistance. While in some systems a response to a particular antigen carries a similar high response to other antigens, this is not always the case, as has been demonstrated in mice.[80] A range of antigenic determinants within a vaccine might elicit diverse contraceptive-effective responses within individuals, and thus decrease the fertility level of the average individual, and the frequency of contraception-resistant individuals. In fact the growing understanding of the complexity of fertility controlling processes, and growing number of candidate target molecules, are leading to suggestions that multiple antigen approaches will be most effective in future immunocontraceptive efforts.[5,81,82] Multiple genetic bases for contraception resistance will be more likely under this approach and resistant individuals would be rarer. As well as improving control a multiple antigen approach would retard the evolution of contraception resistance.

Conclusion

It seems likely that the use of immunocontraception will result in selection pressure for contraception resistance. The development of contraception resistance will vary among target species and may only occur over such a long time frame that changes in control approaches or community

priorities remove the need for concern. However until levels of heritable variation in contraception resistance are assessed in each particular situation, and unless other pertinent factors that are likely to impinge on resistance evolution are evaluated, it is not clear if or how rapidly contraception resistance will develop in a population. The other pertinent factors include:

1. the genetic basis of the resistance
2. the frequency of resistant individuals, both initially and on-going as influenced by immigration from non-contracepted refuges
3. fitness costs associated with the resistance phenotype
4. cross-generation effects, and
5. the efficiency of delivery of the vaccine

If enough information is available on the contraception response and population biology of the target species it should be possible to implement strategies for reducing the rate of evolution of contraception resistance.

Acknowledgements

This paper is based on a report commissioned by the Cooperative Research Centre for Conservation and Management of Marsupials. The study was jointly funded by the Australian Government's CRC Program and Marsupial CRC Core Participant, Landcare Research, a New Zealand Crown Research Institute. The authors acknowledge support from the Australian Research Council through their Special Research Centre program.

For discussion and helpful comments on an earlier draft of this manuscript we thank P. Cowan, D. Kay, J. McKenzie and J. Rodger. We are also grateful to James Rush for sharing his knowledge of immunocontraception genetics, and to two reviewers for valuable suggestions.

ABSTRACT

Immunocontraception with porcine ZP (pZP) can be an effective means of fertility control in feral horses. Previous studies suggest that antibodies produced after pZP vaccination may both inhibit fertilization and cause follicular dysgenesis. Zonastat-H, PZP-22, and SpayVac are three pZP vaccines proposed for use in horses. Although all these vaccines contain the pZP antigen, variations in antigen preparation and vaccine formulation lead to differences in antigenic properties among them. Likewise, despite numerous efficacy and safety studies of Zonastat-H and PZP-22, the contraceptive mechanisms of SpayVac remain unclear. The preparation of pZP for SpayVac is thought to include more nonzona proteins, making it less pure than the other two vaccines. This may result in increased antigenicity of the vaccine. We therefore investigated the immunoreactivity of serum antibodies from SpayVac-vaccinated mares to equine zona protein. Western blot analyses revealed an immunoreactivity of these antibodies to protein isolated from mature equine oocytes, ZP, follicular tissues, and ovarian tissues. Immunohistochemical analyses were used to locate the binding of serum antibodies to the ZP of immature oocytes in ovarian stromal tissue. We also found serum antibodies from SpayVac-treated mares to be predominantly specific for zona protein 3. Collectively, our results suggest a model where serum antibodies produced in response to SpayVac vaccination are immunoreactive to equine zona protein *in vitro*. Our study lends insight into the contraceptive mechanisms underlying the infertility observed after SpayVac vaccination.

1. Introduction

Feral horse (*Equus caballus*) populations residing on lands managed by the Bureau of Land Management and United States Forest Service are federally protected under the Wild Free-Roaming Horses and Burros Act (Public Law 92–195). Provided this protection, in combination with a lack of natural predators, many horse populations can grow 10% to 25% annually [1]. Because their habitats remain constant in size and limited in forage availability, feral horse populations often overwhelm available resources.

Researchers have investigated the use of immunocontraceptive vaccines as an approach to control feral horse population growth [2]. Immunocontraceptive vaccines stimulate an animal's own immune system to interfere with a critical reproductive event [2]. When an antigen is combined with an immunologic adjuvant and injected into an animal, antigen-specific antibodies are produced [3]. These antibodies are thought to bind not only to the antigen for which they are specific but also to structurally similar endogenous

proteins in the target animal. Immunocontraceptive vaccines can therefore target specific hormones or proteins within the animal [4].

Zonastat-H (Humane Society of the United States, Washington, DC, USA), PZP-22 [5], and SpayVac (Immunovaccine Inc., Halifax, Nova Scotia, Canada) are immunocontraceptive vaccines that incorporate the porcine ZP (pZP) antigen. Vaccination with the pZP antigen is reported to stimulate an immune response that can be measured by serum antibody titers [6,7]. Infertility is thought to be achieved by the binding of these serum antibodies to ZP proteins on mature oocytes, thereby inhibiting sperm binding and penetration [8–10]. Follicular dysgenesis characterized by diminished ovulatory ability, absence of mature oocytes and follicles, decreased ovarian weights, and a decline in ovarian estrogen secretion has also been reported after pZP vaccination [11–13]. These studies suggest that serum antibodies produced in response to pZP vaccination may act both on ZP of ovulated oocytes in the oviduct and during folliculogenesis in the ovary.

Despite these valuable pathologic studies in multiple species, the molecular mechanisms by which antibodies produced in response to SpayVac vaccination result in infertility remain unclear. Although serum antibodies may not accurately predict the contraceptive efficacy of a vaccine, understanding whether these antibodies are capable of binding key proteins involved in folliculogenesis and fertilization is a central part of understanding how the vaccine may be acting to inhibit fertility. Our objectives were to (1) determine whether vaccination of feral horse mares with SpayVac results in the production of antibodies immunoreactive to equine zona protein and ovarian tissues and (2) identify the location of binding of these antibodies to equine oocytes and ovarian tissue.

2. Materials and methods

2.1. Animal use

No live animals were used exclusively for this study. All tissue and serum samples from nonvaccinated mares were collected as part of other ongoing research under protocols approved by the Institutional Animal Care and Use Committee at Colorado State University. Serum from SpayVac-vaccinated mares was obtained from samples previously collected under protocols approved by the Fort Collins Science Center's Institutional Animal Care and Use Committee as part of a study on SpayVac immunocontraception (Roelle, U.S. Geological Survey, Pauls Valley, OK, USA).

2.2. Samples

Equine ovaries and renal tissues were harvested from necropsy samples collected at the Animal Reproduction and Biotechnology Laboratory, Colorado State University (Fort Collins, CO, USA). Oocytes were collected by aspirating follicular fluid from follicles on the ovaries. Oocytes were stored in PBS at 4 °C. Tissue samples were either fixed in 4% paraformaldehyde and sent to the Colorado State University's Veterinary Diagnostics Laboratory to be embedded in paraffin or frozen and stored at −80 °C.

Serum from vaccinated mares of known titer levels was obtained from a study on SpayVac immunocontraception. Mares were vaccinated with 200-μg pZP (Immunovaccine Inc.). Blood samples were collected and processed 3 months after vaccination, and serum was stored at −80 °C. Serum antibody titers from these samples were determined using ELISA by Immunovaccine Inc. Titers were read as average optical density across three readings of the same sample and then reported as a percent of standard, where the standard was a serum sample containing a large number of antibodies specific to the vaccine. Percent of standard values, or titers, ranged from less than 50.00 to as high as 178.33, with 100.00 representing a sample that had an antibody profile similar to that of the standard. Mares with higher titer levels, specifically values greater than 100.00, were considered to have an increased number of vaccine-specific antibodies in their serum. Because antibodies against the vaccine are thought to be responsible for the contraceptive effect, higher titer levels correlate to increased vaccination efficacy. Serum samples from eight mares of high titer levels ranging from 97.83% to 178.33% of standard were therefore used interchangeably throughout the study. Serum from two nonvaccinated mares was obtained from other ongoing research at the Animal Reproduction and Biotechnology Laboratory. All serum samples were stored at −80 °C.

2.3. Protein isolation and quantification

Isolation of protein was performed using radioimmunoprecipitation assay (RIPA) lysis buffer (150-mM sodium chloride, 1.0% NP-40, 0.5% sodium deoxycholate, 0.1% sodium dodecyl sulfate, 50-mM Tris, pH 8.0, 1-mM EDTA). Samples were suspended in RIPA, homogenized and sonicated twice, and subjected to centrifugation for 10 minutes at 10,000 revolutions per minute (Centrifuge Model #5417R; Eppendorf, Germany). The supernatant containing protein was recovered, and the DNA-containing pellet was discarded. All protein was isolated just before use and never frozen.

To isolate protein from equine oocytes, cumulus cells were mechanically stripped from four oocytes by a series of passages through a 10-μL embryo pipette (Bioniche, Pullman, WA, USA), while the oocytes were suspended in PBS. Oocytes were suspended in 40-μL RIPA lysis buffer and processed as detailed previously. The final supernatant volume was divided into two 20-μL samples.

To isolate protein from the ZP of equine oocytes, the cumulus cells were mechanically stripped from four equine oocytes and ultrasharp splitting blades (Bioniche) were used to make an incision in each ZP. Turbulence was created to free each ZP from the ooplasm, and the ZP of the four oocytes were suspended in 40-μL RIPA lysis buffer. Protein was isolated as previously described, and the final volume of the supernatant was divided into two 20-μL samples.

To isolate protein from ovarian and renal tissues, a small section of each tissue was excised from the sample, suspended in 300-μL RIPA lysis buffer, and processed as detailed previously. Protein content was quantified following the manufacturer's protocol for the Pierce BCA

Protein Assay Kit (Catalog #23227; Thermo Scientific, Rockford, IL, USA). An aliquot containing 40 μg of each protein sample was transferred to individual 1.7-mL conical tubes and brought up to 20 μL in volume with PBS.

2.4. Electrophoresis and Western blot analysis

Protein samples were incubated with 4-μL 6X Laemmli sample buffer (375-mM Tris-HCL, pH 6.8, 48% glycerol, 6% sodium dodecyl sulfate, 0.01% bromophenol blue, 20% dithiothreitol), loaded into 10% Mini-PROTEAN TGX precast polyacrylamide gels (Bio-Rad, Hercules, CA, USA) in duplicate, separated by electrophoresis, and transferred to Protran nitrocellulose membranes (GE Healthcare Life Sciences, Pittsburgh, PA, USA). Membranes were blocked in 5% blocking buffer (5-g nonfat dried milk in 100-mL 1X TBST—50-mM Tris-HCL, pH 7.4, 150-mM NaCl, 0.1% Tween 20) for 1 hour and then cut down the middle such that each half contained one set of the duplicate protein samples. One half of each membrane was incubated in a dilution (1:50 in 1% blocking buffer—1-g nonfat dried milk in 100-mL 1X TBST) of either serum from a SpayVac-vaccinated mare or serum from a nonvaccinated mare overnight. Both membranes were then incubated with horseradish peroxidase (HRP) –conjugated goat polyclonal secondary antibody to horse immunoglobulin G (IgG; 1:10,000 in 1% blocking buffer; ab102396; Abcam, San Francisco, CA, USA) for 1 hour. Membranes were exposed to SuperSignal West Dura Extended Duration Substrate (Thermo Scientific) for 5 seconds and imaged immediately on a Molecular Imager ChemiDoc XRS+ System (Bio-Rad). Membranes were washed between each step with 1X TBST for 15 minutes.

A mouse anti–β actin monoclonal primary antibody (1:100 in 1% BSA; ab8226; Abcam) followed by an HRP-conjugated donkey antimouse IgG polyclonal secondary antibody (1:1000 in 1% BSA; ab97030; Abcam) was used as a loading control for protein isolated from follicular and ovarian tissues. A rabbit anti-ZP3 polyclonal primary antibody (1:100 in 1% blocking buffer; ap17235b; Abgent) followed by HRP-conjugated goat antirabbit IgG polyclonal secondary antibody (1:1000 in 1% blocking buffer; #170-6515; Bio-Rad) was used for protein isolated from oocytes and ZP as a loading control. Binding specificity was determined by preincubation of the Western blot membranes with either the rabbit anti-ZP3 polyclonal antibody (ap17235b; Abgent) or rabbit anti-ZP4 polyclonal antibody (ap12724b; Abgent) overnight before incubation with serum from a SpayVac-vaccinated mare overnight and use of the HRP-conjugated goat polyclonal secondary antibody to horse IgG (1:10,000 in 1% blocking buffer; ab102396; Abcam).

2.5. Immunohistochemistry

Three consecutive 5-μm sections were sliced from tissue embedded in paraffin blocks and placed on two glass slides. The slides were incubated at 55 °C for 30 minutes. Citrisolv (Thermo Scientific) along with an alcohol gradient was used to dewax and rehydrate the tissue slices.

After rehydration, one of the three slices of tissues was subjected to a hematoxylin and eosin staining protocol. The slide was incubated in hematoxylin for 1 minute, rinsed under running tap water for 5 minutes, incubated in eosin for 5 minutes, rinsed once more under running tap water, and dehydrated through an alcohol and citrisolv gradient. The slide was then left to air dry before being mounted with a coverslip using Cytoseal (Thermo Scientific).

The other slide, containing two tissue slices, was boiled in 10-mM sodium citrate (pH 6.0) for 20 minutes and blocked in 5% natural goat serum in 1% BSA (0.1-g BSA in 10-mL 1X PBS) for 2 hours. The two tissue slices were then incubated with a dilution (1:50 in 1% BSA) of serum from either a SpayVac-vaccinated mare or nonvaccinated mare overnight. The following day, both tissue slices were incubated with the HRP-conjugated goat polyclonal secondary antibody to horse IgG (1:1000 in 1% BSA; ab102396; Abcam) for 1 hour. Impact DAB Peroxidase Substrate Solution (Vector Laboratories, Burlingame, CA, USA) was then applied for 10 minutes. The slide contents were dehydrated through an alcohol and citrisolv gradient, allowed to dry, and mounted with a coverslip using cytoseal. The slide was washed between each step with 1X PBS for 10 minutes, and each incubation step took place in a moist chamber. All samples were imaged using light microscopy.

Binding specificity of serum antibodies from SpayVac-vaccinated mares was determined by presaturating a sample of serum from a SpayVac-vaccinated mare with ZP3 and ZP4 synthetic blocking peptides (bp17235b and bp12724b, respectively; Abgent). An aliquot of 30 μg of each peptide was added to 10 μL of serum in 500-μL 1% BSA before use as the primary antibody for immunohistochemical analysis. The HRP-conjugated goat antihorse IgG polyclonal antibody was used as the secondary antibody (1:1000 in 1% BSA; ab102396; Abcam).

3. Results

3.1. Immunoreactivity of serum antibodies from SpayVac-vaccinated mares to equine zona protein

Western blot analysis revealed the immunoreactivity of serum from SpayVac-vaccinated mares to equine zona protein. Antibodies in the serum of SpayVac-vaccinated mares bound to protein isolated from whole equine oocytes and equine ZP (Fig. 1A), as well as to protein isolated from equine ovarian and follicular tissues (Fig. 1C). These antibodies are not endogenously found in serum from nonvaccinated mares (Fig. 1B, D) and did not bind protein isolated from equine renal tissue (Fig. 1C). Western blot analyses of equine oocytes and ZP were repeated twice and analyses of equine tissues were repeated four times with different protein and serum samples to verify consistency.

3.2. Location of binding of serum antibodies from SpayVac-vaccinated mares to equine ovarian tissue

Immunohistochemical staining of equine ovarian tissue located the binding of serum antibodies from SpayVac-vaccinated mares to the ZP of immature oocytes of primary follicles (Fig. 2E). These serum antibodies did not bind oocytes in primordial follicles, where the ZP was not yet formed as part of folliculogenesis (Fig. 2B). They are also not found in serum from nonvaccinated mares (Fig. 2C, F).

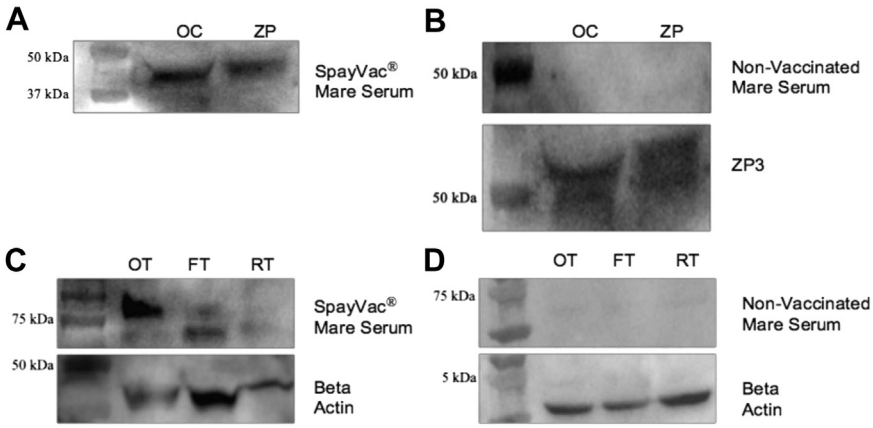

Fig. 1. Immunoreactivity of serum antibodies from SpayVac-vaccinated mares for equine zona protein. Western blot analysis of protein isolated from the equine ZP of two oocytes, two whole equine oocytes (OC), 40-μg equine ovarian tissue (OT), 40-μg equine follicular tissue (FT), and 40-μg equine renal tissue (RT) using serum from a SpayVac-vaccinated mare (A and C) or serum from a nonvaccinated mare (B and D). Protein quantities are expressed per lane. Anti-ZP3 (B) and anti–β actin (D) are used as loading controls. Renal tissue was used as a negative control. Molecular weight standards appear in the leftmost lane of each gel.

Immunohistochemical analyses were repeated twice with different serum and tissue samples.

3.3. *Specificity of serum antibodies from SpayVac-vaccinated mares for equine ZP3*

The addition of ZP3 and ZP4 blocking peptides to a sample of serum from a SpayVac-vaccinated mare successfully saturated antibodies in the serum and blocked their ability to bind zona proteins in the tissue (Fig. 3C). In the absence of blocking peptides, serum antibodies from the SpayVac-vaccinated mare bound to an immature oocyte in the ovarian tissue (Fig. 3B).

Preincubation of a Western blot membrane with anti-ZP3 polyclonal antibody before incubation with serum from a SpayVac-vaccinated mare blocked the ability of serum antibodies to bind to the protein sample (Fig. 4A). These serum antibodies maintained their ability to bind the protein samples after preincubation with anti-ZP4 polyclonal antibody (Fig. 4B).

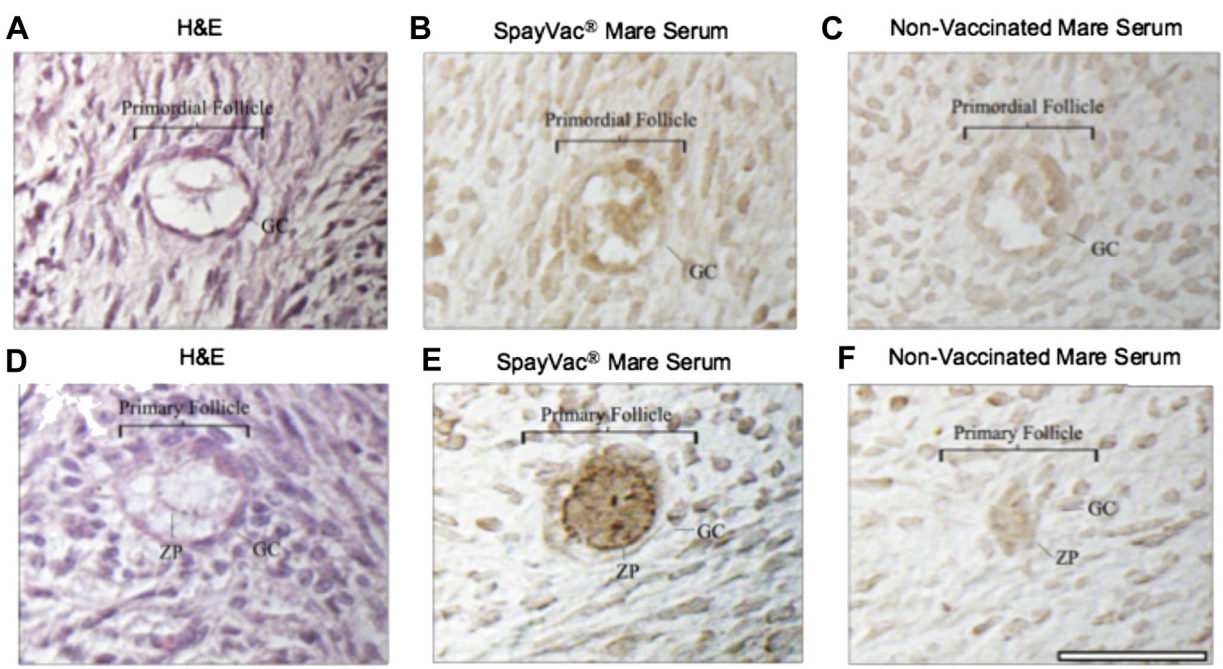

Fig. 2. Localization of serum antibodies from SpayVac-vaccinated mares to the ZP of immature oocytes. Immunohistochemical staining of equine ovarian tissue using serum from a SpayVac-vaccinated mare (B and E) or serum from a nonvaccinated mare (C and F). Serum antibodies bind the ZP of oocytes in primary follicles (E) but did not bind primordial follicles (B). Immunohistochemical staining using serum from nonvaccinated mares is not observed (C and F). H&E staining of ovarian tissue containing a primordial follicle (A) and primary follicle (D). Bar = 20 μm. GC, granulosa cells.

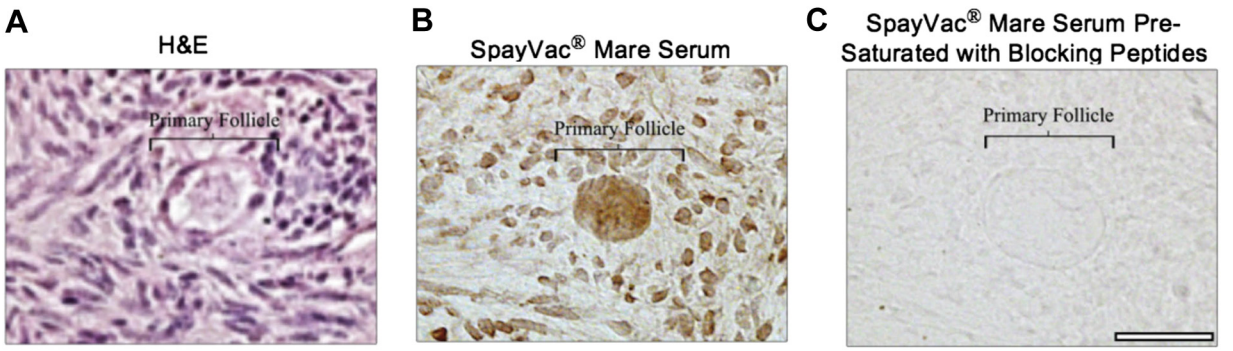

Fig. 3. Specificity of serum antibodies from SpayVac-vaccinated mares for zona protein. H&E staining of of ovarian tissue containing a primary follicle (A). Immunohistochemical staining of equine ovarian tissue using serum from a SpayVac-vaccinated mare (B) or serum from the same SpayVac-vaccinated mare after presaturation of the serum with ZP3 and ZP4 blocking peptides (C). Bar = 20 μm.

4. Discussion

4.1. Immunoreactivity of serum antibodies from SpayVac-vaccinated mares to equine zona protein

Through Western blot analyses of mature preovulatory equine oocytes and ZP, we revealed the presence of antibodies in serum from SpayVac-vaccinated mares that are immunoreactive to equine zona protein. The use of serum from nonvaccinated mares as a control verified that these antibodies are not endogenous to the mare. Western blot analyses also confirmed the immunoreactivity of serum antibodies from SpayVac-vaccinated mares to protein isolated from equine ovarian and follicular tissues.

4.2. Location of binding of serum antibodies from SpayVac-vaccinated mares to equine ovarian tissue

The immunoreactivity of serum antibodies from SpayVac-vaccinated mares to protein isolated from equine ovarian tissue is explained by the localization of antibodies to the ZP of immature oocytes in the tissue. We failed to locate the binding of these serum antibodies to follicular tissue. Because the synthesis of the ZP is an integrated process involving both the oocyte and granulosa cells [14,15], the immunoreactivity of serum antibodies from SpayVac-treated mares to equine follicular tissue is thought to be due to the presence of zona protein precursors in the granulosa cells. Although Western blot analysis may have detected these zona protein precursors because of its high level of sensitivity and stringent cell lysis protocol to release intracellular proteins, high background staining observed in immunohistochemical analyses may have masked any localization to these cells [16]. High background staining is common when the tissue is of the same species as the secondary antibody used [16]. Conversely, the high background staining observed may also be indicative of an immunoreactivity between serum antibodies from SpayVac-vaccinated mares to other proteins located in follicular tissue. Because it is likely that the preparation of SpayVac results in nonzona proteins, such as ovarian and follicular proteins [17], it is possible that serum antibodies from SpayVac-vaccinated mares are immunoreactive to nonzona proteins as well. More research however is required to investigate the immunoreactivity of serum from SpayVac-vaccinated mares to other ovarian and follicular proteins and how this immunoreactivity may relate to efficacy and reversibility of the vaccine.

4.3. Specificity of serum antibodies from SpayVac-vaccinated mares for equine ZP3

Our presaturation and preincubation experiments are indicative of both a specificity of serum antibodies from SpayVac-vaccinated mares for equine zona protein 3 and a lack of nonspecific binding. Because zona proteins are large glycoproteins with varying levels of posttranslational

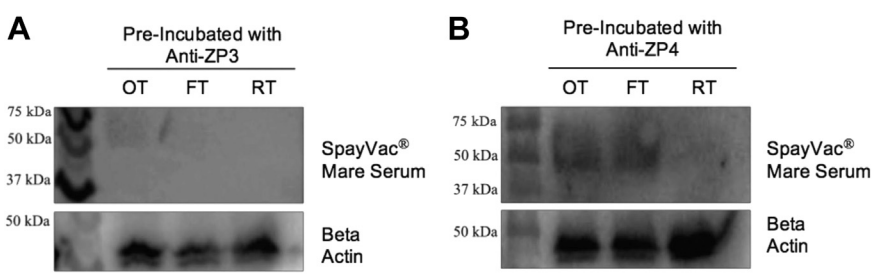

Fig. 4. Specificity of serum antibodies from SpayVac-vaccinated mares for equine zona protein 3. Western blot analysis of protein isolated from equine ovarian tissue (OT), equine follicular (FT), and equine renal (RT) tissues using serum from a SpayVac-vaccinated mare after preincubation with rabbit anti-ZP3 polyclonal antibody (A) or rabbit anti-ZP4 polyclonal antibody (B). Anti–β actin antibody was used as a loading control. Renal tissue was used as a negative control. Molecular weight standards appear in the leftmost lanes of each gel. Forty micrograms of protein was loaded per lane.

modifications, each protein can be observed in a range of molecular weights making the protein difficult to accurately identify by electrophoresis [18–20]. Our experiments lend clarity to the specificity of these serum antibodies. Likewise, this specificity for ZP3 is in agreement with the finding by Wassarman [18] that ZP3 is the major component of the porcine ZP, representing as much as 70% to 80% of total protein content. When the pZP antigen is isolated, the entire ZP is homogenized [21], resulting in a compilation of all zona protein families. It follows that 70% to 80% of the pZP antigen is likely accounted for by ZP3 and, when injected, the mare may produce substantially more antibodies against ZP3 than the other proteins. Furthermore, the pZP antigen is thought to work by eliciting the production of antibodies that bind to ZP proteins on mature oocytes, thereby interfering with sperm binding and penetration [8–10]. Because the zona protein families of ZP1, ZP2, and ZP4 are thought to only be involved in ZP structure, whereas ZP3 has a known role in sperm binding and penetration [20], this specificity for ZP3 coincides with the conclusions of prior studies.

4.4. Limitations of results

There are a few limitations to our study. First, our study focused exclusively on SpayVac as it is less documented in published literature and potentially induces greater duration of infertility in field application. Although all three vaccines incorporate the pZP antigen, they are not a homogenous set of compounds. For instance, it is likely that the preparation of SpayVac results in more nonzona proteins, such as ovarian and follicular proteins, than the other two vaccines [17]. This variation in purity may account for the immunoreactivity of serum antibodies from SpayVac-vaccinated mares to ovarian and follicular tissues seen in our experiments. Specifically, the high background staining observed during our immunohistochemical analysis of equine ovarian tissue may be due to the presence of antibodies immunoreactive to ovarian proteins produced as a result of SpayVac vaccination.

Second, serum samples from vaccinated mares were selectively chosen for their reported high antibody titer levels. Differences in antibody titer and quality depend on the animal immunized and contribute to variability in efficacy among individuals [22]. Accordingly, although serum samples were taken from mares immunized with the same dose of SpayVac, one mare was still able to conceive despite vaccination. Nonetheless, our experiments showed that all eight mares produced antibodies immunoreactive to equine zona protein, regardless of whether the antibodies successfully suppressed the mare's fertility. It is likely that although each mare had sufficient serum antibodies to successfully bind the protein in our experimental samples, overall availability of these antibodies *in vivo* may not have been enough to saturate all possible protein-binding sites and thus result in infertility.

4.5. Conclusions

Our results suggest a model where serum antibodies produced in response to SpayVac vaccination are immunoreactive to equine zona proteins *in vitro*. When zona proteins are isolated from equine tissues and made available to serum samples from SpayVac-vaccinated mares, antibodies in the serum are consistently able to recognize the protein. These serum antibodies appear immunoreactive not only to the ZP of mature preovulatory oocytes isolated from Graafian follicles but also to immature oocytes embedded in ovarian tissue. Although we illustrate a pathway by which serum antibodies from SpayVac-vaccinated mares could act if they are biologically available to these tissues under the correct conditions, it has yet to be investigated whether these antibodies are present in the follicular fluid of follicles or able to permeate ovarian tissue after SpayVac vaccination. We simply showed a model by which antibodies produced in response to SpayVac vaccination may bind zona proteins *in vivo*, thereby interfering with a critical reproductive component, and result in infertility.

Remote delivery of injectable fertility control products is a crucial component for both feasibility and acceptability of contraceptive management practices. While there has been much work in remote delivery of the traditional porcine zona pellucida vaccine, there has been relatively little research with respect to the GnRH based GonaCon vaccine. Due to its high viscosity, it is difficult to find a dart and pressure combination that allows this vaccine to be delivered without loss of product or dart failure. In 2013 a beta design of a slow injection (Slo-inject™) remote delivery device (RDD), equipped with 3.81 cm 14 gage Tri-Port needles and a gel collar positioned 1.27 cm forward of the ferrule, was created and donated by Pneu-Dart Inc. The design promoted a reduced rate of injection while maintaining optimum performance to insure delivery of dart contents. Closed to the public, we tested the performance of this device to deliver GonaCon™-Equine to penned and free-ranging horses at Theodore Roosevelt National Park, North Dakota.

Shots were taken from distances ranging from 10-21 meters. Darts were fired from JM-Special (DanInject) and X-caliber (Pneu-dart) projectors using pressures of 3.0-4.5 bars and 3.5-4.0 bars respectively. Darts hit their intended target at 37-47 m/s which minimized bounce yet allowed for dart discharge. A total of 88 darts were loaded and fired; 74 were recovered and weighed and determined to have delivered a full dose, 6 were lost or otherwise un-weighed but were observed to stick in the animal, there was 1 miss, 2 darts bounced out, and 5 were determined to have delivered an insufficient payload of vaccine. Overall, we observed an 84.1% success rate for delivery of payload among darts fired and 100% overall success in eventual dosing (i.e., with follow-up shots) of all study animals with remote delivery systems.

We found that the contraceptive efficacy in mares that received dart delivered GonaCon™-Equine was comparable to that observed for hand-injected mares in the same population. In the first foaling season when a contraceptive effect was expected, 45.5% of treated mares (5 of 11 individuals) had foals, whereas 84% of control mares (21 of 25 individuals) had foals in 2015.

Problem
An effective, single-injection, multi-year, GnRH contraceptive agent is needed to control reproduction in overabundant white-tailed deer populations.

Method of study
Two GnRH conjugates, GonaCon™ (GnRH–KLH) and GonaCon-B™ (GnRH–blue protein), were prepared in emulsion form as one-injection and two-injection immunocontraceptive vaccine formulations. In addition, the GnRH–KLH protein conjugate was lyophilized and suspended in AdjuVac™ adjuvant to produce a fifth vaccine formulation. Each formulation was administered to a group of five captive adult female white-tailed deer. Reproductive performance of treated female deer was monitored for 5 years to determine the comparative efficacy of the various treatments.

Results
The longevity of the contraceptive response (2–5 years) was strongly influenced by the design of the conjugate antigen, the adjuvant used, and the delivery form of the vaccine.

Conclusion
One-injection and two-injection formulations of GonaCon™ and GonaCon-B™ produced multi-year contraception in adult female white-tailed deer. GonaCon-B™ provided a longer lasting contraceptive effect.

Introduction

Non-lethal tools are needed for the control of overabundant wildlife populations in settings in which traditional management methods, such as regulated sport hunting, cannot be used because of legal prohibitions or safety concerns. The development and use of safe, effective, and humane reproductive inhibitors may provide a partial solution to the problem of overabundant populations of deer and other wildlife in situations in which hunting is not an option. Reproductive inhibitors must be tailored to the physiology of the target species, as no contraceptive agent is effective, practical, and appropriate for use in all species.[1]

GonaCon™ Immunocontraceptive Vaccine is a highly effective contraceptive agent that prevents pregnancy in white-tailed deer (*Odocoileus virginianus*),[2] elk (*Cervus elaphus*),[3] wild horses (*Equus caballus*),[4,5] domestic and feral swine (*Sus scrofa*),[6–8] bison

(*Bison bison*),[9] domestic cats (*Felis catus*),[10] California ground squirrels (*Spermophilus beecheyi*),[11] and Norway rats (*Rattus norvegicus*).[12]

Immunocontraceptive vaccines based on porcine zona pellucida (PZP) and gonadotropin-releasing hormone (GnRH) control fertility by stimulating the production of antibodies that bioneutralize proteins or hormones essential for conception. PZP immunocontraceptive vaccines have been widely tested in white-tailed deer[2,13,14] and other wildlife species.[15,16] Female white-tailed deer vaccinated with PZP may cycle repeatedly and mate several times during the breeding season while still remaining infertile.[17] The multi-cycling problem associated with PZP vaccines prompted investigation into the potential use of GnRH as a contraceptive vaccine.

Gonadotropin-releasing hormone is produced and secreted by the hypothalamus and is responsible for the release of two pituitary hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and the subsequent release of hormones that control the functioning of the ovaries and testes. Antibodies to GnRH induce infertility by binding to circulating endogenous GnRH and preventing the GnRH from binding to pituitary receptors, thereby precluding the release of FSH and LH. The severe reduction or absence of FSH and LH in the bloodstream leads to atrophy of the gonads and concomitant infertility in both sexes. Immunoneutralization of endogenous GnRH through the introduction of a GnRH conjugate in a vaccine appears to be highly specific, and does not appear to affect other hypothalamic-releasing hormones.[18]

An ultimate objective of efforts to develop infertility agents such as immunocontraceptive vaccines is the application of these materials to overabundant populations of free-ranging wildlife to slow the growth of such populations. Much of the early research effort to use GnRH immunization as an infertility method was focused on the contraception of males.[19–21] Reduction of population growth via contraception would be most effectively accomplished by targeting females, however, so most of our studies have dealt with the use of GnRH vaccine to induce infertility in females.

In this paper we describe the use of a newly developed GnRH vaccine in captive, adult, female white-tailed deer. We also describe recent improvements to the vaccine including (i) development of a single-injection technology that provides a multi-year contraceptive effect, (ii) development of a new adjuvant to replace Freund's™ adjuvant, and (iii) replacement of keyhole limpet hemocyanin (KLH) as a protein carrier molecule with a more cost-effective mollusk protein ('blue protein') for conjugation with synthetic GnRH peptide. All of these improvements contributed to the development of a more effective and practical contraceptive vaccine for use in wildlife.

Materials and methods

Deer Research Center at Pennsylvania State University

White-tailed deer used in these studies were born, raised, and maintained at the Pennsylvania State University (PSU) Deer Research Center, where a captive deer herd has been maintained since 1972. The original source of animals for the PSU deer herd was the wild white-tailed deer population in central Pennsylvania. Supplements to the PSU captive deer herd occurred approximately every 5 years until 1996. Since then, the PSU Deer Research Center has maintained a closed herd. During our study, the PSU deer facility encompassed 22 acres of natural woodland/forest habitat, which were divided into nine separate paddock areas that ranged in size from 0.12 to 1.54 ha (0.3–3.8 acres). Vegetation on the open areas consisted of a mixture of clover and orchard grasses, but most of the land was covered with dense eastern deciduous forest that had little understory vegetation. Deer were kept in outdoor paddocks at a density of 25–37 animals per hectare (10–15 animals per acre). During the non-breeding portion of the year, treated female deer were isolated from males. To test vaccine contraceptive efficacy, however, each year, from the first week of November through the end of the following February, four bucks of proven sire ability in the control herd were confined with the aggregated females from all five vaccine treatment groups. The animal facility at the PSU Deer Research Center was accredited by the Association for the Assessment and Accreditation of Laboratory Animal Care (AAALAC). Our study was approved by the Institutional Animal Care and Use Committee of PSU.

Development of the One-shot GnRH Vaccine

The GonaCon™ Immunocontraceptive Vaccine formulations used in this study consisted of synthetic GnRH peptide conjugated to one of two mollusk hemocyanins: KLH (*Megathura crenulata*) or blue

Journal compilation © 2008 Blackwell Munksgaard
No claim to original US government works

protein hemocyanin (*Concholepas concholepas*). Each 1.0-mL dose contained 850 or 1000 μg of the GnRH-mollusk hemocyanin conjugate. Four different treatments resulted from combinations of the two amounts of conjugate and the two protein carriers. A fifth treatment consisted of 1000 μg of the GnRH–KLH conjugate that was lyophilized and then suspended in AdjuVac™ adjuvant.

The Peptide (Hapten)

The Gonadotropin-releasing hormone used in this study was synthesized at Global Peptide Services (Fort Collins, CO, USA), with the structure [pE-HWSYGLRPGGC-SH]. The underlined amino acids represent the native GnRH molecule. The 10-amino-acid GnRH peptide hormone was made immunogenic by coupling it to a large carrier protein that contained numerous T-cell epitopes. Immune responses to the GnRH peptide vary with the coupling position of the GnRH molecule.[22–24] A glycine (G) was added at the C terminus as a spacer, followed by a cysteine (C) to ensure consistent alignment of the peptide to the maleimide-activated protein carrier KLH. This GnRH analog, called GnRH-glycys, has a conformation similar to that of native GnRH.[25]

Mollusk Hemocyanin Protein Carrier

GnRH is a small peptide hormone that is not naturally immunogenic. It becomes immunogenic when it is conjugated to a large carrier protein that contains numerous T-cell epitopes. Carrier proteins used in vaccine production include tetanus toxoid,[21] diphtheria toxoid,[26] bovine serum albumin (BSA), ovalbumin, and KLH.[22,25] BSA is not a good carrier for use in cattle or deer because of the phylogenetic proximity between cattle and deer. Our vaccine formulations incorporated the mollusk hemocyanin proteins KLH (Pierce Chemical, Rockford, IL, USA) and 'blue protein' (Biosonda, Santiago, Chile). These mollusk proteins are highly immunogenic in mammals because of their large sizes (molecular weights of 6–8 million), and because the mollusks are phylogenetically distant from the vertebrate target species.

Optimal Conjugate Design

Bachmann et al.[27] showed that the design of the immunogen is a critical factor in obtaining a strong B-cell response to an individual epitope. In a review of studies of immune responses to hepatitis B vaccines, Banatvala et al.[28] reported that the strength of the primary response is influenced by the antigen dose and structure, and that stronger primary responses result in longer lasting immune memory. To make the conjugate used in our vaccine highly immunogenic, we dissolved the hemocyanin proteins in a 7.5-pH, high-salt buffer that kept the large molecules intact so that coupling would occur on their surfaces. The coupling of as many as 300 GnRH peptide molecules on the surface of a mollusk protein mimicked the immune image of many pathogens, including viruses and bacteria that exhibit rigid, highly organized, highly repetitive protein epitopes. This mimicry of the repetitive nature of pathogen epitopes is an important aspect of the GnRH-hemocyanin conjugate design. Consistent alignment of the peptide facilitates the coupling of the immunogenic protein to the sulfhydryl group of the terminal amino acid and leaves the 10-amino-acid GnRH peptide exposed to the immune system.

Before the GnRH peptide can be coupled to the carrier protein, the carrier protein must be activated so that the available maleimide groups on the carrier protein can react with the terminal sulfhydryl-containing peptides on the GnRH peptide. KLH purchased from Pierce Chemical was pre-activated Imject® (Pierce Biotechnology Inc., Rockford, IL, USA) maleimide-activated mcKLH. Our conjugation process followed Pierce Chemical's recommended procedure with minor modifications. Our primary modification reduced the quantity of GnRH from the recommended GnRH:KLH ratio of 50:50 to 30:70, thus reducing the quantity of excess free GnRH remaining in solution after conjugation.

Blue protein was not maleimide activated when purchased from Biosonda. Maleimide activation was accomplished using sulfo-SMCC purchased from Pierce Chemical. To conjugate the GnRH peptide to the maleimide-activated mollusk protein, we followed the Pierce Chemical instructions except that we changed the ratio of blue protein to GnRH just as we did in the GnRH–KLH procedure.

Adjuvant Design – AdjuVac™

An important component of any vaccine is a non-specific immune stimulant called the adjuvant. A widely used adjuvant is Freund's Complete Adjuvant (FCA; Difco Laboratories, Detroit, MI, USA), which induces strong and long-lasting immunity to a broad

Journal compilation © 2008 Blackwell Munksgaard
No claim to original US government works

range of antigens.[29] Concerns over FCA's severe injection-site reactions and its potential carcinogenicity, however, prompted NWRC scientists to develop a new adjuvant by modifying the USDA-licensed Johne's vaccine, Mycopar™ (Fort Dodge Animal Health, Fort Dodge, IA, USA). Mycopar is approved for use in food animals, thus mitigating the concern for use in deer that may be hunted for human consumption.

The new adjuvant, called AdjuVac, contains a small quantity of killed *Mycobacterium avium*, a common bacterium found in many species of wildlife and domestic animals throughout the world.[30–32] Because *M. avium* is widely distributed in natural environments,[33–35] many animals have been exposed to it, and for that reason they may respond to the bacterium in AdjuVac as a previously encountered bacterial antigen.

Preparation of the Vaccine Emulsion

The creation of a depot at the vaccine injection site may promote a long-lasting immune response through the slow release of antigen.[36,37] To produce a depot effect, we prepared our vaccine as an emulsion. This was accomplished through the dropwise addition of 0.5 mL of the GnRH-carrier protein conjugate in mollusk-stabilizing buffer (MSB) to 0.5 mL of AdjuVac adjuvant with vigorous vortexing. The emulsion was stiffened by passing it through a 22-gauge needle three times.

Animal Handling, Vaccination, and Sample Collection

Twenty female deer were divided into four treatment groups with five deer per group. Four preparations were tested (i) GnRH–KLH-AdjuVac (850 μg one-shot), (ii) GnRH–KLH-AdjuVac (1000 μg/1000 μg two-shot), (iii) GnRH–blue protein-AdjuVac (1000 μg one-shot), and (iv) GnRH–KLH-AdjuVac (1000-μg lyophilized suspension).

Prior to handling and vaccination, animals were sedated with Xylazine™ (100 mg/mL; Bayer, Leverkusen, North Rhine-Westphalia, Germany), which was administered intramuscularly (i.m.) at 2.2–4.4 mg/kg (depending upon the nervousness of the individual animal). Each deer was then given an i.m., hand-injected dose of 1.0 mL of one of the vaccine preparations. Each injection was delivered to the right hindquarter with a 3 mL syringe and a 2.54 cm (1-inch), 19-gauge, hypodermic needle. The sedative effect was then reversed with Tolazine™ (100 mg/mL; Lloyd Inc., Shenandoah, IA, USA) administered intravenously (i.v.) or i.m. at 4.0 mg/kg.

Blood samples were taken before vaccination in July and then again during September, October and February each year. Approximately 7–10 mL of blood was collected from the jugular vein with 10-mL vacutainer blood collection tubes and 2.54 cm (1-inch), 18-gauge needles (Becton Dickinson, Franklin Lakes, NJ, USA). Blood samples were centrifuged and serum was isolated and then stored at −70°C. During the first week of February each year, a blood sample was collected and centrifuged, and the serum was evaluated for progesterone and anti-GnRH antibody titers. At the same time in February, ultrasound examinations were performed to determine if the does were pregnant. Ultimate reproductive efficacy was assessed by evaluating annual fawn production.

Laboratory Testing

Progesterone

The Coat-A-Count Progesterone *In-vitro* Diagnostic Test Kit™ (Diagnostic Products, Los Angeles, CA, USA) was used in these studies according to the manufacturer's recommended procedure. For each test, we used 0.1 mL of serum.

Anti-GnRH antibody titers

The enzyme-linked immunosorbent assay (ELISA) was used to measure anti-GnRH antibody titers. Fifty microlitres of serum was used for each assay. A 96-well plate was prepared by adding 100 ng of BSA-GnRH antigen to each well and then blocking with SeaBlock™ from Pierce Chemical. As either KLH-GnRH or blue protein-GnRH was used in the vaccine, BSA-GnRH was added to the ELISA plate, causing only antibodies to GnRH to be detected.

Deer blood serum was serially diluted from 1:1000 to 1:128,000 in phosphate-buffered saline containing SeaBlock. Antibodies in the deer serum to GnRH on the plate were directed with the following linkages: deer anti-GnRH bound to GnRH on the plate, rabbit anti-deer IgG bound to the deer IgG, and goat anti-rabbit-peroxidase bound to the rabbit IgG. Chromogen tetramethylbenzidine was used to develop the color, and 2 M H_2SO_4 was used to stop the reaction. The color intensity of the sample was read at 450 nm with a Dynatech MR 5000 ELISA plate

reader (Dynatech Laboratories, Alexandria, VA, USA).

Contraceptive efficacy: The mean reproductive success of the entire PSU captive deer herd was used as a control value that was compared with that of the GnRH-treated deer. Deer intentionally bred at the PSU facility during the period 1994–1998 produced an average of 1.7 fawns per year.[2] The deer in the current study were managed at the same facility and were maintained under conditions similar to those during the earlier period. In this study, if a vaccinated doe bore twins, she was physically removed from the treatment group (to reduce animal maintenance costs), but she was retained in our data analysis with the assumption that she would have remained fertile for the remainder of the study. Treated does that bore single fawns remained in the treatment groups.

Results

Group 1: GnRH–KLH-AdjuVac™ (850 μg one-shot)

All five does vaccinated in July 2000 with the formulation of GonaCon™ that contained KLH (850 μg single-shot) were infertile during the 2000–2001 breeding season (Table I). A year later, three of the five does (60%) remained infertile, whereas the remaining two treated does each bore a single fawn. One of the infertile does died in July 2002, leaving four deer remaining in the treatment group. One of the fertile does that produced a fawn in 2002 bore twins in 2003 and was then physically removed from the treatment group. In our analysis, however, we assumed that, in the absence of revaccination, she would have remained fertile throughout the rest of the study. Of the two remaining infertile does, only one produced a fawn (during 2005).

Table I Contraceptive Efficacy of Four GnRH Vaccine Formulations Given to Captive Adult Female White-Tailed Deer

	Year post-treatment				
Treatment group	1	2	3	4	5
GnRH–KLH one-shot	100	60	50[a]	50	25
GnRH–KLH two-shot	100	100	80	60	n/a[b]
GnRH–blue one-shot	100	100	80	80	80
GnRH–KLH lyophilized one-shot	40	0	n/a[b]	n/a[b]	n/a[b]

All vaccine formulations were emulsions except the lyophilized formulation, which was a suspension. Table values are the percentages of treated deer that were infertile each year. Five deer were injected with each vaccine formulation.
GnRH, gonadotropin-releasing hormone; KLH, keyhole limpet hemocyanin.
[a]One doe died during previous year, leaving $n = 4$.
[b]Treatment group was removed from study.

Group 2: GnRH–KLH-AdjuVac™ (1000 μg/1000 μg two-shot)

For 2 years, all five does in this treatment group were infertile. During the third year, four does remained infertile, and during the fourth year, three remained infertile (Table I).

Group 3: GnRH–blue protein-AdjuVac™ (1000 μg one-shot)

All five treated does remained infertile through the first 2 years of the study (Table I). During each of the third and fourth years, only one of five does became pregnant. Interestingly, one doe produced a single fawn in the third season, but did not reproduce during the following year. Another doe that had been infertile for the first three breeding seasons produced a single fawn during the fourth season. Although she was then given a booster vaccine dose (same formulation as the primary dose) that caused her to be infertile during the fifth year of the study, we assumed for the purposes of our analysis that she would have remained fertile in year five had she not been revaccinated.

Group 4: GnRH–KLH-AdjuVac™ (1000 μg lyophilized suspension)

The GnRH–KLH vaccine given as a lyophilized suspension did not provide a long-lasting immune response. Only two of the five deer in this treatment group developed a sufficiently strong antibody response to achieve infertility during the first year (Table I). Titers in these two does dropped below contraceptive level (antibody levels ≥1:64,000 generally are associated with infertility in adult white-tailed deer[2]) during the second year, when all five does became pregnant (Fig. 1, Table I). Hence, the trial was terminated.

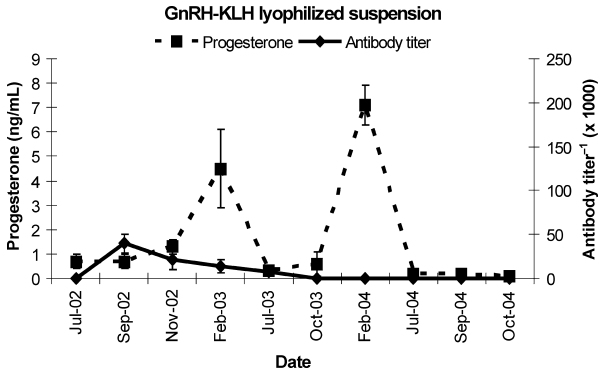

Fig. 1 Gonadotropin-releasing hormone–keyhole limpet hemocyanin lyophilized suspension, one-shot. A single injection (1000 μg) of this GonaCon™ vaccine formulation was given to five captive adult female white-tailed deer during July 2002. The GnRH–KLH conjugate was lyophilized and made into a suspension with the oil-based adjuvant AdjuVac™. A contraceptive effect was induced only in two deer by this vaccine, and it lasted for only 1 year, as reflected in the elevated blood serum progesterone concentrations observed in February 2003 and 2004, as well as in the low anti-GnRH antibody titers, especially after 2002. When vaccine efficacy reached zero during 2004, this trial was terminated.

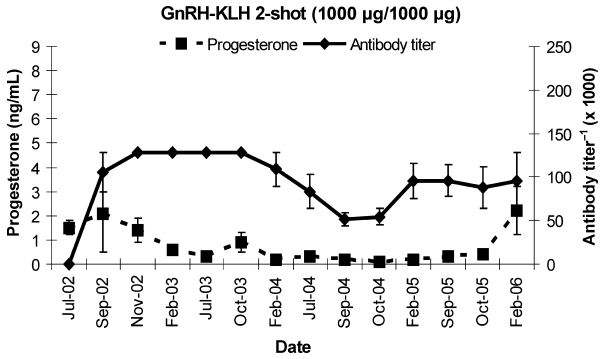

Fig. 3 Gonadotropin-releasing hormone–keyhole limpet hemocyanin emulsion, two-shot. A primary injection (1000 μg) of this GonaCon™ vaccine formulation was given to five captive adult female white-tailed deer during July 2002, and a booster injection (1000 μg) was given during September 2002. The GnRH–KLH conjugate was made into an emulsion with the oil-based adjuvant AdjuVac™. Elevated anti-GnRH antibody titers persisted until 2004, when an apparent self-boosting effect re-elevated the titers. The low blood serum progesterone concentrations observed in deer in this treatment group throughout the 3.5-year trial were associated with a lack of cycling and pregnancy.

Serum Progesterone Concentrations and Ultrasound Examinations

Except in the deer treated with the lyophilized suspension (group 4), serum progesterone concentrations were generally low in treated deer throughout the study (Figs 2–4). Progesterone levels assayed on

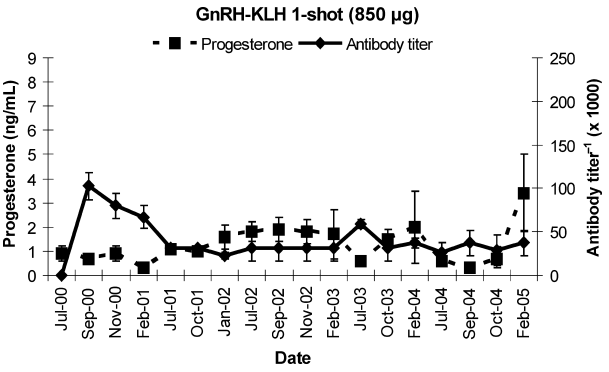

Fig. 2 Gonadotropin-releasing hormone–keyhole limpet hemocyanin emulsion, one-shot. A single injection (850 μg) of this GonaCon™ vaccine formulation was given to five captive adult female white-tailed deer during July 2000. The GnRH–KLH conjugate was made into an emulsion with the oil-based adjuvant AdjuVac™. An initially strong immune response, as indicated by high anti-GnRH antibody titers, resulted in the contraception of all five deer during the first year after vaccination. The immune response declined during the second year and then remained fairly stable throughout the remainder of the 4.5-year trial.

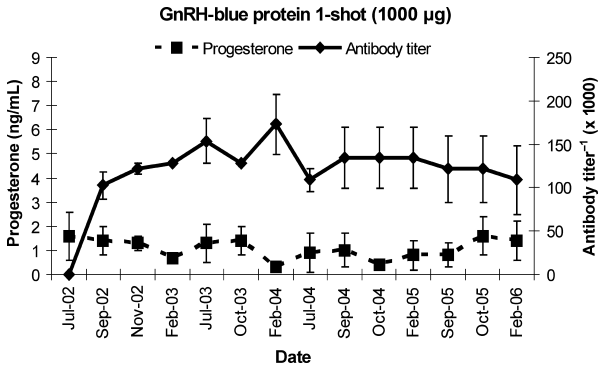

Fig. 4 Gonadotropin-releasing hormone–blue protein emulsion, one-shot. A single injection (1000 μg) of this GonaCon-B™ vaccine formulation was given to five captive adult female white-tailed deer during July 2002. The GnRH–blue protein conjugate was made into an emulsion with the oil-based adjuvant AdjuVac™. Elevated anti-GnRH antibody titers persisted throughout the 3.5-year trial, during which several apparent self-boosting effects occurred. The low blood serum progesterone concentrations observed in deer in this treatment group throughout the trial were associated with a lack of cycling and pregnancy.

serum drawn each February had a strong, positive correlation with spring fawning. Multiple studies have demonstrated that GnRH contracepted deer have serum progesterone concentrations of <1.5 ng/mL in the month of February while controls and deer that are no longer contracepted by GnRH have concentrations >3.0 ng/mL. In this study using

Journal compilation © 2008 Blackwell Munksgaard
No claim to original US government works

progesterone concentrations of >3.0 ng/mL as a positive indicator of pregnancy, we found that the correlation between elevated progesterone and spring fawning was 0.90 ($r^2 = 0.95$, $P < 0.0001$). Ultrasound performed at the same time also had a high correlation with spring fawning ($r^2 = 0.95$, $P < 0.0001$).

Anti-GnRH Antibody Titers

An examination of the anti-GnRH antibody titers measured in deer in the various treatment groups (Figs 1–4) and the corresponding contraceptive effects (Table I) indicated that these factors were directly related. The 850 μg, single-shot KLH treatment produced initially high antibody titers and contraception in all five does during the first year after vaccination (Fig. 2). The decline in antibody levels during the second and subsequent years, however, corresponded with a decline in the contraceptive rate. In vaccine trial 2, the 1000 μg/1000 μg KLH primary and booster doses provided a much longer lasting antibody response (Fig. 3), which produced longer lasting contraceptive effects (Table I). The replacement of KLH by the blue protein carrier produced an immune response with a single injection that was stronger than that observed in response to the KLH two-shot treatment (Figs 3 and 4). This strong antibody response produced a 5-year contraceptive effect in four of five blue protein-treated does (Table I). On the other hand, the use of 1000 μg of GnRH–KLH conjugate, lyophilized and suspended in AdjuVac, provided only a weak, short-term immune response (Fig. 1). Only two of five does were infertile during the first year after vaccination, and, as antibody titers declined during the second year, all five does became pregnant (Fig. 1, Table I).

Discussion

GonaCon™ Immunocontraceptive Vaccine suppresses reproductive activity in female white-tailed deer, and may be effective in reducing undesirable behavior associated with the autumn breeding period or rut. PZP vaccines, on the other hand, may actually increase the incidence of such behavior by extending the duration of the breeding season.[17,38,39] By lengthening the rut, PZP vaccines are likely to increase rut-associated movements of deer, thereby increasing the occurrence of deer–vehicle collisions. On the other hand, two-shot formulations of GnRH-based vaccines such as GonaCon™ have limited potential for practical application as wildlife contraceptive agents, and the Freund's™ adjuvant used in early formulations of GnRH vaccines caused large injection-site granulomas.[40] The development of a non-Freund's, single-injection immunocontraceptive vaccine represents an important breakthrough in wildlife contraception.

Several factors were involved in the production of this single-injection, multi-year vaccine. It has been known for more than 20 years that to produce antibody to GnRH, the peptide must be coupled to a larger protein. Many different proteins and coupling techniques have been used (as discussed in the *Materials and methods* section), but in many cases, much of the resultant antibody production targeted the carrier protein and not the GnRH peptide. Therefore the vaccines required a primary and several booster doses to produce a 6-month-long response.[21,26,41]

In our conjugate, the mollusk protein remained intact because of the presence of a stabilizing buffer, and the GnRH peptide coupled to the surface of the carrier molecule. The immune response of the target animal was highly directed to the repeating GnRH peptides on the surface. This directed response provided a strong antibody response to a normally small, non-immunogenic peptide.

Factors Essential for a Multi-year Response to a Single Vaccine Injection

Emulsion form of delivery

The longevity of the contraceptive response appears to be related to the delivery of the antigen in an emulsion form. A properly prepared emulsion is stable at 4°C for months to years; if the emulsion is not prepared properly, it may begin to separate within weeks.[42] A poor emulsification would preclude the long-term effectiveness of the vaccine. The need to produce a stable emulsion is probably related to the need for a depot effect at the injection site to provide a slow release of the antigen. Although lyophilization of the GnRH-mollusk hemocyanin conjugate and addition of the lyophilized antigen to the AdjuVac™ adjuvant in a suspension form did not provide a long-term, single-injection contraceptive effect (Table I), lyophilized delivery may be effective in a two-shot form.

No claim to original US government works

Presence of Mycobacterium avium in AdjuVac

GonaCon™ vaccine is a mixture of a new, highly immunogenic antigen (GnRH-mollusk hemocyanin) with a previously experienced *M. avium* bacterium. In a GnRH vaccine study with black-tailed deer (*Odocoileus hemionus columbianus*), Perry et al.[43] injected a group of deer with GnRH vaccine in which *M. avium* had been replaced by DD-Dextran in the adjuvant. The first-year response to the DD-Dextran was 14% contraception ($n = 14$). The deer were revaccinated during the following year, resulting in a 90% contraception rate. In the same study, deer ($n = 8$) given a single injection of GonaCon™ vaccine that contained *M. avium* exhibited contraception rates of 79% during the first year after vaccination, and 75% during the second year.[43]

Self boosting: follicular dendritic cells provide continued presence of antigen

The antibody titers illustrated in Figs 2–4 indicate that self-boosting of the GnRH antibody is essential for the single-injection, multi-year contraceptive effect. Follicular dendritic cells (FDC) in the lymph node that drains the site of injection may provide the basis for the long-term immune response associated with some antigens. An immunoglobulin G (IgG) antibody needed for an immunocontraceptive response has a half-life of 23 days.[44] Although antigen-specific memory B-cells are produced with an initial immunization, the induction of immunocontraception that persists for months or years requires a repeated stimulation of these B-cells by the injected antigen.

The long-term immune response is thought to be dependent on the formation of immune-complexes (ICs). In the two-dose paradigm, specific antibodies produced by the primary dose are present at the time of injection of the second dose of antigen, resulting in the formation of ICs. The second dose of antigen selects for the higher affinity antibody-producing B-cells. The higher affinity antibodies are more likely to bind to the target antigen. Affinity maturation of the antibody occurs gradually as new memory B-cells are selected by exposure to small (picogram) quantities of retained antigen.

To be effective in producing long-lasting antibodies, antigen administered in a single dose must be retained in the body long enough to produce specific antibodies that will bind with the antigen to form ICs. These ICs could then bind FDCs, protecting the antigen from macrophage and liver degradation. ICs may begin to form within 7–14 days after a primary injection, or within minutes after a booster injection.[45]

The presence of a specific antibody is the significant difference between primary and secondary antibody responses, as the specific antibody from the primary response combines with the antigen to form immune complexes for transport into draining secondary lymphoid tissues. Many of these immune complexes are eliminated by phagocytic cells, but some are trapped on the surface of FDC for months to years.[27,46]

In the absence of specific antibody, soluble antigen freely diffuses through the draining lymph nodes and interacts with the appropriate immune cells.[45] Initial clearance of antigen is because of catabolism.[45] By the fourth day, there is enough specific antibody to begin a second phase of immune clearance, in which antigen complexes with specific antibody are cleared by macrophages in the afferent and efferent sinuses of the lymph nodes, the sinusoids of the liver, and the marginal sinuses of the spleen.[46,47] FDC trap immune complexes and retain picogram amounts of antigen on their surfaces for long periods.[45]

Antigen availability to the immune system is highly regulated throughout this process. Low levels of specific antigen induce antigen release from FDC, and high antibody concentration inhibits the release of antigen.[45] High concentrations of antibody interact with the antigen on FDC processes and crosslink them so that the antigen is not available to the surrounding cells.[45] In addition, it appears that the antigen released from FDC is significantly more immunogenic than free antigen, such that it may take 1000 pg of free antigen to elicit antibody production, whereas it takes only 10 pg of FDC-retained antigen to elicit the same response.[48] This greater immunogenicity may also be caused by the proximity of the antigen-containing FDC and the B-cells in the draining lymph nodes.

Conclusions

GonaCon™ Immunocontraceptive Vaccine is a highly effective, single-injection, multi-year contraceptive agent based on conjugated GnRH–KLH or GnRH–blue protein. Although both formulations of the vaccine caused infertility in female white-tailed deer, GonaCon-B™, which incorporates the GnRH–blue protein conjugate, was a more effective, longer lasting, and more economical contraceptive agent than the GnRH–KLH formulation. Both conjugate formulations of GonaCon™ vaccine used the adjuvant

Journal compilation © 2008 Blackwell Munksgaard
No claim to original US government works

AdjuVac™ in an emulsion that was injected into the hind limb musculature of the target animal, and both were effective as a single-injection contraceptive agent in captive adult female white-tailed deer. Vaccine delivered as a lyophilized suspension is not as effective when compared to the emulsion form of delivery.

TWENTY YEARS OF IMMUNOCONTRACEPTIVE RESEARCH: LESSONS LEARNED

Lowell A. Miller, Ph.D., Kathleen A. Fagerstone, Ph.D., and Douglas C. Eckery, Ph.D.

Abstract: The National Wildlife Research Center (NWRC) began immunocontraception vaccine research by testing porcine zona pellucida (PZP) on white-tailed deer (*Odocoileus virginianus*). Early PZP research demonstrated that PZP induced infertility; however, increased length of the rut was observed in PZP-treated deer. An alternative vaccine using a keyhole limpet hemocyanin-gonadotropin-releasing hormone (KLH-GnRH) conjugate formulated with modified Freund's adjuvant was developed at NWRC. Suppression of GnRH has reduced reproduction in both sexes but is most effective in females. This vaccine was effective in preventing contraception in female deer for several years after a prime and boost. Due to adverse side effects of Freund's adjuvant, NWRC developed a new adjuvant called AdjuVac, a mineral oil/surfactant adjuvant with the addition of *Mycobacterium avium* as an immunostimulant. The price of KLH prompted a search for a more economical hemocyanin carrier protein for the GnRH peptide. Blue protein, derived from the mollusk *Concholepas concholepas*, proved to be a successful option. Formulation improvements resulted in a vaccine that can be effective as a single injection for multiple years, now called GonaCon. GonaCon is registered with the Environmental Protection Agency (EPA) for use in white-tailed deer in urban/suburban areas and for wild horses (*Equus caballus*) and burros (*Equus asinus*). Future GonaCon applications may include reducing reproduction to manage populations of other wildlife species, such as prairie dogs (*Cynomys ludovicianus*) in urban areas and suppressing reproduction to reduce the spread of venereal diseases such as brucellosis. Research is being conducted to develop a GnRH vaccine used in combination with the rabies vaccine to control population growth in free-roaming dogs, with the secondary effect of managing the spread of rabies. The EPA would regulate all these uses. Research is also ongoing on a GnRH vaccine to delay the onset of adrenocortical disease in pet ferrets (*Mustela putorius*), a use regulated by the United States Department of Agriculture.

Key words: AdjuVac, GonaCon, immunocontraceptive vaccine, KLH, *Mycobacterium avium*.

INTRODUCTION

In 1992, the United States Department of Agriculture National Wildlife Research Center (NWRC) began a project to develop reproductive control methods as an additional nonlethal tool to manage overabundant wildlife. The early focus of the project was on white-tailed deer (*Odocoileus virginianus*) because stakeholders identified overabundant deer populations in urban/suburban areas as a concern because of increases in deer-motor vehicle collisions, property damage, and habitat destruction. The project began by studying porcine zona pellucida (PZP) immunocontraception technology for management of white-tailed deer.[23,47,48] The project's focus later shifted to development of vaccines using gonadotropin-releasing hormone (GnRH) as the antigen for several reasons: first, the PZP vaccines are only effective in females and resulted in prolonged periods of estrus cyclicity because normal reproductive hormones were maintained; second, the project's focus broadened beyond white-tailed deer, and a broadly effective vaccine in most mammals was wanted that would affect both sexes; and third, other researchers were developing PZP vaccines, so duplicate research efforts needed to be minimized. Initial studies were conducted with various formulations of GnRH vaccines. Eventually, the vaccine GonaCon was developed at NWRC, which suppresses reproductive hormone production, estrus, and spermatogenesis in mammals, often after a single injection. For this review, GonaCon is a GnRH-based immunocontraceptive vaccine comprised of numerous GnRH peptide molecules coupled to a mollusk carrier protein (either keyhole limpet hemocyanin [KLH] or blue protein [*Concholepus concholepus*]) mixed with a mineral oil-based adjuvant containing *Mycobacterium avium* (AdjuVac) and made into an emulsion (Table 1). Generally, efficacy for longer than 1 yr is achieved from a single injection, and contraception may be extended by administering a boost vaccination.[48,50] GonaCon proved efficacious in deer, reducing

[a] GonaCon is defined as a GnRH immunocontraceptive vaccine comprised of numerous GnRH protein molecules coupled to a mollusk carrier protein (either keyhole limpet hemocyanin [KLH] or blue protein) mixed with a mineral oil-based adjuvant (AdjuVac) and made into a stiff emulsion.

[b] The EPA registered formulations for GonaCon can contain either keyhole limpet hemocyanin (KLH), or blue protein (*Concholepas concholepas*).

[c] GonaCon is formulated with the adjuvant Adjuvac, a dilution of Mycopar, which contains *Mycobacterium avium*. FCA, Freund's Complete; FIA, Freund's Incomplete.

[d] The standard amount of *M. avium* (approximately 0.17 mg/ml) is the concentration in AdjuVac for the Environmental Protection Agency (EPA) registered products. NA, not applicable.

reproductive behaviors in females and reducing the length of the rut;[13,23] it was also found to induce infertility in many different species of mammals.[9] NWRC has subsequently improved the manufacturing process for GonaCon to include aseptic manufacturing in a clean room, as well as scaling up production to allow GonaCon to be made in larger batches. An adjuvant (AdjuVac) was developed by the NWRC to increase the effectiveness of both PZP and GnRH vaccines.

This manuscript will briefly describe much of the research conducted by the NWRC during the last 20 yr, the vaccines and adjuvant that have been developed, the changes that have been made to improve those products, the lessons NWRC has learned, and what still needs to be determined after 20 yr of research on immunocontraception in wildlife.

VACCINE DESIGN FOR DIFFERENT REPRODUCTIVE SYSTEM TARGETS

Immunocontraceptive vaccines use the animal's immune system to produce antibodies against gamete proteins, reproductive hormones, and other proteins essential for reproduction.[30] The antibodies interfere with the biologic activity of the reproductive proteins,[61] and depending on the antigen and formulation, the vaccines can be effective for 1–4 yr or longer with single or multiple injections.[47,62] Two antigens, PZP and GnRH, have been used to develop immunocontraceptive vaccines for wildlife. The NWRC has conducted research on both PZP and GnRH vaccines. The antigen used, including its mode of action on the reproductive system and the design of the vaccines, is vital in determining vaccine efficacy in different mammalian species.

PZP immunocontraceptive vaccines

The NWRC began its contraceptive research program in 1991 by studying PZP, a combination of three zona pellucida (ZP) proteins extracted from pig ovaries, because PZP had previously been shown to be effective as an antigen in an immunocontraceptive vaccine used for horses (*Equus caballus*).[35] In the authors' early work, it was effective in coyotes (*Canis latrans*) as well.[38] The PZP vaccine targets the ZP, a glycoprotein layer located on the outer surface of the egg. Antibodies to ZP result in infertility either by blocking sperm from penetrating the ZP layer or by interfering with egg maturation within the follicle.[6]

Extracted PZP proteins were initially provided to the NWRC by Dr. Bonnie Dunbar (Baylor College of Medicine, Houston, Texas, 77030, USA) and Dr. Irwin Liu (University of California-Davis, Davis, California 95616, USA) and were produced by the method of Dr. Dunbar.[7] For later NWRC studies, native PZP and SpayVac (PZP encapsulated in liposomes) were produced and provided by Dr. Robert Brown (ImmunoVaccine Technologies [IVT], Nova Scotia, B3H OA8 Canada).[3]

During early research with PZP prepared by the Dunbar method, 11 white-tailed deer does at Pennsylvania State University (University Park, Pennsylvania 16802, USA) received a prime vaccination in July to August and two boost vaccinations in September and October; in November, the does were paddocked with bucks. Extensive observations of breeding activity by a team of Penn State students were made comparing the breeding activity of female deer vaccinated with the vaccine. This PZP preparation was quite effective in preventing pregnancy when deer received both prime and boost doses, with 89% reduction in fawning over a 4-yr period and 76% over 6 yr.[47]

After demonstrating that PZP vaccines could be effective when given as a prime and a boost, NWRC researchers attempted development of a vaccine that could induce a long-lasting immune response after a single injection. A study was subsequently conducted comparing the effectiveness of six different single injection vaccine formulations,[41] containing different PZP preparations (Dunbar preparation, IVT preparation without liposomes, and SpayVac). The study demonstrated that the different production methods for PZP affected the duration of effect of the resulting vaccines. The PZP isolated by IVT produced a longer-lasting response as compared witj the Dunbar PZP isolation method. The IVT PZP with liposomes (SpayVac) and without liposomes were the most efficacious formulations, with 8 of the 10 does in each group contracepted for 5 to 7 yr after a single injection.[41] The normal fertility level for this herd was 1.7 fawns/doe per year.[42] The deer study also compared different adjuvants used with the SpayVac PZP: SpayVac prepared in AdjuVac; lypophilized SpayVac suspended in AdjuVac; and SpayVac mixed with alum as the adjuvant. The water-in-oil emulsion produced with AdjuVac provided a longer-lasting response than the alum or suspension.[41] NWRC researchers were encouraged that vaccines formulated

with AdjuVac provided the long-lasting efficacy with a single injection that would be required for most uses in wildlife.

Because the process of isolating PZP from pig ovaries obtained from pig slaughterhouse facilities is costly and time consuming, an alternative source of PZP was sought. In one study,[45] different recombinant rabbit ZP proteins produced in *Escherichia coli* were studied. The proteins RC55, RC75a, and RC75b all showed cross reactivity with native PZP. Deer vaccinated with these recombinant proteins were compared with deer vaccinated with native PZP. The native PZP was much more effective in contracepting deer than the rabbit recombinant proteins. In another study,[49] the NWRC used selected PZP-derived peptides (generated by Chiron Mimotope Systems, San Diego, 92121, California) identified from published sequence information (National Institutes of Health gene bank, www.ncbi.nlm.nih.gov/genbank) to identify which peptide or peptide groups were responsible for the contraceptive effect. The peptides were screened using serum from a PZP-treated doe, and a ZP1 mimitrope (pins 10–16) demonstrated the greatest response. When this ZP1 peptide was used to vaccinate a group of nine deer, some efficacy was observed, but there was also large variation in the immune response between deer. The deer with the highest antibody titer to this ZP1 peptide exhibited three estrous cycles and had no fawns; however, the average fawning rate in this group was 0.89 fawns/doe, which was indicative of a partial contraceptive effect. It was concluded that the native PZP, which apparently maintains the natural folding of the glycosylated protein, was more consistent in inducing infertility than this or any of the other peptides tested.[49]

By effectively blocking sperm from penetrating the egg without reducing circulating hormone levels, PZP vaccines caused repeated cycling during the rut season in deer at Penn State University,[23] extending the breeding season for the PZP-treated deer for up to seven estrus cycles ($\bar{x} = 2.4$ cycles), with a mean of 98 days and a few deer cycling up to 150 days.[47] This increased length of the breeding season has the potential for increasing car-deer collisions because of increased deer movement. It also causes increased energy expenditures by rutting deer, and if antibody titers drop below a critical threshold late in the breeding season, late season fawns can be produced that may not survive the northern winter climates. Moreover, other researchers were developing PZP vaccines,[30] so duplication of research efforts needed to be minimized. For these reasons, the NWRC discontinued testing of PZP in deer and focused research on developing an alternative contraceptive vaccine for use in ungulates.

GnRH immunocontraceptive vaccines

The NWRC researchers desired a vaccine that would eliminate most reproductive behaviors. GnRH is a key reproductive hormone that controls steroidogenesis and gametogenesis by stimulating the release of gonadotropins from the pituitary gland, triggering the cascade of reproductive hormones that lead to sperm production and ovulation. The NWRC began development of GnRH vaccines in the early 1990s, and the first GnRH vaccine was tested at Penn State University beginning in 1994[23,46] (Table 1). This GnRH vaccine was given to females ($n = 8$) and males ($n = 4$) as a prime injection followed by a boost 1 mo later. Extensive observations of breeding activity were made. Fawning rates in the study were 0.21 fawns/doe per year over 4 yr in the treated does compared with 1.8 fawns/doe per year in control does. The contraceptive activity was correlated with the antibody titer for the vaccine, with fertility returning as the antibody titers dropped. GnRH-treated does showed no breeding behavior, and bucks had no interest in them; the reduction in progesterone shown in the GnRH-treated does suggested that they were not cycling. GnRH immunized bucks had a significant reduction in testosterone and had no interest in sexual activity when paired with control females. Depending on the immunization schedule, antlers in GnRH-treated bucks either dropped early in the fall or remained in velvet.

After years of refinement, a new vaccine (GonaCon Immunocontraceptive Vaccine, NWRC, Fort Collins, Colorado, 80521, USA) was developed by the NWRC that has been shown to suppress reproduction in treated animals of both sexes, can be administered as a single injection,[52] is effective for at least a year in most mammalian species,[9] and is often effective for multiple years.[9] Like earlier GnRH vaccines, GonaCon stimulates the production of antibodies that neutralize GnRH, suppressing reproductive hormone production (i.e., follicle-stimulating hormone [FSH] and luteinizing hormone [LH] from the pituitary gland and estradiol, progesterone, and testosterone from the gonads). The design of GonaCon is the key to its long-term efficacy with a single injection; the

characteristics of the design that allow it to be effective without a boost injection will be discussed in further detail.

VARIATION IN VACCINE EFFICACY AMONG INDIVIDUAL ANIMALS

Users of a contraceptive vaccine need to be aware that, unlike surgical sterilization, which is 100% efficacious, the efficacy of immunocontraceptive vaccines is subject to individual variation, so it is difficult to predict the percent and duration of induced infertility. A certain percentage of vaccinated animals will always be nonresponders or have a reduced immune response to a vaccine.[59] This is true for both disease vaccines and PZP and GnRH immunocontraceptive vaccines. For human or companion animal vaccines, it is possible to give an injection and a follow-up boost that increases the effectiveness of the vaccine and may provide almost 100% efficacy. For wildlife or feral animals, a boost injection is less desirable because the animal must be relocated, it is difficult to individually mark animals, and it is difficult and time consuming to handle an animal more than once. A single injection, long-lasting contraceptive vaccine like GonaCon or SpayVac is a more attractive wildlife management tool because animals would need to be handled or darted less frequently. However, additional studies and/or population models[20,67] will be required to provide managers with recommendations for implementing contraceptive programs as management tools to reduce or maintain wildlife population levels.

Contraceptive vaccine users also need to know that, while GonaCon is effective in both males and females, it has been demonstrated to be effective for a longer period of time in females than in males. In a GnRH vaccine study at Penn State University, male deer ($n = 5$) given a single injection showed reduced testicular size and plasma testosterone for at least three breeding seasons.[29,46] Males given two immunizations tended to remain infertile for an additional 2–3 yr. In contrast, six of nine female deer were contracepted for 4 to 6 yr after a single injection.[41] Similar differences between longevity of vaccine effectiveness in males and females have been demonstrated with cats (*Felis catus*). When a single injection of GonaCon was given to 15 female cats, 93% of vaccinated cats remained infertile for the first year, with 73, 53, 40, and 27% infertile for 2, 3, 4, and 5 yr, respectively. The median duration of contraception was 39.7 mo based on suppression of hormone levels.[32] In a similar study with males given a single injection of GonaCon, 9 of 12 cats responded with high antibody titers and a drop in testosterone to a nondetectable range; however, three treated cats failed to produce a high GnRH titer and showed no suppression of testosterone.[34] The median duration of effect for the male cats that responded to the vaccine was 14 mo, with one treated cat having undetectable testosterone at 34 mo.

As indicated previously, GonaCon-treated white-tailed deer showed a reduced number of estrus cycles or did not cycle at all, an effect probably due to the lack of estrogen. This reduced breeding behavior associated with infertility was typically seen during the first few years following vaccination. Although the single injection of GonaCon induced infertility for multiple years, an occasional return to breeding behavior 4–5 yr after vaccination, prior to the return of fertility (Miller, unpubl. data),[42] was observed. This return of breeding behavior prior to the return of fertility has also been observed in wild horses (Gray, unpubl. data)[18] and in wild boar (*Sus scrofa*).[37] It is speculated that the reason for the return of breeding behavior prior to the return of fertility could be that GonaCon controls LH levels more completely than it controls levels of FSH. As the level of GnRH antibodies drops in immunized animals over several years, sufficient gonadotropins are released to allow estrogen to reach levels that can induce signs of estrus, but GnRH is still sufficiently inhibited to block the LH surge and ovulation. As the GnRH antibody titer drops further, more LH is released, ovulation resumes and the animal can become pregnant. A vaccine boost will enhance the longevity of the vaccine's efficacy in both males and females. Male white-tailed deer were given a boost of GonaCon that lengthened the time that they remained infertile by several years.[29] In a study with female bison (*Bison bison*) at the Northwest Trek Zoo in 2001 (Eatonville,Washington, 98328, USA), a prime dose was effective in contracepting three of five bison; however, a boost given 1 yr later rendered all bison infertile the second year, and they remained infertile for at least 3 yr.[58] Untreated bison in the herd calved normally.

The authors' research has also demonstrated the importance of timing when injecting the vaccine. The vaccine is most effective if given at least a month or more before the onset of reproductive activity. This allows time for an adequate titer level to develop so contraception can occur.[42]

UNDERSTANDING THE SINGLE INJECTION PRINCIPLE

There are very few vaccines on the market that are effective with a single injection, so the statement that GonaCon is effective in contracepting animals with a single injection is often received with skepticism, especially from knowledgeable immunologists. GonaCon is effective as a single injection due to three primary factors: 1) the GnRH antigen is coupled to a large foreign molecule in a systematic manner; 2) the vaccine antigen is made into a stable emulsion; and 3) *M. avium* is included in the adjuvant.

GnRH is a small peptide hormone that is a weak antigen due to its low molecular weight and its being a "self" hormone. However, due to its small size, GnRH can easily be made synthetically. In the GonaCon vaccine, GnRH is made immunogenic by ensuring that each synthetic GnRH peptide molecule is conjugated in a very systematic and predictable manner to a large, nonself, highly immunogenic hemocyanin protein harvested from marine mollusks;[51,52] thus producing a GnRH-mollusk protein conjugate. Many pathogens, including viruses and bacteria, exhibit rigid, highly organized, and highly repetitive surface protein epitopes. The GonaCon design provides a consistent alignment of up to 300 GnRH peptide molecules on the surface of the large mollusk protein, mimicking the repetitive nature of pathogen epitopes, an important aspect of the GnRH-hemocyanin conjugate design. The original mollusk protein used was KLH. However, the high price of KLH (now used in cancer therapy vaccines) prompted a search for a more economical hemocyanin carrier protein for the GnRH peptide. Blue protein, derived from the mollusk *Concholepas concholepas,* proved to be a successful option. The single injection blue protein formulation has been shown to provide a longer-lasting effect compared with the KLH preparation in white-tailed deer.[39,42]

This water-soluble GnRH/mollusk conjugate is then made into a water-in-oil emulsion with the adjuvant AdjuVac. The mineral oil-based emulsion provides a depot effect for the vaccine and protects the antigen from rapid destruction by the macrophages of the target animals' immune system.[39] This provides for a strong prolonged immune response because of the slow release rate of the GnRH conjugate antigen at the injection site. Remnants of vaccine have been observed at the injection site during necropsy up to 2 yr after vaccination (unpubl. obs.). A water-in-oil emulsion appears to be the only formulation that provides a long-term contraceptive response in both PZP and GnRH vaccines with a single injection.

In all of the successful immunocontraceptive vaccine studies, adjuvants have been used as part of the immunocontraceptive vaccine to enhance the immune response of the host animal to the PZP or GnRH antigen. Adjuvants for contraceptive vaccines are critical in providing efficacy, but unfortunately, the immunostimulatory properties of some of the most effective adjuvants can result in localized inflammation and tissue destruction.[1] In initial research on white-tailed deer, the PZP used by the NWRC was formulated as an emulsion with Freund's Complete Adjuvant for the first injection and Freund's Incomplete Adjuvant for subsequent boosts. During discussions with the Food and Drug Administration (FDA) regarding the potential for gaining regulatory approval of immunocontraceptives, the FDA stated their opposition to the use of any vaccine containing Freund's adjuvant because of its known inflammatory effects. The NWRC began work on a safer adjuvant in 1998, leading to development of a new oil-based adjuvant called AdjuVac, which for currently registered uses contains $<$200 μg of killed *M. avium* per 1-ml dose. Inflammatory reactions caused by AdjuVac are less severe than those caused by Freund's complete adjuvant.[2,57,] AdjuVac has been used as the adjuvant for both PZP and GnRH vaccines by the NWRC since 1998.

In addition to the stable emulsion, the long-lasting contraceptive effect of GonaCon is dependent on the presence of *M. avium* in the adjuvant. In early NWRC studies with PZP immunocontraceptive vaccines in deer using Freund's adjuvant, it was necessary to boost with incomplete Freund's at least once, and sometimes several times, to maintain high antibody titers. When it was switched to the new adjuvant AdjuVac, which contains killed *M. avium*, it was found that in most animals (e.g., deer,[42] horses,[24] and prairie dogs [*Cynomys ludovicianus*][66]) a boost was not needed to achieve a long-lasting immune response. *Mycobacterium avium* has been shown to be ubiquitous in nature,[10] having been recovered from almost every environmental compartment that has been investigated, including fresh water, brackish water, biofilms, aerosols, soils, food plants, plant products, and fish. Furthermore, isolation from a hospital water system over a period of 18 mo demonstrated that *M. avium* is commonly found in drinking-water because of its high resistance to ozone and chlorine-based

disinfectants.[31] The authors hypothesize that due to the ubiquitous nature of *M. avium,* it is a key factor in the success of GonaCon.[39,42,55] Most animals will have previously experienced and produced an immune response to *M. avium*; therefore, the immune system is already primed, leading to a more immediate response to the vaccine than would normally be expected after only a single dose.

Current research from the authors' laboratory has shown that a single injection of Gonacon can provide a multiyear contraceptive effect and has also shown that prolonged infertility with GonaCon is directly related to high serum concentration of GnRH antibodies.[42] Burton et al.[4] writes, "To be effective in producing long-lasting antibodies, antigen administered in a single dose must be retained in the body long enough to produce specific antibodies that will bind with the antigen to form immune complexes (ICs)." Fukanoki et al.[11,12] demonstrated in chickens that the slow release of antigen from oil-based emulsions was positively correlated to immune response. A slow antigen release allows ICs to form, creating a greater immune response. These ICs can then bind to follicular dendritic cells (FDCs) that protect the antigen from macrophage and liver degradation. ICs may begin to form within 7–14 days after a primary injection or within minutes after a booster. The FDCs can provide the continued presence of antigen for months to years.[36] Antigen release from the FDCs relates to the level of the antigen-specific antibody. When specific antibody levels drop, the FDCs will release the specific antigen, boosting the circulating antibody.[41] It is believed that the carefully prepared emulsion used in GonaCon serves as a depot, allowing retention and slow release of the target antigen (i.e., GnRH).

USE OF GONACON FOR REPRODUCTIVE, BEHAVIOR, AND DISEASE MANAGEMENT

GonaCon was initially developed as a management tool for urban/suburban populations of the ever-expanding white-tail deer populations that can be used when other management tools, such as hunting, are impractical or not legal. However, it soon became apparent that a GnRH-based contraceptive could apply to other species as well. Because GnRH is common to all mammals, the GonaCon immunocontraceptive vaccine has induced contraception in many overabundant mammalian species, including white-tailed deer,[47] elk (*Cervus elaphus*),[22] wild horses,[24,25,18] bison,[50] California ground squirrels (*Spermophilus beecheyi*),[53] prairie dogs,[66], gray squirrels (*Sciurus carolinensis*),[54,65] captive Norway rats (*Rattus norvegicus*),[44] domestic and feral swine and wild boar,[26,27,51,37] brushtail possums (*Trichosurus vulpecula*),[8] and tammar wallabies (*Macropus eugenii*).[59] In the United States, all of these uses in wildlife will be regulated by the Environmental Protection Agency.

GonaCon is also being tested as a technique to assist in control of feral or wild dogs and in management of rabies. Rabies in domestic dogs (*Canis familiaris*) has been eliminated in most of the developed world through extensive vaccination, and now rabies only persists in wildlife in these areas.[64] However, in the developing world and in poverty-stricken areas, domestic dogs remain the principle vectors of rabies, with dog bites contributing to more than 95% of human rabies cases.[5] Effective rabies control relies on a combination of large-scale vaccination as well as effective dog population control strategies. Most population control programs have moved away from culling of animals toward surgical sterilization, which is expensive, labor intensive, and does not always reach enough of the dog population to be effective. GonaCon is being investigated as a tool to provide contraception of dogs through a single injection that can be administered in conjunction with a rabies vaccine during annual vaccination campaigns. Simultaneous injection of GonaCon with a canine rabies vaccine in dogs did not affect the development of rabies antibodies.[2] Further research is being conducted to determine the effectiveness of combined contraceptive and rabies vaccine programs as a rabies control tool in field situations.

GonaCon has also been tested in zoo animals, livestock, and companion animals for situations in which animals are not intended to be bred. It has induced contraception in domestic cats,[32,33] and domestic swine.[26,27] GonaCon has also been proposed as a technique for eliminating unwanted behaviors associated with reproduction in companion or work animals. However, because the current GonaCon formulation is designed to last for several years, which may not be desirable in certain situations, the formulation would need to be redesigned to last only a few months to a year as needed. Regardless, uses of GonaCon in domestic or zoo animals would be regulated by the FDA's Center for Veterinary Medicine; these uses will not be pursued by the NWRC but could be pursued by collaborators.

Contraception with GonaCon offers potential as a disease management tool for certain diseases,

most notably, venereally transmitted diseases or diseases transmitted at parturition, such as brucellosis. Swine brucellosis is transmitted through the venereal route as well as through contact with aborted fetuses and placental membranes and fluids. Bovine brucellosis is transmitted among cattle (*Bos taurus*), bison, and elk, primarily through contact with infected aborted fetuses and placentas and to calves from infected milk.[58] GonaCon has been and is currently being tested to prevent parturition in bison. Studies in bison showed that a single dose of the vaccine resulted in infertility in all vaccinates for multiple years.[50] If ongoing studies demonstrate GonaCon's utility in decreasing shedding of *Brucella abortus*, the vaccine could provide a potential nonlethal management tool to prevent transmission of the disease in an infected population.

GonaCon has been tested as a tool for the treatment and prevention of adrenal cortical disease (ACD) in domestic ferrets.[40] ACD is a common problem in neutered middle-aged and older ferrets, affecting the majority of animals by 7 yr of age, often causing alopecia, adrenal hyperplasia, and tumors. ACD is caused by the excessive continuous production of LH due to the lack of negative feedback from gonadal hormones in neutered ferrets, resulting in overproduction of sex steroids by the adrenal glands. Injection with GonaCon reduces the production of LH, and thus the adrenal sex hormones, thereby reducing ACD and its clinical signs. In an ongoing study, 88 neutered young male and female ferrets were vaccinated with GonaCon.[40] Only 25% of treated ferrets developed clinical signs of ACD by 8 yr of age compared with 84% of control ferrets, indicating that GonaCon may offer a therapeutic tool for the prevention of ACD in ferrets.

SAFETY AND TOXICITY OF GONACON

The NWRC has conducted several studies that have shown that GonaCon can reduce fertility in deer for multiple years without any obvious side effects other than injection site reactions visible upon necropsy. GonaCon is currently registered with the Environmental Protection Agency (EPA) for use in white-tailed deer and in wild horses and burros (GonaCon-Equine). A safety study was designed to evaluate the potential for negative health effects if deer accidentally received multiple injections of GonaCon.[21] In the study, seven does were given a single injection of GonaCon (EPA-registered formulation) and another six does were given three injections at 2-wk intervals. Both groups were compared with a saline control group ($n = 6$). Blood samples were drawn periodically, and the deer were observed for general health. At 20 wk, the deer were euthanized, necropsies were conducted, and the blood was tested using hematology and chemistry health profiles. Aside from some granulomata formation seen at necropsy in the muscle at the injection site, typically evidenced by a tan-yellow appearance and a bulge at the cut surface, there were no toxic or health effects associated either with GonaCon given in a single injection or in multiple injections.

Another potential concern addressed by the NWRC was the health of animals when injected with GonaCon while pregnant. The mechanisms required for the maintenance of pregnancy differ between species; however, in all mammalian species progesterone, from the corpus luteum and or placenta, is required at some stage. In many years of using GonaCon in white-tailed deer, no indications of abortions after treatment were noted; however, to test this, GonaCon was injected into six deer that tested positive for pregnancy by ultrasound in the first week of February. All deer gave birth to healthy fawns but were then infertile for 2 to 3 yr.[43] Other animals have also been injected with GonaCon while pregnant, including elk, bison, and wild horses;[56,50,28] all delivered normal offspring the next year and then were infertile in the following years. Thus, in species tested to date, GonaCon is safe for use in pregnant animals.

Research was also conducted to determine the effect of using GonaCon on white-tailed deer fawns, because it is sometimes difficult to tell a fawn from a doe in the late summer through winter, when darting with an immunocontraceptive vaccine could occur.[43] To determine the effects on fawns, six male and six female fawns were given two injections of 450 μg of GonaCon 1 mo apart at 3 and 4 mo of age, in September and October. All fawns developed initial elevated titers to GnRH; however, the GnRH antibody titers in 11/12 fawns dropped by the following fall, and those fawns came into breeding condition. Only one female retained a high antibody titer and remained infertile throughout the 3-yr study.[43]

Another of the concerns with using an immunocontraceptive vaccine is the occurrence of injection site reactions. Successful stimulation of the immune system requires some level of injection site reaction because the injection site represents the area where the animals' immune system sees and attacks the invading foreign

material, creating an immune response. As discussed, vaccines that are able to remain at the injection site, without being destroyed, can provide a long-lasting immune response. Injection site reactions vary among vaccine formulations, species, and animals. For example, vaccines containing mineral oil-based adjuvants produce more frequent injection site reactions because of the vaccine emulsion remaining at the injection site. If the vaccine is not cleared from the injection site area, the body walls this area off, forming a granuloma. In some cases, more severe reactions occur that result in open sores or draining abscesses.

There are large differences among species in susceptibility to injection site reactions. Some species, including cats,[32] wallabies,[60] and grey kangaroos (*Macropus giganteus*),[60] appear to be less prone to injection site reactions than others after treatment with GonaCon. After a single GonaCon injection, Levy reported no injection site reactions in female cats during the first 2 yr of a study; at 2 yr, the appearance of a nonpainful but persistent late-onset injection site mass was reported in some animals.[32] Lyn Hinds (pers. comm.) also noticed no initial injection site reactions in grey kangaroos or wallabies but observed in some wallabies late-onset nonpainful injection masses (up to 2 cm wide) that would come and go over a period of months in the GonaCon injection site.

In contrast, dogs ($n = 3$) treated with GonaCon (registered formulation; Table 1) experienced severe injection site reactions.[19] This may be due to general differences between species, with dogs being more susceptible to these types of reactions. It is suspect that the amount of *M. avium* in the vaccine is, at least in part, responsible for the injection site reactions in dogs. In a subsequent trial, dogs ($n = 12$) were treated with GonaCon that contained half the amount of *M. avium* than was previously tested. Dogs still experienced injection site reactions, but they were less severe (S. Bender, pers. comm.). A third trial was conducted in Mexico, where dogs were treated using only one-fourth of the *M. avium*.[63] No severe injection site reactions occurred, and there were no signs of pain or limping in the dogs because of vaccination. At necropsy, there was evidence of gross and microscopic lesions in muscle tissue, but reactions were much reduced compared with previous trials. Additional trials are ongoing with GonaCon-Canine, a formulation with the reduced *M. avium* concentration.

In the authors' studies, injection site reactions have occurred more frequently in field trials than in pen trials with white-tailed deer.[13,14] During the 19 yr of vaccinating deer housed in Penn State University pens, there were no visible injection site reactions in any of the deer, and necropsies following the studies did not show any remarkable injection site reaction. These Penn State deer were fed a high-quality diet and were medicated three times a year to ensure they were parasite free. Because of the complete lack of injection site reactions, it was a surprising that some of the deer in the field studies[13,14] developed injection site reactions that were visible upon necropsy. The deer were in poor health because of overpopulation of the deer herd, and at necropsy we found the deer were infested with many parasites. It is possible that poor general health and/or high parasite load may be correlated with an increase in injection site reactions, but further research is necessary to explain the mechanism behind the differences seen.[15]

Similarly, contraceptive efficacy of GonaCon was consistently higher in captive than in free-ranging white-tailed deer and feral horses.[13,14,18] It was hypothesized that parasites in the free-ranging study animals may have reduced their hosts' immune responses to vaccination with GonaCon. Captive animals in these trials received optimal nutrition and regular veterinary care, including routine deworming, whereas free-ranging wild deer and horses received no veterinary intervention. Similar variation in vaccine efficacy has been observed in humans, where several vaccines used in infants failed to confer the expected protection in heavily helminth-parasitized populations but were highly efficacious in populations in which parasitism was uncommon.[15] Abundant experimental evidence from studies in humans and animal models indicates that parasitic helminths can suppress or divert host immune responses and reduce vaccine efficacy. Therefore, inferences on effectiveness of a contraceptive vaccine based on pen studies may be overly optimistic.

DEVELOPING A PHARMACEUTICAL-GRADE VACCINE

To move from a benchtop experimental vaccine to one that could be registered by the EPA and potentially licensed to a manufacturer, the NWRC needed to make changes in some of the GonaCon vaccine inert ingredients and the manufacturing process. Changes included using higher-quality mineral oil and surfactant, moving the

manufacturing process from a chemistry benchtop to a clean room, and developing an aseptic manufacturing technique to deliver a sterile vaccine product.

For GonaCon to be mass-produced for sale, the need for a more efficient and economical production system is needed. Several steps have been made to produce larger GonaCon batches, reduce the cost of reagents, and reduce the time involved in the manufacturing process. Production of GonaCon requires the proper conjugation of GnRH peptides to a mollusk carrier protein and the preparation of a stable water-in-oil emulsion of the GnRH conjugate with the AdjuVac adjuvant. The authors' were able to shorten the time required to make the GnRH conjugate and the amount of reagents used. This allowed the production of a quality emulsion by using a commercial emulsifier machine (Microfluidics, Newtown, Massachusetts, 02464, USA). This helps to reduce variability between batches and allows for the vaccine to be preloaded in syringes, thus eliminating the need to mix vaccines in the field. Quality control steps have been added to the manufacturing process for GonaCon, including a determination of the amount of the active ingredient, the GnRH peptide, in the GonaCon vaccine.[16] Determination of the stability of the active ingredient is required by the EPA for the GonaCon registration, so the chemistry section of the NWRC developed an analytical method to determine the amount of the active ingredient in GonaCon; this method was used to perform a vaccine stability study. In addition to the chemistry analytical method, a biologic assay in rabbits was used to determine efficacy of the GonaCon vaccine. These studies have allowed for a 6-mo shelf life on the outgoing GonaCon vaccine when it is stored and shipped at 4°C.

SUMMARY AND FUTURE DIRECTIONS FOR NWRC REPRODUCTIVE CONTROL RESEARCH

During the 20 yr that the NWRC has been conducting research on immunocontraceptives, the NWRC has had successes and failures and has learned some important general lessons. Both PZP and GnRH antigens can be effective antigens for immunocontraceptive vaccines in many species. Each of these products has advantages and disadvantages, and its use needs to be based on evaluation of the wildlife problem to be solved. The effectiveness of the vaccines is dependent on their formulation and on the proper presentation of the target antigen. The vaccines require a powerful adjuvant and a water-in-oil emulsion to be most effective. The presence of a ubiquitous *Mycobacterium* (killed) in the adjuvant enhances vaccine efficacy.

When used in combination with AdjuVac, SpayVac (a PZP vaccine), and GonaCon (a GnRH vaccine), formulations can provide single injection, multiple year effectiveness. A boost vaccination can extend the effectiveness of the vaccines, sometimes making the animal permanently infertile, but the effectiveness of vaccines varies between species and among individuals. A certain proportion of animals will be nonresponders and will not generate a high antibody titer. Vaccines are most effective if injected at least a month or more before the onset of reproductive activity to allow time for antibody development. Field efficacy of a vaccine may be lessened by high parasite load and poor body condition. Localized, nonpainful injection site reactions caused by the long-term presence of the vaccine can occur but may be part of the process of developing a long-lasting antibody response after a single injection. Animals treated with either PZP or GonaCon vaccines can be consumed because the protein antigens are broken down into amino acids in the gastrointestinal tract.

In addition to these general lessons, the NWRC has gained considerable insight into PZP vaccines. For example, the native PZP was shown to be much more antigenic than peptides or recombinant proteins. Also, PZP vaccines are not effective in all mammalian species.[17] PZP vaccines may cause undesirable behavioral effects such as multiestrus.

During its development and testing, the NWRC has observed that GonaCon is effective in most mammalian species, with contraceptive effects lasting longer in females than in males. GonaCon can be safely given to pregnant animals without interfering with the pregnancy. GonaCon can eliminate almost all reproductive behaviors, including estrus cycles and theoretically some undesirable behaviors in companion animals. It may also provide a potential management tool for venereally transmitted diseases or diseases transmitted at parturition. GonaCon can effectively prevent ACD in domestic ferrets by reducing LH levels. However, approval for use of GonaCon in companion animals or for disease prevention will be through regulatory agencies other than the EPA and will not be pursued by the Animal Plant Health Infection Service.

Future research at the NWRC will continue to look for new applications for the use of GonaCon and will continue research into understanding the immunology behind the variations in effectiveness from species to species. It is hoped that information on the timeframe in which to give a boost to improve the length of the contraceptive response can be developed. The NWRC also hopes to pursue studies on its effective use as a management tool and to develop private sources of manufacturing for GonaCon in efforts to commercialize the product and make it more widely available.

Abstract: *In the face of continuing habitat fragmentation and isolation, the optimal level of connectivity between populations has become a central issue in conservation biology. A common rule of thumb holds that one migrant per generation into a subpopulation is sufficient to minimize the loss of polymorphism and heterozygosity within subpopulations while allowing for divergence in allele frequencies among subpopulations. The one-migrant-per-generation rule is based on numerous simplifying assumptions that may not hold in natural populations. We examine the conceptual and theoretical basis of the rule and consider both genetic and nongenetic factors that influence the desired level of connectivity among subpopulations. We conclude that one migrant per generation is a desirable minimum, but it may be inadequate for many natural populations. We suggest that a minimum of 1 and a maximum of 10 migrants per generation would be an appropriate general rule of thumb for genetic purposes, bearing in mind that factors other than genetics may further influence the ideal level of connectivity.*

La regla de Un-Migrante-Por-Generación en Conservación y Manejo

Resumen: *Debido a la continua fragmentación y aislamiento de habitats, el nivel óptimo de conectividad entre poblaciones se ha convertido en un tema central en la biología de la conservación. Una regla común sostiene que un amigrante por generación en una subpoblación es suficiente para minimizar la pérdida de polimorfismo y heterocigosidad en las subpoblaciones y al mismo tiempo permite la divergencia de frecuencias alélicas entre subpoblaciones. La regla de un-migrante-por-generación se basa en numerosas suposiciones simplifican que tal vez no sucedan en poblaciones naturales. En este trabajo examinamos las bases conceptuales y teóricas de la regla y consideramos factores genéticos y no genéticos que influyen en el nivel deseado de conectividad entre subpoblaciones. Concluimos que un migrante por generación es un mínimo deseable, pero puede ser inadecuado para muchas poblaciones naturales. Surgerimos que un mínimo de uno y un máximo de diez migrantes por generación seria una regla general apropiada para fines genéticos, sin olvidar que factores no genéticos pueden influir en el nivel ideal de conectividad.*

> . . . evolution depends on a certain balance among its factors. There must be gene mutation, but an excessive rate gives an array of freaks, not evolution; there must be selection, but too severe a process destroys the field of variability, and thus the basis for further advance; prevalence of local inbreeding within a species has extremely important evolutionary consequences, but too close inbreeding leads merely to extinction. A certain amount of crossbreeding is favorable but not too much. In this dependence on balance the species is like a living organism. At all levels of organization life depends on the maintenance of a certain balance among its factors.

> —S. Wright (1932:365)

Introduction

By the 1930s Sewall Wright had clearly established—based on experiments and historical breeding records—

Paper submitted December 1, 1995; revised manuscript accepted May 20, 1996.

that inbreeding depression in small, isolated populations typically leads to adaptive decline and extinction (Provine 1986). In Wright's view small amounts of gene flow between partially isolated demes are necessary for long-term persistence. Prompted by Wright's work, the question of how many immigrants ("migrants" in population genetics literature) are needed to prevent population differentiation became the subject of a vast body of theoretical analysis (for review see Slatkin [1985, 1987]). From this analysis emerged a genetic rule of thumb that one migrant individual per local population per generation (OMPG) is sufficient to obscure any disruptive effects of drift (Spieth 1974; see also Kimura and Ohta 1971; Lewontin 1974).

Biologists concerned with population insularization caused by habitat fragmentation began advocating the application of this principle for conservation purposes. Several of the most cited papers advocating, in some sense, the movement of one individual per generation between isolated populations for conservation purposes include Franklin (1980), Frankel and Soulé (1981), and Allendorf (1983). More recently, the OMPG concept has been widely applied by scientists and managers charged with initiating connectivity between potentially isolated populations. For example, Gogan (1990) makes the statement for mammals in general that "Immigration to a subpopulation of only one individual once every five years reduces concerns about inbreeding depression to a negligible level." Triggs et al. (1989) suggest for the critically endangered kakapo (*Strigops habroptilus*) that "In future generations, exchanges of one young kakapo per generation between populations should be made to help maintain genetic variation and reduce inbreeding."

Mace and Lande (1991) have used the OMPG rule as a criterion for fragmentation in defining threatened species categories of the World Conservation Union. In the United States nearly every recovery plan that considers genetic issues and insularization applies the OMPG rule. For example, the black-footed ferret (*Mustela nigripes*) recovery plan states that "If the effective population size is to be maintained among many smaller populations, then exchange of genetic material at the rate of one individual/generation between local populations to ensure random and adaptive divergence among populations is necessary" (U.S. Fish and Wildlife Service 1988:18).

The simplicity of the OMPG—and its widespread adoption—belies confusion over the derivation of the rule, its real generality, and the specifics of implementing it (Varvio et al. 1986). Indeed, immediately after stating that subpopulations would not become fixed for different alleles if there were "an interchange of only one individual every other generation," Wright noted that violations of simplifying assumptions may mean that ". . . an interchange of the order of thousands of individuals per generation between neighboring subgroups of a widely distributed species might well be insufficient to prevent a considerable random drifting apart in their genetic compositions" (Wright 1931:128). Thus, from the outset Wright acknowledged the complicating role of the social, ecological, and genetic characteristics of immigrants; these real-world complexities are often neglected in contemporary reference to the OMPG rule.

Human-caused habitat modification is reducing many continuous populations to isolated or semi-isolated fragments (Soulé et al. 1988; Mills 1995). In light of these changes, concerns over the appropriate level of gene flow in fragments are well grounded, both because of the increased potential for demic extinction in isolated populations (Senner 1980; Soulé 1987; Lynch & Gabriel 1990; Mills & Smouse 1994) and because of potential consequences for adaptation to future disturbances (Soulé 1980; Frankel & Soulé 1981). The issue of actually prescribing gene flow in a management context is complicated, however, and it has received little empirical or theoretical consideration.

We describe the OMPG rule, present its theoretical underpinnings, and discuss its application and limitations from a genetics perspective. Finally, we make recommendations that apply both to highly manipulated systems, where managers physically move individuals, as well as to systems in which the movement rate is affected by the size and shape of available habitat or movement corridors.

The One-Migrant-per-Generation Rule

The one-migrant-per-generation rule originated in Wright's analysis of the interplay between genetic drift and gene flow in determining the expected patterns of genetic divergence among a series of subpopulations. Consider a large number of subpopulations in which genetic drift produces genetic divergence among the subpopulations at a rate inversely proportional to the local effective population size (N_e), which is assumed to equal the census size, N. Assume that in each generation a proportion m of the individuals in each subpopulation are migrants from outside that subpopulation and that the allele frequency in migrant individuals is the average allele frequency in all subpopulations. Such migration will limit the amount of divergence that will occur among subpopulations.

This model leads to the surprisingly simple result that at equilibrium the amount of divergence among subpopulations for reasonably small values of m is approximately

$$F_{ST} \approx \frac{1}{4mN + 1}, \quad (1)$$

where F_{ST} is the proportion of total gene diversity (heterozygosity) due to divergence among subpopulations. Note that because m is the proportion of migrants and N is the population size, mN is the actual number of migrants entering a subpopulation each generation.

The amount of divergence among subpopulations as measured by F_{ST} is independent of the total amount of gene diversity in a population (H_T). The F_{ST} can also be thought of as the reduction in heterozygosity within subpopulations (H_S) caused by random genetic drift and divergence among subpopulations. That is,

$$F_{ST} = 1 - \frac{H_S}{H_T}, \quad (2)$$

and F_{ST} is usually called the fixation index. In the case of more than two alleles, each allele may have a different fixation index. Nei (1973) introduced an analogous value (G_{ST}, the coefficient of genetic differentiation) that can be used to describe genetic differentiation for many loci with more than two alleles (Chakraborty & Leimar 1987).

This analysis has two notable results. First, the amount of divergence is dependent only on the number of migrants (mN) and is in a sense independent of population size. For example, we expect the same amount of divergence among subpopulations of size 1000 with 2.5% migration as we do among subpopulations of size 50 with 50% migration; in both cases there are 25 migrants per generation.

The dependence of divergence on the number of migrants, rather than the population size (N) or rate of migration (m), may at first seem counter-intuitive. Divergence, however, results from the opposing effects of migration and genetic drift. The larger the subpopulations, the slower they are diverging through drift; thus, proportionally fewer migrants are needed to counteract the effects of drift. Small subpopulations diverge rapidly though drift, and thus proportionally more migrants are needed to counteract drift.

The second notable aspect of this result is that remarkably small amounts of migration can have powerful genetic consequences on divergence among subpopulations at equilibrium; for example, OMPG is expected to yield an equilibrium F_{ST} of 0.2 (Fig. 1). If we examine the actual distribution of allele frequencies among subpopulations, it is clear that OMPG will also make it unlikely that polymorphism will be lost within subpopulations (Fig. 2; Wright 1931; Fig. 6). With at least one migrant per generation, subpopulations are unlikely to reach equilibrium gene frequencies where one allele or the other is lost (frequency of zero) or "fixed" (frequency of 1.0).

Nevertheless, substantial divergence in allele frequencies across populations is expected with one migrant per generation (Wright 1931, 1969; Allendorf & Phelps 1981). Thus, OMPG provides a desirable balance between drift and gene flow by preventing the loss of alleles and minimizing loss of heterozygosity within subpopulations but allowing genetic divergence to exist among subpopulations. Low amounts of exchange will maintain qualitative similarity among subpopulations and also allow substantial quantitative divergence in allele frequencies.

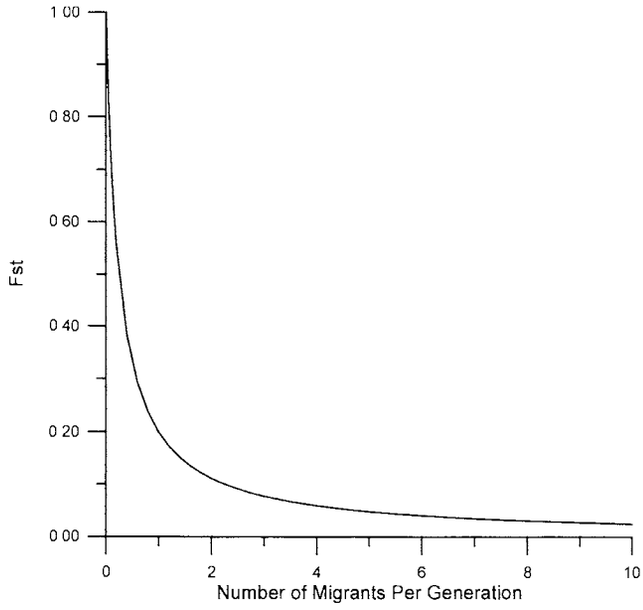

Figure 1. Relationship between number of migrants per generation (mN) *and the fixation index* (F_{ST}).

We want to emphasize that OMPG is not a discrete quantitative threshold and does not imply panmixia (random mating) among individuals of different populations. Rather, the basis of OMPG originates from a qualitative evaluation of tradeoffs between loss of genetic diversity within populations versus homogenization among populations.

Assumptions of the Rule

The OMPG rule results from a simple model of population structure based upon a host of unrealistic assumptions. We consider the primary assumptions that affect the applications of the results of this basic model to conservation.

(1) *Island model of migration*: A migrant is equally likely to come from any subpopulation so that there is no geographical pattern to gene flow. The assumption is also usually made that there are an infinite number of subpopulations of equal size.

(2) *Selective neutrality and no mutation*: There are no selective differences among genotypes, and no new mutations enter the population. That is, gene-frequency dynamics are determined entirely by the interaction between genetic drift and gene flow.

(3) *Ideal populations*: The subpopulations have the characteristics of an ideal genetic population, so that the census number of individuals equals the effective population size. For general purposes, the ideal population consists of a constant number of N diploid individuals ($N/2$ females and $N/2$ males) in which all parents have

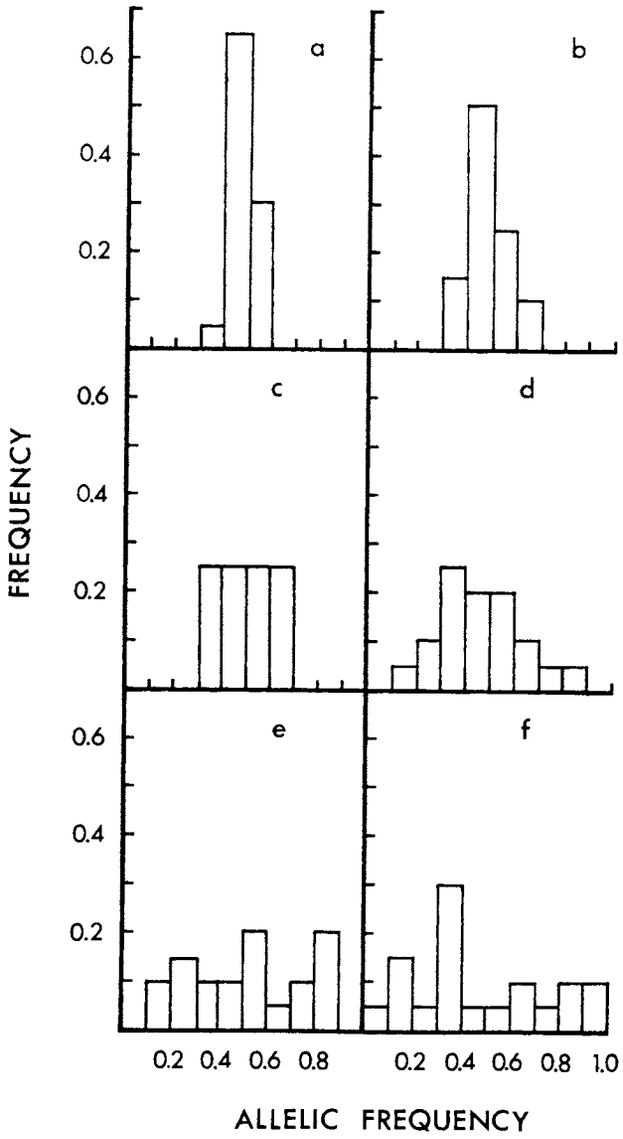

Figure 2. Distribution of allele frequencies in 20 subpopulations (N = Ne = *200 each) with different amounts of migration, based upon computer simulations of the island model for two alleles at a single locus (Allendorf & Phelps 1981). For panels a-e, number of migrants per generation decreases and* F_{ST} *increases, as follows:* mN = *25,* F_{ST} = *0.0080 (a);* mN = *10,* F_{ST} = *0.0175 (b);* mN = *5,* F_{ST} = *0.0509 (c);* mN = *2,* F_{ST} = *0.1104 (d);* mN = *1,* F_{ST} = *0.2513 (e); and* mN = *0.5,* F_{ST} = *0.3221 (f).*

equal probability of contributing an offspring to the next generation.

(4) *Demographic equality*: Immigrants have the same demographic attributes, in terms of survival and reproduction probabilities, as resident individuals.

(5) *Equilibrium*: The subpopulations persist long enough to reach steady-state or equilibrium conditions with respect to gene frequencies.

Limitations of the Rule

What are the consequences of violating the simplistic assumptions of the OMPG rule? We consider how population size may affect the predicted effects of OMPG, then evaluate each of its assumptions. In each case we determine whether each complicating factor is expected to increase or decrease the effectiveness of OMPG or whether "it depends."

Census Population Size

As noted in the derivation of the OMPG rule, one of its interesting and attractive features is that it is independent of population size, as long as gene dynamics are driven entirely by drift and gene flow (mutation and selection play no role). There are, however, at least two caveats to this generalization. First, mN migrants into a small population will represent a larger proportion of the population than if they had entered a larger population; any disruptive social or mating system effects of the immigration will therefore be magnified in smaller populations (Frankel & Soulé 1981; Frankel 1983).

Second, the usual formulation for the loss of genetic variation under drift-migration equilibrium (Eq. 1) is an approximation of the exact equation and holds true only when m (migration rate) is "small" (Wright 1969:291). For a fixed mN, such as one migrant, m becomes large with small population size. For example, when $N = 2$, $m = 0.5$, a large value that leads to less loss in variation (smaller F_{ST}), with the exact equation than expected with the approximation (Fig. 3). We note, however, that the overestimation of F_{ST} with the approximate equation is insignificant with subpopulation sizes large enough to be likely to persist in the face of demographic stochasticity for even relatively short periods of time. For example, for $N = 20$, the exact F_{ST} is 94% of the approximation.

Both of these issues imply that when populations become quite small less migration may be appropriate, both because of possible social disruption and because very small populations are not losing variation as fast as predicted by the F_{ST} approximation. Other factors, such as Allee effects and demographic or environmental stochasticity, lead to the opposite conclusion, with immigrants initiating an important "rescue effect" (Brown & Kodric-Brown 1977).

Island Model: Pattern of Migration

The immigrants in Wright's infinite island model are randomly chosen from the pool of an infinite number of subpopulations. If individuals in the real world come from nearby populations, their gene frequencies would differ little from the target population, so more immigrants would be necessary to prevent loss of variation

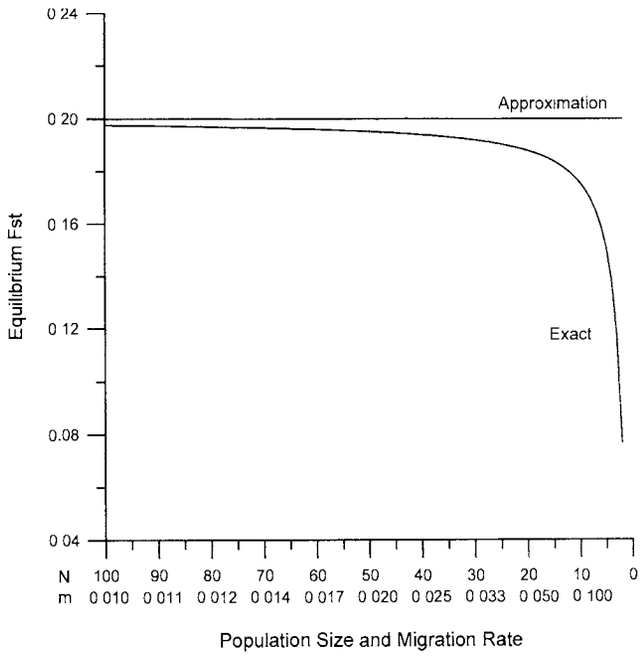

Figure 3. Expected F_{ST} *at equilibrium for one migrant per generation (*mN = *1) using the exact equation (from Eq. 12.2 in Wright 1969) and the commonly used approximation (Eq. 1). Unlike the approximation, which assumes small* m, *the exact equation changes as* m *changes.*

(Wright 1931; Levin 1988). Crow and Aoki (1984) conclude, however, that unless the number of populations is very large, this neighborhood effect is relatively small; in a finite population model, migrants from neighboring groups are about half as effective in their genetic effects. Kin-structured migration—in which individuals disperse in the company of relatives—will also have the effect of requiring more immigrants for the same effect on genetic drift (Levin 1988).

Directional movement patterns are an important and widespread exception to the assumption of the island migration model. In many situations migrants from a relatively large subpopulation may be moved into a smaller subpopulation that is isolated; this is referred to as a continent-island pattern of migration (Hedrick 1983:278). For example, grizzly bears (*Ursus arctos*) from the Yellowstone National Park region are isolated from other populations. The recovery plan for grizzly bears includes regularly moving bears from more northern populations in Montana that are contiguous with grizzly bear populations in Canada into the Yellowstone region (U.S. Fish and Wildlife Service 1993).

The genetic effects of this type of directional movement pattern are compatible with the OMPG rule. The isolated population can be considered one subpopulation of the island model in which migrants from the larger population represent the migrant pool of the island model. Thus, the predictions of the OMPG rule will be valid as long as the donor population is large so that genetic drift is minimal. Weishampel (1990) cautions that if the donor population has lower genetic variation than the receiving population, migration can actually decrease genetic variation in the population of interest.

Another characteristic of the pattern of migration is the interval between immigrants. In its simplest form the island model assumes that probability of migration per generation is constant. Will 1 migrant per generation have the same effect as 10 migrants every 10 generations? Lacy (1987:153) concludes that sporadic immigration should be just as effective as a steady supplementation, provided that the same long-term average rate is maintained. On the other hand, Levin (1988:645) concludes that "a variable migration rate homogenizes neutral allele frequencies less than a uniform migration rate with the same mean." This effect is quite small, however, based upon theory (Nagylaki 1979). Experimental work offers no insight into this question. In many cases the driving criteria for the timing of immigrants will probably not be genetic calculations but logistical concerns (transplanting one animal per generation will often be impractical) and behavioral and social considerations whereby groups of immigrants are more likely to experience successful reproduction.

In short, real-world deviations from the simple pattern of migration used to derive the OMPG rule mean that somewhat more than one migrant per generation may be necessary to achieve the desired genetic goals; the necessary increase will depend on particular circumstances, but it is probably small.

Island Model: Number of Subpopulations

The expected value of F_{ST} at equilibrium can be corrected as shown below to take into account a finite number (n) of subpopulations (Slatkin 1995):

$$F_{ST} \approx \frac{1}{4mNa + 1}, \tag{3}$$

where

$$a = \left(\frac{n}{n-1}\right)^2. \tag{4}$$

Total gene diversity (H_T) can be partitioned into within- and between-subpopulation components. Isolation causes a decrease in within-subpopulation variation (H_S), whereas fixation for different alleles maintains total gene diversity (H_T). As long as the subpopulations are connected by gene flow, an allele will eventually be lost from all subpopulations (and therefore the entire population) by genetic drift if there are a finite number of subpopulations. If the subpopulations are isolated, however, then different alleles will drift to fixation in differ-

ent populations, so more alleles will be maintained in the entire population.

There may be merit (Chesser 1983) in maintaining isolated populations so that more alleles can be retained in the entire population. Nevertheless, these benefits must be weighed against increased probability of extinction due to within-population inbreeding depression (Varvio et al. 1986; Mills & Smouse 1994). In short, the tradeoff between within- and among-population variation may dictate more or less migration than the OMPG rule does (Figs. 1 & 2).

Natural Selection and Mutation

The theoretical model upon which the OMPG rule is based assumes selective neutrality—that is, there are no differences in fitness among genotypes. Nevertheless, the OMPG rule itself does take into account natural selection. The OMPG rule was chosen because it is sufficient to avoid the loss of alleles in subpopulations caused by genetic drift but will allow the allele frequencies within subpopulations to respond to local selective pressures.

Even weak natural selection can have a major effect on the amount of genetic divergence among populations (Allendorf 1983). The effects of natural selection will be greater in larger subpopulations because of the reduced effects of drift in larger populations. In general, natural selection will not have a major effect on the distribution of allele frequencies if the selection coefficient (s) is less than the migration rate (m) (Wright 1940). Thus, natural selection will have less effect on allele frequency divergence among subpopulations with smaller subpopulations for the same amount of migration (mN) (Allendorf 1983).

The effect of selection upon the expected amount of divergence with a given amount of gene flow depends upon the pattern of selection. Similar selection in different subpopulations will tend to reduce divergence, whereas different selective conditions will increase divergence among subpopulations (Allendorf 1983). It is likely that both of these patterns of selection will occur at different loci within the same population. Thus, the OMPG rule seems appropriate when we consider the potential effects of natural selection.

Mutation is expected to have little effect on the application of the OMPG rule. The expected amount of divergence at equilibrium for G_{ST} (the multiple-allele form of F_{ST}) is independent of the mutation rate and the number of alleles, as long as the migration rate is much greater than the mutation rate (Hartl & Clark 1989). This condition will be met for all loci in which migration rates are on the order of one per generation ($mN = 1$) or greater.

Ideal Populations and Demographic Equality

The ratio of effective population size to census population size is expected to affect the consequences of varying migration rates. Wright (1931:128, 1969:292) noted that the smaller N_e is relative to the census N, the larger the number of migrants necessary to minimize differentiation. This is because as N_e decreases below N the population loses variation faster via drift, and a given migrant contributes less to the breeding population, than when N_e equals N. Therefore, populations with highly skewed N_e/N ratios, as is often the case in wild vertebrates (Frankham 1995), may require more than one migrant per generation. How many more are necessary is uncertain; presumably it will depend on why N_e is less than N (for example, because of skewed sex ratio or variance in family size) and on the reproductive characteristics of the immigrants.

Demographic equality also assumes that immigrants are equivalent to residents. To the extent that an immigrant is more or less likely to survive and breed relative to individuals in the target population, it may count as more or less than one migrant. It seems unlikely that immigrants will be demographically equivalent to resident individuals in most situations. In the case in which immigration is imposed by moving captured individuals, there are a variety of reasons to expect immigrants to be less likely to survive and reproduce than residents.

There are also a few situations in which immigrants may be more successful than residents. For example, individuals with rare genotypes have a reproductive advantage in plant species with self-incompatibility systems (Charlesworth 1985). Thus, immigrants from a genetically different subpopulation may have a reproductive advantage in this case.

Because deviations from ideal population structure will tend to compromise the effectiveness of migration relative to expectations, including social structure and taking into account the relative reproductive success of immigrants will mean that more than one migrant per generation may be necessary.

Equilibrium

The OMPG rule is based upon the assumption of equilibrium between the effects of migration and genetic drift. Equilibrium will be reached more quickly with smaller population sizes and higher migration rates (Varvio et al. 1986). Thus, greater migration may be initially desirable with larger subpopulations in order to reach equilibrium more quickly. Equilibrium between gene flow and drift is approached fairly quickly with small population sizes (Table 1; see also Allendorf & Phelps 1981; Table 2).

Before the population reaches equilibrium, the restorative effect of immigration is initially greater for small populations than for large because they have drifted to lower levels of variation (Lacy 1987). This implies that increases above OMPG may well be beneficial when migration is initiated for the first time.

Table 1. Observed and expected genetic divergence among five subpopulations of Leadbeater's opossum connected by gene flow in a simulation study (Lindenmayer & Lacy 1995).*

mN	H_s	*Expected* F_{ST}	*Observed* F_{ST} *20 yr*	*50 yr*	*100 yr*
0	0.28	1.000	0.170	0.309	0.509
0.7	0.60	0.186	0.105	0.128	0.130
1.5	0.70	0.096	0.074	0.068	0.079
7.4	0.80	0.021	0.021	0.022	0.024

**The* mN *values were calculated with the annual migration rate (*m*) used in the simulations, a generation interval of 3.71 years and an* N *of 40 based on carrying capacity (see text for discussion of using* N *versus* N_e*).* H_s *values represent observed mean heterozygosity within subpopulations at 100 years. Expected* F_{ST} *at equilibrium was calculated using Eq. 3 and the actual* mN *values used in the simulations. Observed* F_{ST} *values were calculated using Eq. 2.*

Implicit in the equilibrium assumption is that populations all persist long enough to reach equilibrium. McCauley (1993) reviews the consequences of relaxing this assumption: incorporating extinction and recolonization dynamics can either increase or decrease genetic differentiation, depending on how high population turnover rates are, where the migrants originate, how many migrants move together, and whether the migrants settle in unoccupied or occupied patches. Extinction and recolonization dynamics tend to accentuate population differentiation most when migrant individuals move into established populations more than colonizing new patches. Therefore, if conspecific attraction (Reed & Dobson 1993) tends to increase the likelihood of a dispenser settling in an already occupied area rather than an unoccupied area in a metapopulation, then those migrants will be less effective at minimizing differentiation in the metapopulation; if they settle more in empty patches, then extinction and recolonization dynamics predict that fewer migrants are needed to prevent differentiation (McCauley 1993).

In general, then, violation of the equilibrium assumption means that somewhat more than one migrant per generation may be beneficial. Extinction and recolonization dynamics could either increase or decrease the desirable number.

Empirical and Simulation Results

What insights can be gained from field studies, laboratory experiments, and comprehensive computer studies of natural populations that violate many of the above assumptions at the same time? Because it is not possible to test the predictions of the OMPG rule within a reasonable time frame for most species of interest, empirical tests will initially come from model genetic species with short generation times.

Little experimental work considers the issue of how many migrants are optimal in natural—or even captive—populations. The most direct experimental work is that of Spielman and Frankham (1992). They found strong and significant increases in reproductive fitness in 10 replicate inbred lines of *Drosophila melanogaster* that received only a single immigrant per generation. On average, OMPG restored nearly 50% of that fitness lost under isolation. Newman (1996) has found similar results with experimental populations of the plant *Brassica campestris*. One migrant per generation among 10 subpopulations had a significantly positive effect for five of six fitness components measured. In contrast to these results, Backus et al. (1995) found no increase in fitness associated with a single immigrant (although higher levels of gene flow did increase fitness) among five subpopulations of the housefly (*Musca domestica*).

Studies that use simulations or analytical approaches incorporating actual life-history information for long-lived species also provide insight into how effective OMPG is expected to be in the face of real-world deviations from the simplifying assumptions. For example, Hedrick (1995) used a variety of theoretical population genetic models to test the validity of the OMPG rule in the case of the Florida panther (*Felis concolor coryi*). The report of a workshop for genetic restoration of the Florida panther recommended an initial influx of 20% of the population, followed by gene flow of one animal per generation. Hedrick's models included various combinations of gene flow and genetic drift. He also examined several violations of the assumptions of the basic model: natural selection, directional gene flow, and nonequilibrium initial conditions. Despite these complicating factors, he concluded that this recommendation was sufficient to eliminate lowered fitness due to inbreeding depression and to retain adaptive alleles in the Florida population.

Allendorf et al. (1991) used simulations with the computer program GAPPS (Harris et al. 1986; Harris & Allendorf 1989) to examine the effects of immigration on effective population size and the rate of loss of genetic variation in an isolated population of grizzly bears in the Rocky Mountains. These simulations used a directional (continent-island) pattern of gene flow in a discrete-time, stochastic computer program that followed each individual bear from birth to death. The estimated effective population size of the isolated population was approximately 30% of the census population size. Their results are in general agreement with those expected with the basic model: the introduction of a few bears per generation greatly reduced the rate of loss of variation in the isolated population. The introduction of males had a greater effect than the introduction of females in the model, but this effect may be outweighed by the reduced likelihood of males being incorporated in the breeding population into which they are introduced be-

cause of the behavioral differences between males and females (Allendorf et al. 1991; U.S. Fish and Wildlife Service 1993).

Dobson et al. (1991) used GAPPS to simulate the viability of isolated populations of black rhinos (*Diceros bicornis*) in Kenya. They used an island-continent pattern of migration and demographic data obtained from black rhino sanctuaries. They also included the effects of inbreeding depression in some of their simulations. They found that one immigrant every 10 years had a major effect on the population size and persistence of isolated populations.

The most realistic test of the OMPG rule using simulations that we are aware of was done by Lindenmayer and Lacy (1995) with Leadbeater's possum (*Gymnobelideus leadbeateri*). They used the computer program VORTEX (Lacy 1993) to model the viability of metapopulations with subpopulations occupying a small number of habitat patches of varying sizes. They used values for life-history parameters drawn from extensive field studies, allowed local subpopulations to become extinct, and included the effects of inbreeding depression. Dramatic effects of migration were observed in their largest metapopulation, which consisted of five subpopulations of 40 individuals each (Table 1).

The results for Leadbeater's possum also can be used to quantitatively test the predictions in a system that violates many of the assumptions upon which the OMPG is based. The observed amount of genetic divergence among the five subpopulations estimated from the data of Lindenmayer and Lacy (1995) is similar to that predicted by the simple equilibrium model (Table 1). As expected, near-equilibrium values were obtained more rapidly with greater amounts of gene flow. Even with $mN = 1.5$, however, the observed F_{ST} value was nearly 75% of that expected at equilibrium after approximately five generations.

Recommendations for Implementing Gene Flow

When connectivity is implemented for genetic purposes, we are interested in finding the middle ground between loss of alleles in local populations (fixation, or loss in heterozygosity) and uniformity of allele frequencies across local populations. One migrant per generation is an appropriate lower limit to the amount of gene flow that is desirable. Nevertheless, sometimes more than an average of one migrant per generation will be necessary because of deviations in real populations from the ideal conditions assumed in developing the OMPG rule.

We hesitate to give "cookbook" prescriptions, but an increase in migration above the mean of one migrant per generation may be desirable under the following conditions: (1) inbreeding depression is thought to be a problem in the local population; (2) migrants are closely related to each other or to the local population; (3) social, behavioral, or logistical factors prevent single individuals from immigrating, so that movement is in pulses of several animals every several generations; (4) N_e is much less than total population size; (5) migrants are likely to be at a disadvantage in terms of survival and breeding success; (6) the receiving population has been isolated for many generations; and (7) demographic or environmental variation indicates a high danger of extinction without aggressive supplementation.

If one migrant per generation is not enough in many circumstances, then the next question is how much gene flow may be too much to maintain the balance we are seeking. This question is difficult to answer without extensive genetic and demographic information on the population under consideration. Concerns over local adaptation and outbreeding depression dictate that, under some conditions of phenotypic or genotypic dissimilarity, immigration into an isolated population should be minimized (for cogent discussions see Templeton [1986] and Leberg [1990]). Frankel and Soulé (1981) proposed an upper limit of 5 migrants per generation because of concerns with disruptive effects on social structure in small populations. We suggest that up to 10 migrants per generation is not likely to tip the balance too far by causing uniformity of allele frequencies across subpopulations (Fig. 2).

The characteristics of the migrants is as important as the number of migrants. Social, behavioral, and demographic characteristics that affect the likelihood of survival and reproduction of migrants may overwhelm genetic considerations in assessing the "ideal" candidates to recruit as migrants (Kleiman 1989; Stanley-Price 1989; Short et al. 1992). Likewise, considerations of mating system and social structure will affect the genetic impact of an immigrant. Greater numbers of randomly chosen migrants may be necessary to achieve the same genetic effect as fewer migrants chosen to maximize contribution to the effective population size.

Finally, we stress that criteria other than genetic variation will often play pivotal roles in determining the appropriate level of connectivity between semi-isolated fragments. For example, small populations subject to blinking out due to demographic or environmental stochasticity can experience a "rescue effect" (Brown & Kodric-Brown 1977), with immigrants increasing numbers away from the boundary of zero. In this case more migrants increase population persistence, regardless of genetic considerations. On the other hand, contagious diseases have been raised as a factor decreasing the benefits of connectivity (Wilson et al. 1994; Hess 1994).

Conclusions

The OMPG rule has provided much-needed guidance in management and has illuminated the need for genetic

connectivity among isolated populations. Like many theoretical applications in conservation, its utility is strongest when its complexity is appreciated (Doak & Mills 1994). We have seen several compelling real-world factors that suggest more than one migrant per generation may be necessary to achieve genetic goals, and some situations (albeit fewer) in which less connectivity is desirable. One key to practical decision making is to define clearly the desired genetic outcome, as well as other objectives and constraints of the supplementation program (Lacy 1987).

One migrant per generation is an acceptable minimum, but it may be inadequate for many natural populations. Different levels and schedules of supplementation are appropriate under different environmental conditions and with different species. Nevertheless, we suggest that a minimum of 1 and a maximum of 10 migrants per generation would be an appropriate general rule of thumb for genetic purposes.

Acknowledgments

Abstract

This presentation reviews multiple wildlife health considerations associated with contraception of wildlife, at the level of both the individual animal and wildlife population. Review of the literature demonstrates that many contraceptives studied in the past have had potential adverse effects characterized as follows: harmful effects on pregnant animals, inhibition of parturition or dystocia, changes in ovarian structure or function, changes in sex ratio, changes in lactation or mammary glands, impact on fertility of young, changes in testicular structure or function, changes in secondary sex characteristics, changes in bodyweight, changes in behaviour, changes in annual breeding season, other physiologic and pathologic changes, abscesses or inflammatory reactions, toxicity, interference with diagnostic tests and ecological alterations. Concern is expressed that the use of immunocontraception could create genetic changes in the target population that would influence disease resistance. The use of infectious agents as vectors to deliver immunocontraceptives was not considered wise animal health management because the product will be a new reproductive disease that could be difficult to contain within the target population. Criteria that need to be fulfilled for the safe use of contraceptives in wildlife are offered.

Serum anti-Müllerian Hormone Following Zona Pellucida Immunocontraceptive Vaccination of Mares

M.B. Nolan*[a], H.J. Bertschinger[a], M. Crampton[b], M.L. Schulman[a]

[a] Department of Production Animal Studies, Faculty of Veterinary Science, University of Pretoria, Onderstepoort, South Africa
[b] CSIR Biosciences, Pretoria, South Africa

Ovarian suppression was recently suggested as an inherent feature of effective zona pellucida (ZP) based immunocontraception across various species including horses. Measuring anti-Müllerian hormone (AMH) in immunocontracepted mares may provide a novel and minimally-invasive tool for the assessment of ovarian function (Joone. et. al. Theriogenology. 2018; 106(2): 214-220). This study aimed to assess the utility of measuring serum AMH concentrations by comparison with clinical parameters for monitoring ovarian activity following ZP-based immunocontraception in a population of horse mares. Mares (n=31) were subdivided into age-categorised (<3y, 3-6y, >6y) treatment groups for active immunisation with either: native porcine ZP proteins (pZP; University of Pretoria, South Africa) (n=7; 2 treatments), novel recombinant ZP proteins (reZP; CSIR, South Africa) (n=8; 3 treatments) or combined pZP and reZP proteins (n=8; 2 treatments). Antigens were prepared in a combination adjuvant formulation (6% polymeric adjuvant (Montanide™ Pet Gel A, Seppic, France) and 500 μg polyinosinic-polycytidylic acid - TLR3-agonist (Poly (I:C) HMW VacciGrade™, Invivogen, USA) all with a 1ml total injection volume. A control group (n=8; 2 treatments) received the same combination adjuvant formulation without antigen. Treatments and measurements were initiated in December (D=0) (southern hemisphere summer) with measurements and, or blood sampling for AMH and serum progesterone concentration (SPC) repeated in January (D=35), February (D=70), March (D=105) and May (D=175). Mares were examined by trans-rectal palpation and ultrasonography of the reproductive tract to establish individual ovarian activity status. Recorded variables included; ovarian volume, uterine and cervical tone, uterine oedema, presence and number of follicles ≥15mm diameter and presence of corpora lutea retrospectively confirmed by SPC assay. Ovarian activity established at each time-point on a composite outcome measurement categorised mares as displaying cyclic ovarian activity if ovarian activity was detected by; trans-rectal palpation, ultrasonographic examination or SPC ≥ 1ng/ml. The various measures of ovarian cyclic activity agreed in 172 of 195 cases. Ovarian suppression was established if all 3 measures of detection were negative. Serum AMH concentrations were determined by ELISA (AMH Gen II ELISA; Beckman Coulter, Brea, USA). Data were analysed using general and mixed linear models. Both time, treatment and time treatment interaction had significant effects on functional ovarian status ($P<0.001$, $P<0.001$, $P<0.001$, respectively) becoming evident from D105, most markedly in the reZP group (7/8 inactive) and furthermore a significant treatment effect on serum AMH concentrations was observed on D175 ($P<0.05$). Notably, mare age positively influenced serum AMH with lower concentrations observed in mares ≤3y. Both pZP and reZP immunisation were associated with ovarian suppression in treated mares. Treatment effects associated with serum AMH concentrations, however, only became apparent 5 weeks later. Serum AMH concentrations proved useful for inferring suppression of ovarian function following completion of the ZP immunocontraception protocol.

Highlights

- Ovarian suppression is evident in the short term following immunocontraception of mares using reZP proteins formulated with non-Freund's adjuvant.
- Serum AMH concentrations are correlated with ovarian volume, serum progesterone and mare age when employing infrequent sampling techniques.
- Serum AMH is higher in older than younger, albeit sexually mature, mares.

Abstract

the following vaccine formulations, native porcine zona pellucida (pZP), recombinant zona pellucida proteins ZP3 and ZP4 (reZP), pZP and reZP combined or a commercially available anti-GnRH vaccine. The ZP antigens were prepared in an adjuvant formulation consisting of 6% polymeric adjuvant (Montanide™ PetGel A, Seppic, France) and 500 μg polyinosinic-polycytidylic acid - TLR3-agonist (Poly(I:C) HMW VacciGrade™, Invivogen, USA). A vehicle-only control group was administered the adjuvant formulation without antigen. Ovarian activity was monitored using clinical observations (transrectal palpation and ultrasonography of the reproductive tract) in addition to blood sampling for serum progesterone and anti-Müllerian hormone (AMH) concentrations while employing a low sampling frequency. Treatments and measurements were initiated in December (southern hemisphere summer) and subsequent data collection was performed in January, February, March and May. Both reZP and anti-GnRH vaccination were associated with clinically evident ovarian suppression in the short term. Ovarian activity in mares administered a reZP or anti-GnRH vaccine was significantly different to adjuvant control and pZP treated mares. Serum AMH concentrations were different between pZP and anti-GnRH treated mares 3.5 months after the final vaccination. Serum AMH concentrations were significantly correlated with mare age, serum progesterone and ovarian volume.

Antibody Response and Safety of a Novel Recombinant Zona Pellucida Vaccine Formulation in Mares

M.B. Nolan, H.J. Bertschinger, M.L. Schulman*

Department of Production Animal Studies, Faculty of Veterinary Science, University of Pretoria, Onderstepoort, South Africa

Commercial and regulatory limitations associated with porcine zona pellucida (pZP) vaccines may be overcome by developing effective recombinant ZP-based vaccines. Similarly, reported undesirable side effects associated with traditionally-utilised Freund's adjuvants in ZP-vaccines warrants investigation of alternative formulations. This study aimed to assess serum anti-ZP antibody response and safety following administration of novel ZP-based formulations to horse mares. Mares (n=31) were subdivided into age-categorised (<3y, 3-6y, >6y) treatment groups for active immunisation with either: porcine ZP proteins (pZP; University of Pretoria, South Africa) (n=7; 2 treatments), novel recombinant ZP proteins (reZP; CSIR, South Africa) (n=8; 3 treatments) or combined pZP and reZP proteins (n=8; 2 treatments). Antigens were prepared in a combination adjuvant formulation (6% polymeric adjuvant (Montanide™ Pet Gel A, Seppic, France) and 500 μg Polyinosinic-polycytidylic acid - TLR3-agonist (Poly (I:C) HMW VacciGrade™, Invivogen, USA) with a total injection volume of 1ml. A control group (n=8; 2 treatments) received the same combination adjuvant formulation without antigen. Treatments and measurements were initiated in December (D=0) (southern hemisphere summer) with measurements or jugular blood sampling repeated in January (D=35), February (D=70), March (D=105) and May (D=175). Injection site reactions were assessed by inspection and palpation of gluteal intramuscular injection sites for 7 days post-treatment using a 3-point scale and rectal temperature was measured. Anti-ZP antibody response was measured by enzyme immunoassay. Linear models examined data for treatment and time effects. Both treatment and time had a significant effect on anti-ZP antibody titres ($P<0.001$, $P<0.001$ respectively). Treatment group differences were assessed at the time of assumed maximal antibody titres (D=105). All treatment groups' antibody concentrations differed significantly to the control group ($P<0.001$). No differences were measured between Groups 1 (pZP) and 2 (reZP) ($P>0.05$) but Groups 1 and 3 (pZP and reZP) differed significantly, with lower concentrations in Group 3 ($P<0.001$) and differences remained at the end of monitoring (D=175). Temporal changes in antibody titres in all ZP treatment groups followed patterns seen previously in various species treated with pZP and Freund's adjuvants. Correlation analysis for anti-ZP antibody titres with age and BCS were non-significant ($P=0.92$, $P=0.16$, respectively). Injection site reactions, categorised as 0 (none), 1 (slight), or 2 (visible and pain) occurred in 55%, 46%, 47%, and 22% and elevated temperatures (≥39°C) in 20%, 26%, 9%, and 20% of examinations in Groups 1, 2, 3, and 4, respectively. Significant effects of treatment and time on injection site reactions were evident ($P<0.01$), occurring more frequently with subsequent treatments. The majority of reactions were mild (0-1: 97.5%), resolving within 7 days. A similar pattern was observed with elevated rectal temperatures. This represents the first application of a reZP vaccine evoking a similar antibody titre response to native pZP vaccine in mares. Furthermore, incorporation of a novel non-Freund's adjuvant provided an alternative effective formulation for ZP-based immunocontraception.

Immunocontraception in Wild Horses (*Equus caballus*) Extends Reproductive Cycling Beyond the Normal Breeding Season

Cassandra M. V. Nuñez*, James S. Adelman, Daniel I. Rubenstein

Department of Ecology and Evolutionary Biology, Princeton University, Princeton, New Jersey, United States of America

Abstract

Background: Although the physiological effects of immunocontraceptive treatment with porcine zona pellucida (PZP) have been well studied, little is known about PZP's effects on the scheduling of reproductive cycling. Recent behavioral research has suggested that recipients of PZP extend the receptive breeding period into what is normally the non-breeding season.

Methodology/Principal Findings: To determine if this is the case, we compiled foaling data from wild horses (*Equus caballus*) living on Shackleford Banks, North Carolina for 4 years pre- and 8 years post-contraception management with PZP (pre-contraception, n = 65 births from 45 mares; post-contraception, n = 97 births from 46 mares). Gestation lasts approximately 11–12 months in wild horses, placing conception at approximately 11.5 months prior to birth. Since the contraception program began in January 2000, foaling has occurred over a significantly broader range than it had before the contraception program. Foaling in PZP recipients (n = 45 births from 27 mares) has consistently occurred over a broader range than has foaling in non-recipients (n = 52 births from 19 mares). In addition, current recipients of PZP foaled later in the year than did prior recipient and non-recipient mares. Females receiving more consecutive PZP applications gave birth later in the season than did females receiving fewer applications. Finally, the efficacy of PZP declined with increasing consecutive applications before reaching 100% after five consecutive applications.

Conclusions/Significance: For a gregarious species such as the horse, the extension of reproductive cycling into the fall months has important social consequences, including decreased group stability and the extension of male reproductive behavior. In addition, reproductive cycling into the fall months could have long-term effects on foal survivorship. Managers should consider these factors before enacting immunocontraceptive programs in new populations. We suggest minor alterations to management strategies to help alleviate such unintended effects in new populations.

Introduction

The extirpation of predator species has resulted in the expansion of free-ranging ungulate populations in North America [1], necessitating their regulation. Immunocontraceptive management has become increasingly popular as culling programs are seldom well-received by the general public. In females, the most common form of immunocontraception, porcine zona pellucida (PZP), stimulates the production of antibodies that bind sperm receptors on the egg's surface, thereby preventing sperm attachment and fertilization [2].

In recent decades, the wild horse (*Equus caballus*) has become a model for evaluating the effects of PZP, thanks chiefly to the seminal nine-year study of contracepted mares on Assateague Island National Seashore [3]. Subsequent research on this population has shown that PZP has little to no effect on recipient physiology or behavior [4,5,6]. For example, in Assateague horses, PZP has no effect on the duration of individual estrous cycles [6], and researchers have reported only minor ovulation failure and depressed urinary oestrogen concentrations with repeated applications [4]. However, behavioral research on the horses of Shackleford Banks, North Carolina, and other wild ungulate species suggests that PZP affects the reproductive physiology of recipient animals [7,8,9]. In each of these studies, females treated with PZP extended reproductive behaviors into the non-breeding season. While these results are consistent with an extension of ovulatory cycling into the post-breeding season when most females are normally anovulatory [10,11], this possibility has not yet been tested.

Mares are seasonally polyestrous and extended estrous periods have been documented [11]. Tropical species, for example, are less strictly seasonal, and in some cases, reproduce throughout the year [12,13]. In addition, variability in the cycling schedules and receptivity of individual mares [14], and the performance of estrous behavior and copulatory activities during the non-breeding season [15] have been documented in temperate species. Such

variation in ovulatory scheduling and receptivity suggest that the seasonality of reproductive behavior in *Equus caballus* females is characterized by a substantial degree of plasticity. As the physiological state of contracepted animals has been significantly altered, the possibility of prolonged extended cycling is even more feasible.

In wild horse societies, the harem is the core social group, consisting of usually one, but sometimes two or three harem male(s), one to several female(s), and their offspring [16,17,18,19,20,21]. Harem males will sometimes fight to acquire mares from other groups, but stallions almost always retain their mares [18,19,20,22]. In temperate environments, food availability is lower during the fall and winter months and free-ranging horses will alter their activity to maximize food intake and reduce energetic costs [23,24]. Mares are typically anovulatory at this time and sexual behavior in males is largely absent [11,14].

On Shackleford Banks, increased reproductive behavior in the post-breeding season by mares has resulted in increased male attentiveness [9]. Such behavior (by males) has been shown to restrict the movement of females, thus reducing their grazing efficiency [21,25]. The occurrence of this behavior during a time of year when animals typically increase group spread to acquire adequate forage [19,24], represents a change in behavior fundamental to the animals' survival [26,27]. Offspring conceived during the post-breeding season are likely subject to decreased resource availability as lower quality forage can affect mares' ability to produce sufficient milk [27]. Finally, regardless of the timing of titer decline post-treatment [9,28,58], when anti-PZP antibody titers decrease during the fall months [28,29], extended reproductive cycling among recipient mares will increase their chances of conception, thereby lowering the vaccine's overall efficacy. Determining whether PZP recipients are likely to extend reproductive cycling is therefore of great importance if managers are to limit animal numbers while still maintaining functional, healthy populations.

Here we use the birth dates of foals to estimate dates of conception for PZP recipient and non-recipient mares on Shackleford Banks, North Carolina. Gestation length in wild horses is 11–12 months [30]. Therefore, dates of conception can be reliably estimated as approximately 11.5 months prior to birth. Breeding normally occurs from March through August, with most births occurring in April and May [11]. Given the extension of reproductive behavior in PZP- treated mares [9], we hypothesize that PZP recipients will extend cycling into the non-breeding season more often than will non-recipients. Therefore, when PZP recipients conceive and give birth, they will do so later on average and over a wider range of months than will non-recipients.

Methods

Study area

This study was conducted on Shackleford Banks, a barrier island located approximately 3 km off the coast of North Carolina, USA. The island was 15 km in length, and varied between 0.5 and 3 km in width. The horse population on Shackleford Banks has been co-managed by the National Park Service and the Foundation for Shackleford Horses since 1996.

Study subjects

The reproductive units of Shackleford horses are typical of feral equids. They are coherent harem groups of one, or sometimes two or three stallion(s), one to several mare(s) and their offspring [18]. Predominantly, the harem groups are not territorial and animals move within overlapping home ranges, although this has not always been the case [18].

Management

PZP Contraception. In January 2000, the National Park Service began the application of PZP for the purposes of immunocontraception. The National Park Service administers PZP in the spring (late February through April) each year. Mares receive their initial treatment at 1.5–2 years of age. Each injection includes 100 micrograms of PZP with an adjuvant (combined at the darting site). Initial doses include Freund's Complete Adjuvant, Modified, Mycobacterium butyricum (Calbiochem #344289). All succeeding doses include Freund's Incomplete Adjuvant (Sigma #F5506). In a given year, an average of 63% of all reproductive mares are inoculated with the vaccine (range = 37–88%). The authors of the present study are not and have never been in charge of making management decisions regarding this herd.

Gathers and Removals. The National Park Service began their management of the Shackleford Banks population prior to the use of PZP, performing five gathers between November 1996 and January 2000. During these gathers the majority of the population was rounded up and individuals testing positive for equine infectious anemia were removed and either euthanized or quarantined. As such forms of management could conceivably influence reproductive cycling, we analyzed foaling dates before and after gathers (but before contraception management) using a linear mixed effects model (see Statistical Analyses).

From January 2000 – January 2008, 38 foals (conceived due to contraception failure or administration scheduling) were removed from the island for the purpose of population control. The majority of removals (92%) were conducted in the January following the foals' birth.

Foaling Data

We recorded foaling data before contraception management (1995–1997) during a study of mother-infant behavior [31]. We obtained foaling data for 2000 and post-contraception years (2001–2008) from the National Park Service at Cape Lookout National Seashore, North Carolina. Although PZP was first administered in 2000, foals born in this year were conceived before contraception management. As such, we considered 2000 a pre-contraception year.

We identified individual horses by color, sex, age, physical condition, and other distinguishing markings including freeze brands. We monitored pregnant mares 2–3 times per week to ensure accurate estimation of foaling date. Births are not commonly witnessed, as mares will generally give birth away from their harem group [31]. This does not significantly affect the determination of birth dates because typically, mares return to their groups within hours (depending on the length of the foaling process and the mares' and foals' condition afterward). In the event that we did not locate mares for more than one week, the birth dates of new foals were estimated by comparing the condition of the foals' coat, mane and tail hair, and locomotor ability to that of foals for which the exact age was known. Using these methods, we were able to estimate birthdays within a range of 1–2 days to 1 week. Focal animals in this study were observed from a minimum of 15 m away at all times. The observers did not obstruct or manipulate the animals' natural behavior in any way. As such, approval for this study by a review board or ethics committee was unnecessary.

We designated births as coming from current recipient, prior recipient, or non-recipient mares. Current recipients received PZP

treatment the year they conceived (the year previous to foaling). Prior recipients received PZP treatment at some point earlier in their lifetime, but not the year of conception. Non-recipients had never received PZP at the time of conception.

Physical Condition

Physical condition is an important factor to consider when monitoring reproductive behaviors. Animals in better condition will have more resources to allocate to mating behavior and physiology than will animals in poorer condition. We assessed mare condition via rump scoring. We determined rump scores examining the curvature of the line between the tailbone and the point of the hip. Scores were based on a scale from 1 to 5; a score of 1 being the poorest [32].

Weather Data

We collected all climatology data from the Morehead City WNW Station at 34° 44′N; 76° 44′W, approximately 8 km from the study site. We obtained all data from the National Climate Data Center (2009) [33].

Statistical Analyses

We analyzed data in R version 2.11.1 (R Core Group, Vienna Austria) and JMP, version 7 (SAS, Cary NC, USA). We used Fligner-Killeen tests to determine if variation in foaling dates differed before and after contraception management and between PZP recipients and non-recipients. This test is more conservative than Fisher's or Bartlett's tests and is less sensitive to outliers and non-normal data [34]. Results from these tests show Bonferroni corrected *P*-values.

We used linear mixed effects models to analyze monthly weather patterns. These statistical models included year as a random effect and the following fixed effects: linear through fourth order polynomial functions of month (to account for nonlinear fluctuations in temperature and rainfall), management regime (before or after contraception management), and two-way interactions with management regime. We selected best fit models using Akaike's Information Criterion adjusted for small sample size (AICc). Because temperature data were temporally auto-correlated, we included an autoregressive moving average correlation structure [35]. For each year of the study, we calculated the mean of the monthly residual values from both the rainfall and temperature models from July through November. We included these terms in the mixed effects models described below to determine if weather affected foaling date.

To test for differences in foaling date with PZP treatment, while controlling for pseudo-replication and unequal variances, we used a linear mixed effects model. The model included mare ID as a random effect and a function allowing different variances across groups (pre-contraception management, post-contraception management non-recipient, post-contraception management current recipient, and post-contraception management prior recipient) [35]. We included mare age as a covariate, as this has been suggested to influence female reproductive behaviors and physiology [36,37]. Additionally, a one-way ANOVA revealed no differences in mare age among treatment groups ($F_{2,84} = 2.03$, $P = 0.14$), suggesting that age did not confound differences among groups. From the above mixed effects model, differences in foaling dates among current, prior, and non-recipients were calculated using an F-test for linear combinations [35].

As gathers could have affected foaling date, we used a linear mixed effects model to test for differences between foaling dates before and after gathers (but before contraception management). After controlling for weather and mare age, mean foaling date did not differ before and after gathers ($P = 0.63$). Additionally, the range of birth dates did not differ significantly between these groups (SD before gathers = 1.04, SD after gathers = 0.77, $P = 0.36$). Finally, AICc from our analysis of foaling dates (see Results) suggested that combining data before and after gathers yielded a more parsimonious model than did separating those categories (AICc separating pre- and post-gathers = 551.02, AICc combining pre- and post-gathers = 550.60). Consequently these groups were combined as pre-contraception management animals for all analyses.

To determine whether the number of PZP applications (total or consecutive) or the number of years between pregnancies (total or consecutive) influenced foaling date, we ran separate linear mixed effects models using these as predictor variables. Each model used only data from PZP recipients and included mare ID as a random effect. To determine if results from this analysis could be influenced by year, we ran a linear mixed effects model on post-management, non-recipients predicting foaling date by year.

We analyzed PZP efficacy using a generalized linear mixed effects model with a binomial error distribution and mare ID as a random effect [38]. This analyzed the probability of conceiving using age at first PZP application and the number of consecutive PZP applications as fixed effects. All mixed effects models initially included two-way interactions, which were removed if their *P*-values were >0.10.

Results

Foaling

After contraception management, foaling occurred over a broader range of months than before contraception management (see Fig. 1, SD pre-contraception = 0.91 months, SD post-contraception = 2.04 months; Fligner-Killeen Test for Homogeneity of Variances: Median Chi Square = 28.10, $P<0.0001$; pre-contraception: n = 65 births from 45 mares over 4 years; post-contraception: n = 97 births from 46 mares, over 8 years). In the eight years following contraception management, mares receiving PZP foaled over a broader range of months than did non-recipient mares (see Fig. 1, SD recipients = 2.40 months, SD non-recipients = 1.54 months; Fligner-Killeen Test for Homogeneity of Variances: Median Chi Square = 11.76, $P = 0.001$; recipients: n = 45 births from 27 mares; non-recipients: n = 52 births from 19 mares).

On average, current PZP recipients gave birth 3.36 months later than did pre-contraception mares, according to our linear mixed effects model, which controlled for heterogeneity of variances, weather influences, and mare age (estimate = 3.36, SE = 0.51, t = 6.64, $P<0.001$; overall model: Likelihood ratio (compared to null model): 40.79, generalized $r^2 = 0.48$, $P<0.001$). Mares that had received PZP earlier in their lifetime, but not during the year of conception (prior recipients), gave birth 0.90 months later than pre-contraception mares on average (estimate = 0.90, SE = 0.40, t = 2.27, $P = 0.03$). Non-recipient mares that never received PZP themselves, but gave birth after the general population was managed with PZP, gave birth 1.01 months later than pre-contraception mares on average (estimate = 1.01, SE = 0.25, t = 4.04, $P = 0.001$). This translates into current PZP recipients giving birth 2.34 months later than non-recipient animals and 2.46 months later than prior recipients (F-tests for linear combinations: $F>16$, $P<0.001$ for each comparison). Furthermore, birth dates were about 0.38 months later for each degree centigrade above average in the latter half of the breeding season and 0.05 months later for each centimeter of rain above average (temperature residuals July-Nov: estimate = 0.38, SE = 0.13, t = 2.84, $P = 0.001$; rainfall residuals July-Nov: esti-

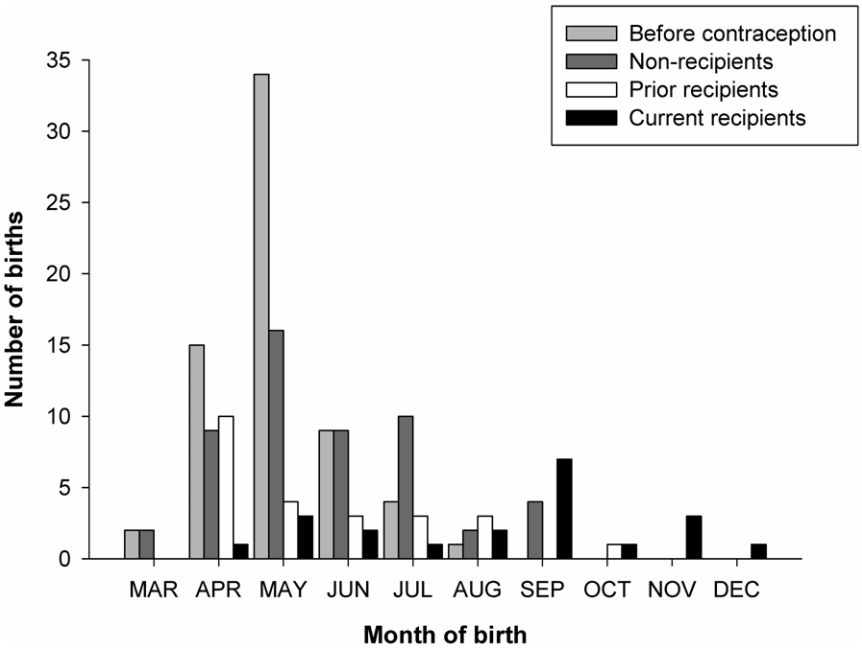

Figure 1. The distribution of births for mares on Shackleford Banks, NC, pre-contraception and post-contraception management. Mares gave birth over a wider range of months after the onset of contraception; this effect was more pronounced in PZP recipients than non-recipients.
doi:10.1371/journal.pone.0013635.g001

mate = 0.05, SE = 0.03, t = 1.83, $P = 0.07$). In general, mares gave birth 0.05 months earlier for every year of age (estimate = −0.05, SE = 0.02, t = −2.03, $P = 0.05$).

Among mares treated with PZP, those receiving a higher total number of applications foaled later in the season than did those receiving fewer applications, with each additional application associated with a 0.5 month delay in foaling date (Linear Mixed Effects Model: estimate = 0.55, SE = 0.21, t = 2.61, $r^2 = 0.65$, $P = 0.01$, see Fig. 2A). In addition, each consecutive PZP application was associated with a 0.8 month delay in foaling date, on average (Linear Mixed Effects Model: estimate = 0.83, SE = 0.23, t = 3.64, $r^2 = 0.65$, $P<0.0008$, see Fig. 2B). While the consecutive and total number of PZP applications were highly correlated, comparing the AICc between the prior two models suggested that the number of consecutive PZP treatments more accurately predicted month of birth than did the total number of PZP treatments (AICc total = 202.96, AICc consecutive = 196.83). The number of years that mares did not conceive (total or consecutive), however, did not correlate with foaling date (Linear Mixed Effects Model: total years: estimate = 0.31, SE = 0.26, t = 1.19, $r^2 = 0.57$, $P = 0.24$; consecutive years: estimate = 0.26, SE = 0.28, t = 0.92, $r^2 = 0.44$, $P = 0.36$). It is unlikely that these patterns resulted from a general trend across years, as birth dates among non-recipient animals did not change with calendar year (Linear Mixed Effects Model: $r^2 = 0.17$, estimate = 0.05, SE = 0.09, t = 0.57, $P = 0.57$).

Mare Condition

A generalized linear model, which controlled for mare age, showed that among post-contraception animals, recipient mares (both current and prior) were in better physical condition, with rump scores approximately 0.4 points higher than those of non-recipients (overall model (compared to null model): Chi Square = 7.74, $P = 0.05$; PZP treatment: estimate = 0.38, SE = 0.15, Chi Square = 6.13, $P = 0.01$; age: estimate = −0.005, SE = 0.06, Chi Square = 0.007, $P = 0.93$; PZP treatment × age: estimate = −0.02, SE = 0.06, Chi Square = 0.13, $P = 0.72$).

Weather

The best fit model of monthly mean temperature showed that overall temperatures were approximately 0.6°Cwarmer after the onset of contraception management (see Fig. 3A; overall model: Likelihood ratio (compared to null model) = 358.40, $P<0.0001$, generalized $r^2 = 0.88$; month: estimate = −8.49, SE = −.97, t = −8.78, $P<0.0001$; $month^2$: estimate = 3.88, SE = 0.29, t = 13.43, $P<0.0001$; $month^3$: estimate = −0.45, SE = 0.03, t = −13.70, $P<0.0001$; $month^4$: estimate = 0.015, SE = 0.001, t = 12.20, $P<0.0001$; contraception management (before): estimate = 0.58, SE = 0.27, t = −2.13, $P = 0.06$). The best fit model of monthly precipitation showed no overall differences between the periods before and after contraception management, but there were significant interactions between month of the year and the periods before and after contraception (see Fig. 3B; overall model: Likelihood ratio (compared to null model) = 38.43, $P<0.0001$, generalized $r^2 = 0.20$, $P<0.0001$; month: estimate = −11.19, SE = 4.96, t = −2.25, $P = 0.03$; $month^2$: estimate = 3.66, SE = 1.46, t = 2.51, $P = 0.01$; $month^3$: estimate = −0.38, SE = 0.17, t = −2.27, $P = 0.02$; $month^4$: estimate = −0.01, SE = 0.006, t = 1.88, $P = 0.06$; contraception management (before): estimate = 6.99, SE = 4.22, t = 1.66, $P = 0.12$; month × contraception management (before): estimate = −2.97, SE = 1.43, t = −2.07, $P = 0.04$; $month^2$ × contraception management (before): estimate = 0.22, SE = 0.11, t = −2.03, $P = 0.04$).

PZP Efficacy

We defined PZP efficacy during the year of administration as the number of vaccinated mares that did not became pregnant divided by the total number receiving the vaccine. Across the first four consecutive PZP applications, this efficacy declined from 97% to 87%, returning to 100% after five or more consecutive applications (see Fig. 4). A generalized mixed effects model shows that this pattern

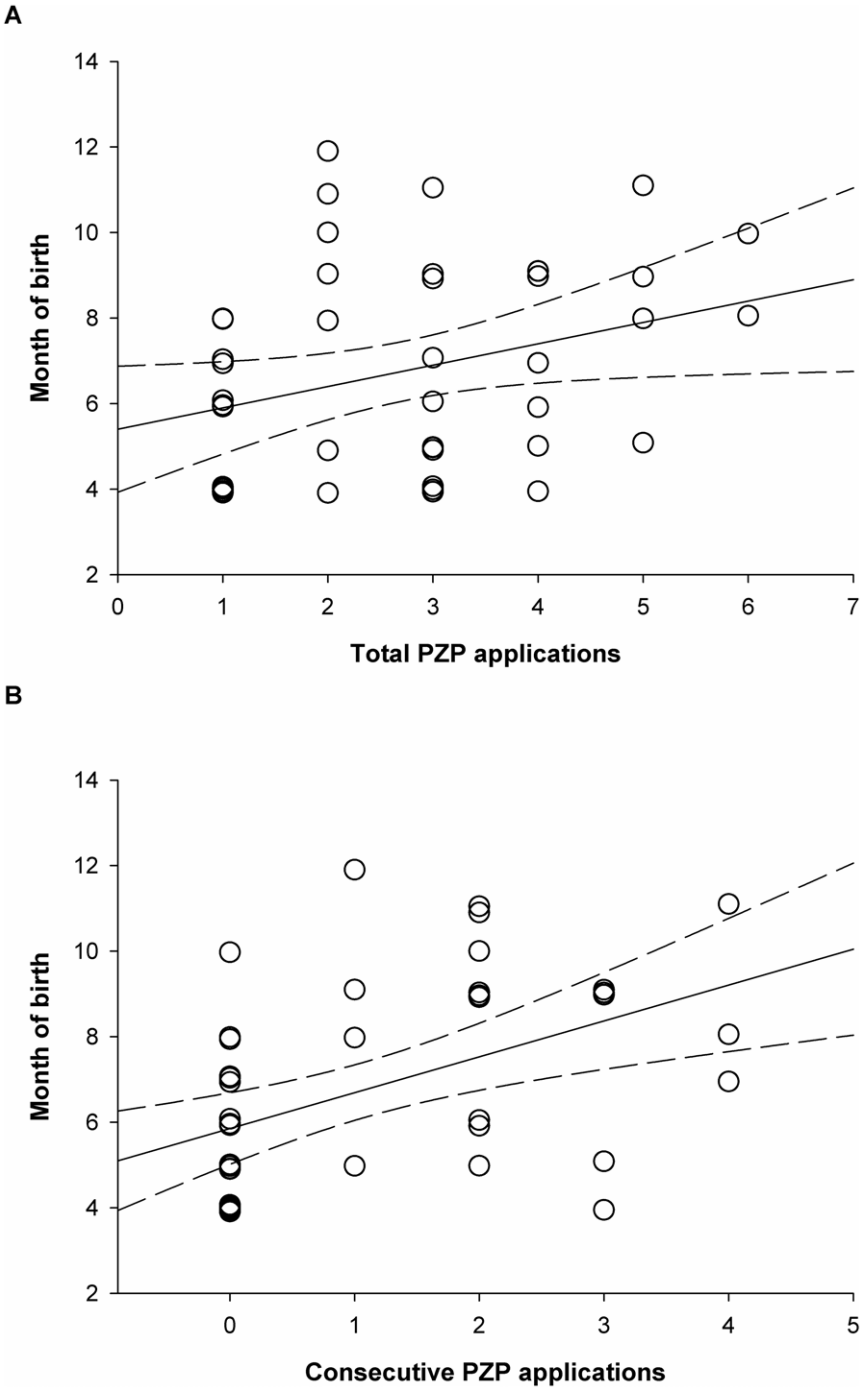

Figure 2. Birth month and number of A) total PZP applications, and B) consecutive PZP applications. In the events of ties, month of birth has been jittered by 0.2 years to allow clear visualization of every individual. Mares receiving more applications of PZP foaled later in the year on average than did mares receiving fewer applications. Although the number of total and consecutive applications is highly correlated, AICc suggests that the number of consecutive applications explains more of the variation in the data.
doi:10.1371/journal.pone.0013635.g002

is significant, even when controlling for mare age (overall model with binomial error distribution: Log Likelihood = −61.79, $P = 0.01$, generalized $r^2 = 0.17$; consecutive PZP applications: estimate = 2.98, SE = 1.20, z = 2.49, $P = 0.01$; $(\text{consecutive PZP applications})^2$: estimate = −0.51, SE = 0.22, z = −2.33, $P = 0.02$; age at first PZP application: estimate = 0.10, SE = 0.05, z = 1.84, $P = 0.07$). Prior research has shown that five to seven years of consecutive PZP treatment can be associated with ovulation failure [4]. The present dataset is consistent with this result, as no mare receiving the vaccine for five or more consecutive years became pregnant.

Discussion

Here we show that PZP recipients exhibited a change in their reproductive schedule: recipient mares gave birth over a broader time period than did non-recipients, with current recipients giving

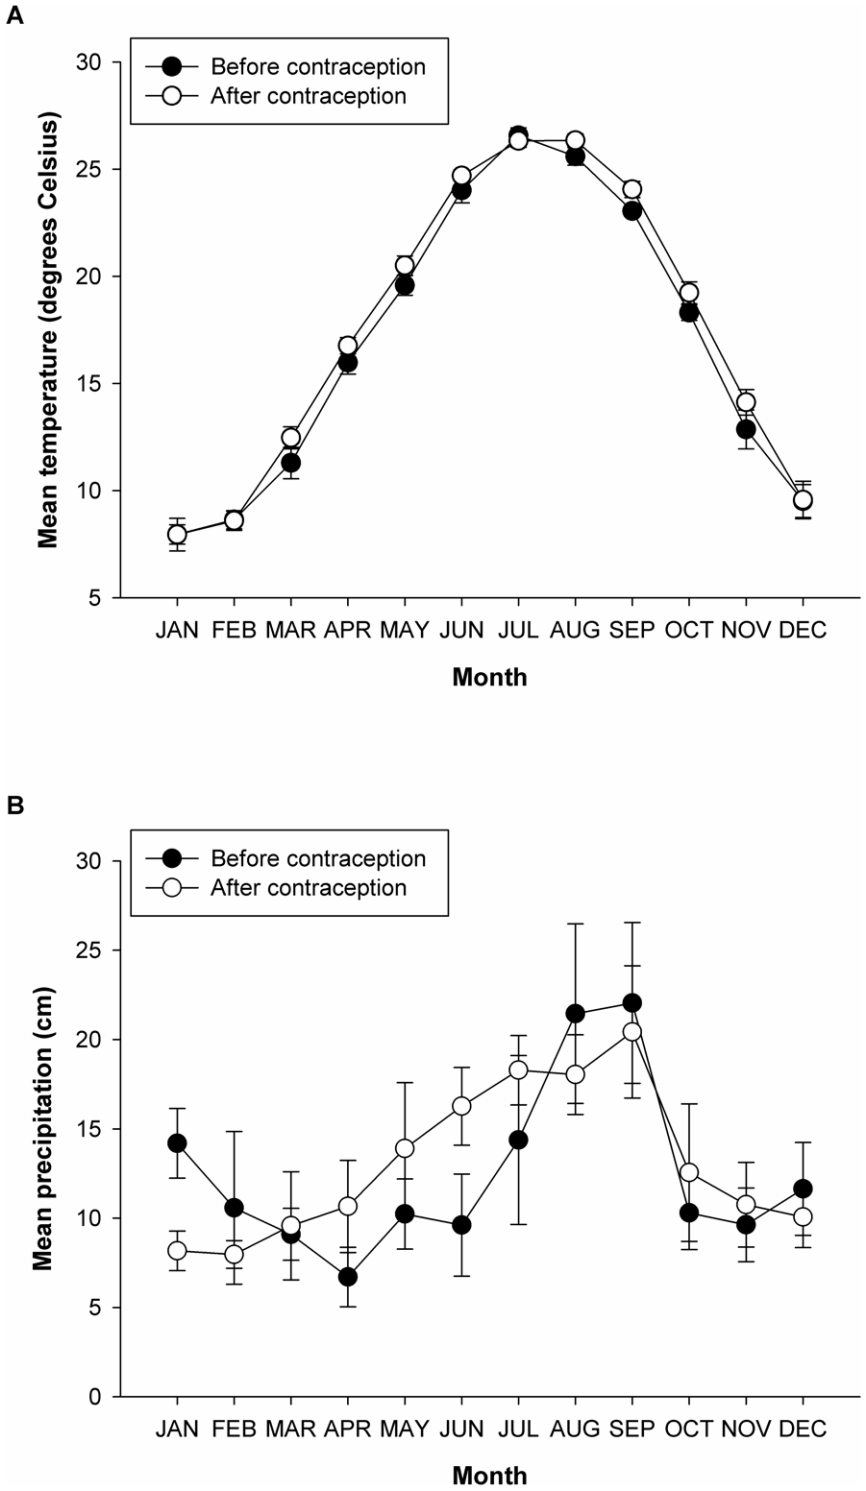

Figure 3. Weather data for six years pre-contraception (1995–2000) and eight years post-contraception (2001–2008) management. Data were collected from Morehead City, North Carolina, approximately 8 km from the study site (Shackleford Banks, North Carolina). Temperatures (A) were marginally warmer post-contraception than they had been pre-contraception. Overall rainfall (B) did not differ before and after contraception, though the seasonal patterns were marginally different pre- and post-contraception.
doi:10.1371/journal.pone.0013635.g003

birth later in the year than prior recipient and non-recipient mares. Given that gestation in wild horses lasts approximately 11 to 12 months [30], this change indicates a corresponding change in the schedule of ovulatory cycling. Contraception with porcine zona pellucida is popular amongst managers specifically because it effectively reduces the odds of conception without the application of exogenous steroids [2]. Long-term studies on Assateague Island have reported that PZP has little to no effect on reproductive

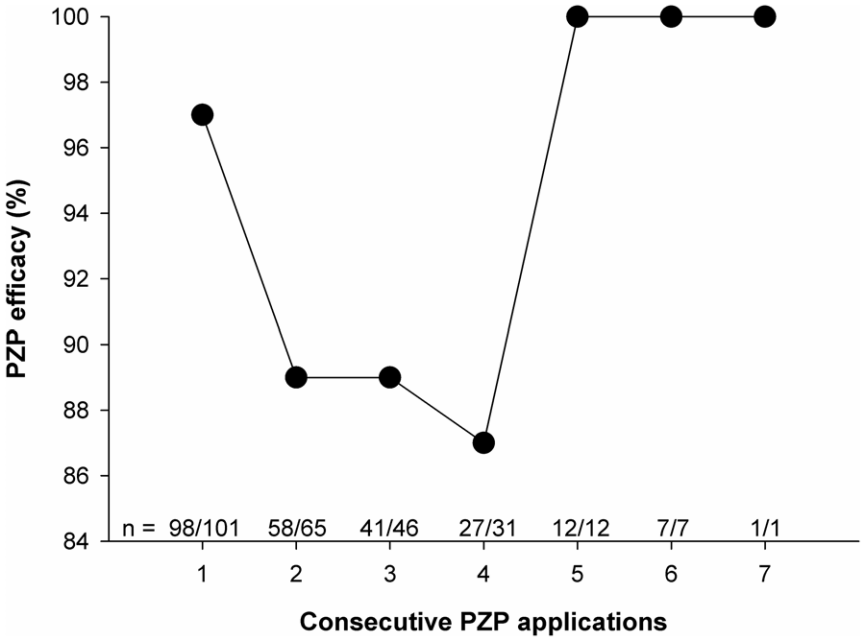

Figure 4. PZP efficacy and number of consecutive PZP applications. PZP efficacy was defined as the number of recipient mares that did not become pregnant divided by the total number of mares receiving the vaccine. Across the first four consecutive applications, PZP efficacy declined, returning to 100% after five or more consecutive applications (5–7 applications have been shown to result in ovulation failure and decreased oestrogen levels [5,40]).
doi:10.1371/journal.pone.0013635.g004

hormone levels, the schedule of reproductive cycling, or the social behaviors of recipient animals [4]. However, studies in other wild horse populations have shown that recipient mares both initiate and receive more instances of reproductive behavior during both the breeding [39] and non-breeding seasons [9]. This study provides the first evidence that mares treated with PZP can extend ovulatory cycling beyond the normal breeding season. This suggests that populations of wild ungulates can vary in their response to similar contraceptive treatment. Careful consideration of baseline population dynamics should be made prior to treatment in order to fully assess possible PZP effects.

Foaling Date

Mares receiving PZP at any point during their lifetime gave birth over a broader time period than did non-recipient animals. This larger variance among PZP mares is likely driven by the fact that current recipients gave birth later than did prior recipients (see Results, Fig. 1). Moreover, mares receiving more consecutive applications foaled later in the season than did mares receiving fewer applications. Increases in the average interbirth interval for recipient mares did not seem to be driving this result, as foaling date was not affected by the number of years (cumulative or consecutive) that mares failed to conceive. This discrepancy may be due to high variability in the conception and foaling dates of treated mares. First, it is less likely that an animal vaccinated with PZP will conceive at all, thus reducing sample size. Second, due to contraceptive failure, some treated mares will conceive during the normal breeding season, further increasing variability. Interestingly, prior to the application of PZP, the average month of birth did tend to increase with interbirth interval (Linear Mixed Effects Model: estimate = 0.30, SE = 0.17, t = 1.82, $r^2 = 0.06$, $P = 0.07$) [22], demonstrating at least some plasticity in the scheduling of reproductive cycling in Shackleford mares. On Assateague, PZP recipients experience normal reproductive cycling and mate at rates similar to non-recipients [40]. However, when such behavior fails to result in conception over several years, it follows that individuals extending reproductive cycling will be able to achieve conception later in the year if the contraceptive effects of PZP have decreased sufficiently [28,29].

Because feral horses are highly social, such changes can have cascading effects on other group members and throughout the population. Our research has shown that after contraception management, PZP recipients both attract and initiate more instances of reproductive behavior [9] and are more often the harem male's nearest neighbor during the fall/winter (Nuñez, unpublished data), indicating that group spreads are reduced. Such changes represent an increase in energy expenditure and a potential decrease in nutrient intake during a time of year when sufficient energy reserves are at a premium [27]. Moreover, early foal development in unmanaged populations typically occurs during the spring and summer when resources are plentiful [11,27]. Offspring born in the fall/winter months face nutritional and thermoregulatory challenges not experienced by their counterparts born during the normal foaling season, potentially making developmental benchmarks difficult to achieve [27].

Such predictions are not consistent with data from Assateague Island where mares show increased survival, only minimal physiological side effects, and no behavioral or demographic changes [4,5,6]. In addition, foal survival does not differ between foals born in or out of the normal foaling season [41]. However, on Shackleford Banks, recipient mares change groups more often, elicit and receive more instances of reproductive behavior, and receive more harassment from harem males [9,42]. Given these differences in mare response to PZP management in the two populations, it follows that predictions based on the data from one site are not necessarily applicable to the other.

These population differences may be due to the scheduling of PZP administration at the two sites. When the contraception

program on Assateague began in 1994, the priorities for treatment followed a hierarchical approach based on the previous breeding success of the population, ensuring that all mares were given an opportunity to reproduce [3]. Females for which there was a high priority for treatment included those that had produced at least one surviving offspring. Low priority females included those that were less than four years of age. Females greater than four years old that had not produced surviving offspring did not receive treatment. In addition, the plan stipulated that only mares that had produced at least three surviving offspring or two generations of offspring would receive more than three consecutive years of treatment. Foals were not to be removed as removal increases a mare's reproductive success in the subsequent year [43,44,45]. Finally, it was recognized that this plan was subject to change as the population numbers decreased [46]. In the present study, Shackleford mares were contracepted between 1.5 and 2 years of age and received an average of 3.4 ± 0.2 (mean $\pm$ standard error) consecutive years of contraception, regardless of their productivity. To further control population numbers, foals born to these mares (due to contraception failure or changes in the application schedule), were likely to be removed. This difference in PZP administration and subsequent discrepancy in early life experience may contribute to the behavioral differences between the populations, as the ability to conceive with a harem male is likely critical to establishing lasting harem fidelity [16] and the retention of foals (until at least two years of age) is important to maintaining normal reproductive function [43,44,45].

Possible Mechanisms

Although the effect was more pronounced in recipients of PZP, both recipients and non-recipients showed a wider range of foaling dates after contraception management (after 2001). While relatively rare, such extended periods of estrous have been documented in several equine species. Tropical species, for example, have been observed to reproduce throughout the year [12,13,47]. Similarly, studies of temperate species have shown that individuals can vary significantly in reproductive timing [14] and estrous behaviors during the non-breeding season [15]. Our data show that Shackleford mares exhibit at least some plasticity in their reproductive cycling. This plasticity enables mares to time their reproductive cycling according to ecological, sociological, and physiological cues.

For example, our results show that the reproductive changes exhibited by Shackleford mares correlate with warmer temperatures occurring later in the calendar year, after contraception management. Increases in rainfall late in the breeding season also correlate (albeit weakly) with later births. Both warmer temperatures and increased rainfall could result in higher resource availability [27] and afford females the additional reserves necessary to extend reproductive cycling into what is typically the non-breeding season.

The physical condition of mares may also play an important role in the extension of reproductive cycling. On Shackleford Banks, recipient mares are currently in better physical condition than are non-recipients. This is likely due to the fact that successfully contracepted mares are unconstrained by the costs of pregnancy and lactation [48]. Recipient mares will therefore have more resources to allocate to additional reproductive cycles. This effect of PZP, coupled with warmer temperatures occurring later in the year, may act to increase a mare's chances of conceiving later in the calendar year, if PZP antibody titers are sufficiently low [29].

Additionally, extended cycling in non-recipient mares could be influenced by the physiology and behavior of recipients. Shackleford males exhibit higher rates of sexual behavior towards recipient females during both breeding and non-breeding seasons [9,42]. These overt social stimuli may entrain some non-recipients to continue reproductive behaviors and cycling into the early fall. Such stimuli are commonly used to induce receptivity in several domestic species including horses [49], pigs [50], and cows [51]. In the wild, courtship signals from conspecifics advance gonadal cycles or maturation in several taxa, including mammals [52,53,54], birds [55], amphibians [56], and reptiles [57]. Given the importance of social cues in the timing of reproduction among such diverse species, this possibility warrants further investigation in Shackleford mares.

Finally, the declining efficacy of PZP with increased consecutive applications is likely a contributing factor to the later foaling dates of recipient mares. Lyda and colleagues' research with captive, wild mares has shown that antibody titers against PZP remain high for up to ten months after initial treatment [28]. In addition, research with both Shackleford and Assateague horses has shown that initial applications of PZP are often effective over multiple years [9,58], suggesting that antibody titers can remain high for longer. However, laboratory research has shown considerable variability in anti-PZP titers [29], as did Lyda and colleagues' work in which half the mares treated with PZP and Freund's Complete Adjuvant fell below contraceptive levels within the ten months of study [28]. Our data show that increasing the number of consecutive applications can reduce the single year efficacy of PZP by roughly 10%, indicating that either antibody titer or reactivity can decrease more rapidly with consecutive applications. Such patterns could result from the induction of immunological tolerance [59], which reduces responsiveness to self-tissues or repeatedly encountered, non-pathogenic antigens [60]. PZP is designed to mimic host tissue and induce an immune response against self tissue: the recipient's own zona pellucida [2]. As such, it seems reasonable that at least some animals would mount tolerance mechanisms to combat this autoimmunity. In addition, the repeated application of a specific antigen generates an antibody response that is increasingly more specific to that particular antigen [29]. The antibodies produced by mares against porcine zona pellucida should, therefore, become less cross reactive with horse zona pellucida over time. Of course, PZP efficacy will vary depending on mare age and timing of inoculation [61]. Regardless, if PZP recipients extend reproductive cycling and behavior into the non-breeding season, any decrease in efficacy that leaves them fertile in the fall/winter will help drive increases in late season conception.

Although the removal of offspring can induce estrous cycling in ungulate species [62], it is unlikely that the removal of foals has influenced foaling date among PZP-treated mares on Shackleford Banks. Thirty-nine foals (conceived due to contraception failure or administration scheduling) have been removed from the island. Approximately 55% of these foals were born to non-recipient animals. The majority of foal removals were conducted in the January following foal births. Given that non-recipient animals did not give birth later than September and most recipient animals gave birth before December, it is unlikely that foal removals in January induced late-season estrus in Shackleford mares. It is equally unlikely that increases in mare condition due to the alleviation of lactation costs resulted in early resumption of estrus the following spring [27]. If that were the case, during the early spring months we would expect to see an increase in the number of foals born to mares subjected to offspring removal. This is not borne out by the data. Still, the removal of foals is ill-advised as it increases mare fecundity the following year [43,44,45].

Management Implications

When the alternative (gather and removal) is considered, PZP is currently managers' most humane and effective option for population control. However, careful study of the animals' demography, physiology, and behavior is necessary prior to and during treatment to ensure that a) the potential effects of PZP can be assessed accurately, and b) within managerial constraints, unintended effects of PZP are ameliorated. Differences in habitat, resource availability, and demography among conspecific populations will undoubtedly affect their physiological and behavioral responses to PZP contraception, and need to be considered. For instance, while Assateague horses show no behavioral and only minor physiological responses to PZP, horses on Shackleford Banks [9,42] and in the western United States [39] alter social and reproductive behaviors in response to PZP. Our data suggest that mare condition and warming trends may present additional complications. Increases in physical condition and changes in average temperature may interact with management regimes, enabling mares to alter their reproductive physiology even further. Moreover, these data emphasize the importance of study during both the breeding and non-breeding seasons. Much of the research showing little to no effect of PZP on feral horse behavior or physiology has been performed exclusively during the breeding season [4,5,10], potentially missing important differences in recipient response.

If population numbers are managers' primary concern, our data show that giving five or more consecutive applications of PZP will result in 100% contraception efficacy. This is consistent with data from Assateague where mares receiving 5–7 consecutive PZP applications exhibited ovulation failure and decreased urinary oestrogen concentrations [5,40]. However, if managers are tasked with the maintenance of natural behaviors and foaling schedules, consecutive PZP applications should be avoided. Research has shown that one application of PZP is often effective over multiple years, exhibiting yearly efficacy declines similar to that of 2–4 consecutive treatments (on Shackleford) [9,58]. Our data show that current recipients gave birth later than both prior recipient and non-recipient animals. However, prior recipients of PZP gave birth on schedules similar to non-recipients, suggesting that breaks between treatments can ameliorate unintended behavioral and physiological changes in recipient animals. Contraception on such schedules will still maintain lower pregnancy rates, but will allow for the birth of a manageable number of offspring which are also important to the maintenance of normal behaviors [9]. These foals should be allowed to remain in the population for at least two years as earlier removal has been shown to increase a mare's reproductive success in the subsequent year [43,44,45]. Additionally, subadult, dispersing females should be allowed to settle into harems and have at least one foal before receiving contraception [16]. Management regimes such as this would of course necessitate a higher minimum population level. Additional research is needed to determine whether these larger, but still limited population sizes could achieve management goals. If so, this could prove a cost-effective means of controlling animal numbers while maintaining their natural physiology and behavior.

The broader implications of this research are considerable. As this study suggests, the physiological and behavioral effects of PZP are not fully understood. Still, the vaccine is currently administered to many different species including white-tailed deer, *Odocoileus virginianus* [7], elk, *Cervus elaphus* [8], black bears *Ursus americanus* [63], and African elephants, *Loxodonta Africana* [64]. As with conspecific equid populations, habitat, resource, and demographic differences among species will affect their responses to PZP contraception and need to be considered. For social species like the horse, a proper balance between managing population size and maintaining a more natural physiological and behavioral regime is particularly important.

Acknowledgments

We would like to thank Dr. S. Stuska of the Cape Lookout National Seashore, National Park Service, C. Mason of the Foundation for Shackleford Horses, and M.A. Kearns for their additional data, Dr. A. Graham for her insight, and two anonymous reviewers for their comments on the manuscript.

ABSTRACT

Feral horses (*Equus caballus*) have a complex social structure, the stability of which is important to their overall health. Behavioral and demographic research has shown that decreases in group (or band) stability reduce female fitness, but the potential effects on the physiological stress response have not been demonstrated. To fully understand how band stability affects group-member fitness, we need to understand not only behavioral and demographic, but also physiological consequences of decreases to that stability. We studied group changes in feral mares (an activity that induces instability, including both male and female aggression) on Shackleford Banks, NC. We found that mares in the midst of changing groups exhibit increased fecal cortisol levels. In addition, mares making more group transfers show higher levels of cortisol two weeks post-behavior. These results offer insights into how social instability is integrated into an animal's physiological phenotype. In addition, our results have important implications for feral horse management. On Shackleford Banks, mares contracepted with porcine zona pellucida (PZP) make approximately 10 times as many group changes as do untreated mares. Such animals may therefore be at higher risk of chronic stress. These results support the growing consensus that links between behavior and physiological stress must be taken into account when managing for healthy, functional populations.

1. Introduction

Social mammals typically organize themselves into coherent groups that feed, rest, and travel together (Alexander, 1974). Social living affords several benefits, but can also accrue costs, including increased competition for resources (Sterck et al., 1997), exposure to parasites and disease (Côté and Poulin, 1995), and stress (Sapolsky, 1983). Social interactions, dominance rank, and variations in population density due to territorial intrusion, predation risk, and food availability are all associated with increases in glucocorticoid levels in several vertebrate species (Creel et al., 2013).

The mammalian stress response occurs when adverse situations trigger the adrenal glands, resulting in increased secretion of glucocorticoids and/or catecholamines (Mostl and Palme, 2002). Short-lived stressful situations are commonplace for a wide range of species (Sapolsky, 2005), and the stress response is adaptive in that it helps organisms escape these dangerous or otherwise taxing situations (Mostl and Palme, 2002; Sapolsky, 2005). For example, increases in glucocorticoids in response to adverse conditions can facilitate facultative migration (Ramenofsky et al., 2012), stimulate immune responses (Martin, 2009), and regulate food intake (Wingfield et al., 1998). When experienced chronically, however, the stress response can become pathogenic (Sapolsky, 2005). Animals that are more persistently stressed exhibit higher basal glucocorticoid concentrations (but see Dickens et al. (2009)), enlarged adrenal glands, and impaired sensitivity of the adrenal system to regulation by negative feedbacks (Sapolsky, 2005). Continued stress can also adversely affect cardiovascular function, inhibit reproduction, compromise immune function, and result in a number of adverse neurobiological effects including decreased neurogenesis, dendritic atrophy, and diminishing synaptic plasticity in the hippocampus (Sapolsky, 2005).

Feral horses (*Equus caballus*) have a complex social structure: social groups, or bands, typically consist of one (though sometimes more than one) male(s), one to several female(s), and their offspring. Excepting dispersal of both male and female offspring, stable bands will remain together for several years (Klingel, 1975). Mares will often remain in the same band for most of their adult lives and will form close associations with one another (Cameron et al., 2009). Reductions in band stability have been correlated with decreases in mare fitness, including increases in parasite load, and

declines in body condition, fecundity, foal survival, and time spent engaged in preferred behaviors (Klingel, 1975; Linklater et al., 1999; Rubenstein, 1986). Such decreases in stability, whether due to increased male and/or female harassment (including increases in aggressive and/or reproductive behaviors) or the addition/subtraction of various group members, could induce a physiological stress response in mares, especially if stability is not restored. However, the potential effects of such behavior on mare stress physiology have not been documented. Such studies are important as they give managers and researchers a method to more quantitatively measure the physiological effects of behavioral stressors on individual health (Wikelski and Cooke, 2006). In addition, a greater understanding of the physiological responses to social instability may shed light on how the social milieu affects overall female fitness.

Here we seek to elucidate the links between social behavior and physiology in a highly social ungulate, the feral horse. Specifically, we investigate the effects of band transfers on mare stress physiology via fecal cortisol concentrations, a demonstrated indicator of individual stress level (Mostl and Palme, 2002; Wasser et al., 2000). In addition, we investigate the more general effect that increased frequency of band transfer has on mare stress physiology.

2. Materials and methods

2.1. Study area

We conducted this study on Shackleford Banks, a barrier island located approximately 3 km off the coast of North Carolina, USA. The island is 15 km in length, and varies between 0.5 and 3 km in width. The specific study area extended approximately 7.7 km from the center to the eastern end of the island.

The horse population on Shackleford Banks has been co-managed by the National Park Service and the Foundation for Shackleford Horses since 1996. The Shackleford Banks Wild Horses Protection Act stipulated that the Shackleford population consist of no less than 100 and no more than 110 horses (United States Congress, 1997), similar to the population occurring in 1981 (104 horses) (Rubenstein, 1981; Rubenstein and Dobson, 2000). At the time of this study, the population consisted of 124 and 118 horses during the breeding and non-breeding seasons, respectively. The National Park Service and the Foundation for Shackelford Horses maintain the population at this level through contraceptive management with porcine zona pellucida (PZP).

2.2. Study subjects

The social groups of Shackleford horses are typical of feral equids. They consist of coherent bands of one or sometimes two or three stallion(s) with one to several mare(s) and their offspring. Although the bands are predominantly non-territorial and the animals move freely within overlapping home ranges (Rubenstein, 1981), individual bands are spatially distinct from one another and individuals of particular bands rarely interact (Feist and McCullough, 1976; Rubenstein, 1981, 1986). When interactions do occur, they typically involve younger individuals engaging in play and/or exploration, the dispersal of sub-adult individuals (both male and female), and the transfer of adult females from one band to another (personal observation).

Historically, the bands on Shackleford Banks were long-lasting with most changes involving the dispersal of immature individuals (Nuñez, 2000; Rubenstein, 1981). Males sometimes fought to acquire mares from other groups, but stallions almost always retained their mares (Nuñez, 2000; Rubenstein, 1981). During a five-year study (Rubenstein, 1981), only 10.8% of the mares studied transferred groups, as is typical in other feral horse populations (Berger, 1977; Feist and McCullough, 1976). More recently, mares treated with PZP contraception have been shown to change groups more often, making approximately 10 times more group changes than untreated mares and visiting up to 5 times as many groups (Madosky et al., 2010; Nuñez et al., 2009). During a 2.5-month study in 2008, 44% of the mares studied (in a population of 121 horses) transferred groups. Group changes typically involve aggressive herds, chases, and increased reproductive activity by both the band and new stallions, and/or aggression from the new females (personal observation). Population densities at the time of the study were equivalent to those of the 1981 population (see Section 2.1), indicating that these increases in group changing behavior are not due to significant increases in encounter rates between/among bands. All of the mares in this study received PZP at some point during their lifetime (Stuska, 2000–2010) also, see Table 1.

2.3. Animal welfare

All sampling was conducted in accordance with National Research Council standards (National Research Council, 2011). Given the non-invasive nature of this study, neither the Princeton University Institutional Animal Care and Use Committee nor the National Park Service deemed permitting necessary.

2.4. Behavioral and demographic sampling

This study was conducted by three observers during the breeding season (June–August, 2009, J. Smith, J.J. Schurle, and C.M.V. Nuñez) and two observers during the non-breeding season (December, 2009, C.M.V. Nuñez and J.S. Adelman) totaling over 181 hours of behavioral observation (84.67 h, breeding season; 96.75 h, non-breeding season). Horses were identified individually by color, sex, age, physical condition, and other distinguishing markings, including freeze brands. Ages are known from long-term records for the identified horses of Shackleford Banks (Rubenstein and Nuñez, 2009) and from National Park Service data (S. Stuska, unpublished data).

Table 2
Breakdown of sample sizes for entire study.

	Breeding (Br)	Non-breeding (NBr)	Total
Fecal samples meeting inclusion criteria	90	36	126
No. unique mares with fecal and behavioral samples	8 in Br only 12 in both seasons	4 in NBr only	24
Fecal samples/mare mean ± 1SE (range)	4.50 ± 0.84 (1–13)	2.25 ± 0.42 (1–6)	5.28 ± 0.81 (1–14)
No. unique mares changing groups	10 in Br only 3 in both seasons	3 in NBr only	16
Group changes/mare mean ± 1SE (range)	2.30 ± 0.32 (1–4)	1.50 ± 0.34 (1–3)	2.43 ± 0.29 (1–4)

We located each study group an average of 1.76 and 1.54 times per week in the breeding and non-breeding seasons, respectively. We recorded each group's GPS location and composition, noting the presence or absence of individual mares. We observed a total of 24 mares (see Table 2). Twelve mares were observed in both seasons; the remaining mares were observed in either the breeding ($n = 8$) or non-breeding ($n = 4$) seasons, representing 53% and 40% of the study population, respectively. Of these, 16 made group transfers (breeding season, $n = 13$ mares; non-breeding season, $n = 6$ mares).

Mare transfer activity was rarely witnessed directly (breeding season, $n = 1$; non-breeding season, $n = 1$); therefore, mare absence from a band was an important metric with which to measure the number of transfers between groups. We remained with each group for a minimum of 30 min to ensure that individuals recorded as absent were not actually nearby, but out of our sight. Transfer behavior was confirmed by the mares' presence in new bands, usually within 1–7 days of mare absence (breeding season, $n = 28/30$; non-breeding season, $n = 8/9$). The remaining instances were confirmed within 16 and 8 days in the breeding non-breeding seasons, respectively.

2.5. Non-invasive hormonal sampling

Fecal samples were collected *ad libitum* (Altmann, 1974). We only collected samples when we were certain of the mares' identity and the location on the ground. Fecal samples were collected within minutes of defecation and stored in 20 ml vials at a 2.5:1 ratio of 95% ethanol to feces (Khan et al., 2002). Samples were stored in a cooler (from 1–5 days) until they could be frozen at −20 °C (June–August) or frozen at −20 °C on the day of collection (December).

Three of the aforementioned observers (J. Smith, C.M.V. Nuñez, and J.S. Adelman) collected fecal samples. We collected samples from a total of 24 mares (see Section 2.4 and Table 2). Limitations in staff, travel logistics, and the rates of mare defecation precluded us from sampling all mares in the study area. A total of 126 samples met our timing criteria and were included in our analyses (breeding season, $n = 90$; non-breeding season $n = 36$). Mares contributed a total of 4.50 ± 0.84 (range = 1–13) and 2.25 ± 0.42 (range = 1–6) samples in the breeding and non-breeding seasons, respectively (see Table 2). We collected an average of 1.52 samples (breeding season) and 2.25 samples (non-breeding season) per day.

2.6. Hormone analysis

In the laboratory, ethanol was evaporated from the samples which were then freeze-dried and sifted to remove vegetative matter. 0.2 g fecal powder was extracted into 2 ml 90% methanol and then run through a prepped Oasis cartridge for solid phase extraction (Beehner et al., 2006; Khan et al., 2002). All samples were stored at −20 °C prior to assay.

Fecal glucocorticoids were quantified using modified protocols of the Immuchem Double Antibody Corticosterone RIA Kit for Rats and Mice, MP Biomedicals, LLC, Orangeburg, NY (Beehner et al., 2006; Wasser et al., 2000), in eight separate assays. This specific method has been validated in a closely related, wild equid, the Grevy's zebra (*Equus grevyi*): the anti-corticosterone antibody detects a rise in cortisol metabolites after an individual is presented with an ACTH challenge (Franceschini et al., 2008). Moreover, fecal metabolites have been shown to increase with circulating glucocorticoids in the domestic horse (*Equus caballus*) (Merl et al., 2000; Mostl et al., 1999). We validated the assay as in Khan et al. (2002). A serial dilution of a horse fecal pool showed parallelism to the corticosterone standard curve (Linear Model; estimate = 6.30, $t = 0.70$, $P = 0.50$). Intra- and inter-assay coefficients of variation (%CV = [mean/SD] × 100) were 5.7 ± 0.6% (mean ± SE) and 9.6% for the fecal extract pool, and 7.4 ± 2.9% and 13.9% for the high concentration controls ($n = 8$). All samples were run in duplicate and any duplicate with a CV >15% was rerun. Mean assay accuracy (observed/expected × 100) was 105 ± 2.2.

Recently, concerns have been raised about the use of fecal metabolites in determining the physiological state of free-living species (Goymann, 2012). Individual, sex, seasonal, and dietary variation can significantly affect how hormones are metabolized. Here, we examine changes in fecal cortisol within individual, female, feral horses. The mares lived in similar ecological conditions (see Section 2.1), and we analyzed changes within season, thereby controlling for such potential differences.

2.7. Statistical analysis

2.7.1. Test 1

We analyzed the effects of group transfers on mare cortisol levels with Linear Mixed Effects Models in R, version 2.13.0 (R Development Core Team, 2011). For each female, cortisol level was analyzed with regards to its timing around group transfers, i.e., before, during, and after group transfers. These categories were defined as follows (also see Fig. 1):

- Before–cortisol levels exhibited before any group transfer(s) occurred (weeks 1–2).
- During–cortisol levels exhibited while the group transfer(s) were occurring (weeks 3–4).
- After–cortisol levels exhibited after the final group transfer occurred (weeks 6–10); these samples were collected a minimum of 7 days after the mares' last group transfer.

For this analysis, mares contributed 3.92 ± 0.82 samples (range = 1–10) and 3.83 ± 0.75 samples (range = 3–6) in the breeding and non-breeding seasons, respectively (also see Table 3 and Supplementary material, Fig. S1). The model included mare ID as a random effect and the following fixed effects: season (breeding/non-breeding), the timing of fecal deposition relative to the group transfer (before, during, or after), and the interaction between season and the timing of fecal deposition. We conducted this analysis in two ways.

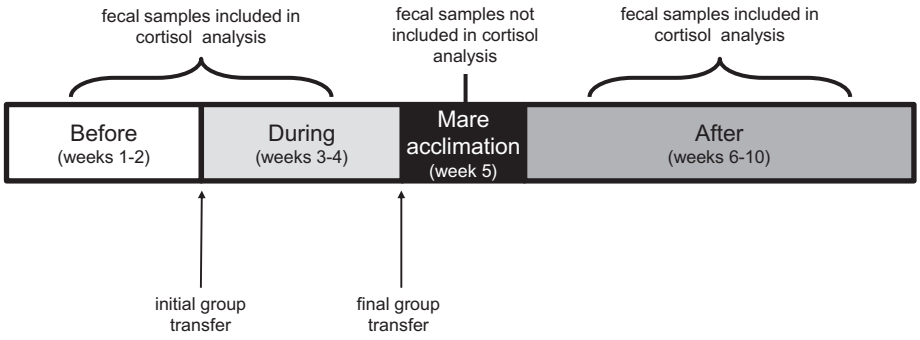

Fig. 1. Timeline for fecal sampling (Test 1).

Table 3
Breakdown of sample sizes for timing relative to group transfer analysis (Test 1, Fig. 4).

	Breeding (Br)	Non-breeding (NBr)	Total
Fecal samples meeting inclusion criteria	51	23	74
No unique mares with fecal and behavioral samples	10 in Br only 3 in both seasons	3 in NBr only	16
Fecal samples/mare mean ± 1SE (range)	3.92 ± 0.82 (1–10)	3.83 ± 0.75 (3–6)	4.63 ± 0.81 (1–11)
No unique mares changing groups	10 in Br only 3 in both seasons	3 in NBr only	16
Group changes/mare mean ± 1SE (range)	2.69 ± 0.26 (1–4)	1.16 ± 0.16 (1–2)	1.81 ± 0.26 (1–4)

- Model 1: included all mares for which appropriate samples were available; not every mare contributed to all time points ($n = 16$ mares; 74 samples; see Supplementary material, Fig. S1).
- Model 2: included only mares for which samples from all time points were available ($n = 6$ mares; 37 samples; see Supplementary material, Fig. S1). Samples from mares for all time points were obtainable during the breeding season only.

2.7.2. Test 2

Cortisol levels were also analyzed with respect to the number of group transfers females made. Samples for this analysis were collected two weeks after the final group transfer. Mares contributed 4.39 ± 0.89 samples (range = 1–13) and 1.36 ± 0.17 samples (range = 1–3) in the breeding and non-breeding seasons, respectively (also see Table 4). The model included mare ID as a random effect and the following fixed effects: season (breeding/non-breeding), the number of group transfers made prior to fecal collection, and the interaction between season and the number of group transfers.

All of the mares in this study received PZP at some point during their lifetime (Stuska, 2000–2010); therefore, tests regarding the possible effects of infertility were not possible.

3. Results

As the breeding season progressed, we detected an increase in mare transfers, with a peak in the middle of the study period, after which group transfers decreased to levels exhibited earlier in the season (see Fig. 2). 65% of the mares studied transferred groups at least one time, with 45% transferring groups 2–4 times (see Fig. 3). During the non-breeding season, we detected more group transfers earlier in the study period (see Fig. 2). 37.5% of the mares studied transferred groups, with 12.5% transferring groups 2–3 times (see Fig. 3). Subsequently, 86% and 60% of the bands observed were affected (i.e. mares left/joined the bands) during the breeding and non-breeding seasons, respectively.

3.1. Timing of group transfers and cortisol levels (Test 1)

Timing of fecal deposition relative to group transfer(s) affected cortisol levels (Linear Mixed Effects Model (LME); overall model: Likelihood ratio (compared to null model) = −290.78, $P = 0.0008$; $F_{2,53} = 3.23$, $P = 0.05$). Season did not have a significant effect on this pattern (Season: $F_{1,53} = 2.75$, $P = 0.10$; Season*Timing of fecal deposition relative to group transfer(s): $F_{2,53} = 1.23$, $P = 0.30$). On

Table 4
Breakdown of sample sizes for number of group changes analysis (Test 2, Fig. 5).

	Breeding (Br)	Non-breeding (NBr)	Total
Fecal samples meeting inclusion criteria	79	19	98
No unique mares with fecal and behavioral samples	7 in Br only 11 in both seasons	3 in NBr only	21
Fecal samples/mare mean ± 1SE (range)	4.39 ± 0.89 (1-13)	1.36 ± 0.17 (1-3)	4.67 ± 0.84 (1-14)
No unique mares changing groups	8 in Br only 2 in both seasons	2 in NBr only	12
Group changes/mare mean ± 1SE (range)	1.90 ± 0.31 (1-4)	1.50 ± 0.50 (1-3)	2.08 ± 0.31 (1-4)

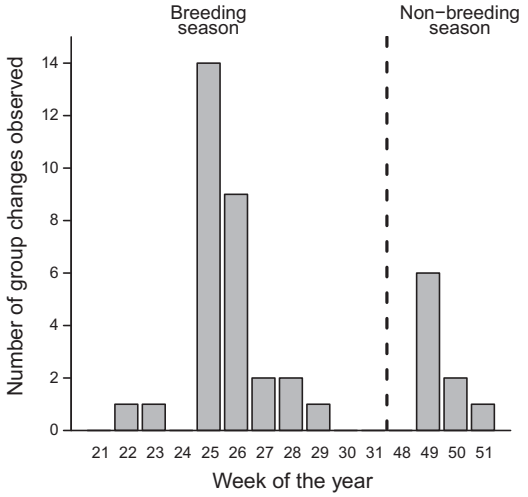

Fig. 2. Distribution of group transfers in the breeding and non-breeding seasons.

average, mares exhibited higher cortisol levels during group transfer(s) than before group transfer(s) (LME: estimate = 7.22, $t = 2.33$, $P = 0.02$; Fig. 4). Cortisol levels exhibited after group transfer(s) did

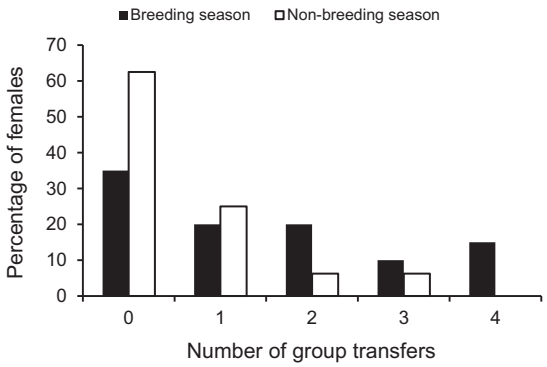

Fig. 3. Percentage of females making 0, 1, 2, 3, and 4 group transfers. During the breeding season (■), more mares transfer groups than do not; the majority of transferring mares make more than 1 transfer. During the non-breeding season (□), there is less transfer activity with fewer mares transferring groups; the majority of mares transferring groups make 1 transfer.

not differ from those exhibited before or during transfer(s) (before: LME: estimate = 1.90, $t = 0.54$, $P = 0.59$; during: F-test for linear combinations, $F_{1,56} = 2.83$, $P = 0.10$; Fig. 4).

Analysis of our second model (including only mares for which we had all samples) yielded equivalent results (Linear Mixed Effects Model (LME); overall model: Likelihood ratio (compared to null model) = −150.90, $P = 0.0003$; $F_{2,29} = 4.14$, $P = 0.05$).

3.2. Number of group transfers and cortisol levels (Test 2)

Mares engaging in this behavior more frequently showed higher cortisol levels two weeks post-transfer(s) (LME; overall model: Likelihood ratio (compared to null model) = −382.24, $P < 0.0004$; $F_{2,72} = 3.51$, $P = 0.03$). Season did not have a significant effect on this pattern (Season: $F_{1,72} = 0.92$, $P = 0.34$; Season*Timing of fecal deposition relative to group transfer(s): $F_{2,72} = 0.67$, $P = 0.51$). Two weeks after their final group transfer, mares making 2+ transfers exhibited higher cortisol levels than mares making 0 transfers (LME: estimate = 9.61, $t = 2.58$, $P = 0.01$; Fig. 5) and marginally higher cortisol levels than mares making only 1 group transfer

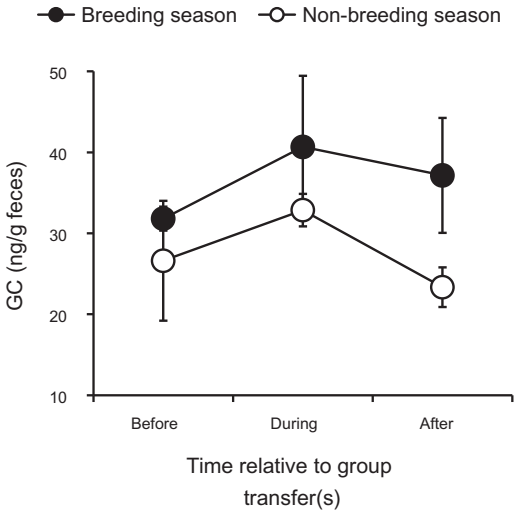

Fig. 4. Mare cortisol level and the timing relative to group transfer(s) in the breeding (●) and non-breeding (○) seasons. Mares showed increases in cortisol during group transfer behavior.

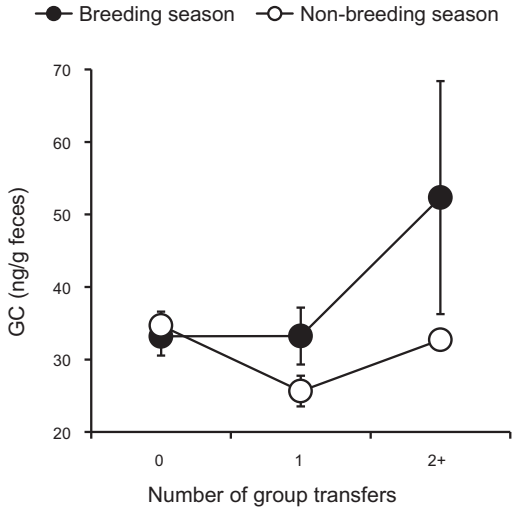

Fig. 5. Mare cortisol level 2 weeks post-group transfer(s) during the breeding (●) and non-breeding (○) seasons. Mares making more group transfers exhibited higher cortisol levels 2 weeks post-behavior than did mares making fewer group transfers.

($F_{1,73} = 3.32$, $P = 0.07$; Fig. 5). Mares making only 1 group transfer exhibited cortisol levels similar to mares making 0 changes (LME: estimate = 0.24, $t = 0.07$, $P = 0.94$; Fig. 5).

4. Discussion

Here we show for the first time that social instability has significant impacts on stress physiology in feral mares. Specifically, we show that mare cortisol levels increase during group transfers (Test 1) and that mares making more band transfers exhibit higher cortisol levels two weeks following transfer behavior (Test 2). Although we did not detect an effect of season on this pattern, the data show trends towards higher cortisol levels during the breeding season (see Figs. 4 and 5). This is not surprising as certain elements of stallion/mare aggression are elevated at this time (Stevens, 1990), but see Romero (2002). Regardless, the patterns of cortisol increase are consistent across season, indicating that the changes in mare cortisol levels are due to their group transfer behavior and not to season alone. Our results show that social

instability and the resultant behaviors, including increased reproductive interest and aggression, are integrated into a mare's physiological phenotype.

Many social changes are associated with group transfers: mares changing groups will often experience behavioral stressors in the form of harassment from both the male(s) (including herds, chases, and increased reproductive interest) and resident females (including kicks, chases, and bites) (Kearns, 2009; Madosky, 2011; Monard and Duncan, 1996; Rutberg, 1990). We cannot precisely determine which of these behaviors drive the patterns recorded in this study. However, the discrete increases in fecal cortisol occurring during group transfers indicate a direct link between the mares' social environment and their physiological response (Test 1). Moreover, the fact that higher cortisol levels are maintained for at least two weeks post-transfer behavior suggests that decreases in social stability have at least some lasting effect on mare physiology (Test 2). We know much about the effects of social environment on mare behavior and fitness (Cameron et al., 2009; Kaseda et al., 1995; Linklater et al., 1999). Our data give insights into how that social environment may be translated into fitness costs for mares via their stress physiology.

The mares in this study exhibited increases in cortisol (7.22 ng/g) comparable to the highest levels exhibited by Grevy's zebra (~10 ng/g) during captivity after capture and relocation (Franceschini et al., 2008). These data indicate that group transfer behavior incurs a significant cost to mares. Although such stress in itself is not inherently detrimental to animal fitness or well-being (Moberg, 2000), the stress response can become pathogenic when experienced chronically (Sapolsky, 2005). On Shackleford Banks, N.C., mares transferring bands more frequently are often subject to a negative feedback loop: their behavior leads to harassment which induces additional group changes, resulting in further harassment and so on (Madosky, 2011), also see Linklater et al. (1999). Results from the present study suggest that such mares are likely experiencing increased stress levels at more regular intervals, and may therefore be at higher risk of chronic stress.

Moreover, mares on Shackleford that are contracepted with porcine zona pellucida (PZP) have been shown to make up to 10 times more group transfers than untreated mares (Madosky, 2011; Nuñez et al., 2009). Direct tests of treated versus untreated mares were not possible in this study (see Section 2.2). However, mares contracepted for the first time in January 2009 and those receiving repeated applications (range = 2–8) over several years (Stuska, 2000–2010) exhibit the same increases in cortisol levels with group transfer behavior (see Supplementary material for analysis and Fig. S2). These results show that PZP treatment itself does not increase cortisol levels in recipient animals. However, changes in the frequency of group transfer behavior by consistently infertile mares (Madosky et al., 2010; Nuñez et al., 2009) may put them at higher risk of chronic stress. PZP contraception has also been conducted on Assateague Island National Seashore (Kirkpatrick, 1995), a site ecologically similar to Shackleford Banks. Currently, no systematic studies of group changing behavior with PZP treatment have been conducted there, thus limiting our ability to compare the behavior of Shackleford and Assateague mares. A study addressing potential changes to treated mares' activity budgets, aggression, and spatial relationships with the stallion on Assateague found no differences (Powell, 1999), indicating little to no effect of PZP treatment on mare behavior. However, it is worth noting that control mares in the Assateague study had been treated with PZP for three consecutive years before testing, and that different behavioral effects have been found in populations other than Shackleford Banks (Ransom et al., 2010, 2013).

Our results may seem to contrast those showing that contracepted mares (on both Assateague Island and Shackleford Banks) live longer and are in better body condition than uncontracepted mares (Kirkpatrick and Turner, 2007; Nuñez et al., 2010). However, longevity and body condition are not the only measures of animal health. High condition scores and long life can often be maintained despite cumulative changes to other physiological systems in response to recurring stressful events (McEwen and Wingfield, 2003). For example, repeated stressors can result in more chronically dysregulated glucocorticoid secretion, chronically elevated food consumption, insulin resistance, and increased deposition of fat which, in some species, can contribute to high condition scores (Leibowitz and Hoebel, 1997; McEwen and Wingfield, 2003; Sapolsky, 2005). Moreover, research with crimson finches (*Neochmia phaeton*) has shown that accepted condition measures do not reliably predict reproductive success or survival (Milenkaya, 2013), suggesting that the value of condition scores for assessing integrative animal health may be insufficient.

How then are we to understand the relevance of increased cortisol in mares that change groups more often? The benefits of lower stress environments (to animals in general) and band stability (to feral horses in particular) have been well documented. Persistently stressed animals show a range of deleterious effects (Sapolsky, 2005), and in feral horses, band instability has been associated with decreased time spent in preferred behaviors, increased offspring mortality, and increased parasite load (Kaseda et al., 1995; Linklater et al., 1999). All of these factors can be explored further; however, future studies investigating parasite burden more closely may yield the most relevant information (Rubenstein and Hohmann, 1989). Because parasites can have important effects on host fitness, such measures could reveal much about overall animal health and ability to fight off infection (Booth et al., 1993). In addition, this metric would offer managers an important, non-invasive tool with which to further quantify animal well-being.

Our results present new evidence that should be considered when evaluating management tools. We show that social stressors are integrated into an animal's physiology via increased cortisol which, when experienced at increased frequency, can increase the risk of chronic stress (Sapolsky, 2005). In addition, such behavioral changes can decrease the mares' ability to form the stable social relationships with one another that are important to decreasing overall male harassment (Cameron et al., 2009). Furthermore, given the high degree of sociality in feral horses, the behaviors of these individuals have the potential to affect the population as a whole. For example, on Shackleford, increases in reproductive behavior (by mares) in the post-breeding season has resulted in increased male attentiveness (Nuñez et al., 2009), which in turn, limits mare movement and foraging efficiency (Rubenstein, 1986; Sundaresan et al., 2007) during a time of year when the conservation of resources is of utmost priority. Similar shifts in the reproductive behavior (Ransom et al., 2010) and subsequent parturition in feral mares (Ransom et al., 2013) have been shown in the Little Book Cliffs, McCullough Peaks and Pryor Mountains populations in the western United States. In the former study, treated mares received 54.5% more reproductive behaviors than did their untreated counterparts (Ransom et al., 2010). In addition, factors that usually determine rates of reproductive behavior directed toward untreated mares (by the stallion) did not exist for treated mares. Typically, stallions engage in higher rates of reproductive behavior with mares aged 9–14 years that are more likely to produce viable offspring. This preference did not hold with treated mares; harem males showed higher rates of reproductive behavior with these females, regardless of mare age and survival probability of the subsequent offspring. In the latter study, Ransom et al. (2013) investigated the effects of prior PZP treatment(s) on the timing of parturition in feral mares after fertility was regained. Time to regain fertility ranged between 1.5–8 years and was highly dependent upon the number of treatments received. On average,

these post-treated mares exhibited peaks in parturition 31.5 days later than did untreated mares (but see Kirkpatrick and Turner (2003)). Subsequently, post-treated mares were more likely to give birth as forage was declining, resulting in fewer resources available to mares and offspring during late term pregnancy and lactation. Such cascading behavioral effects are not uncommon in social species. For example, alterations to female song preference in brown-headed cowbirds (*Molothrus ater*) induce increased solicitation of males by other females, changes in male dominance structure, and a less stable and connected social network (Maguire et al., 2013).

While the changes to feral horse behavior and physiology discussed here could help reduce population numbers, the mechanisms by which such reductions are achieved (decreased social stability and social connectedness amongst mares, increased male/female aggression) also affect the welfare of these animals. Such effects may be of limited concern when population reduction is an urgent priority. However, their consideration is vital if managers are to maintain healthy, functional populations, particularly in social species like the feral horse, in which the manipulation of individuals can have implications for the population as a whole.

Acknowledgments

We thank Dr. J. Altmann for the use of her laboratory: this work would not have been possible without her contribution. We also thank J.J. Schurle for her additional data, Dr. S. Stuska for her help in the field, and Drs. J.Q. Ouyang and I.T. Moore for their insightful comments on an earlier version of this manuscript. This study was funded by Princeton University and the National Science Foundation (IIS-0705311 to D.I. Rubenstein).

Synthesis

Consequences of porcine zona pellucida immunocontraception to feral horses

Cassandra M. V. Nuñez, 2310 Pammel Drive, 339 Science Hall II, Iowa State University, Ames, IA 50011, USA *nunezcmv@iastate.edu*

Abstract: Porcine zona pellucida (PZP) immunocontraception was developed to provide a more humane, effective, and inexpensive method of population regulation for wildlife species. It has been used to regulate populations of several species including white tailed deer (*Odocoileus virginianus),* elk (*Cervus elaphus*), black bear (*Ursus americanus*), and the feral horse (*Equus ferus caballus*) with varying levels of success. Early studies on Assateague Island National Seashore, Maryland, USA, suggested PZP was as an ideal form of fertility control because it reduced the likelihood of conception to <10%, could be delivered remotely, was thought to be reversible, lacked debilitating physiological side effects, could not pass through the food chain, and showed minimal effects to social behaviors in a closed population of feral horses. However, research on Shackleford Banks, North Carolina, USA and on 3 western populations located in Little Brook Cliffs (Grand Junction, Colorado, USA), McCollough Peaks (east of Cody, Wyoming, USA), and the Pryor Mountains (Lovell, Wyoming, USA) has revealed behavioral and physiological side effects of long-term PZP use. When compared to untreated mares (those that have never received treatment), treated mares demonstrated decreased fidelity to the band stallion, increased and prolonged reproductive behavior, and an increased likelihood of extending reproductive cycling into the nonbreeding season. These effects were more pronounced in animals receiving more total and/or consecutive contraception treatments and can persist even after several years of treatment cessation. Finally, new data indicate that these changes to previously treated mares can affect the behavior and stress physiology of their band stallions, demonstrating the potential for the contraception of individuals to have population-level effects. These results are important to consider if we are to achieve both the effective management of feral horse populations in addition to the maintenance of their overall health and well-being.

Key words: behavior, *Equus ferus caballus*, feral horse, immunocontraception, physiology, porcine zona pellucida (PZP), reproductive, stress, treatment schedule

Feral horses (*Equus ferus caballus*) are a beloved icon of the American West. In 1971, the U.S. Congress, with the passage of the Wild Free-Roaming Horse and Burro Act (WFRHBA), designated feral horses as "wild" horses that are "living symbols of the historic and pioneer spirit of the West" (United States Congress 1971). The WFRHBA designation, the shift in public thinking that sparked it, and conflicting views on the status of feral horses as native or non-native wildlife (Weinstock et al. 2005, Mihlbachler et al. 2011), have likely contributed to the controversy surrounding feral horse management (Garrott et al. 1991). However, with few predators capable of taking feral horses (Eberhardt et al. 1982, Turner et al. 1992, Turner and Morrison 2001) and no legal hunting, unregulated feral horse populations can adversely impact both the local environment (Furbish 1990, Levin et al. 2002) and other wildlife (Ostermann-Kelm et al. 2008, Gooch et al. 2017, Hall et al. 2018) across the United States.

Feral horse population increases on Shackleford Banks, North Carolina, USA resulted in reduced vegetation, higher bird and crab diversity, and lower fish density and species richness in horse-grazed versus ungrazed marshes (Furbish and Albano 1994). In Nevada and Southern California, USA, feral horses outcompete bighorn sheep (*Ovis* spp.) and pronghorn (*Antilocapra americana*) for water; such competition can have serious implications in these desert habitats. Finally, conflict between humans and feral horse populations are particularly acute in the western United States, where the degradation of rangeland plants, soils, and water quality has been documented (Bureau of Land Management 2013).

Despite these impacts, the status of feral horses and their federal protection means

that managers have few options to regulate population numbers. Gathers, in which animals are rounded up by helicopter and either re-released or removed from the range, divide social groups (commonly referred to as bands) and decrease band stability (Kirkpatrick et al. 1997). In addition, the use of hormonal contraception (in both male and female animals) proved problematic due to the dosage needed to achieve infertility, the issue of possible consumption by non-target species, and the subsequent changes to recipient behavior (Turner and Kirkpatrick 1991).

On the other hand, immunocontraception proved easier to administer, did not pass through the food chain, and because of its mechanism of action (in comparison to hormonal contraception in which treatment-induced changes to recipient hormone levels directly affect behavior [Turner and Kirkpatrick 1991]), immunocontraceptive treatment itself caused little to no change to recipient behavior (Kirkpatrick 1990, Turner and Kirkpatrick 1991, Kirkpatrick 1995, Kirkpatrick and Turner 2002). Immunocontraception induces the production of antibodies against structural or functional molecules necessary for reproduction. These antibodies obstruct the normal cell biology of reproduction, reducing the likelihood of pregnancy (Turner and Kirkpatrick 1991).

In the case of the porcine zona pellucida (PZP) vaccine, antibodies bind sperm receptors on the egg's surface, preventing sperm attachment and fertilization over the course of 1 breeding season (Sacco 1977). Though hugely promising, initial work researching the potential effects of PZP on recipient animals did not consider the potential for behavioral effects of prolonged subfertility (Kirkpatrick and Turner 1991). Today, PZP is used with varying levels of success to control reproduction in several free-ranging ungulate species, including white-tailed deer (*Odocoileus virginianus;* McShea et al. 1997), elk (*Cervus elaphus;* Heilmann et al. 1998), and the feral horse (Kirkpatrick 1990, Turner et al. 2002).

Initially, most of the research examining the effects of PZP-induced subfertility on feral horses stemmed from 1 long-term study on Assateague Island National Seashore, Maryland, USA. Researchers reported no debilitating side effects to PZP recipients and only minor ovulation failure and depressed urinary oestrogen concentrations with repeated applications (Kirkpatrick et al. 1996). In addition, the contraceptive effects of PZP were shown to be reversible, safe for pregnant females, and did not adversely affect the survivorship or subsequent fertility of offspring born to treated individuals (Kirkpatrick and Turner 2002).

However, an important caveat was made; on average, mares receiving 4–5 consecutive treatments took 4.4 years to return to fertility (range = 1–8 years), and those receiving 7 consecutive treatments did not return to fertility during a 7-year, treatment-free interval (Kirkpatrick and Turner 2002). These results should have served as a warning to managers that more aggressive treatment could grossly affect future fertility in treated mares (potentially limiting future management options); however, such caution seems to have been taken only rarely (Ransom et al. 2013, Nuñez et al. 2017).

Early on, very little investigation was devoted to the potential for behavioral effects of PZP contraception. Powell (1999) found little to no effect; however, true controls (i.e., animals that had never been treated) were not available for comparison. More recent studies on feral horses living on Shackleford Banks and in the western United States demonstrate important differences in recipient behavior and physiology (Nuñez et al. 2009, Madosky et al. 2010, Nuñez et al. 2010, Ransom et al. 2010). For a gregarious species like the horse, such changes may have serious social and demographic consequences.

Herein, I provide a synthesis of the literature regarding the potential effects of PZP contraception on mares and band social structure. I compare the effects of PZP in different populations and use results from a 17-year dataset to offer management suggestions that may prevent or ameliorate these effects. The research reviewed here was conducted on horse populations in which the individual identity and treatment history of mares was known; therefore, these recommendations will likely not be applicable to all situations (Turner et al. 2001, Killian et al. 2008). However, the potential benefits to feral horse health and well-being and the assurance that future management options remain available (Nuñez et al. 2017) indicate that the suggestions proposed should be applied whenever possible.

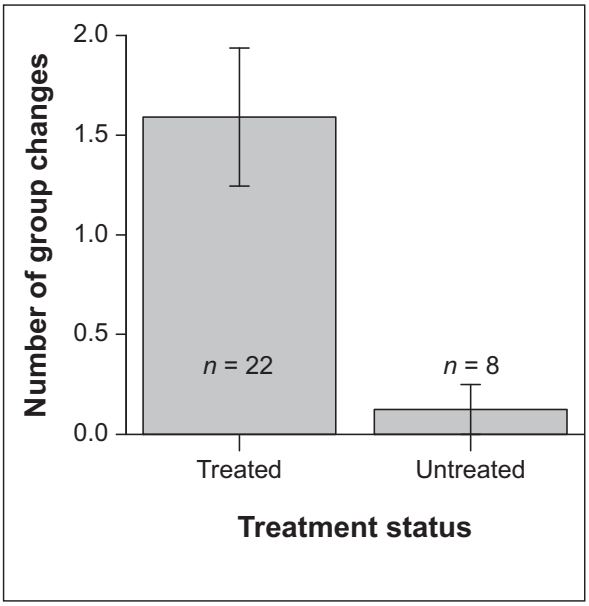

Figure 1. Number of group changes for treated and untreated mares. Even when controlling for the effect of age, treated mares changed groups more often than did their untreated counterparts. Adapted from Nuñez et al. (2009).

Effects of PZP-induced subfertility

PZP-induced subfertility can have important behavioral and physiological consequences for recipient animals (Nuñez et al. 2009, Madosky et al. 2010, Nuñez et al. 2010, Ransom et al. 2010, Ransom et al. 2013). This was especially the case with mares receiving ≥4 total and/or consecutive treatments (Nuñez 2005, unpublished data; Nuñez et al. 2010). Moreover, changes to mare behavior and physiology have the potential to become long-term (especially in mares that received ≥4 total treatments; Nuñez et al. 2017). Finally, such changes in recipient animals can significantly affect the behavior and physiology of their band stallions (Jones and Nuñez 2017, unpublished data). Although such aggressive treatment may be deemed necessary when rapid reductions in animal numbers are of paramount importance, the resultant changes to mare behavior and physiology can limit future management options (Nuñez et al. 2010, Ransom et al. 2014, Nuñez et al. 2017).

Conversely, animals receiving fewer treatments exhibited behavior and reproductive physiology more typical of untreated animals. Moreover, animals receiving fewer treatments were more likely to return to fertility after the suspension of treatment (Nuñez et al. 2017), thereby maintaining flexibility should future management goals change. Although such considerations will not be practical with all populations (Turner et al. 2001, Killian et al. 2008), more careful consideration to feral horse behavior and physiology can help ensure more effective, flexible population management.

Behavior

On Shackleford Banks, PZP-treated mares were up to 10 times more likely to change bands than their untreated counterparts (Nuñez et al. 2009; Figure 1). Moreover, mares receiving 4–6 total treatments were more likely to engage in the behavior than those receiving 1–3 or 0 treatments (Nuñez 2005, unpublished data). This is an important shift in behavior, as band stability, which is affected by the degree of female loyalty to the band stallion (Kaseda et al. 1995), is important to overall animal health. Decreases in band stability have been associated with decreased physical condition and female fecundity, increased parasite load and offspring mortality, and less time spent in preferred behaviors (Linklater et al. 1999). Moreover, increased mare turnover can disturb resident females (Monard and Duncan 1996), causing an overall increase in their levels of aggression (Rutberg 1990, Monard and Duncan 1996). In addition, repeated changes to band composition may prevent the establishment of stable female dominance hierarchies, which are critical to maintaining social cohesion among mares and overall group stability (Berger 1977, Houpt and Wolski 1980, Heitor et al. 2006).

Evidence suggested that such decreases in mare fidelity to the band stallion were related to PZP-induced subfertility: mares that conceived more often over a 5-year period (i.e., mares that were left untreated or for which treatment had failed), were less likely to engage in group changing behavior (Nuñez et al. 2009; Figure 2). Though these results were confounded by PZP treatment (see Figure 2), given the vaccine's mechanism of action, and the demonstrated effects of treatment regime, it seems more likely that prolonged subfertility is the causal mechanism behind decreases in mare fidelity.

Similar to white-tailed deer does (McShea et al. 1997) and free-ranging elk cows (Heilmann et al. 1998), treated mares were also more likely to solicit and receive reproductive behaviors from males (Nuñez et al. 2009, Ransom et al. 2010).

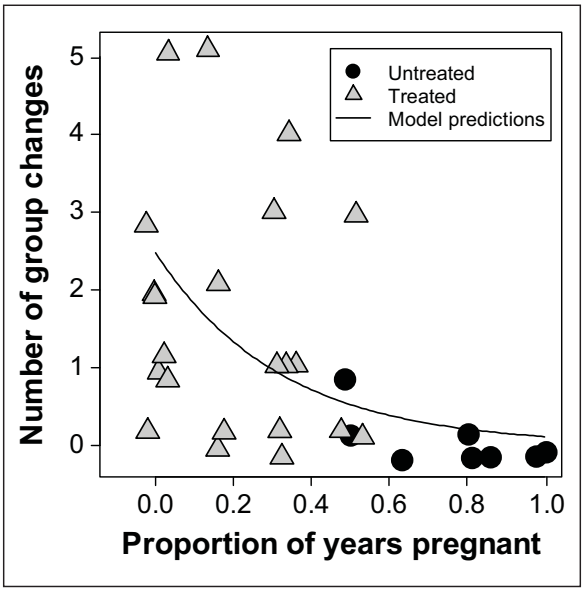

Figure 2. Number of group changes and the proportion of years pregnant from January 2000 to January 2005. Points have been jittered to allow clear visualization of every individual. The number of changes mares made decreased with the proportion of years they were pregnant. Adapted from Nuñez et al. (2009).

In addition, stallions in western populations were more likely to breed PZP-treated versus untreated mares regardless of their age or the probability of producing viable offspring, 2 factors that normally affect male mate choice (Ransom et al. 2010; Figure 3). In the absence of pregnancy, the increased frequency of reproductive cycling demonstrated by treated mares was undoubtedly a factor driving male behavior. In addition, there was the potential for a perceived increase in reproductive "failures" (by mares) to drive female reproductive behavior.

Stress physiology

Because stallions will vigorously attempt to retrieve and maintain resident mares, mares attempting to change groups are often subject to direct male harassment, including aggressive herds, chases, and increased reproductive activity by either the band or new stallion (Madosky 2011), and/or find themselves in close proximity to highly escalated male–male contests (Feist and McCullough 1976, Rubenstein 1981). In addition, if mares are successful at leaving their current band to join a new one, they are often subject to harassment by resident mares establishing their dominance (Rutberg 1990).

On Shackleford Banks, this increased social instability affected mare stress physiology. During group changing behavior, mares exhibited increased fecal cortisol (Nuñez et al. 2014; Figure 4), a reliable measure of stress in several mammalian taxa (Wasser et al. 2000, Mostl and Palme 2002). This effect was not fleeting; mares changing groups more often continued to show elevated cortisol levels for up to 2 weeks post their group changing behavior (Nuñez et al. 2014; Figure 5).

These studies indicate that group transfer behavior can incur a significant cost to mares. Although stress in itself is not inherently detrimental to animal fitness or well-being (Moberg 2000), the stress response can become pathogenic when experienced chronically (Sapolsky 2005), resulting in adverse effects to cardiovascular and immune function, reproduction, and, in extreme cases, neurological functioning. On Shackleford Banks, mares changing bands more frequently can be subject to a negative feedback loop: their behavior leads to harassment, which may induce additional group changes, resulting in further harassment (Madosky et al. 2010; also see Linklater et al. 1999). It is unlikely that the mares observed in our study experienced chronic stress as defined by Sapolsky (2005). However, our data suggest that mares making more group changes experienced increased stress levels at more regular intervals than did mares making fewer group changes. There can be little doubt, therefore, that group changing behavior incurs a physiological cost to mares.

These results have important implications for feral horse management. On Shackleford, PZP-induced subfertility was associated with increased group changing behavior (see Behavior). Though the lack of any untreated mares at the time of our study precluded a direct comparison of the cortisol levels of treated versus untreated mares (Nuñez et al. 2014), the logic was clear: group changing behavior and the associated decreases to social stability induced a physiological stress response in mares. Mares that engage in this behavior more often may be at higher risk for the deleterious effects of the repeated stressor.

Contracepted mares consistently demonstrated improved physical condition and increased longevity when compared to uncontracepted mares (Kirkpatrick and Turner 2007, Nuñez et al. 2010). However, the potential effects of

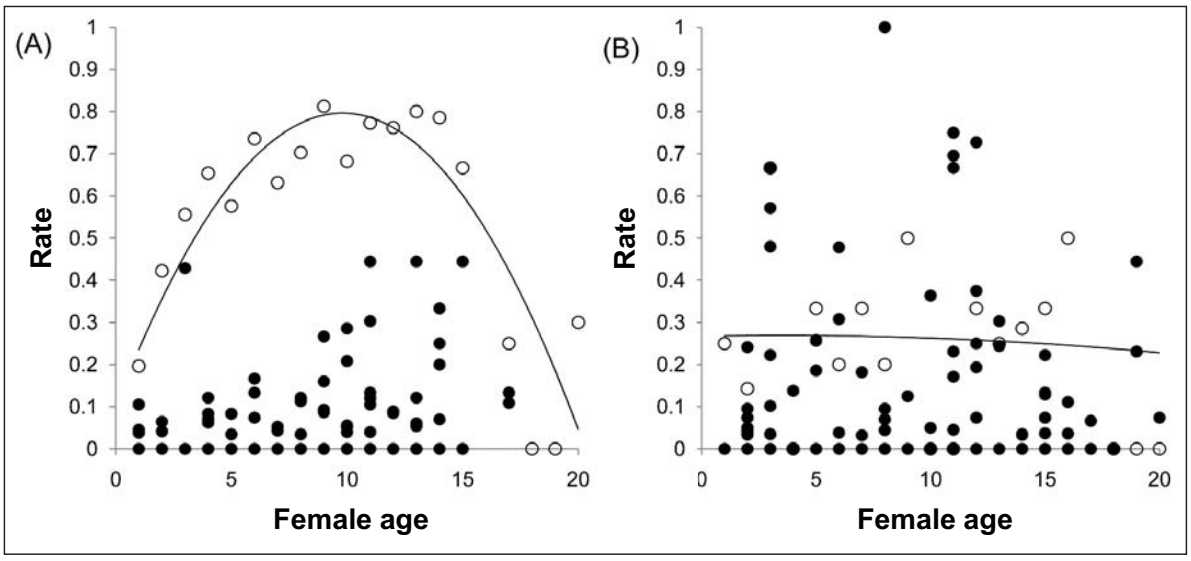

Figure 3. Rate of stallion reproductive behaviors exhibited per hour (●) as a function of mare age, and mean rate of viable foal production (○) as a function of mare age at conception, for repeated observations of 99 untreated mares (A) and 56 treated mares (B) at Little Book Cliffs Wild Horse Range, Grand Junction, Colorado, USA; McCullough Peaks Herd Management Area (HMA), east of Cody, Wyoming, USA; and Pryor Mountain Wild Horse Range, Wyoming and Montana, USA, 2003–2006. The rate of reproductive behavior expressed toward females (by males) generally followed the relationship between viable foal production and age of the female at the time of conception for untreated mares (A). This relationship deteriorated in treated mares (B) and the rate of reproductive behaviors expressed was both higher than control females and exhibited no clear pattern among age cohorts. Adapted from Ransom et al. (2010).

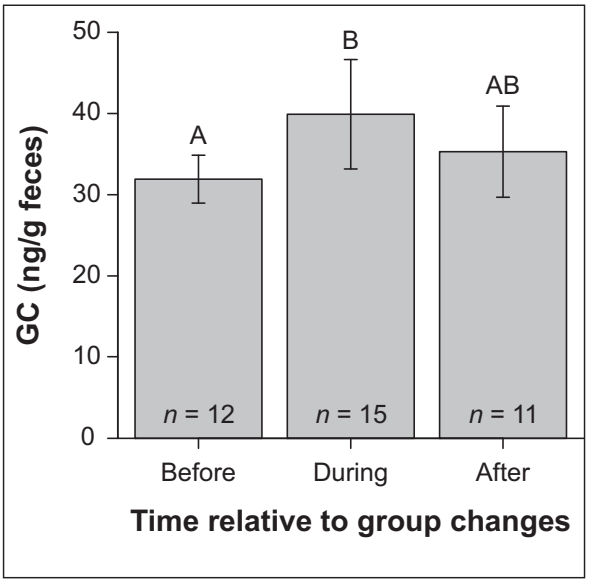

Figure 4. Mare cortisol level and the timing relative to group change behavior. Mares showed increases in cortisol during group changes. Adapted from Nuñez (2014).

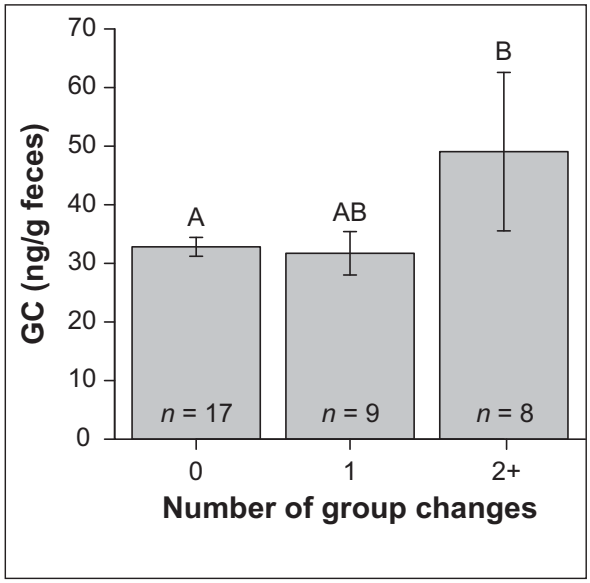

Figure 5. Mare cortisol level 2 weeks post group changing behavior. Mares making more group changes exhibited higher cortisol levels 2 weeks post behavior than did mares making fewer group changes. Adapted from Nuñez et al. (2014).

repeated stressors to treated mares is not trivial. For instance, repeated stress can result in more frequently dysregulated glucocorticoid secretion, elevated food consumption, insulin resistance, and increased fat deposition, which, in some species, can contribute to high condition scores (Leibowitz and Hoebel 1997, McEwen and Wingfield 2003, Sapolsky 2005). Moreover, recent research in other taxa suggests that accepted condition measures do not reliably predict animal survival (crimson finches [*Neochmia phaeton*]) or other constituents of body condition, including

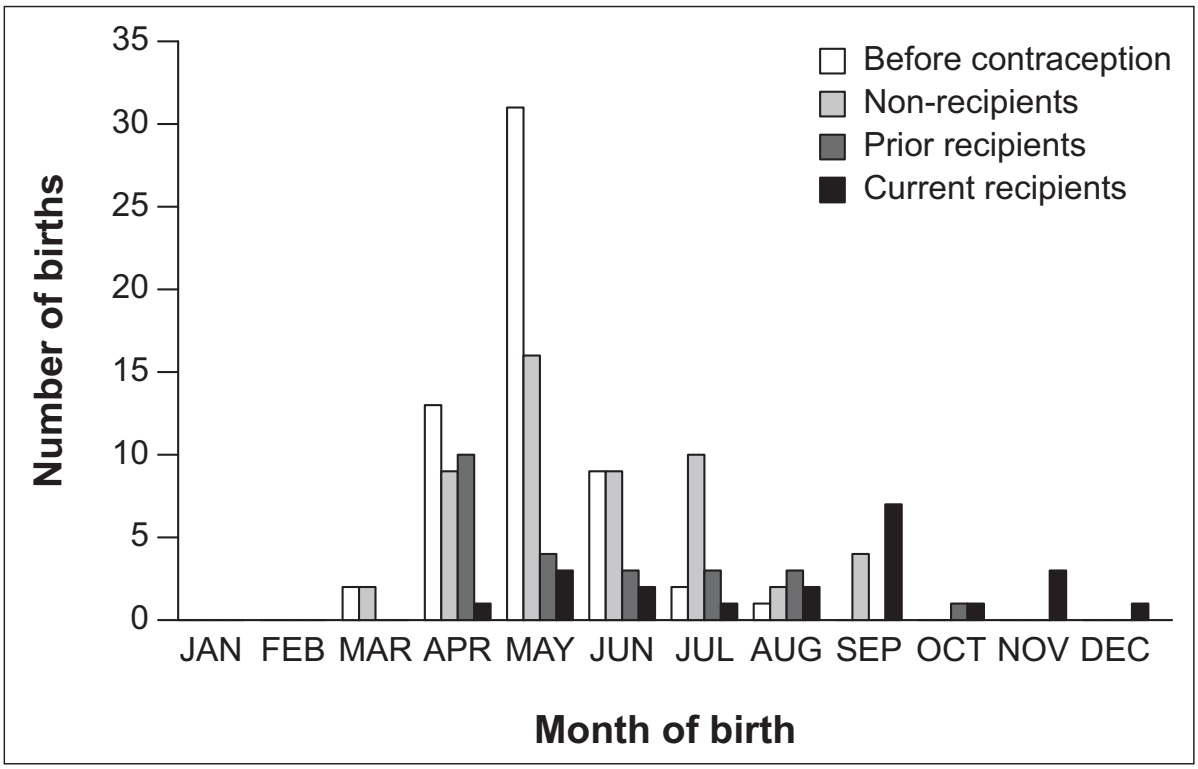

Figure 6. The distribution of births for mares on Shackleford Banks, North Carolina, USA, pre-contraception and post-contraception management. Mares gave birth over a wider range of months and later, on average, after the onset of contraception; this effect was more pronounced in PZP recipients than non-recipients. Adapted from Nuñez (2010).

fat and lean mass (lizards [*Anolis sagrei*]), suggesting that such scoring methods, regardless of what they may indicate, may not be sufficient for the assessment of integrative animal health (Milenkaya et al. 2015, Warner et al. 2016).

Reproductive physiology

In both the Shackleford and western populations studied, mares treated with PZP were more likely to extend reproductive cycling into what is typically considered the non-breeding season (fall and winter) than were untreated mares. This resulted in an increased number of fall and winter births to treated, compared to untreated, mares (Nuñez et al. 2010, Ransom et al. 2013; Figures 6 and 7). On Shackleford, this effect was especially pronounced in mares receiving a greater number of consecutive applications. Each additional consecutive treatment resulted in a 25-day delay in foaling (Nuñez et al. 2010).

These changes constituted an important shift in reproductive physiology, as mares living in temperate climates are typically anovulatory during the non-breeding season (Asa 2002). Gestation lasts approximately 11–13 months in feral horses (Asa 2002). Consequently, mares give birth to foals in seasonal conditions similar to those in which they conceive (i.e., they give birth during the same season the following year). A cessation of ovulatory cycling during the non-breeding season is adaptive in that it precludes conception and subsequent birth during a time of year when resources are at their lowest (Stevens 1990).

Continued cycling into the non-breeding season and the associated fall and winter births could contribute to higher foal mortality; however, management interventions (such as the removal of "at risk" animals) has made the accurate analysis of this possibility infeasible on Shackleford Banks. In areas like the western United States, harsher climatic conditions will likely exacerbate the potential effects of extended cycling to offspring and mare health (Ransom et al. 2013).

Potential for long-term effects of PZP treatment

The potential for long-term effects of PZP-induced subfertility is highly dependent upon the number of treatments females receive during

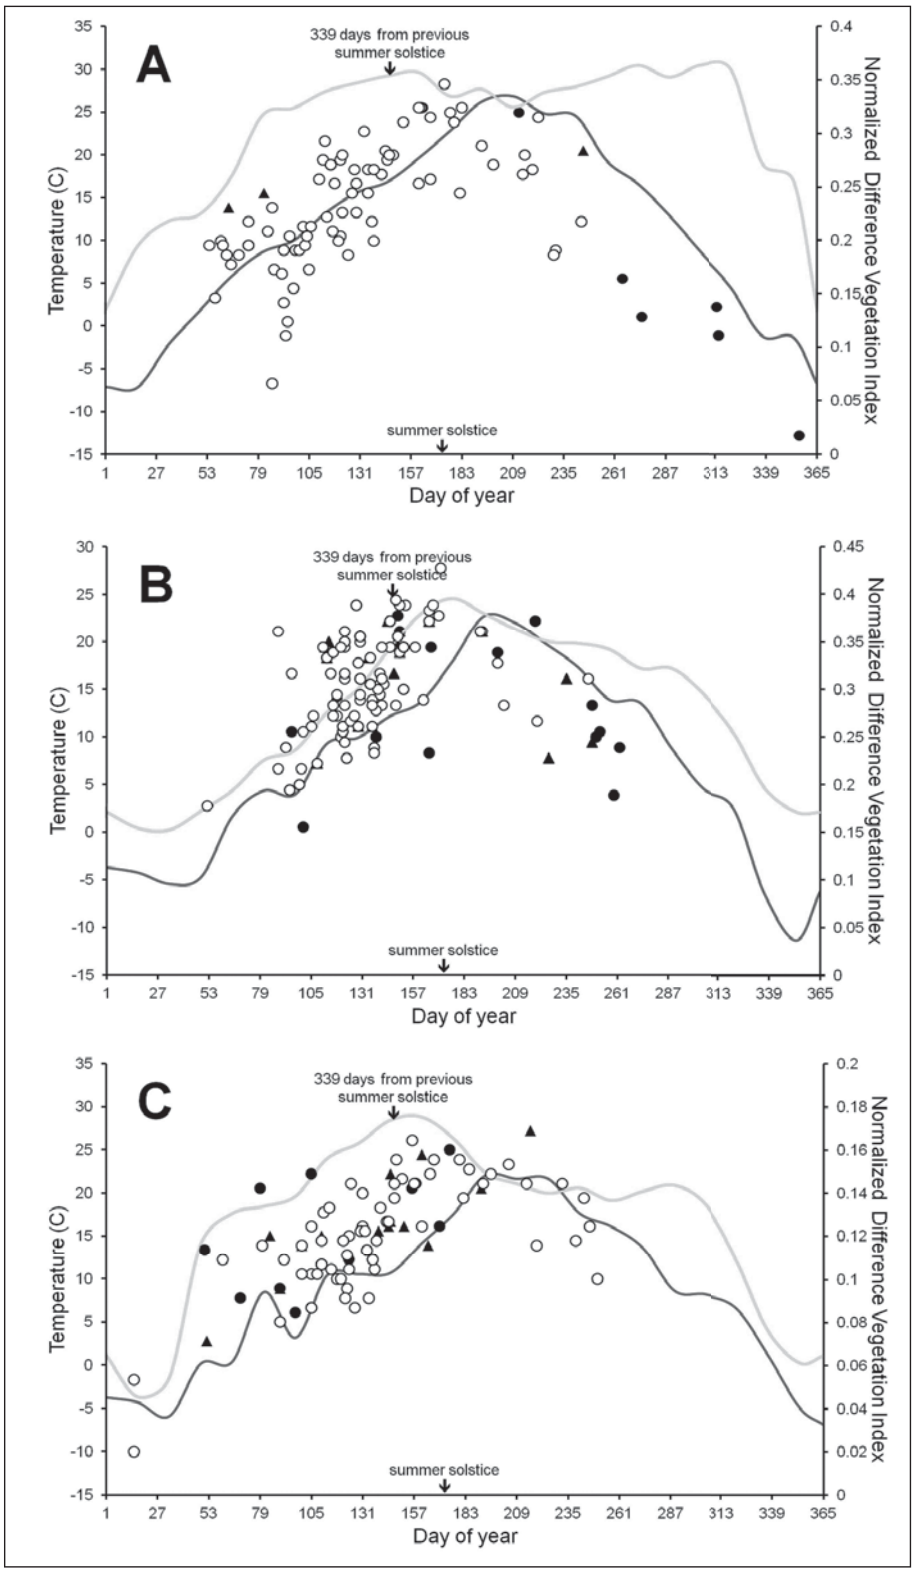

Figure 7. Birth phenology of untreated (○) and post-treated mares (● = first post-treatment birth, ▲ = birth subsequent to ●). Births are shown as a function of temperature at approximate conception date for populations at (A) Little Book Cliffs Wild Horse Range, Grand Junction, Colorado, USA, 2005–2011; (B) Pryor Mountain Wild Horse Range, Wyoming and Montana, USA, 2005–2011; and (C) McCullough Peaks Herd Management Area (HMA), east of Cody, Wyoming, USA, 2007–2011. Post-treated females were previously inoculated with the immunocontraceptive porcine zona pellucida (PZP). Mean Normalized Difference Vegetation Index (shown in lighter gray) represents temporal availability of forage. Mean daily surface temperature is also included (shown in darker gray). Adapted from Ransom et al. (2013).

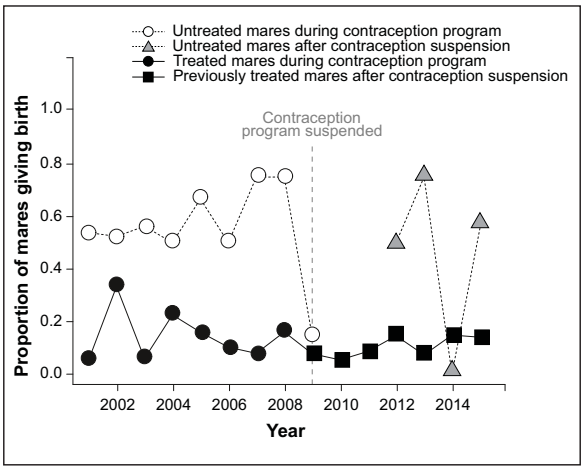

Figure 8. Proportion of mares giving birth in the years during and after contraception management. During the contraception program, treated mares showed markedly lower birth rates than did untreated mares. In 2009, all untreated mares received PZP, leaving no untreated animals of reproductive age on the island in 2010 and 2011. Even after the suspension of treatment, previously treated mares did not return to a level of fertility comparable to untreated mares before 2009 or to younger, untreated animals that became reproductive between 2012 and 2015. Adapted from Nuñez et al. (2017).

their lifetime (Nuñez et al. 2017). In 2009, after 9 years of intensive contraception management on Shackleford Banks, the program was largely but temporarily suspended to allow for controlled population growth (S. Stuska, National Park Service, personal communication). Even when controlling for the effects of mare age on fertility, previously treated mares were less likely to foal than were untreated mares during 5 years of contraception suspension (Figure 8). However, for mares that previously received fewer total treatments (1–3 applications), foaling probability increased with time since their last treatment before declining at approximately 6 years post-treatment. This was not the case for mares that previously received more intensive treatment (≥4 [range = 4–9] total applications); for these mares, there was no increase in foaling probability after contraception suspension. Again, these effects were significant even when controlling for the effects of mare age on fertility.

Moreover, previously treated mares receiving any level of treatment continued to conceive later into the year than did untreated mares, demonstrating prolonged reproductive cycling, and mares previously receiving ≥4 treatments continued to change groups more often than did untreated mares (even after 4–6 years without treatment), demonstrating a prolonged decrease in loyalty to their band stallions (Nuñez et al. 2017).

These results demonstrate the potential for long-term behavioral and physiological effects of PZP-induced subfertility (even after the cessation of treatment). They also show that such effects can be ameliorated with less intense application schedules. When at all possible, careful consideration to the frequency of PZP treatment is important to the maintenance of more typical feral horse behavior and physiology. Moreover, and perhaps just as important, the likelihood that mares will return to fertility (and thus, the ability to maintain future management options) may be compromised if females are kept subfertile for extended periods of time.

Finally, it is critical to note that these results are not anomalous. Similar effects have been demonstrated in western populations of feral horses (Ransom et al. 2013), in other free-ranging species including bison (*Bison bison*; Duncan et al. 2017) and white-tailed deer (Miller et al. 2001), and in several captive species including Asian elephants (*Elephas maximus*), African elephants (*Loxodonta africana*), Seba's bats (*Carollia perspicillata*), big cats (*Felidae*), wildebeest (*Connochaetes*), white rhinoceros (*Ceratotherium simum*), and stingrays (*Myliobatoidei*; Songer 1996).

Effects to untreated associates

In social species, the effects of prolonged PZP-induced subfertility are likely to affect the behavior and physiology of their untreated associates. For instance, increased female group changing behavior could result in increased male–male and male–female aggression (Madosky 2011). Such changes to behavior could subsequently impact the endocrinology of untreated associates, including increases in cortisol and/or testosterone levels. Such impacts have been demonstrated in several taxa including primates, birds, and fish (Wikelski et al. 1999, Cavigelli and Pereira 2000, Hirschenhauser and Oliveira 2006).

Preliminary work on Shackleford Banks strongly suggested such patterns (Jones and Nuñez 2017, unpublished data) indicating that when managing social species, the changes we

effect in target animals are likely to affect the behavior and physiology of their non-target associates. When at all possible, we should attempt to minimize such changes to target animals.

The studies reviewed here show that mares receiving fewer (1–3) total and/or consecutive treatments demonstrate more typical behavior and physiology than do mares receiving more (≥4) treatments. If the primary management goal is to reduce population size, it is unlikely (and perhaps less important) that managers achieve a balance between population control and the maintenance of more typical feral horse behavior and physiology. However, in areas or situations in which the social and physiological functioning of animals is of concern and mare identity and treatment history can be tracked, the application of fewer treatments, including "breaks" during which mares are allowed to reproduce, is recommended. Such treatment will better ensure the health and overall well-being of the population and, depending on managerial goals, more effective, flexible management.

Management implications

Feral horse management via direct population regulation will continue to be a difficult task. With every decision, managers and policymakers must consider the efficacy, feasibility, costs, and benefits of different strategies, the potential effects to feral horse health and welfare, and the impacts of public opinion on management implementation. In the absence of natural predators to regulate feral horse populations, any method we choose will likely necessitate ongoing human intervention. Obtaining balance between the costs and benefits to both feral horse and human populations and the ecology of western rangelands remains challenging. However, results from the studies reviewed here show that with fewer total and/or consecutive treatments, we can maintain more natural behavior and physiology in feral horses.

Mares receiving fewer treatments are less likely to engage in group changing behavior and give birth at times of the year that more closely approximate those of untreated mares. Moreover, these mares are more likely to return to fertility after treatment suspension, maintaining future management options, more natural behavior and physiology, and more typical band stallion behaviors. Finally, given the fact that group changing behavior induces a physiological stress response in mares, the data reviewed here strongly suggest that mares receiving fewer total and/or consecutive treatments will be at lower risk for repeated stressors. Such refinements to contraception scheduling are likely to apply regardless of the methods or vaccines used, as long as it is mare subfertility and not the treatment itself that causes changes to mare behavior and physiology. Lastly, though such methods may not be possible or practical in all areas, in smaller, closed populations, where the identification of individuals and the careful tracking of treatment history is plausible, care should be taken to maintain more typical animal behavior and physiology.

Acknowledgments

I would like to thank T. Messmer for inviting me to write this review. Thanks also to J. Adelman and 3 anonymous reviewers for their comments on an earlier version of this manuscript, and to J. Ransom for assistance in adapting his figures.

ABSTRACT

The behavioral effects of the immunocontraceptive agent porcine zona pellucida (PZP) have not been adequately studied. Important managerial decisions for several species, including the wild horse (*Equus caballus*), have been based on this limited research. We studied 30 horses on Shackleford Banks, North Carolina, USA to determine the effects of PZP contraception on female fidelity to the harem male. We examined two classes of females: contracepts, recipients of the PZP vaccine ($n = 22$); and controls, females that have never received PZP ($n = 8$). We conducted the study during the non-breeding season from December 2005 to February 2006, totaling 102.2 h of observation. Contracepted mares changed groups more often than control mares ($P = 0.04$). Contracepts also visited more harem groups than did control mares ($P = 0.02$) and exhibited more reproductive interest ($P = 0.05$). For both contracepted and control females, the number of group changes ($P = 0.01$) and number of groups visited ($P = 0.003$) decreased with the proportion of years mares were pregnant. Our study shows that the application of PZP has significant consequences for the social behavior of Shackleford Banks horses. In gregarious species such as the horse, PZP application may disrupt social ties among individuals and inhibit normal social functioning at the population level.

1. Introduction

Due to the extirpation of their natural predators, ungulate populations in North America have expanded, necessitating their regulation through culling or contraception management (Eberhardt et al., 1982). Immunocontraceptives are widely used to control reproduction in free-ranging ungulates (Kirkpatrick et al., 1990; Turner et al., 1992). In females, the most common form of immunocontraception, porcine zona pellucida (PZP), stimulates the production of antibodies that bind sperm receptors on the egg's surface, thereby preventing sperm attachment and fertilization (Sacco, 1977). While PZP effectively inhibits conception in several different mammalian species (Kirkpatrick et al., 1996), little is known about its potential effects on recipient behavior. Studies in free-ranging elk (*Cervus elaphus*) and white-tailed deer (*Odocoileus virginianus*) indicate that females receiving PZP extend reproductive behaviors into the post-breeding season (McShea et al., 1997; Heilmann et al., 1998). Authors suggest that in response to repeated unsuccessful mating attempts, females continue cycling in an attempt to gain additional reproductive opportunities. Such changes in behavior can have serious consequences for social species, particularly for those that are polygynous with males defending and retaining several females.

Several studies have examined the effects of PZP application to wild horses (*Equus caballus*). These studies have focused primarily on the physiological effects (both

doi:10.1016/j.applanim.2008.12.001

reproductive and otherwise) of the vaccine (Kirkpatrick et al., 1992, 1997; Turner and Kirkpatrick, 2002). Researchers have reported no debilitating side effects to PZP recipients and only minor ovulation failure and depressed urinary oestrogen concentrations with repeated applications (Kirkpatrick et al., 1996). In addition, the contraceptive effects of PZP have been shown to be reversible, safe for pregnant females, and do not adversely affect the survivorship or subsequent fertility of offspring born to treated individuals (Kirkpatrick and Turner, 2002).

Researchers claim that the contraceptive has no effect on recipient behavior (Kirkpatrick et al., 1996, 1997; Powell and Monfort, 2001), but present no quantitative data to support their conclusions. In fact, no systematic study has specifically addressed this issue with true controls, animals that have never received PZP during their lifetime (Powell, 1999). Additionally, no study on wild horses has focused on the post-breeding period, when the effects of PZP appear most pronounced in other ungulates (McShea et al., 1997; Heilmann et al., 1998).

In wild horse societies, the harem is the core social group, consisting of usually one, but sometimes two or three harem male(s), one to several female(s), and their offspring (Feist and McCullough, 1976; Rubenstein, 1981, 1986; Linklater et al., 2000). Harem groups are typically stable units, showing very few changes in composition over months or years (Klingel, 1975). Female loyalty to the harem male and the male's ability to retain females is paramount to maintaining this stability (Feist and McCullough, 1976; Rubenstein, 1981; Goodloe et al., 2000). Decreases in harem stability have been shown to affect several aspects of mare well-being, resulting in lower overall reproductive success (Kaseda et al., 1995), less time for preferred behaviors, decreased body condition and fecundity, elevated parasite levels, and increased offspring mortality (Linklater et al., 1999).

For the most part, wild horses are non-territorial, with several harems sharing both feeding and water resources (Feist and McCullough, 1976; Rubenstein, 1981; Cameron et al., 2003). Given this ecology, decreases in the stability of individual harems have the potential to affect the interactions and social relationships of neighboring harems and thereby, may affect significant change at the population level. As such, understanding the potential effects of PZP on individual behavior is of broad importance to maintaining a functional population of feral horses.

In this study we investigate the behavioral effects of PZP on the horses of Shackleford Banks, North Carolina, USA during the non-breeding season. Specifically, we examine female propensity to switch harems, the number of harem groups visited, and the occurrence of reproductive behavior. Since the first application of the contraceptive in January 2000, a reduction in the fidelity of resident mares to their harem males has been noted, albeit anecdotally (C. Mason, personal observation). Based on this information, we hypothesized that contracepted females would change groups more often, would visit more groups, and would exhibit reproductive behaviors more often than would control mares (those never having received the vaccine).

2. Materials and methods

2.1. Study area

Shackleford Banks is a barrier island approximately 3 km off the coast of North Carolina, USA located at 34°40′04.94″N and 76°35′39.39″W. The island stretches 15 km in length, and varies between 0.5 and 3 km in width. The specific study area extended approximately 7 km and was located in the center of the island. This site contained all study animals.

Daylight hours, measured from sunrise to sunset times, ranged from 9 h and 53 min at the beginning of the study on 10 December 2005 to 10 h and 35 min at the conclusion of the study on 3 February 2006 (U.S. Naval Observatory Data Services, 2008). In Beaufort, NC, 7.8 km from the study site, average daily temperatures ± 1 S.E. for the past 20 years for December, January, and February were 7.93 ± 0.40 °C, 7.08 ± 0.28 °C, and 7.95 ± 0.26 °C, respectively. During the present study average daily temperatures ± 1 S.E. in Beaufort, NC for December, January, and February were 6.86 ± 1.65 °C, 7.19 ± 0.48 °C, and 7.26 ± 0.30 °C, respectively (National Climate Data Center, 2008).

2.2. Study subjects

The reproductive units of Shackleford horses are typical of feral equids, consisting of coherent harem groups of one or, sometimes two or three stallion(s) with one to several mare(s) and their offspring (Rubenstein, 1981). While multi-male harems are more common in some populations (Linklater and Cameron, 2000), they occur less frequently on Shackleford Banks, accounting for only 19% of all harems on the island at the time of this study. For the most part, these social units are not territorial, and the animals move freely within their overlapping home ranges.

Normally, harem groups are long lasting with most changes involving the dispersal of immature individuals (both male and female). Harem males will sometimes fight to acquire mares from other groups, but stallions almost always retain their mares (Feist and McCullough, 1976; Rubenstein, 1981).

The application of PZP for the purposes of immunocontraception was begun by the National Park Service in January 2000. At that time, eight control mares were identified; one from each of the distinct genetic lineages on the island. These mares would not receive the vaccine at any point during their lifetime. Females younger than 2 years of age were not considered for control status. These procedures determined the current age distribution of control and contracepted animals on Shackleford Banks. The authors of this study were not involved in establishing the number of control and/or contracepted animals.

We observed 30 females that organized themselves into 13 harem groups. Twenty-two mares were treated with PZP at least once between January 2000 and January 2005; the remaining control animals had never been treated. Six of the harem groups investigated contained contracepted females only; two groups contained control females only; the remaining five groups contained both contracepted and control females (see Table 1). All harems considered in this study contained only one harem male. At the time of the study, five of the control mares were pregnant; three of which were nursing foals. An additional control mare nursed a foal, but was not pregnant. Three contracepted mares were pregnant. Two of these females had not received PZP treatment the previous spring; the remaining mare's pregnancy suggests a failure of the treatment. Two other contracepted mares nursed foals; these mares had not received treatment the previous spring. The inoculation, pregnancy, and foaling records for all study animals are shown in Tables 2 and 3.

2.3. PZP contraception

The National Park Service administers PZP from late February through April each year. Mares are first treated at 2 years of age. Each injection contains 100 μg of PZP plus an adjuvant (mixed at the darting site). Initial doses contain Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem, Gibbstown, NJ, USA, #344289). All subsequent doses contain Freund's Incomplete Adjuvant (Sigma, St. Louis, MO, USA, #F5506).

For the animals in this study, PZP deterred pregnancy in 97% of cases when administered during the same year. This efficacy dropped to 76% in

Table 1
Initial harem configurations of focal animals.

Harem male	Group type	Control females	Contracepted females	Focal females
Adam	Control	1	0	1
Edge	Control	1	0	1
Axl*	Contracept	0	2	1
Duchovny	Contracept	0	1	1
Pacino	Contracept	0	6	6
Phinius*	Contracept	0	4	1
Teddy*	Contracept	0	5	1
Toro*	Contracept	0	4	4
Clint	Mixed	1	1	2
Dionysis	Mixed	1	1	2
Satellite	Mixed	1	2	3
Stobbs	Mixed	1	2	3
Winston	Mixed	2	2	4

Four of the harems listed reside outside of the study area and were not observed as focal groups (*). However, at least one female from each of these harems moved into focal groups during our study. The focal females column reflects only the number of individuals from each harem that were observed systematically during the study. Other columns show the initial group composition of each harem at the study's outset.

the second year after PZP inoculation. These values are similar to those published for Assateague horses, 94% and 86%, in the first and second years, respectively (Turner et al., 2007).

While we were unable to obtain blood samples for mares during this study, anti-PZP antibody titers in domestic mares remain above control levels for up to 40 weeks post-injection when using similar doses and adjuvant mixtures (Willis, 1994). The National Park Service routinely inoculates mares from February through April. Therefore, in animals inoculated in 2005, anti-PZP antibody levels would have been high during the breeding season, but were likely approaching control levels at the time of this study.

2.4. Pregnancy testing

Fecal samples are collected by the National Park Service in January of each year. All pregnancy testing is completed by enzymeimmunoassay of fecal material at the Science and Conservation Center at ZooMontana in Billings, MT, USA. Using the methods of Kirkpatrick et al. (1991), water extracts of fecal samples are assayed for estrone conjugates and nonspecific progesterone metabolites. Foaling records from the summers following testing were used to supplement assay results.

2.5. Behavioral and demographic sampling

The study was conducted by one observer (C.M.V. Nuñez) during the non-breeding season from December 2005 to February 2006, totaling 102.2 h of observation. Horses were identified individually by color, sex, age, physical condition, and other distinguishing markings including freeze brands. Ages are known from long-term records for the identified horses of Shackleford Banks (Nuñez, 2000).

We located each harem and noted its composition an average of four times each week. We recorded its GPS location and composition, paying particular attention to the presence or absence of females. These data allowed us to assess female willingness (or ability) to remain with their harems. The following measures were analyzed:

- Number of changes that females made, i.e. how many times females switched groups during the study.
- Number of different groups that females visited, i.e. the total number of groups in whom a female was seen during the study.
- The age of the harem male with whom a female was most often associated.
- The size of the group in which the female was most often found.

All incidences of reproductive interest (including copulation, mounting, genital sniffing, and rump rubbing) directed to and initiated by mares were recorded *ad libitum* during scan sampling (Altmann, 1974). Behaviors of reproductive interest were defined as follows:

- Mounting—male places forelimbs around a female's flank; does not include insertion of the penis.
- Copulation—male mounts female; insertion of penis achieved.
- Genital sniffing—animal (male or female) actively places the snout to the genitals of another animal of the opposite sex.
- Rump rubbing—the initiator (male or female) places the chin and/or neck on the rump of a recipient of the opposite sex; initiator rubs its neck back and forth horizontally over recipient's rump.

2.6. Statistical analyses

We analyzed the effect of contraception on the number of group changes, the number of different groups females visited, and the occurrence of reproductive interest (either received or initiated by mares) using generalized linear models in R (version 2.7.1). All variables were poisson distributed and were analyzed using models with a quasipoisson error distribution and a log link function. All models were weighted by the number of times a mare was observed.

Many factors in addition to PZP treatment may affect the number of group changes, the number of groups visited, and the occurrence of reproductive interest. Such factors include mare and harem male age, group size, pregnancy status, the presence of a foal, and the percentage of females contracepted in each group (Feist and McCullough, 1976; Rutberg and Greenberg, 1990; Linklater et al., 2000). We included mare age, PZP treatment, and their interaction in the initial, maximal generalized linear models discussed above. As PZP treatment was correlated with harem male age, group size, pregnancy status, the presence of a foal, and the percentage of contracepted mares in a group, these latter terms were not included in our models to avoid multicolinearity. Non-significant terms were removed from the

Table 2
Pregnancy and foaling histories for control mares.

Column headings: F, foal present (was conceived in prior year); PZP, contraception during the pre-breeding season (spring) of the listed year; Pr, pregnant during post-breeding season (fall) of the listed year. "+" indicates the presence of a foal, that the animal was pregnant, and/or that the animal was inoculated with PZP; "–" indicates the absence of a foal, that the animal was not pregnant, and/or that an animal was not inoculated with PZP; "**" indicates that an animal foaled, but that the offspring died before reaching 1 year of age; "n/a" indicates that an animal was 0–2 years old and not eligible for contraception. PZP administration began in January 2000; foals present that year are not indicative of PZP efficacy and are not included. The status for the animals during the study period is highlighted.

models by backwards elimination. As sample sizes were limited, terms were retained if their *P*-value was less than 0.10.

To address whether harem male age, group size, pregnancy status, the presence of a foal, and the percentage of contracepted mares in a group had a significant influence on mare behavior, we analyzed them separately for control and PZP groups using Spearman rank correlations against the following variables: number of group changes, groups visited, and occurrences of reproductive interest (see Table 4).

Table 4
Spearman's rank correlations between response variables and predictor variables that correlated with contraceptive treatment.

Predictor variable	Response variable		
	Total changes among groups	Number of groups visited	Instances of reproductive behavior
Male age	*Controls*: $\rho = -0.58$, $P = 0.13$ *Contracepts*: $\rho = -0.16$, $P = 0.47$	*Controls*: $\rho = -0.58$, $P = 0.13$ *Contracepts*: $\rho = -0.18$, $P = 0.43$	*Controls*: $\rho = 0.08$, $P = 0.85$ *Contracepts*: $\rho = -0.03$, $P = 0.88$
Group size	*Controls*: $\rho = -0.44$, $P = 0.28$ *Contracepts*: $\rho = -0.28$, $P = 0.22$	*Controls*: $\rho = -0.44$, $P = 0.28$ *Contracepts*: $\rho = -0.22$, $P = 0.35$	*Controls*: $\rho = 0.01.$, $P = 0.99$ *Contracepts*: $\rho = 0.02$, $P = 0.95$
Percentage of group members contracepted	*Controls*: $\rho = 0.18$, $P = 0.68$ *Contracepts*: $\rho = 0.11$, $P = 0.67$	*Controls*: $\rho = 0.18$, $P = 0.68$ *Contracepts*: $\rho = 0.09$, $P = 0.71$	*Controls*: $\rho = 0.62$, $P = 0.10$ *Contracepts*: $\rho = 0.13$, $P = 0.59$
Pregnant or with foal during study	*Controls*: $\rho = -0.66$, $P = 0.08$ *Contracepts*: $\rho = -0.41$, $P = 0.06$	*Controls*: $\rho = -0.66$, $P = 0.08$ *Contracepts*: $\rho = -0.41$, $P = 0.06$	*Controls*: $\rho = -0.66$, $P = 0.08$ *Contracepts*: $\rho = -0.12$, $P = 0.58$

Each correlation was performed separately for control ($n = 8$) and contracepted ($n = 22$) groups.

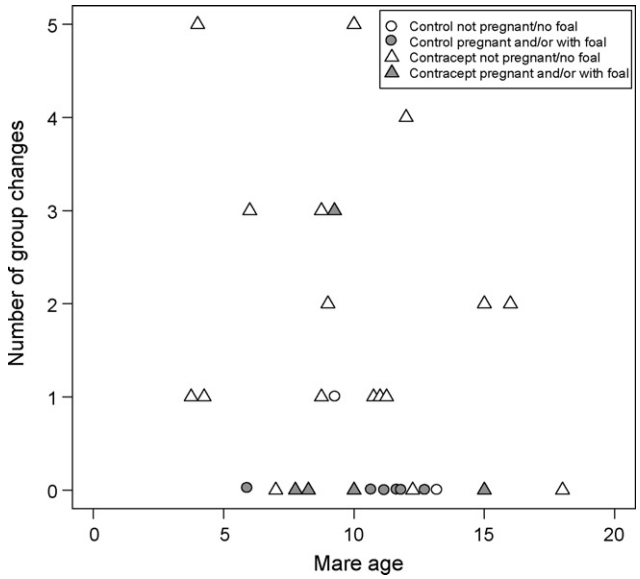

Fig. 1. Number of group changes during the study period by mare age for control ($n = 8$) and contracepted mares ($n = 22$). Even when controlling for the effect of age, contracepted mares change groups more often than do controls. Filled symbols represent mares that were either pregnant or nursing a foal at the time of the study. In the events of ties, mare age has been jittered by 0.2 years to allow clear visualization of every individual.

3. Results

3.1. Number of group changes

A generalized linear model shows that PZP treated mares changed groups significantly more often than did controls, even when accounting for mare age (analysis of deviance, overall GLM: $F_{2,27} = 6.73$, $P = 0.004$; PZP treatment: estimate = 1.99, $t = 2.11$, $P = 0.04$; mare age: estimate = −0.13, $t = -1.92$, $P = 0.07$, see Fig. 1). Pregnancy and/or the presence of a foal seemed to have a marginal effect (see Section 3.3). Spearman rank correlations within treatment groups show that harem male age, group size, and the percentage of contracepted mares in the group had no effect on the number of group changes (see Table 4), suggesting that their influence was not substantial.

3.2. Number of groups visited

A separate generalized linear model shows that contracepted females visited significantly more groups than did control mares, again controlling for mare age (analysis of deviance, overall model: $F_{2,27} = 6.83$, $P = 0.004$; PZP treatment: estimate = 0.49, $t = 2.42$, $P = 0.02$; mare age: estimate = −0.06, $t = -2.39$, $P = 0.02$, see Fig. 2). As above, pregnancy and/or the presence of a foal seemed to have a marginal effect (see below). Spearman rank correlations within treatment groups show that harem male age, group size, and the percentage of contracepted mares in the group had no effect on the number of males consorted with (see Table 4).

3.3. Pregnancy and foal presence

Both control and contracepted mares that were pregnant and/or had foals tended to change groups less often and visit fewer groups than did other mares (Spearman rank correlation: controls, $\rho = -0.66$, $P = 0.08$; contracepts, $\rho = -0.41$, $P = 0.06$; also see Table 4). Given this trend, we investigated whether a mare's history of pregnancy or foaling (over multiple years) affected behavior. For each female, we calculated the proportion of years pregnant and the proportion of years with a foal from January 2000 to January 2005, considering only those years in which the mare was sexually mature. A generalized linear model shows that mares pregnant for a greater proportion of years changed groups less often (overall model: $F_{1,28} = 10.75$, $P = 0.003$; % years pregnant: estimate = −3.11, $t = -2.79$, $P = 0.01$, see Fig. 3A) and visited fewer groups (overall model: $F_{1,28} = 11.77$, $P = 0.002$; % years pregnant: estimate = −1.03, $t = -3.31$, $P = 0.003$, see Fig. 3B). Mare age did not contribute significant explanatory power to these models and was thus removed. The proportion of years that mares had foals from 2000 to 2005 did not affect mare behavior (Group changes, overall model: $F_{2,27} = 2.64$, $P = 0.09$; % years with foal: estimate = −1.96, $t = -1.16$, $P = 0.25$. Groups visited, overall model: $F_{2,27} = 4.63$, $P = 0.04$; % years with foal: estimate = −1.39, $t = -1.44$, $P = 0.16$).

3.4. Reproductive interest

Contracepted mares received and exhibited more reproductive interest (see Section 2.5) than did control mares (analysis of deviance, overall GLM: $F_{2,27} = 6.46$, $P = 0.005$; PZP treatment: estimate = 2.04, $t = 2.03$, $P = 0.05$; mare age: estimate = −0.13, $t = -1.91$, $P = 0.07$, see Fig. 4). Spearman rank correlations within treatment groups show that harem male age, group size, the presence of a foal, and the percentage of contracepted mares in the group had no effect on the occurrence of reproductive

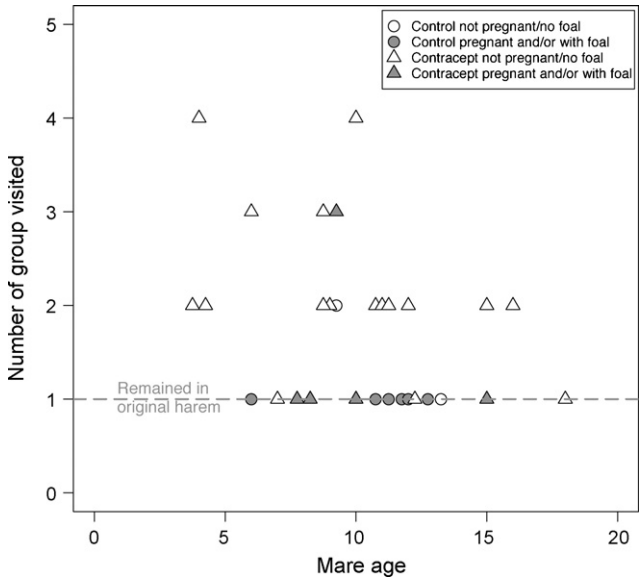

Fig. 2. Number of different groups visited during the study period by mare age for control ($n = 8$) and contracepted mares ($n = 22$). Even when controlling for the effect of age, contracepted mares visit more groups than do controls. Individuals on the dotted line did not change groups during the study. Filled symbols represent mares that were either pregnant or nursing a foal at the time of the study. In the events of ties, mare age has been jittered by 0.2 years to allow clear visualization of every individual.

interest (see Table 4). Pregnancy may have had a marginal effect on the reproductive interest received by control mares (Spearman rank correlation: $\rho = -0.66$, $P = 0.08$). This result is not conclusive however, since only one non-pregnant control mare received any reproductive interest. Pregnancy had no effect on the reproductive interest received or initiated by contracepted mares (Spearman rank correlation: $\rho = -0.12$, $P = 0.58$).

4. Discussion

According to past research, contraception with PZP has little to no effect on the behavior of wild horses (Kirkpatrick et al., 1996, 1997; Powell and Monfort, 2001). The results of this study refute that assertion. Much of the aforementioned research has been based on a single island population, all studies have been conducted

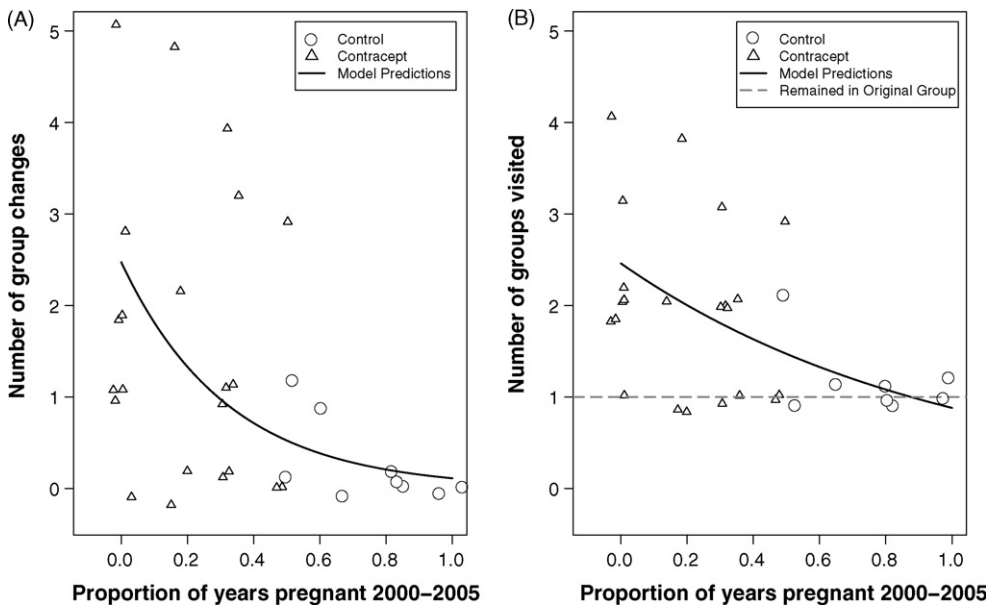

Fig. 3. Number of group changes (A) and groups visited (B) by the proportion of years pregnant from January 2000 to January 2005. Lines show that according to the generalized linear model of the data (see Section 3.3), the number of group changes and groups visited decrease with the proportion of years mares are pregnant. Points have been jittered to allow clear visualization of every individual.

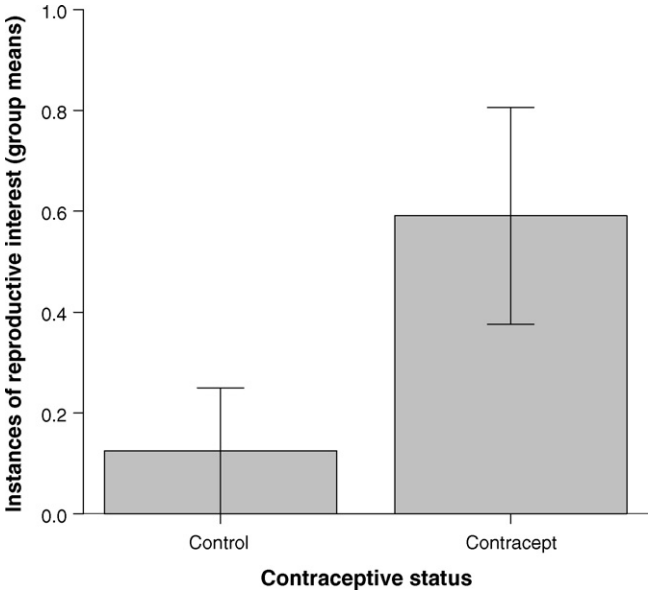

Fig. 4. Instances of reproductive interest during the study period by PZP treatment (means ± S.E.). Contracepted mares exhibit and receive more reproductive interest than do control mares.

solely during the breeding season, and no study has had adequate controls against which to compare PZP-treated females (Kirkpatrick et al., 1997; Powell, 1999). Here, we studied horses during the non-breeding season on Shackleford Banks, North Carolina, making use of animals that had never received contraception as controls. In our study, PZP treatment increased the number of group changes, the number of different groups visited, and the occurrence of reproductive interest, both received and initiated by females. In addition, our results show that even 10 months after PZP inoculation, when anti-PZP antibody titers are likely low, the indirect behavioral effects on recipient animals remain strong. The potential implications of these results for feral horse management are of substantial importance and need to be investigated further.

4.1. Fidelity to the harem male and reproductive interest

Contracepted mares are more likely to switch harem groups and visit more groups than are control mares. Decreases in mare fidelity to the harem male have debilitating consequences for harem stability (see Section 1). Resident females are often disturbed by the addition of new mares, especially if they are strangers (Monard and Duncan, 1996; Parker, 2001), and will become increasingly aggressive in their presence (Rutberg, 1990; Monard and Duncan, 1996). In addition, frequent changes to a harem's composition are likely to prohibit the establishment of a stable female dominance hierarchy, which is paramount to maintaining social cohesion among mares and overall group stability (Berger, 1977; Houpt and Wolski, 1980; Heitor et al., 2006). Moreover, the instability caused by these switching females may adversely affect the resident females' relationship with the harem male, reducing group cohesion even further. Because contracepted females do not simply switch repeatedly between two well-known groups, but rather interact with several different groups, these detrimental effects of harem instability may be felt throughout the entire population.

Contracepted mares both receive and initiate more instances of reproductive interest than do control mares. Reproductive behavior is energetically costly (Galimberti et al., 2000). Repeated bouts of male harassment have been shown to reduce total time foraging in equid species (Rubenstein, 1986; Sundaresan et al., 2007). The relative cost of such behaviors may be especially high during the post-breeding season when resources are scarce (Stevens, 1990). In addition, the costs of this behavior may outweigh the potential benefits, i.e. increased reproductive success. Gestation in wild horses lasts approximately 11–12 months (Asa, 2002). Offspring conceived during the winter months are therefore subject to higher mortality due to the cold temperatures and poor quality forage available at birth.

The differences we observed in harem fidelity and reproductive behavior may result from prolonged estrous cycling into the post-breeding season in response to repeated failures to conceive. This hypothesis has been proposed to explain reproductive behavior during the post-breeding season in both PZP-treated elk (Heilmann et al., 1998) and white-tailed deer (McShea et al., 1997). In equids, reproductive behaviors including copulation, mounting, clitoral winking, and tail raising occur most frequently during estrous when the mare is nearing ovulation (Asa et al., 1979). Additionally, Asa et al. (1979) have shown that mare approaches to, and follows of the harem male are excellent predictors of the transition between estrous and diestrous. We propose that group changes may reflect a similar pattern, with PZP-treated mares approaching non-harem males more frequently during prolonged estrous cycling.

Extended periods of estrous, while relatively rare, have been documented in equids. Tropical species, for example, are less strictly seasonal, with some reproducing throughout the year (Grubb, 1981; Churcher, 1993). In addition, substantial variability in the cycling schedules and receptivity of individual mares (Asa et al., 1979), and the performance of estrous behavior and copulatory activities during the non-breeding season (Asa et al., 1980) have been documented in temperate species. Since the implementation of contraception, at least one winter birth, and therefore winter copulation, has occurred on Shackleford Banks (Susan Stuska, National Park Service, Cape Lookout National Seashore, personal communication). These variations in receptivity, ovulatory schedules, and foaling suggest that the seasonality of reproductive behaviors in *E. caballus* females has the potential to be quite plastic. As contracepted animals have experienced a significant alteration to their physiological state, extended cycling is even more feasible. Future work on Shackleford will test for additional estrous periods in PZP-treated mares by assaying total estrogens and progestins in fecal samples (Asa et al., 2001) during the fall and winter months.

Alternatively, mares may perceive the failure to conceive as a problem with the harem male. This perception alone may be sufficient to cause the observed differences in behavior, regardless of differential estrous cycling. Mares that did not conceive during the prior summer may then switch groups more often during the winter in an effort to prepare for the upcoming breeding season. Such group changes are likely to be less costly in the post-breeding season, as the spacing between band members increases and male herding and aggression decline during this period (Stevens, 1990). This seasonal decrease in harem male attentiveness may have contributed to the observed numbers of group changes and groups visited during this study. Given the strong relationship between contraceptive status and mare fidelity, however, it is unlikely that season is the sole cause of mare behavior. Still, additional study during the breeding season (April–August) is recommended to assess whether the changes in mare behavior result from an interaction between season and contraceptive status.

4.2. The effects of pregnancy

Mare movement between groups is normally rare (see Sections 1 and 2.2). The results of this study strongly suggest that pregnancy and, possibly lactation, are important components to that stability. Regardless of contraception status, pregnant and/or nursing females tend to change groups less often, and over time, mares with a greater proportion of years pregnant are less likely to change groups. These decreases in pregnancy (and possibly lactation) may be the mechanism by which PZP treatment increases the propensity to change groups.

Additionally, decreased pregnancy and increased group switching have the potential to feedback on each other, resulting in even lower overall stability. Increased group switching has the potential to decrease mare fertility via male harassment. The more moves females make, the more male harassment they tend to receive (Rubenstein and Nuñez, 2008). Such harassment can lower female reproductive success, as measured by the number of offspring surviving to independence (Rubenstein, 1986; Rubenstein and Nuñez, 2008). As evidenced by our results, such decreases in pregnancy increase the likelihood that females will change groups. These cascading effects have the potential to adversely affect entire populations (see Section 1) and are worth serious consideration when making management decisions.

4.3. Management implications

If feral horse populations are to be maintained in the most natural state possible, we suggest that a small population of mares never be inoculated with PZP. Although the control mares' effects on group structure on Shackleford Banks have yet to be fully determined, the results clearly demonstrate that they are more faithful to their harem males than are contracepted mares. Mare fidelity to the harem male is important to overall harem stability. As such, it is likely, especially when one considers the sociality of these animals, that control females afford a stabilizing influence not only to individual harems, but also to the entire herd.

We also suggest that the subset of animals designated for control status be more fully representative of female demography. For example, at the time of this study, all control mares on Shackleford were between 8 and 15 years of age (see Figs. 1 and 2). This distribution does not currently afford for the behavior of very young or very old animals. Time can always provide for older individuals, but younger controls are needed to approximate the female population's age structure and natural behavior. For instance, contracepted, dispersing, subadult females likely move between more harems than they would naturally. Therefore, this demographic may adversely affect the entire herd's stability level. Allowing some portion of these animals to disperse, join harems, and reproduce normally could help to stabilize population behavior and structure.

Reevaluating the scheduling of PZP administration may also prove beneficial. An inoculation schedule that allows mares to conceive and give birth may help to ameliorate the most deleterious behavioral effects of PZP. Inoculating females every second and even every third year significantly reduces pregnancy in Shackleford Banks horses (see Section 2.3) and other wild populations (Turner et al., 2007). Contraception on such schedules will keep pregnancy rates low, but will allow for the birth of a manageable number of individuals which, according to this study, have a stabilizing influence on female behavior. Additional research is needed to determine if such contraception schedules will limit population size effectively. If so, this could provide a cost-effective means of controlling animal numbers while maintaining their natural behavior.

The broader management implications of this research are substantial. PZP has been reported to have little to no effect on the behavior of wild horses, specifically, but also wild ungulates in general (Kirkpatrick et al., 1996, 1997; Powell, 1999). The results of this study refute those claims, and in fact, highlight the pitfalls of generalizing recipient and group responses to PZP from one population to another. Moreover, these data emphasize the necessity of

study during all stages of the animals' reproductive cycle to determine the effects of contraception on social behavior. Managers of feral horse and other ungulate populations must use caution in basing contraceptive decisions upon data collected only during the breeding season and from a few, separate populations. Regardless of the ecological and sociological similarities between sites, subtle differences in factors such as demography, ready access to resources, and, as this paper suggests, seasonality, may prove important. Among different populations, such factors may shape the physiological and behavioral effects of PZP in unique and potentially unpredictable ways. Finally the trade-offs between managing population size and maintaining animal health and well-being are worth serious consideration. For social species such as the horse, such consideration is crucial if managers are to maintain behaviorally functional populations.

5. Conclusion

In this study, mares contracepted with PZP behaved differently from control mares. They changed groups more often, visited more groups, and both exhibited and initiated more reproductive interest. These differences in behavior have the potential to adversely affect the stability not only of individual harems, but the entire population on Shackleford Banks, North Carolina. Additional study into the mechanism behind these behavioral differences and into the scheduling of PZP administration will help ameliorate these effects.

Acknowledgements

We first acknowledge Dr. Sue Stuska of the Cape Lookout National Seashore, National Park Service, for her data on the Shackleford herd and her assistance with an early version of the manuscript. We also thank M. Hau, S.J. Hauck, C.D. Nadell, I.R. Fischhoff, S.R. Sundaresan, and two anonymous reviewers for their comments and contributions. We would like to acknowledge D. and T. Schooley for their support. This study was funded by the Foundation for Shackleford Horses, Inc. and the National Science Foundation (IIS-0705311 to D. I. Rubenstein).

Due to the extirpation of their natural predators, feral horse populations have expanded across the United States, necessitating their management. Contraception of females (mares) with porcine zona pellucida (PZP) is a popular option; however, effects to physiology and behavior can be substantial. On Shackleford Banks, North Carolina, USA, treated mares have exhibited cycling during the non-breeding season and demonstrated decreased fidelity to the band stallion, but PZP's long-term effects on mare physiology and behavior remain largely unexplored. After the contraception program was suspended in this population, we examined how prior exposure to varying levels of PZP treatment impacted (1) foaling probability and foaling dates (a proxy for ovulatory cycling) from 2009 to 2014 and (2) mare fidelity to the band stallion and reproductive behavior during 2013 and 2015. Additionally, we evaluated the effects of time since the mares' last treatment on these factors. Mares receiving any level of prior PZP treatment were less likely to foal than were untreated mares. Among mares that received 1–3 PZP applications, foaling probability increased with time since last treatment before declining, at ~6 years post-treatment. Mares that received 4+ applications did not exhibit a significant increase in foaling probability with time since last treatment. Moreover, previously treated mares continued to conceive later than did untreated mares. Finally, mares previously receiving 4+ treatments changed groups more often than did untreated mares, though reproductive behavior did not differ with contraception history. Our results suggest that although PZP-induced subfertility and its associated behavioral effects can persist after the cessation of treatment, these effects can be ameliorated for some factors with less intense treatment. Careful consideration to the frequency of PZP treatment is important to maintaining more naturally functioning populations; the ability to manage populations adaptively may be compromised if females are kept subfertile for extended periods of time.

Key words: Contraception, feral horse, immunocontraception, management, prolonged subfertility

Introduction

The extirpation of predator species in North America has precipitated the expansion of free-ranging ungulate populations (Eberhardt *et al.*, 1982; McCullough *et al.*, 1997), escalating human–wildlife conflict (Conover, 1995). Perhaps the most well-known example is that of increasing white-tailed deer (*Odocoileus virginianus*) populations across the United States.

These deer damage crops, feast on suburban ornamentals, spread disease, and are involved in both vehicle and train collisions (Conover, 1997), resulting in human injury, the loss of human life and costs amounting to more than 1 billion USD of property damage per year (Mastro *et al.*, 2008). Elk (*Cervus canadensis*) populations have also increased in some areas, with severe ecological impacts. In the Yellowstone ecosystem, unfettered elk populations have been associated with an ecological cascade of diverse effects including a reduction in available forage (Ripple and Beschta, 2003) and subsequent decreases in various vertebrate species including grizzly bears (*Ursus ortcos*) (Ripple *et al.*, 2014) and various songbird species, including the Common Yellowthroat (*Geothlypis trichas*), Lincoln's sparrow (*Melospiza lincolnii*), and Warbling Vireo (*Vireo gilvus*) (Baril *et al.*, 2011). Feral horse populations have also greatly expanded across the United Sates. In the west, feral horses and livestock compete for forage and water (BLM, 2011), while in the east, feral horses can negatively impact barrier island plant (Furbish, 1980) and estuarine (Levin *et al.*, 2002) communities. Managers have few options with which to control these populations (e.g. culls, removals), and fewer still that are acceptable to the public (Hobbs *et al.*, 2000; Porton, 2005). Consequently, contraceptive management has become increasingly popular (Hobbs *et al.*, 2000; Porton, 2005).

A commonly used contraceptive in female ungulates, porcine zona pellucida (PZP), stimulates the production of antibodies that bind sperm receptors on the egg's surface, thereby blocking fertilization while still allowing ovulation and the associated cycles of sex hormones (Sacco, 1977). Because PZP does not affect hormone levels directly, it was previously suggested that PZP treatment did not significantly affect recipient behavior or physiology (Kirkpatrick *et al.*, 1996, 1997; Powell and Monfort, 2001; Turner *et al.*, 1997). However, research on white-tailed deer, elk and feral horses has shown that there can be unintended effects on reproductive behavior (McShea *et al.*, 1997; Heilmann *et al.*, 1998; Nuñez *et al.*, 2009; Madosky *et al.*, 2010; Ransom *et al.*, 2010) and physiology (Nuñez *et al.*, 2010; Ransom *et al.*, 2013); in feral horses, these effects can be exacerbated in mares receiving higher numbers of total and/or consecutive PZP applications (Madosky *et al.*, 2010; Nuñez *et al.*, 2010). Briefly, studies investigating the response of free-ranging elk and white-tailed deer to PZP treatment indicate that recipient females extend reproductive behaviors into the post-breeding season (McShea *et al.*, 1997; Heilmann *et al.*, 1998). Authors suggest that in response to repeated unsuccessful mating attempts, females continue cycling in an attempt to gain additional reproductive opportunities (McShea *et al.*, 1997; Heilmann *et al.*, 1998). In feral horses, PZP-induced subfertility was also correlated with reproductive cycling in the non-breeding season (Nuñez *et al.*, 2010; Ransom *et al.*, 2013), increases in the amount of reproductive behavior directed towards mares by band stallions (Ransom *et al.*, 2010), and an increase in group transfer and reproductive behavior by mares (Nuñez *et al.*, 2009; Madosky *et al.*, 2010). Few studies have documented how permanent such side-effects may be (Kirkpatrick, 1995; Madosky *et al.*, 2010; Ransom *et al.*, 2013) and to our knowledge, none have investigated whether the intensity of PZP management can influence female physiology and behavior after the suspension of treatment in managed populations.

Here, we examine the rate at which mares on Shackleford Banks, North Carolina, USA are able to return to their physiological and behavioral baselines after varying levels of contraception management and with increasing time since treatment. Specifically, we monitored per capita births and the effects of varying levels of PZP treatment on the likelihood of conception in individual mares, and foal birth dates from 2009 to 2014, during which time the contraception program was largely suspended. In addition, we examined mare group transfer and reproductive behavior in the summers of 2013 and 2015 to determine whether PZP-induced subfertility had any long-term behavioral effects on previously treated mares. This information is critical to understanding the full effects of long-term subfertility on individuals and populations, and will be integral to designing best-management practices for PZP contraception.

Methods

Study area

Shackleford Banks is a barrier island ~3 km off the coast of North Carolina, USA. The island measures ~15 km in length, and varies between 0.5 and 3 km in width. The Shackleford horses are of Spanish origin and were likely first introduced ~400 years ago (Conant *et al.*, 2012). Currently, the population is co-managed by the National Park Service and the Foundation for Shackleford Horses (National Park Service, 2004). In 1997, federal law was instituted mandating the maintenance of at least 100–110 horses on Shackleford Banks (United States Congress, 1997). The National Park Service and the Foundation for Shackelford Horses limit the population to ~120 individuals, to reduce damage to the ecosystem.

Study subjects

The reproductive units of Shackleford horses are typical of feral equids, consisting of coherent bands of one, or sometimes two or three stallion(s), with one to several mares and their offspring (Rubenstein, 1981). Double-male bands are present, though they make up a small portion of the Shackleford population (5–10% of bands during the course of this study). In addition, differences in the degree of band territoriality have been associated with the island's varying ecology, making the region in which animals reside a reliable proxy for social variation in this population (Rubenstein, 1981). Though the bands are predominantly non-territorial, individual bands are spatially distinct from one another (Feist and McCullough, 1976; Rubenstein, 1981, 1986). Interactions that occur between different bands typically involve younger individuals engaging in exploration and/or play, the dispersal of sub-adult individuals

(both male and female), male–male assessments and/or contests, and the transfer of mares from one band to another (personal observation). Historically, band membership has been long lasting with most changes involving the dispersal of immature individuals. Band stallions sometimes fought to acquire mares from other groups, but stallions almost always retained their mares (Feist and McCullough, 1976; Rubenstein, 1981). More recently, PZP-induced subfertility has been associated with decreases in mare fidelity to the band stallion, increases in mare reproductive behavior, and mare cycling in what is typically the non-breeding season for these mares (Nuñez *et al.*, 2009, 2010; Madosky *et al.*, 2010).

PZP contraception

The National Park Service began the application of PZP for the purposes of immunocontraception in January 2000. In 2009, the program was provisionally suspended because the population was deemed stable (Mason, 2017). The contraception of all but five previously treated mares was halted, and all previously untreated mares of reproductive age were given one dose and booster of PZP. All treatments were administered by the National Park Service from late February through April each year. Each injection contained 100 micrograms of PZP plus an adjuvant (mixed at the darting site). Initial doses contained Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem #344 289). All subsequent boosters contained Freund's Incomplete Adjuvant (Sigma #F5506).

For the animals in this study, PZP deterred pregnancy in 99.91% of cases when administered during the same year (Stuska, 2014). These values are similar to those published for Assateague horses, in which PZP deterred pregnancy in 94% of cases (Turner *et al.*, 1997). Over the course of the contraception program, ~19% of pregnancies were due to contraception failures. The contraception histories for the mares considered in this study are displayed in Table S1.

Pregnancy and foaling

Fecal samples are collected by the National Park Service in January of each year. All pregnancy testing is completed by enzyme immunoassay of fecal material at the Science and Conservation Center at ZooMontana in Billings, Montana. Using the methods of Kirkpatrick *et al.* (1991), water extracts of fecal samples are assayed for estrone conjugates and nonspecific progesterone metabolites. In addition, the National Park Service has tracked the foaling records, including foal birth dates, for each mare since 2000 (Stuska, 2014). These data were used to supplement assay results.

Behavioral and demographic sampling

Behavioral and demographic sampling was conducted primarily by two observers (C. Alvarez in 2013 and H. Carr in 2015) and was supplemented with data from three additional observers (B. Streater, 2013; M.A.F. Kent and K.E. Monroe, 2015). All observers were trained by C.M.V. Nuñez. We observed behavior in the majority of reproductive mares (aged 4 years and older) present during the study. We recorded group changing and reproductive behavior for 73% (43/59) and 95% (55/58) of mares in 2013 and 2015, respectively. The number of bands we observed comprised 68% (13/19) and 95% (18/19) of bands on the island in 2013 and 2015. Comparable to previous studies (Nuñez *et al.*, 2009; Ransom *et al.*, 2010), we observed mares for 7 weeks each year from mid-June to late August, totaling 350.15 hours of observation, averaging 3.13 h per mare (range = 1–6.05, SE ± 0.12). Horses were identified individually by color, sex, age, physical condition and other distinguishing markings including freeze brands. Ages are known from long-term records for the identified horses of Shackleford Banks (Nuñez, 2000).

We located each band an average of 0.87 times each week (range = 0.28–1.83, SE ± 0.03). We recorded its GPS location and composition, paying particular attention to the presence or absence of females. Group transfers were recorded if a mare was (a) not in the band she had been seen with previously, or (b) in a different band than she had been seen with previously. Mares did not need to remain with the 'new' group for a minimum length of time for the behavior to be considered a group transfer since even short-lived changes can affect band stability (Madosky *et al.*, 2010) and mare stress physiology (Nunez *et al.*, 2014). We remained with each group for a minimum of 30 min to ensure that individuals recorded as absent were not actually nearby, but out of our sight; when compared to 60-min field observations, 30 min ensured accurate data collection and allowed for larger sample sizes (Nuñez *et al.* 2010). We rarely witnessed mare transfer activity directly ($n = 1$); therefore, mare absence from a band was an important metric with which we measured the number of mare transfers between groups. On average, transfer behavior was confirmed by the mares' presence in new bands within 12.32 days of mare absence (range = 2–31, SE ± 1.44).

All incidences of reproductive interest (including copulation, mounting, genital sniffing, and rump rubbing) directed to and initiated by mares were recorded *ad libitum* during scan sampling (Altmann, 1974) as in Nuñez *et al.* (2009).

Statistical analyses

We analyzed data in R version 3.1.1. We used a linear mixed effects model (nlme package; Pinheiro and Bates, 2000) to determine whether the number of births had increased after the suspension of the contraception program ($n = 157$ total births; 112 births during the program; 45 births after program suspension). All births, regardless of mare age and treatment status at the time of foaling, were included in this analysis. Models included year as a random effect and the following fixed effects: mare treatment (previously treated/untreated), timing (during/after the contraception program), the interaction between mare treatment regime and timing, and a function allowing different variances across groups. We analyzed our data in both raw and arcsine-square root

transformed formats as per Ahrens *et al.* (1990). The arcsine-square root transformation has been shown to correct deficiencies in the normality of error terms, homogeneity of variance, and additivity of percentage data (Ahrens *et al.*, 1990).

To determine whether a mare's contraception history (number of total treatments received) affected her ability to foal in the years following contraception suspension, we used a generalized linear mixed model with a penalized quasi-likelihood (PQL) function (package MASS (Venables and Ripley, 2002)). The GLMM accounts for intra-subject correlation and individual heterogeneity (Jang and Lim, 2006) while the PQL function has proven reliable for the analysis of independent counts (Dean *et al.*, 2004). Models included mare identity as a random effect and the following fixed effects: linear and second-order polynomial functions of mare age (to account for both linear and non-linear effects on the likelihood of foaling), mare contraception history (0 treatments/1–3 treatments/4+ treatments (Kirkpatrick and Turner, 2002), n = 68 mares, Table S1), and island region.

To test for differences in mares' average foaling date with contraception history, we used linear mixed effects models, including a function allowing different variances across groups, and the following fixed effects: linear and second-order polynomial functions of mare age, mare contraception history (0 treatments/1–3 treatments/4+ treatments), and island region. We considered 37 births from 24 mares for this analysis (see Table S1).

To examine mare group changing and reproductive behavior, we analyzed the number of group changes mares made and the number of instances of reproductive interest both initiated and received by mares (n = 59 mares) over two field seasons conducted in 2013 and 2015 (see Table S1). We used linear mixed effects models including mare as a random factor, and the following fixed effects: linear and second-order polynomial functions of mare age, mare contraception history (0 treatments/1–3 treatments/4+ treatments), and island region. All behavioral data were Poisson distributed and log-transformed for analysis.

Parameters were removed from models by backwards elimination if $P > 0.05$. For each analysis, final models were run including linear and second- order polynomial functions of time since last treatment; for this analysis, only mares receiving at least one PZP treatment were considered (see Table S1). Mares less than 4 years of age and the 5 individuals that received treatment between 2009 and 2014 were excluded from all analyses save our per capita birth analysis (see above). In addition, where applicable, models were run both with and without mares belonging to double-male bands. Excluding these mares did not significantly change our findings; therefore, the models presented here include mares belonging to both single- and double-male bands. Where appropriate, we selected best fit models using Akaike's Information Criterion adjusted for small sample size (AICc) (Burnham and Anderson, 2002).

Results

Births

Not surprisingly, yearly per capita births were considerably lower for treated mares than for untreated mares during the contraception program (Linear Mixed Effects Model: mare treatment regime (previously treated); estimate = −0.41, SE = 0.08, t = −5.30, P = 0.0003). This pattern did not change from 2009 to 2014 when the contraception program was largely suspended; previously contracepted mares continued to exhibit subfertility even after the cessation of treatment (Linear Mixed Effects Model: treatment group (previously treated) * timing (after contraception suspension); estimate = 0.07, SE = 0.13, t = 0.50, P = 0.62, Fig. 1). Results were similar with arcsine-square root transformed data (Ahrens *et al.*, 1990) (Linear Mixed Effects Model: mare treatment regime (previously treated); estimate = −0.46, SE = 0.10, t = −4.61, P = 0.0007; treatment group (previously treated) * timing (after contraception suspension); estimate = 0.13, SE = 0.17, t = 0.74, P = 0.50). AICc analysis suggested that models without a variance function were a better fit to the data (AICc without variance function = 5.97 (raw), 24.19 (arcsine transformed); AICc with variance function = 8.89 (raw), 28.20 (arcsine transformed)).

Contraception history and foaling after contraception suspension

Even while controlling for the effects of mare age (Generalized Linear Mixed Model, mare age: estimate = 0.59, SE = 0.27, t = 2.20, P = 0.03; mare age^2: estimate = −0.02, SE = 0.01, t = −2.18, P = 0.03), previously treated mares were less likely to give birth during the study period, regardless of the number of prior treatments received (Generalized Linear Mixed Model, number of treatments (1–3 treatments): estimate = −3.00, SE = 1.24, t = −2.40, P = 0.02; (4+ treatments): estimate = −4.19, SE = 1.27, t = −3.30 P = 0.001, Fig. 2). Island region had no effect on the probability of mare foaling (all $P > 0.20$). These results cannot be explained by inherent subfertility in mares slated for treatment; prior to contraceptive treatment, all mares exhibited equivalent fertility (Generalized Linear Mixed Model, treated vs. untreated: estimate = 0.36, SE = 0.43, t = 0.84, P = 0.41, Table S2).

In addition, we sought to determine whether time since last treatment impacted the probability of foaling in previously treated mares. We found that mares previously receiving 1–3 treatments exhibited an initial increase in foaling probability, followed by a subsequent decrease (Generalized Linear Mixed Model, time since last treatment: estimate = 2.03, SE = 0.43, t = 4.67, $P < 0.00001$; time since last treatment^2: estimate = −0.18, SE = 0.04, t = −4.07, P = 0.0001, Fig. 3A). Conversely, mares receiving 4+ treatments did not exhibit a discernable increase in foaling probability even after several post-treatment years (Generalized Linear Mixed Model, time since last

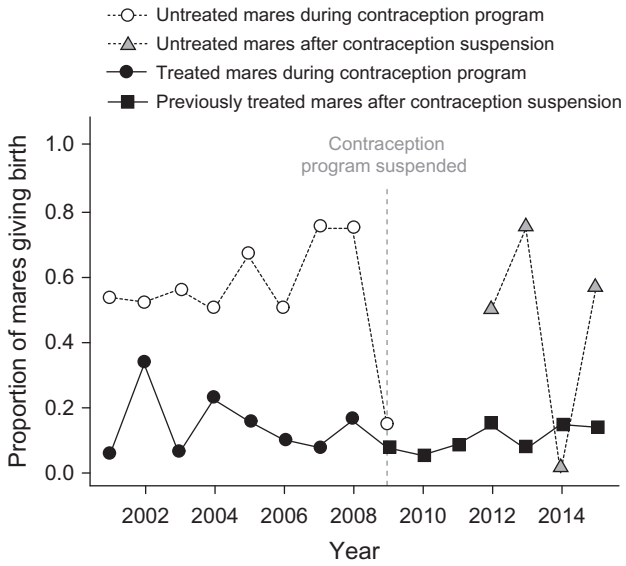

Figure 1: Proportion of mares giving birth in the years during and after contraception management. During the contraception program, treated mares (black circles) showed markedly lower birth rates than did untreated mares (open circles). In 2009, all untreated mares received PZP, leaving no untreated animals of reproductive age on the island in 2010 and 2011. Even after the suspension of treatment, previously treated mares (black squares) did not return to a level of fertility comparable to untreated mares before 2009 (open circles) or to younger, untreated animals that became reproductive between 2012 and 2015 (gray triangles).

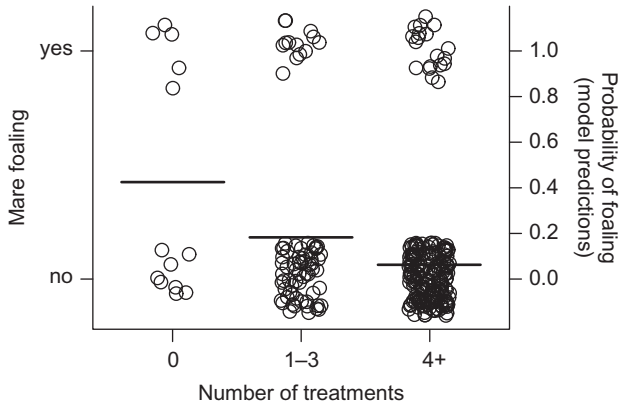

Figure 2: Probability of foaling and contraception treatment; circles represent individual births. Mares previously receiving any level of treatment were less likely to give birth than were untreated mares.

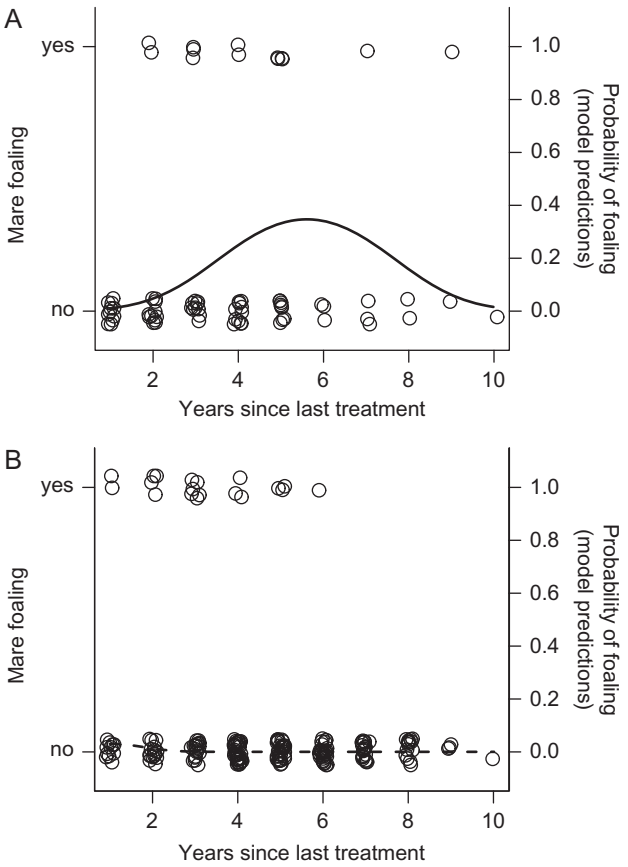

Figure 3: Probability of foaling after contraception suspension and mare treatment; circles represent individual births; solid and dashed lines indicate model predictions. Mares previously receiving 1–3 treatments (**A**) showed a gradual increase in foaling probability, peaking at ~6 years post-treatment, followed by a subsequent decrease. Mares previously receiving 4+ treatments (**B**) did not show a significant increase in foaling probability regardless of time since last treatment.

treatment * number of treatments (4+treatments): estimate = −0.79, SE = 0.25, t = −3.14, P = = 0.002, Fig. 3B).

Foaling date

Mares previously receiving any level of treatment gave birth later in the year than did untreated mares (Linear Mixed Effects Model, number of treatments (1–3 treatments): estimate = 2.29, SE = 0.78, t = 2.92, P < 0.00001; (4+ treatments): estimate = 3.50, SE = 0.90, t = 3.88, P < 0.0001, Fig. 4). Mares having received 1–3 treatments and 4+ treatments did not differ in their average foaling date (Tukey Honest Significant Difference Test: estimate = 1.21, SE = 0.87, z = 1.39, P = 0.34, Fig. 4). Island region and linear and second-order polynomial functions of both time since last treatment and mare age proved insignificant (all P-values > 0.08). Results suggested that models including a variance function were a better fit to the data (AICc with variance function = 155.56; AICc without variance function = 163.02).

Mare fidelity and reproductive behavior

Contraception history had a significant effect on mares' group changing behavior. Even after controlling for the effects of mare age (Linear Model: estimate = −0.04, SE = 0.01, t = −3.04, P = 0.004), mares that previously received 4+ contraceptive treatments changed groups more often than did

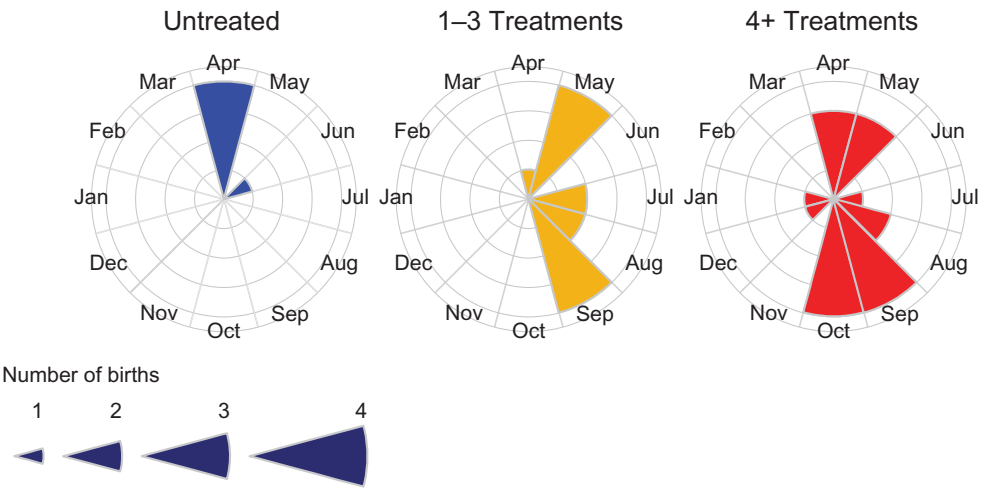

Figure 4: Average foaling date for untreated mares vs. previously treated mares. Mares previously receiving any level of treatment foaled later in the season than did untreated mares. Mares previously receiving 1–3 and 4+ treatments did not differ in their average foaling date.

untreated mares (Linear Model: estimate = 0.75, SE = 0.27, t = 2.80, P = 0.007, Fig. 5). Mares that previously received 1–3 treatments were equivalent to both untreated mares (Linear Model: estimate = 0.43, SE = 0.26, t = 1.66, P = 0.10, Fig. 5) and those receiving 4+ treatments (Tukey Honest Significant Difference Test: estimate = 0.32, SE = 0.15, z = 2.04, P = 0.10, Fig. 5). Island region, linear and second-order polynomial functions of time since last treatment, and second-order polynomial functions of mare age proved nonsignificant (all P-values > 0.08). Results suggested that models without variance functions were better fits to the data (AICc without variance function = 206.55; AICc with variance function = 207.62).

Contraception history did not affect mare reproductive behavior (Linear Mixed Effects Model: all P-values > 0.10). Results suggested that models without variance functions were better fits to the data (AICc without variance function = 131.49; AICc with variance function = 133.76). Island region, linear and second-order polynomial functions of both time since last treatment and mare age proved insignificant (all P-values > 0.07).

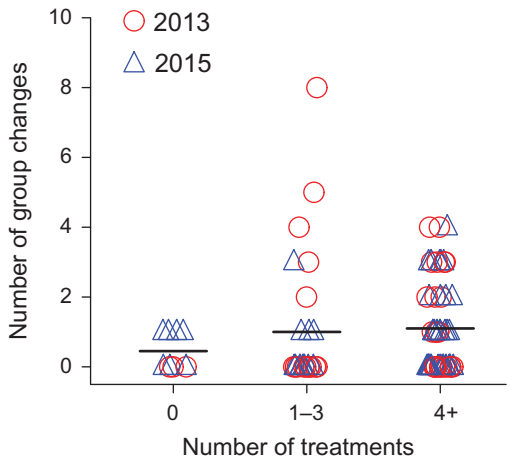

Figure 5: Number of group changes for untreated mares vs. previously treated mares in 2013 (red circles) and 2015 (blue triangles). Mares previously receiving 4+ contraceptive treatments made more group changes than did untreated mares. Mares previously receiving 1–3 treatments did not differ from untreated mares or those receiving 4+ treatments. Segmented lines indicate mean values.

Discussion

We investigated the likelihood that previously treated mares on Shackleford Banks, North Carolina USA, would return to baseline fertility, foaling dates and behavior after the cessation of contraceptive treatment with PZP. Mares received varying numbers of total PZP inoculations, allowing us to more closely investigate the effects of treatment intensity on mare fertility and subsequent effects to mare behavior. This contraceptive has been administered to several mammalian species including, white-tailed deer (*O. virginianus*) (Miller *et al.*, 1999), elk (*C. canadensis*) (Shideler *et al.*, 2001), black bears (*Ursus americanus*) (Lane *et al.*, 2007), bison (*Bison bison*) (Duncan *et al.*, 2013), and African elephants (*Loxodonta africana*) (Fayrer-Hosken *et al.*, 2000); these species have evolved an array of reproductive behaviors and social systems, which are vital to their survival and well-being. A more complete understanding of PZP contraception's potential long-term effects on recipient physiology and behavior is, therefore, of utmost importance if we are to manage and conserve species in the most effective and ethical manner possible. Feral horses have evolved a complex social structure, the maintenance of which is paramount to the overall health of group members

(Kaseda *et al.*, 1995; Linklater *et al.*, 1999). Careful study of mare physiological and behavioral responses to long-term contraception management can serve as a model for other social species for which the formation and maintenance of social bonds is necessary for survival.

Even when controlling for the effects of mare age on fertility, previously treated mares were less likely to give birth than were untreated mares during the study period. Moreover, the number of treatments that mares previously received affected the likelihood that mares would return to fertility after treatment suspension. Regardless of age, mares that previously received 1–3 treatments were more likely to return to fertility than were mares that received 4+ treatments. These results cannot be explained by inherent subfertility in mares slated for treatment: prior to contraceptive treatment, all mares exhibited equivalent fertility. In addition, time since last treatment was an important predictor of foaling probability for mares that received 1–3 treatments, but not 4+ treatments. Mares receiving 4+ treatments remained largely subfertile even after several post-treatment years. Conversely, mares that received fewer treatments exhibited a gradual increase in foaling probability until ~6 years post-treatment, after which, foaling probability decreased. This decrease was likely due to the typical age-specific reproduction in feral mares (Garrott *et al.*, 1991; Carnevale *et al.*, 1994). Feral mares more than 15 years of age exhibit decreased foaling rates (Garrott *et al.*, 1991) and pony mares at or older than 20 years of age are less likely to ovulate at regular intervals (Carnevale *et al.*, 1994). In this study, mares that previously received 1–3 treatments were, on average, 12.42 years of age in 2009, when they received their last inoculation. At 6 years post-treatment, these mares would have been old enough to exhibit the reproductive senescence typical of the species. However, the fact that mares receiving fewer treatments were able to return to fertility while mares receiving more treatments were not is telling; these results demonstrate that mares can retain more natural physiological functioning with less intense contraceptive treatment.

Foaling date was also was also affected by contraception history. Mares previously receiving any level of treatment exhibited later foaling dates than did untreated mares. The persistence of this effect after treatment suspension may be related to increases in mare condition commonly associated with contraception treatment (Turner and Kirkpatrick, 2002). In domestic mares, increased body condition or 'fatness' has been associated with higher circulating levels of leptin (Fitzgerald and Bates, 2000). Mares exhibiting higher circulating leptin were more likely to exhibit reproductive activity during the winter months, suggesting that leptin may modify mare reproductive response to inhibitory photoperiod (Fitzgerald and McManus, 2000). Treated Shackleford mares exhibit the increased physical condition typically demonstrated by contracepted mares (Nuñez *et al.*, 2010). It may be, therefore, that increases in body condition and concomitant increases in circulating leptin have contributed to prolonged effects on mare cycling even after contraception treatment suspension.

Potential effects of late birth dates to foal survival are difficult to assess on Shackleford Banks. In the past, animals perceived to be in poor condition have been removed from the island and adopted off, complicating the analysis of foal survival. As such, we cannot look to our data with confidence to determine if foal survival is compromised by later birth dates. Notably, foal survival is affected by birth date in western feral horses (Ransom *et al.*, 2013). In these populations, the probability of foal survival decreases as parturition date moves further away from the summer peak in resources (Ransom *et al.*, 2013), though these animals are undoubtedly subject to harsher environmental conditions than are Shackleford horses.

Contraception history also had an effect on mare fidelity to the band stallion. Mares that previously received 4+ treatments changed groups more frequently than did untreated mares. Mares that previously received 1–3 treatments did not differ from either untreated mares or those that previously received 4+ treatments. Combined with our findings on fertility, these results demonstrate that unintended side-effects of PZP treatment have the potential to become long term, i.e. they persist with continued subfertility, even if treatment, per se, has ended. However, our results also show that with less frequent treatment, some of these effects can be ameliorated with time, enabling more flexible population management.

Interestingly, our mare fidelity results are similar to those demonstrated in previous studies conducted during the contraception program (Nuñez *et al.*, 2009; Madosky *et al.*, 2010). In those studies, treated mares transferred groups more often than did untreated mares. These behaviors were linked to the presence of a foal (Nuñez *et al.*, 2009): mares with foals, regardless of treatment status, tended to change groups less often, indicating that mares, having successfully reproduced with a stallion, were more likely to remain with said stallion and/or, that mares with foals required a more stable environment in which to raise offspring. In the present study, we found that mares that had previously received 4+ treatments changed groups more often than did untreated mares. The lower foaling probability exhibited by these mares, even after several post-treatment years, is likely the proximate mechanism behind this behavior, rather than PZP treatment, per se. These results show that changes in mare behavior formerly associated with active contraception treatment have persisted with prolonged subfertility, lending additional support to the assertion that such unintended side-effects can persist, even after active contraceptive treatment has ended. Moreover, such behavior represents a significant decrease in mare fidelity by previously treated mares. Prior to the contraception program, Rubenstein (1981) reported that across the entire island, only 10.8% of mares transferred groups, indicating high band fidelity by females. This is in stark contrast to

what was found in our previous study, during which 53% of mares changed groups (Nuñez *et al.*, 2009), in the 2 years of the Madosky study during which 66% and 73% of mares changed groups in 2007 and 2008, respectively (Madosky *et al.*, 2010), and in our current study, during which 42% and 49% of mares changed groups, in 2013 and 2015, respectively.

Contrary to our results from an earlier study (Nuñez *et al.*, 2009), previously treated mares did not engage in more reproductive behavior than did untreated mares. The disparity in our results may be due to differences in the timing of the two studies: the current study was conducted during the breeding season, when breeding behavior is relatively frequent amongst reproductive individuals; our previous study was conducted during the non-breeding season when breeding behavior is more variable. It is worth noting that in the Madosky study (2011), also conducted during the breeding season, Shackleford mares treated with PZP received more harassment from band stallions than did untreated mares. Taken together, these results could suggest that the amount of reproductive behavior in previously treated mares has returned to baseline levels. However, it is not clear whether 'harassment' (Madosky, 2011) is indicative of reproductive behaviors as we have defined them here. As such, our ability to compare results across time is limited.

Our results demonstrate the potential for long-term physiological and behavioral effects to PZP-treated individuals and that these effects can persist with continued subfertility, even after the cessation of treatment. However, our results also suggest that with less frequent treatment, these effects can be ameliorated with time, enabling more flexible population management.

Our results also contrast with claims that PZP is 'completely reversible'; claims upon which feral horse management decisions have been defended (BLM, 2010). Similar long-term subfertility with intense PZP treatment has been found in feral horse populations living on Assateague Island National Seashore, MD (Kirkpatrick and Turner, 2002), in the closely related, but critically endangered Przewalski's horse (*E. ferus przewalskii*) (Feh, 2012), and in feral horses living in the western United States (CO and WY) (Ransom *et al.*, 2013), indicating that these effects are not limited to specific sites or populations, but are pervasive amongst equids. In the Assateague study, nearly 70% of mares receiving three consecutive PZP treatments failed to demonstrate fertility for 1–4 years post-treatment (Kirkpatrick and Turner, 2002). In the Przewalski's horse, only 45% of 20 mares that had been treated with PZP for three consecutive years demonstrated fertility; those that did foal, did not do so until 6.7 years after their last treatment, on average. Moreover, four of nine females receiving only one treatment (one primer injection and one booster injection) did not produce offspring for 4+ years post-treatment (Feh, 2012). Though the mechanism behind the prolonged subfertility in Przewalski's mares is unknown, some of the Assateague mares demonstrated ovulatory failure (Kirkpatrick *et al.*, 1992; Kirkpatrick and Turner, 2002). In western feral horse populations, previously treated mares were less likely to give birth and gave birth later into the calendar year for up to six post-treatment years, again demonstrating the potential for long-term side effects of prolonged, PZP-induced subfertility (Ransom *et al.*, 2013).

The present study demonstrates that the intensity of treatment is also important: mares previously receiving 4+ treatments are less likely to return to fertility and exhibit decreased fidelity to the band stallion. Mares receiving any level of treatment are more likely to give birth later into the calendar year. Conversely, mares receiving 1–3 treatments are more likely to return to fertility and demonstrate behavior more typical of the species (Feist and McCullough, 1976; Rubenstein, 1981; Berger, 1986). These results largely support our previous assertion that more natural physiology and behavior can be maintained in feral horses with less aggressive contraception schedules (Nuñez *et al.*, 2009).

Results similar to those demonstrated in this study have been documented in several captive species (Penfold *et al.*, 2014). A retrospective analysis, combined with published literature and reliable anecdotal reports, demonstrated that extended periods of infertility in females can induce reproductive changes that negatively impact future fertility. This was the case for individuals treated with a contraceptive agent and also for those left untreated, but separated from male counterparts (Penfold *et al.*, 2014). The mechanisms underlying these impacts are varied, but include endometrial hyperplasia [(Asian (*Elephas maximus*) and African elephants, Seba's bats (*Carollia perspicillata*), felids], uterine insufficiencies [wildebeest (*Connochaetes*)], asymmetric reproductive aging [white rhinoceros (*Ceratotherium simum*)], and enlarged ovaries and exuberant uterine responses [stingrays (*Myliobatoidei*)] (Penfold *et al.*, 2014).

The close association with PZP-induced subfertility and mare behavior demonstrated here points to an important link between animal physiology and behavior that should be considered when implementing any management program. Alterations to an animal's reproductive physiology—for whatever managerial gain—will likely be associated with concomitant changes in behavior (McShea *et al.*, 1997; Heilmann *et al.*, 1998; Nuñez *et al.*, 2009; Gilman *et al.*, 2010; Madosky *et al.*, 2010; Ransom *et al.*, 2010). The effects of these subsequent changes—both to management program efficacy and to animal welfare—ought to be weighed against the perceived advantages of our physiological manipulations.

The broader implications of this research are notable. Because other methods for controlling feral horse populations can have pronounced side effects and are often unpopular with the public, PZP is undoubtedly an important option in a manager's toolkit (Hobbs *et al.*, 2000; Kirkpatrick and Turner, 2003; Porton, 2005). However, our results suggest

that the best use of this tool will balance attaining target population sizes against over-treating individual animals. Although the prolonged effects of PZP contraception outlined here could actually assist managers in keeping population sizes low (in feral horses and other over-abundant wildlife), the use of PZP with small populations and/or those of conservation concern should be approached with caution (Ransom *et al.*, 2014). For instance, the fact that mares do not easily return to fertility after the cessation of treatment could limit the ability of populations to rebound in the face of stochastic declines. In the case of Shackleford Banks horses, prolonged PZP-induced subfertility has likely reduced the ability to adaptively manage the population; stopping treatment has not resulted in increased fertility, particularly for mares that previously received 4+ treatments. Given these results and the prolonged effects of PZP-induced subfertility on foaling schedules and behavior (and the potential for additional effects to non-recipient animals (Ransom *et al.*, 2010)), we suggest that monitoring individual treatment histories, or modeling the statistical probability of multiple treatments per individual, could prove critical in maintaining more natural physiological and social dynamics, all while allowing for maximal flexibility in attaining management objectives.

Preliminary Evaluation of Porcine Zona Pellucida (PZP) Immunocontraception for Behavioral Effects in Feral Horses (*Equus caballus*)

David M. Powell

Department of Zoological Research
National Zoological Park
and
Department of Biology
University of Maryland

Successful management of captive populations of wild animals requires effective control of reproduction. Contraception is one tool for controlling reproduction of animals in zoos; however, the options available to the animal manager are limited. Contraceptives vary in efficacy, reversibility, and side effects, and thus may not be suitable for widespread use. One consideration when selecting a contraceptive is its potential for side effects on behavior, especially given the fact that reproduction plays such a prominent role in the biology of any species. To date, there have been few evaluations of contraceptives for behavioral effects, and those that have been conducted have focused on hormone-based contraceptives. This study sought to evaluate a novel method of population control, immunocontraception, for behavioral effects in a population of feral horses. Porcine zona pellucida (PZP) immunocontraception prevents fertilization of ova and does not alter normal hormone secretion patterns. It therefore should leave the animal behaviorally intact in terms of reproductive behavior. The study examined the behavior of 43 sexually mature mares on Assateague Island during the 1997 breeding season and, with help from Earthwatch volunteers, collected observations over a 3-month period. The study found no significant differences between treated and untreated mares in general activity budget, aggression given or received, and spatial relationships relative to the stallion. These preliminary findings indicate that PZP contraception seems to have no acute behavioral effects on the behavior of individuals. The study findings also suggest that PZP could be a desirable

and effective management tool for captive species in which social behavior plays an integral role in group dynamics. Analyses of group level effects and population level effects are continuing.

One of the many challenges facing zoological parks and aquaria is the management and maintenance of genetically viable populations of endangered species. In theory, these populations will eventually serve as reservoirs of genetic diversity for the reinforcement or reestablishment of "wild" populations of nonhuman animals. To meet this goal, animal populations must be managed efficiently and effectively, given the constraints of space and resources. Breeding must be managed to maximize the production of genetically valuable individuals and to minimize the numbers of either overrepresented or genetically inferior individuals. In cooperation with the American Zoo and Aquarium Association, zoos and aquaria have developed a variety of tools to facilitate the development and execution of successful breeding programs. These tools include studbooks, population management plans, and species survival plans (SSPs) that, in one way or another, contribute to making recommendations about allocation of captive space and pairing of individuals for reproduction. Coordination of breeding programs often involves many animals distributed over many institutions. In general, the institutions participating in a breeding program agree on the means by which to achieve the program's objectives; however, unplanned pregnancies do occur, and variation in litter or clutch sizes produces surplus individuals.

In most cases, the number of offspring required from an individual to maintain a genetically healthy captive population is significantly lower than the potential number of offspring it could produce. Thus, by their very design, programs like SSPs require animal managers to have a variety of tools available to allow for compliance with breeding recommendations (Asa, Porton, Baker, & Plotka, 1996). These tools often must be applied to nonendangered species as well, because they occupy valuable space or consume resources that may be needed for endangered species programs.

Two methods by which breeding can be managed are separation of the sexes and establishment of same-sex groups of individuals. Separating the sexes may lead to negative effects on animal health and behavior (Conway, 1976). The practice of establishing same-sex groups is in its infancy in zoological parks, though some groups have been established and maintained with success (T. Stoinski, personal communication, May 1, 1997). Given the current limitations of these methods, contraception seems to be the best tool available for effective management of reproduction.

NEED FOR RESEARCH AND SHARED INFORMATION

Research involving various contraceptive methods has traditionally been aimed at humans, companion animals, and wildlife. Much less is known about the effi-

cacy and safety of contraceptives in captive exotic species (Knowles, 1986). In 1989, the American Zoo and Aquarium Association (AZA), responding to this lack of knowledge, formed a contraception task force, later formalized as the AZA Contraception Advisory Group (CAG). Its goals include (a) the collection and dissemination of data on the efficacy and safety of contraceptives and (b) the coordination and recommendation of research on contraceptive use in captive exotic species (Wemmer, 1989). The CAG has conducted surveys of zoos to assess the extent of use, efficacy, and effects of various contraceptives in primates, carnivores, and ungulates. These surveys are ongoing and updated as new data come in on an annual basis. A database has been created to find taxon-specific recommendations about which contraceptives should be used (Porton, Asa, & Baker, 1990; Porton & Hornbeck, 1993). Despite the number of different contraceptives available, a captive manager's available options for a given species remain limited because of the inherent characteristics of the contraceptive, its mode of action, and the unique biology of the species. A tremendous need remains for both contraceptive research in exotic animals and data sharing on contraceptive use among institutions (Asa et al., 1996).

Full Understanding of Potential Effects

One aspect of contraceptives about which we know comparatively little is how they affect the behavior of the contracepted individual and the conspecifics with which it interacts. By comparison, our knowledge of how contraceptives affect the physiology of the reproductive process is much greater. Clearly, for recommendations to be made about contraception, we must have a complete understanding of all its potential effects. In general, we know more about how hormone-based contraceptives affect behavior because of the history of research on behavioral endocrinology. However, research in this area is restricted to relatively few taxa and has rarely focused on exotic species. In addition, we know virtually nothing about the potential effects that non-hormone-based contraceptives (e.g., immunocontraception) may have on behavior. I provide a brief discussion of some studies that have examined the effects of contraception on the behavior of captive exotic wildlife. For a more general discussion of contraception in exotic species, see Asa et al. (1996).

Hormone-Based Contraception and Behavior of Captive Exotic Animals

Portugal and Asa (1995) assessed the effects of melengestrol acetate (MGA) implants on behavior in Hamadryas baboons (*Papio hamadryas*). Hayes, Feistner,

and Halliwell (1996) assessed the implants' behavioral effects on Rodrigues fruit bats (*Pteropus rodricensis*). Portugal and Asa's first experiment compared the behavior of female baboons immediately before and following implant insertion. They documented significant decreases in open-mouth grin (an aggressive behavior) and time spent foraging during MGA treatment. In addition, they reported nonsignificant trends toward decreased locomotion and increased time spent immobile during treatment. Portugal and Asa also noted that perineal tumescence did not recede entirely in treated females. In their second experiment, they compared the behavior of female baboons after long-term (2 years) treatment with their behavior after implant removal. They found a significant increase in affiliative behavior received by the females following treatment and a trend toward increased affiliative behavior initiated by the females. All females had gained weight during the treatment period (ranging from a 17.3% to 47.6% increase over starting weights). They also found that perineal swellings never fully subsided, indicating that some tissue hypertrophy may have been permanent. In a study of stumptail macaques (*Macaca arctoides*), Linn and Steklis (1990) found that during treatment with depo-medroxyprogesterone (Depo-Provera), another synthetic progestin, there was a decrease in rates of affiliation and a tendency for higher rates of aggression.

Hayes et al. (1996) observed the behavior of control and MGA-implanted Rodrigues fruit bats during a preimplantation period, 1 month postimplantation, and 6 months postimplantation. During the preimplantation period, there were no differences in activity budget between control and treated bats. At 1 month postimplantation, they found that implanted bats moved significantly more than control bats. At 6 months postimplantation, this trend had reversed; however, both groups showed decreased movement compared to 1 month postimplantation. In addition, Hayes et al. noted within-group changes during these study periods. In an analysis of spatial relationships, they found that at 1 month postimplantation, treated bats spent significantly more time with a nearest neighbor than control bats who tended to roost apart from others. Hayes et al. found no effects of treatment on the age–sex structure of neighbors or in the number of displacements given or received. They saw no effect of treatment on the rate of copulation. The authors suggested that the changes in activity budget between groups were most likely due to changes that occurred within groups and not to implants. They found that implanted females had gained weight (more than 8% of body weight), and 7 of 9 treated bats showed poor regrowth of hair and some scarring over the implant insertion site.

Porcine Zona Pellucida (PZP) Immunocontraception

Immunocontraception relies on the body's production of antibodies that interfere with some critical event in reproduction. Immunocontraceptive vaccines have so far been developed against neuropeptides, gonadotropins (Moudgal et al., 1986),

steroid hormones (Al-Kawafi, Hopwood, Pineda, & Faulkner, 1974), sperm (Primikoff, Lathrop, Woolman, Cowan, & Myles, 1988), and ova (Sacco, 1987). To date, the most promising of these vaccines are those directed against the zona pellucida (ZP; Aitken, Richardson, & Hulme, 1984; Sacco & Yurewicz, 1989).

The ZP is a noncellular layer surrounding all mammalian oocytes. The ZP contains two glycoproteins (designated ZP3 and ZP4) that are thought to serve as sperm receptor molecules (Florman & Wassarman, 1985; Hasagawa, Koyama, Inoue, Takemura, & Isojima, 1992). These glycoproteins are so highly conserved in structure across mammals that the ZP of pigs has been used to block fertilization in various nonhuman primates (Sacco, 1987), rabbits (Wood, Liu, & Dunbar, 1981), dogs (Mahi-Brown, Yanagimachi, Hoffman, & Huang, 1985), and humans (Sacco, Pierce, Subramanian, Yurewicz, & Dukelow, 1987). The basic mechanism of action for these ZP vaccines depends on this structural similarity across taxa. When injected, ZP from pig ova causes the host's immune system to produce antibodies to the ZP. These antibodies bind to the PZP as well as to the ZP on the host's oocytes, effectively blocking sperm binding and fertilization.

Emphasizing Variability

To date, PZP has had variable effects on health and reproductive function, depending on the taxon (AZA Contraception Advisory Group, 1995; Kirkpatrick, Naugle, Liu, Bernoco, & Turner, 1995). Among feral horses, PZP contraception appears to be completely reversible and to have no ill effects on ovarian function when animals are contracepted for fewer than 3 consecutive years (Kirkpatrick, 1995; Kirkpatrick, Liu, Turner, Naugle, & Keiper, 1992). After 3 years of contraception with PZP, effects on ovarian function were noted. Treated mares showed lower ovulation rates and depressed estrogen levels (Kirkpatrick et al., 1992). In order for this contraception to be reversed, antibody titers have to decrease to levels that permit successful ovulation and fertilization. Mares treated for 3 consecutive years and then taken off contraception for breeding have at least a 2-year latency to reproduction (Unpublished U.S. National Park Service data). Seven consecutive years of contraception with PZP severely alters ovarian function and endocrine production (Kirkpatrick et al., 1995). It should be emphasized that immune response is variable across individuals and species, and this variability may be manifested in magnitude or duration of response (Fraser, 1980). Further research on immunocontraceptive techniques should include assessments of factors affecting immune response to vaccines.

McShea, Monfort, and Munson (1997) evaluated the efficacy of PZP immunocontraception and its impact on behavior of white-tailed deer (*Odocoileus virginianus*). Does were divided into one control group and two treatment groups. The two treatment groups differed in the total dose of PZP. Treatment with the

smaller of two doses in this study did not prevent parturition, but it significantly delayed parturition dates in treated does. As in the MGA studies discussed previously, treated does showed significantly more weight gain than control does during the study period. McShea et al. found that males exhibited longer breeding seasons during the first year of their study; in the second year, they noted that the breeding season was not longer but had started over 2 weeks earlier. Among does, contracepted females were more active (exhibited more running or walking) than untreated does, though this difference was only evident during estrus and may have been due to the treated does undergoing one to two nonconceptive cycles before getting pregnant. Treated does also exhibited estrous periods later in the season than control does (McShea et al., 1997).

Heilmann, Garrott, Cadwell, and Tiller (1998) analyzed behavioral responses of free-ranging elk to PZP immunocontraception. They found that sexual interaction rates of treated and untreated cows were similar during the normal breeding season for this species but that rates of sexual interaction remained at breeding season levels for treated cows after the end of the normal breeding period. They also found no differences in proportion of time spent feeding, idling, or moving between contracepted and uncontracepted cows.

Hypotheses Tested

I generated a series of hypotheses about how contracepted and uncontracepted mares might differ in their behavior. I first hypothesized that, if contraception was having a severe impact on behavior, I would expect to find differences in the overall activity budgets of contracepted and uncontracepted mares. My second hypothesis predicted differences in spatial relationships between contracepted and uncontracepted mares relative to the stallion in the harem band. One could imagine that contracepted mares either might (a) be close to the stallion more often because they are continuously cycling during the breeding season and hence would show repeated periods of estrous behavior or (b) be far from the stallion and on the periphery of the group because the stallion might find them unsuitable as mates. Finally, I hypothesized that contracepted and uncontracepted mares would differ in social rank and the amount of aggression they gave and received.

METHODS

Study Animals

With the assistance of Earthwatch volunteers, I conducted behavioral observations on a population of feral horses (*Equus caballus*) living on Assateague Is-

land National Seashore, a 33-mile long barrier island running along the coasts of Maryland and Virginia. Observations were restricted to the Maryland herd, which contains approximately 173 individuals and is essentially unmanaged, except for population control.

Though equid social organization appears closely tied to ecology (Rubenstein, 1981), the typical social group in feral horses is the harem band, which contains one breeding male, several reproductive mares, and their dependent offspring. Harem bands on Assateague occupy overlapping home ranges and are not characterized by territoriality. A dominance hierarchy exists within each harem band, and the stallion may not be the alpha animal (Houpt & Keiper, 1982). Among mares, rank correlates most highly with tenure (Seligsohn, 1987) but also very highly with age (Keiper & Sambraus, 1986; Rutberg & Greenberg, 1990). Female hierarchies tend to be stable with few reversals (Berger, 1986; Keiper & Sambraus, 1986). In 1997, nine bands of horses were observed from June 1 to September 5. These bands contained 43 sexually mature mares.

National Park Service personnel and outside researchers had documented significant impacts by the horses on the island's vegetation during the 1980s. Concern over the size of the herd led to the development of a plan to reduce the population using the immunocontraceptive, PZP. Widespread inoculation of the herd began in 1994, though some mares had been treated previously as part of research on PZP's reversibility. Of the 43 mares observed in this study, 24 were contracepted and 19 were uncontracepted during the breeding season of 1997, though all mares in the study had been contracepted for some period in the past. Contracepted mares had been on contraception for an average of 2.54 consecutive breeding seasons (range = 1 to 5). Eighteen of the 19 uncontracepted mares had been on contraception for the previous 3 breeding seasons (1994–1996) and were taken off treatment either to decrease potential side effects of longer term treatment or to allow for breeding.

Behavioral Observations

Observations were conducted from 7 a.m. until 7 p.m. and were approximately balanced across time of day. Each band was observed twice per week on average. Observers received an average of 2.5 days of training in behavioral observation techniques specific to this project. Observers were left to work on their own only after they had achieved a criterion of 85% reliability with the principal investigator. At least two observers were assigned to observe a band during an observation period.

Focal animal observations (Altmann, 1974) were conducted with scan sampling of each sexually mature mare in the band—defined as 2 years old and beyond (Keiper, 1985). Mares were observed in random order. Every 5 min, the identities

of the nearest neighbor to the focal mare and the stallion were recorded. The nearest and most distant adult mare to or from the stallion was also recorded on the 5-min mark. Every 10 min the activity of every group member was recorded. Some of the behavioral categories used in these observations were grazing, standing, resting, locomotion, grooming, and social. Social included any behavior in which the focal animal was interacting with any other animal (including sexual behavior, aggression, mutual grooming, and nursing). In addition, on the 10-min mark, the identities of the most distant animal and most distant sexually mature mare in the group were recorded. Determining which individual had the greatest distance between him or herself and his or her nearest neighbor (who could be any age or sex) scored this. In cases where distances between horses appeared equal, we tried to determine which individual was most distant from the *core* of the group. Core was defined as the subgroup containing the most individuals. All occurrences of sexual, aggressive, and affiliative behaviors were recorded.

Data on aggressive encounters and their outcomes were used to rank individuals in a hierarchy according to the method of Schein and Fohrman (1955). A dominance index was then calculated for each mare that would allow for comparison of mares across differently sized bands (Clutton-Brock, Guinness, & Albon, 1982). Each band, except for 1 band of 3 uncontracepted mares, contained both contracepted and uncontracepted mares. There was no relation between age and contraception status (Mann–Whitney $U = 233, p = .5144$) nor between group size and proportion of mares in the group that were contracepted ($r_s = .1952, n = 8, p = .643$). For these reasons, data for contracepted and uncontracepted mares were pooled across bands. Nonparametric statistical tests were used, and significance was assessed when $p < .05$.

RESULTS

Contracepted and uncontracepted mares had virtually identical activity budgets for most behaviors scored. There was a trend for contracepted mares to be engaged in more social behavior than uncontracepted mares; however, there were no statistically significant differences for any of the behavior categories scored (Table 1).

A mean percentage of scans in which a female was the nearest mare to the stallion and the most distant female from the stallion was calculated for each mare. These were then scaled by group size. There were no significant differences for either measure between contracepted and uncontracepted mares (stallion's nearest female: $U = 116, p = .1661$; most distant female from stallion: $U = 144, p = .6105$; Figure 1).

Mean dominance index was compared between contracepted and uncontracepted mares. Each of three mares who switched bands during the study was

treated as two separate data points because her social rank could potentially change on entering a new group (Seligsohn, 1987). There was no significant difference in mean dominance index between treated and untreated mares ($U = 253, p = .8339$). There also was no significant difference in aggression received ($U = 206.5, p = .7338$) or aggression given ($U = 179, p = .3016$) between contracepted and uncontracepted mares (Figure 2).

DISCUSSION

Previous studies of MGA contraception and one study of PZP contraception have found differences in activity budgets between contracepted and uncontracepted animals (Hayes et al., 1996; McShea et al., 1997; Portugal & Asa, 1995). I found no differences between treated and untreated feral horse mares in this study. There was a nonsignificant trend for treated mares to spend more time en-

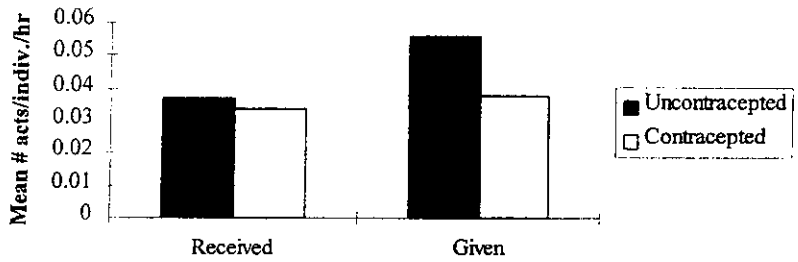

FIGURE 2 Comparison of rates of aggression between contracepted and uncontracepted mares.

gaged in social behavior. This finding might be expected, given that treated mares undergo repeated nonconceptive cycles and thus demonstrate estrous behavior at regular intervals. Heilmann et al. (1998) demonstrated that PZP-treated elk cows showed higher rates of sexual interaction outside the normal breeding season, though their rates were similar to those of untreated cows during the breeding season. Their findings of no significant impact on overall activity budget are in agreement with the results of this study, although fewer categories were scored. Studies of horse behavior on Assateague before implementation of the contraception program indicated that the horses spent an average of 50% of their time foraging (Keiper, 1985). Studies of other populations of feral equids have found that the percentage of time spent grazing ranges from roughly 35% to 70% during the summer months (June, July, August), depending on the habitat (Berger, 1977; Rubenstein, 1981). The results of these studies indicate that both the contracepted and uncontracepted mares in this study have activity patterns that are similar, at least in terms of grazing, to feral horses that have never been exposed to contraception.

Spatial Relationships Unaffected

PZP immunocontraception did not appear to affect spatial relationships between mares and stallions in this study. Contracepted and uncontracepted mares were equally as likely to be the closest or most distant mare from the stallion in the harem band. This may indicate that the contraception status of a mare is not discernable to other individuals in the group. PZP treatment did not appear to affect social rank or rates of aggression given or received in this study. Rutberg and Greenberg (1990) reported aggression rates ranging from .6 to 1.9 aggressive acts per sampling hour in this population before contraception. During the 1997 breeding season, I observed an average of 1.94 aggressive acts per sampling hour.

As mentioned earlier, current data for this population of horses indicate that a mare who has been on PZP for 3 years probably requires 2 years to become fertile again. To date, all mares who have been on PZP for 3 consecutive years and then taken off have become pregnant within 3 years post-treatment. Kirkpatrick (1995) reported that antibody titers only remained high enough to provide contraception for 1 year; thus an annual booster must be given to ensure continued contraception. All but one of the uncontracepted mares in this study had been off PZP only a little more than 1 year. If antibody titers were still high, however, these mares may still have been behaviorally contracepted. Currently, it is unclear how high titers must be to suppress reproduction without affecting behavior. Although much is known about how behavior affects the immune system, there is a paucity of information on how the immune system might affect behavior. Most studies addressing this topic have focused on the effects of exposure toxins rather than non-infectious proteins, and these studies have used neonates of selectively bred individuals as test subjects (Granger, Hood, Ikeda, Reed, & Block, 1996).

A control group of untreated (unexposed) mares was not available for this study. At the beginning of observations, virtually every mare on the island was either on PZP or had been exposed to the vaccine previously. On Assateague, young females are treated in either October of their first year or March of their second year to prevent conception during their second summer. Observations of these females before treatment would not serve as a proper control because they would not have been sexually mature. For most of the behavioral variables reported here, similar values have been reported either for this population before contraception or for other populations of feral horses. However for more complex analyses, valid comparisons probably cannot be made. This underlines the need to conduct baseline studies before interventions of any kind are taken with populations of animals either in the wild or in captivity. A baseline study that addresses behavior and, in many cases, ecology is necessary to identify unambiguously the effects of intervention later. National parks and refuges typically do not have the resources in terms of staff and time to conduct these kinds of studies, which require many hours of observation. Therefore, it is imperative that they solicit local universities, zoos, and other research institutions for assistance so that correctly controlled studies can be done.

Duration of Breeding Behavior Extended

These data should not be taken to mean that PZP contraception has absolutely no effects on the behavior of feral horses. By default, this contraceptive very likely extends the duration of breeding behavior. Normally, mares would get pregnant during a foal heat or in one to two cycles; however, PZP-treated mares continually undergo nonconceptive cycles and thus demonstrate estrous behav-

ior throughout the season. Similarly, stallions continue to tend and mate with mares until they cease to cycle in the fall. Whether this extension of the breeding season has negative effects on behavior remains to be seen. For Hamadryas baboons, it has been suggested that contraceptive methods that allow for continued, nonconceptive cycles should be avoided (Portugal & Asa, 1995). The veterinary literature has also documented the negative effects of repeated exposure to a female's own endogenous hormone cycles associated with ovulation. Immunocontraceptives that do not affect hormone levels (e.g., PZP) and allow for normal ovulatory cycles should be used with caution.

Effects on Sociosexual Behavior

Contraceptives may also have more complex effects on sociosexual behavior. Females who fail to become pregnant after repeated ovulations may seek out new mates (e.g., subordinate males), thus disrupting group stability and order. In situations where only a portion of the females in a group are contracepted, a contraceptive that suppresses estrous behavior may intensify male–male competition for those females who show normal sexual behavior (Asa et al., 1996). Contracepted females may also be aggressive toward other females and their infants.

This is a preliminary evaluation of this contraceptive. Data are currently being analyzed to determine if activity budgets differ between treated and untreated mares during the estrous period. Longitudinal fecal samples were collected from a sample of mares to assess ovarian function and reversibility. Behavioral data will be matched with hormonal data to determine if contracepted and uncontracepted mares exhibit similar patterns of sexual behavior. Data are also being analyzed to assess group stability. Membership in feral horse bands tends to be stable; however, females do change bands occasionally. These membership changes may be temporary or permanent. The National Park Service has conducted a monthly census of the herd for the past 9 years. During the census, membership in each band is recorded. I am currently trying to determine if contracepted mares are more likely than uncontracepted mares to change bands. One could envision a scenario in which a mare leaves a band because she repeatedly fails to get pregnant by a certain stallion. Similarly, a stallion might expel a seemingly barren mare from the harem. Finally, data from the 1997 and 1998 breeding seasons are being analyzed to determine if there are within-individual differences in behavior that are attributable to contraception.

Research Participation and Information Exchange

We clearly need more studies of contraception in wild and captive exotic animals. Many of the methods currently used are still considered experimental—

even for humans. The current data strongly indicate that there is considerable individual and species variability in contraceptive dose, efficacy, and safety (Asa et al., 1996). A contraceptive that effectively halts reproduction while disrupting social behavior may not be desirable to animal managers or humane to the treated animals. For this reason, it is also important for behavioral effects to be included in assessments of contraceptives. If we are to improve and validate our recommendations for the use of contraceptives in exotic wildlife, there must be greater participation in research trials coordinated by the Contraception Advisory Group, and there must be more exchange of information among zoos, wildlife agencies, and university researchers.

ACKNOWLEDGMENTS

These results were presented as part of a poster presentation at the 7th World Conference on Breeding Endangered Species in May 1999, Cincinnati, OH.

Funding for this project was provided by Earthwatch Institute, Biology of Small Populations Training Grant BIR 9602266 at the University of Maryland, the National Zoological Park of the Smithsonian Institution, and the Chesapeake Bay Foundation. The National Park Service also provided logistical and technical support, as well as housing for the researchers and volunteers.

I thank Dr. Devra Kleiman (National Zoo), Dr. Cheryl Asa (St. Louis Zoo), and Dr. Jay Kirkpatrick (Zoo Montana) for their comments on this research, as well as National Park Service personnel Carl Zimmerman, Jack Kumer, and Allison Turner for access to historical records on the Assateague horses.

Front Royal, Virginia

The study used noninvasive fecal hormone monitoring to assess whether contraception with porcine zona pellucida (PZP) had an impact on estrous cycle characteristics in a herd of feral horses living on Assateague Island, Maryland. The study assayed longitudinal fecal samples, collected over a 2-year interval, for total estrogens (estradiol and estrone) and progestagens. Follicular (6.4 ± 2.4 days) and luteal (11.2 ± 3.2 days) phase durations were within the range reported for domestic horses, with an average estrous cycle duration of 18.6 ± 2.5 days. There were no differences ($p > .05$) in phase durations between currently treated and currently untreated mares in either year of the study. Endocrine data suggested that ovulatory failure occurred frequently in Assateague mares; however, we could not link this phenomenon directly to contraception. Overall, no estrous cycle characteristics differed between currently treated and currently untreated mares. However, all mares in this study had been treated with PZP at some point in the previous 10 years. Because PZP has been shown to induce decreased ovulation rates in several *mammalian taxa*, including Assateague horses, we speculate that in addition to blocking sperm binding PZP may adversely impact ovarian function in mares.

Requests for reprints should be sent to David Powell, Department of Conservation Biology, Smithsonian's National Zoological Park, 3001 Connecticut Avenue NW, Washington, DC 20008. E-mail: powelldm@nzp.si.edu

The zona pellucida (ZP) and its potential role in contraception have received substantial attention (Skinner, Timmons, Schwoebel, & Dunbar,1990). Immunocontraception relies on the body's production of antibodies that interfere with critical events in reproduction. To date, vaccines have been developed against neuropeptides, gonadotropins (Moudgal et al., 1986), steroid hormones (Al-Kawafi, Hopwood, Pineda, & Faulker, 1974), sperm (Primikoff, Lathrop, Woolman, Cowan, & Myles, 1988), and ova (Sacco, 1987). The most promising vaccines are those directed against the ZP (Aitken, Richardson, & Hulme, 1984; Sacco & Yurewicz, 1989). Injection of foreign ZP into a host stimulates the production of antibodies that prevent sperm binding to ZP sperm receptors (Florman & Wassarman, 1985; Hasegawa, Koyama, Inoue, Takemura, & Isojima, 1992). The structure of these glycoprotein receptors has been so highly conserved among mammalian species that porcine ZP (PZP) can be used to immunize various taxa such as nonhuman primates (Sacco, 1987), rabbits (Wood, Liu, & Dunbar, 1981), dogs (Mahi-Brown, Yanagimachi, Hoffman, & Huang, 1985), and ungulates (Kirkpatrick, Turner, Liu, & Fayrer-Hosken, 1996). Subsequent contraception is achieved when host-produced antibodies physically block fertilization by binding to ZP sperm receptors.

PZP-induced immunocontraception is an attractive option for controlling wildlife populations because, in theory, this form of contraception does not alter hormone secretion and, therefore, is presumed to leave the treated individual behaviorally and physiologically intact. However, many studies of laboratory and free-ranging animals have shown that PZP treatment can cause abnormalities in ovarian steroid production and histology (Bamezai, Das, & Talwar, 1986; Gulyas, Gwatkin, & Yuan, 1983; Hasegawa et al., 1992; Kirkpatrick, Liu, Turner, Naugle, & Keiper, 1992; Kirkpatrick, Naugle, Liu, Bernoco, & Turner, 1995; Mahi-Brown et al., 1985; Sacco, Pierce, Subramanian, Yurewicz, & Dukelow, 1987; Skinner, Mills, Kirchick, & Dunbar, 1984; Wood et al., 1981). Among horses, no abnormalities in ovarian histology were documented after 1 year of treatment with PZP (Liu, Bernoco, & Feldman, 1989); however, feral mares on PZP for 3 consecutive years demonstrated diminished urinary estrogen conjugate levels and lower ovulation rates than untreated mares (Kirkpatrick et al., 1992). The decline in estrogen excretion and ovulation rate continued in mares that had been on PZP for up to 7 years (Kirkpatrick et al., 1995). These data suggest that, in addition to preventing sperm binding, PZP immunocontraception also may have an adverse impact on ovarian follicular development or function, or both.

In this study, estrous cycle characteristics were analyzed in a population of Assateague horses who were part of a long-term contraceptive field trial (Kirkpatrick et al., 1992, 1995). Young mares (age 2 years) are given two injections of PZP 2 to 4 weeks apart to begin contraception (Kirkpatrick et al., 1992). Liu et al. (1989) determined that PZP immunocontraception lasts for 1 year in mares; thus, on Assateague contraception is prolonged by administering an annual booster of vac-

cine. Noninvasive fecal hormone monitoring was used to facilitate consistent sampling in these feral, free-ranging horses. Fecal sampling also permitted behavioral monitoring to be conducted without animal disturbance. Cyclic fluctuations in fecal estrogen and progesterone metabolites are known to reflect ovarian follicular and luteal dynamics, respectively, in a diversity of wildlife species, including horses (Brown, Wasser, Wildt, Graham, & Monfort, 1997). Specific comparisons between currently treated and currently untreated mares in this study focused on examining differences in follicular and luteal phase lengths and ovulation rates. We assumed that mares who did not receive an annual booster prior to the onset of our study during the 1997 breeding season no longer were effectively contracepted. We tested the hypothesis that estrous cycle parameters would differ in currently treated and currently untreated mares because PZP is an immunocontraceptive that should not interfere with estrous cycles or ovarian hormone production. Thus, any effects that PZP may have while a mare is treated in the 12-month period following initial or booster injection should not be evident once treatment has expired—more than 12 months after initial or booster injection.

METHOD

Sample Collection

The study site and population was described previously (Powell, 1999). Fresh fecal samples were collected from individually identified mares (see Table 1) every 2 to 5 days during the following intervals: July 3 to September 4, 1997 (n = 13 mares); and June 9 to July 23, 1998 (n = 12 mares). The terms *currently treated* and *currently untreated* refer to mares that did or did not receive an inoculation with PZP for contraception during the breeding season.

Fecal samples were collected off the ground within 1 to 3 min after animals defecated. A composite sample of each fecal pile was collected to ensure a homogenous sample, and samples were collected only from animals who could be positively identified. No samples were taken from fecal piles on which the stallion urinated. Feces were stored in polypropylene tubes at –20 °C or –80 °C until assay.

Fecal Extraction and RIA

We conducted fecal hormone metabolite assays according to the methods of Wasser, Monfort, Southers, & Wildt (1994). Briefly, ~ 0.025 g of dried, pulverized feces were boiled in 100% ethanol for 20 min and centrifuged for 18 min at 1500 revolutions per minute. The supernatant was decanted into a clean tube, evaporated to dryness, reconstituted in 1 ml methanol, and then diluted 1:10 with phosphate-buffered saline for the progestagen radioimmunoassay (RIA; Brown, Wasser, Wildt, & Gra-

Note. PZP = zona pellucida.

ham, 1994) and diluted 1:10 with steroid diluent buffer for the total estrogens RIA (see following). Tritiated estradiol (~ 6,000 d.p.m.) and ^{14}C-labeled progesterone (~ 1,700 d.p.m.) were added to each fecal sample before extraction to monitor procedural losses. The ^{125}I-progestagen RIA employed a broad-spectrum monoclonal antiserum that cross-reacts with progesterone, 100%; 5α-pregnane-3β-ol-20-one, 96%; 5α-pregnane-3α-ol-20-one, 36%; 17β-hydroxyprogesterone, 15%; pregnenolone, 13%; 5β-pregnane-3α-ol-20-one, 7%; 5β-pregnane-3α, 17α-diol, 20α-one, 5% (Brown, Wasser, et al., 1994; Wasser et al., 1994). Fecal extracts were assayed for total estrogens (unconjugated estradiol-17β [E_2] and estrone [E_1] using a commercially available, double antibody ^{125}I kit (ICN Pharmaceuticals, Inc., Costa Mesa, CA) that cross-reacts with estradiol-17β, 100%; estrone, 100%; estriol, 9%; estradiol-17α, 7%; and equilin, 2.5%. Assays for fecal progestagens and total estrogens were validated using standard techniques to confirm specificity, sensitivity, accuracy, and precision.

Estrous Cycle Duration

We calculated follicular and luteal phase duration estimates using an iterative process described by Brown, Citino, Shaw, & Miller (1994) in which high values for total estrogens or progestagens (considered separately) for each mare

within a sampling year (1997 or 1998) were excluded if they exceeded the mean hormone concentration for all fecal samples plus 2 standard deviations. After exclusion of these values, calculations were iterated until no further outliers (i.e., values that exceeded baseline) were identified. The remaining values were used to approximate baseline estrogen or progestagen concentrations. Follicular and luteal phase duration estimates were obtained by regressing second-order polynomial curves through each outlying point and the adjacent baseline points on either side. The resulting equation was solved for x (day) when y (hormone level) exceeded a 95% confidence interval for the mean baseline value for that hormone. The values obtained were measured to the nearest 0.1 day. The regressions proved to be a good fit for the data (r = .98 for estrogens and .89 for progestagens) and provided more precise estimates for phase lengths than could be obtained by using the fecal samples alone. Phase length estimates are presented as mean ± standard deviation.

Behavioral Data Collection

All occurrences of sexual behavior were recorded using an ethogram modified from Asa, Goldfoot, & Ginther (1979) as part of a larger study of social behavior in this population of horses. For each instance of sexual behavior, we recorded the actor, behavior(s), recipient(s), and any responses. When fecal samples were collected from a group, behavioral data were not formally collected because sampling sometimes produced disturbance in the group (e.g., moving away from the observer); however, ad lib notes were taken on any sexual behavior observed, and a mare was characterized as "in heat" if she demonstrated frequent urination, presenting, or if she allowed the stallion to mount.

Statistical Analysis

Estrous cycle characteristics were compared between years using t tests or Mann–Whitney U tests when the assumption of normality could not be met.

RESULTS

Fecal Extraction and RIA

Fecal progestagens RIA. Serial dilutions of pooled fecal extracts (neat to 1:16,000) yielded displacement curves parallel to those obtained with standard preparations of progesterone. Recovery of unlabeled progesterone (3.75–480 pg/tube) from pooled fecal extracts was 102.0% ± 3.7%. Linear regression analysis of the amount of progesterone measured compared to the amount added, after subtraction of endogenous hormone, yielded a correlation coefficient of 0.98 for the fe-

cal extract ($y = -3.2 + 1.3x$). Assay sensitivity was 1.8 pg/tube, whereas interassay coefficients of variation for high- (~ 30% binding) and low- (~ 60% binding) mass internal controls were 9.8% and 11.1% ($n = 9$), respectively. Intraassay coefficients of variation were less than 10%. Hormone concentrations were expressed as mass equivalents of hormone per gram of dry feces.

RIA of fecal extracts after high performance liquid chromatography (HPLC) revealed at least nine immunoreactivity peaks. One peak (40.7% of total immunoreactivity) coeluted with progesterone, whereas each of the other minor peaks constituted 4.4% to 10.8% of total immunoreactivity.

Fecal total estrogens RIA. Serial dilutions of pooled fecal extracts (neat to 1:16,000) yielded displacement curves parallel to those obtained with standard preparations of estradiol (E_2). Recovery of unlabeled E_2 (1.25–100 pg/tube) from pooled fecal extracts was 106.0% ± 4.5%. Linear regression analysis of the amount of E_2 measured compared to the amount added, after subtraction of endogenous hormone, yielded a correlation coefficient of 0.99 for the fecal extract ($y = 0.16 + 0.97x$). Assay sensitivity was 0.63 pg/tube, whereas interassay coefficients of variation for high (~ 25% binding) and low (~ 67% binding) mass internal controls were 8.5% and 16.8% ($n = 5$), respectively. Intraassay coefficients of variation were less than 10%.

RIA of HPLC-separated fractions of fecal total estrogens showed immunoreactive peaks at fractions 37 to 40 that coeluted with the ^{3}H-E_2 tracer, and this peak accounted for 91.3% of the total immunoreactivity in the fecal pool.

Estrous Cycle Characteristics

In 1997, mean estrous cycle duration was 17.9 ± 2.1 days ($n = 6$ mares showing a follicular phase and subsequent luteal phase) compared to 19.7 ± 3.3 days in 1998 ($n = 3$), giving a composite mean of 18.6 ± 2.5 days. Mean follicular phase duration in 1997 was 6.1 ± 2.3 days versus 6.6 ± 2.5 days in 1998. Mean luteal phase estimates were 11.2 ± 3.3 and 10.5 ± 4.4 days in 1997 and 1998, respectively. A typical estrous cycle is shown in Figure 1.

There was no significant difference in follicular phase durations between currently treated and currently untreated mares in 1997 or 1998: 1997, $t(11) = -0.68$, $p = .51$; 1998, Mann–Whitney $U = 28$, $n = 5, 8$, $p = .35$ (see Figure 2). Luteal phase durations between currently treated and currently untreated mares were not different in either year: 1997, $t(10) = -1.89$, $p = .09$; 1998, $t(5) = 0.27$.

The occurrence of estrous behavior generally coincided with periods of high total estrogens or low progestagens, or both (see Figure 1). The majority (80%, $n = 15$) of mounts and observations of estrus occurred within 1 to 3 days of an estrogen peak or progestagen nadir. All observations of low-intensity sexual receptivity (approaching male, sniffing, proximity) also occurred during these periods. Of the

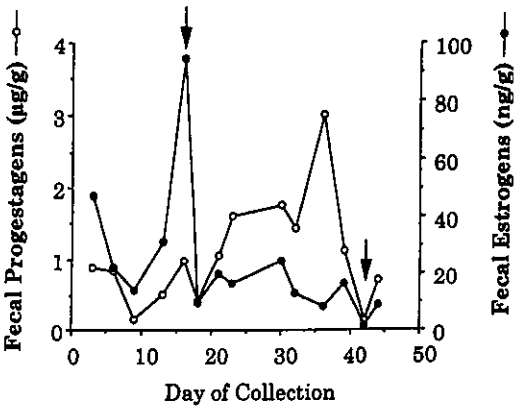

FIGURE 1 A typical pattern of fecal total estrogen and progestagen excretion in an Assateague, Maryland mare treated with porcine zona pellucida for 7 consecutive years. Black arrows indicate observations of estrous behavior.

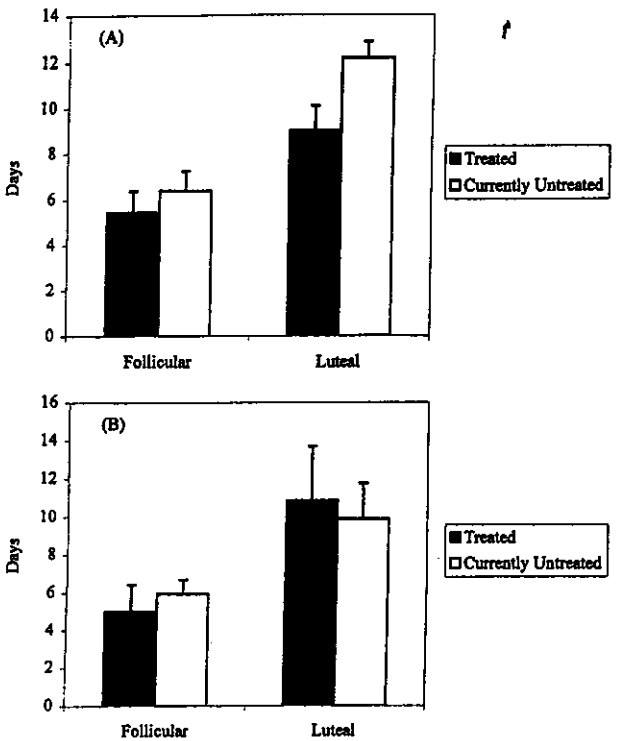

FIGURE 2 Follicular and luteal phase durations in porcine zona pellucida treated and currently untreated Assateague, Maryland mares in the 1997 (A) and 1998 (B) breeding seasons.

15 mares sampled, 7 (47%) showed signs of high-intensity sexual receptivity (frequent urination, presenting, allowed mounting) during the fecal sampling period. Using a logistic regression model, Powell (2000) demonstrated that contraception has no effect on performance of sexual behavior.

Apparent ovulatory failure. Overall, endocrine data from 11 (52%) of the 21 hormone profiles examined (1997 and 1998) suggested ovulatory failure. Presumed anovulatory cycles were characterized by a significant ($p < .05$) increase in total estrogen excretion that was not followed by a corresponding increase in luteal progestagen excretion. The incidence of ovulatory failure was 41.7% in 1997 (5/12): 66.6% (2/3) of currently treated mares and 33.3% (3/9) of currently untreated mares (Fisher exact $p = .60$). Additionally, there was no significant difference in the number of years on PZP treatment between mares that demonstrated ovulatory failure and mares that did not (Mann–Whitney $U = 37.5, n = 5, 7, p = .43$).

The ovulatory failure rate in 1998 (66.6%, 6/9) was not significantly different from the rate observed in 1997 (Fisher exact $p = .71$). Because there was a 7-day gap in fecal sampling in 1998, cases in which the peri-ovulatory estrogen peak immediately preceded the sampling gap were not included because a portion of a luteal phase could have been missed. In 1998, the incidence of ovulatory failure was 60% (3/5) for currently treated mares versus 75% (3/4) for currently untreated mares (Fisher exact $p = 1.0$). As in 1997, there were no significant differences in the number of years on PZP treatment between mares who demonstrated ovulatory failure and mares who did not (Mann–Whitney $U = 16, n = 3, 6, p = .91$).

One mare, N6BP, experienced ovulatory failure in both years, and although luteal activity appeared to precede an anovulatory cycle in 1997, there was no evidence of a luteal progestagen excretion in 1998 (see Figure 3). This mare had been treated for 3 consecutive years but was not treated in 1997. No other females, whether they were treated or not, experienced ovulatory failure in both years.

Of the 11 profiles indicating ovulatory failure, 6 (55%) of these profiles showed significant rises in progesterone at some other point during the sampling period within that year. The 5 remaining profiles were obtained from five different mares, and each of these mares demonstrated normal cycles during the other of the two sampling periods (1997 or 1998). None of the mares in our samples, treated or not, gave birth during the study period.

DISCUSSION

These results and those of Barkuff, Carpenter, & Kirkpatrick (1993) demonstrate that fecal hormone monitoring is useful for tracking ovarian cyclicity and identifying follicular and luteal phases of the estrous cycle in feral horses. Fecal steroid analysis has also been used to track ovarian function in a variety of mam-

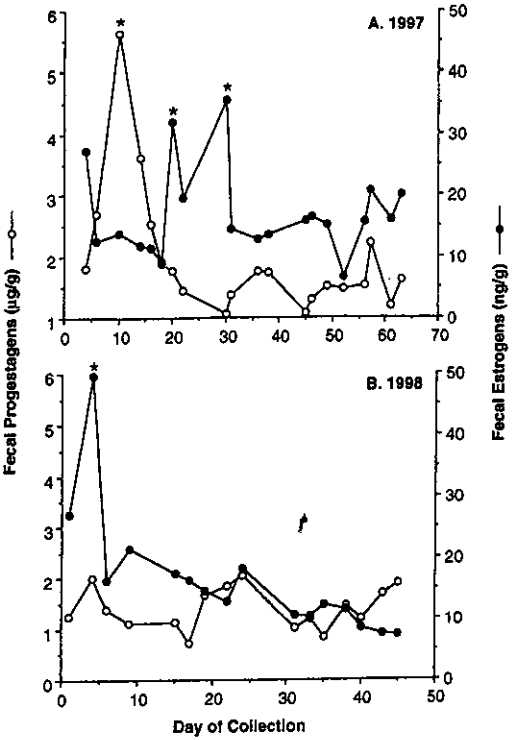

FIGURE 3 Instances of apparent ovulatory failure in mare N6BP in 1997 (A) and 1998 (B). Asterisks indicate data points significantly different from baseline.

malian taxa, including primates, perissodactyls, artiodactyls, and carnivores (Schwarzenberger, Mostl, Palme, & Bamberg, 1996). Assay of fecal progestagens and total estrogens in this population of horses produced patterns of hormone excretion that were similar to those reported for equids using blood or urine (or both) hormone analyses (Ginther, 1992). Lag time between hormone secretion in blood circulation and excretion in the feces was not determined in this study; however, analyses of digesta passage in equines have found an average retention time of 23 hr (Uden, Rounsaville, Wiggans, & Van Soest, 1982); therefore a minimum lag time of approximately 1 day might be expected.

Progesterone accounted for only a small proportion of the total immunoreactive progestagens in feral horse feces, and, based on HPLC results, at least eight other metabolites were detected by our antibody. Schwarzenberger et al. (1996) found that unmetabolized progesterone was virtually absent in feces and generally is metabolized before excretion to several 5α- and 5β-reduced pregnanes with the 20-oxo, 20α-, or 20β-hydroxylated group. In scimitar-horned oryx (*Oryx dammah*) feces, 5α- and 5β-reduced pregnanes were measured, and unmetabolized progesterone contributed a small proportion of total progestagen

immunoreactivity (Morrow & Monfort, 1998). In contrast to progesterone, estradiol and estrone accounted for nearly all of the immunoreactivity in horse feces, and this is in agreement with studies conducted in numerous mammalian species (Schwarzenberger et al., 1996; Brown et al., 1997).

Average estrous cycle lengths reported in this study were generally shorter than those reported in studies of domestic horses, although they were within the range of reported variability (Ginther, 1992). Follicular phase durations for the Assateague mares were very similar to those of domestic mares; however, luteal phase durations were at the lower end of the range reported for domestic mares. These discrepancies may be related to variability introduced by less than daily fecal sampling. Among-individual variability in phase durations in Assateague mares was similar to variation observed in domestic mares (Ginther, 1992). There were no significant differences in phase durations between years or between currently treated and currently untreated mares, although there was a nonsignificant trend toward longer luteal phases in currently untreated mares.

The Assateague mares were contracepted with PZP for 1 to 7 years consecutively, and all showed some evidence of ovarian cyclicity during the 2-year study. Assateague mares appeared to experience a high incidence of ovulatory failure. However, the sample size precluded making a direct link between contraceptive treatment and ovulatory failure in this study. It appears that the apparent ovulatory failure seen in some mares in this study is episodic. Our data show that all mares who demonstrated ovulatory failure did have significant luteal increases in progesterone or normal estrous cycles (or both) at some time during the 2-year sampling period; however, none of the sampled mares foaled. Longer term and more frequent sampling would be required to determine conclusively the rate of occurrence of apparent ovulatory failure in these mares.

Kirkpatrick et al. (1992) found that Assateague mares treated with PZP for 3 years excreted reduced concentrations of urinary estrone conjugates compared to currently untreated mares, and the absence of a luteal phase increase in progesterone metabolites suggested that some treated females were anovulatory. In a later study, Kirkpatrick et al. (1995) found that the percentage of mares excreting normal range concentrations of urinary estrone conjugates declined from 80% for mares treated with PZP for 1 year to 0% for mares treated for 7 years. Hormonal assessments of mares conducted after 1, 2, 3, 6, and 7 years of annual PZP administration revealed that 50% of the treated mares excreted reduced concentrations of urinary estrone conjugates, although most females continued to cycle at least intermittently (Kirkpatrick et al., 1995). Here we present data from a sample of mares assessed in 2 consecutive years. We have demonstrated that the apparently anovulatory condition of some mares is episodic and that the duration of these episodes is variable. Some mares showing ovulatory failure did show evidence of a normal cycle in the same breeding season. Other mares did not show a normal cycle during one breeding season but did so in the other. Contrary to Kirkpatrick et al (1995), we found no association between the number of years of PZP treatment

and the incidence of ovulatory failure. We also have documented one case of a mare showing ovulatory failure in 2 consecutive years.

In summary, ovarian activity in PZP-treated mares (for 1 to 7 consecutive years) ranged from anovulation to intermittent cycles to completely normal estrous cycles (Kirkpatrick et al., 1995; Liu et al., 1989). To date, all mares who have been treated with PZP for 3 years and then taken off contraception have produced healthy foals within 3 years posttreatment (unpublished National Parks Service raw data). However, our data suggest that PZP immunocontraception may not be reversible in all mares after only 1 year. In addition, our data indicate that ovulatory failure appears to be episodic as opposed to chronic in these mares because all mares showed evidence of a luteal phase at some point during the 2-year study.

Ovulatory failure, defined as an increase in estrogen not followed by a sustained increase in progesterone secretion, has been documented in several other mammalian species after treatment with PZP (Bamezai et al., 1986; Gulyas et al., 1983; Mahi-Brown et al., 1985; McShea et al., 1997; Skinner & Dunbar, 1984; Skinner et al., 1984). In the only study to examine PZP-mediated ovarian pathology in mares, Liu et al. (1989) found no histological abnormalities in females ovariectomized 1 year after PZP immunization. However, significant ovarian pathology has been associated with PZP treatment in several other species (Gulyas et al., 1983; Hasegawa et al., 1992; Mahi-Brown et al., 1985; Sacco et al., 1987; Sacco, Subramanian, Yurewicz, DeMayo, & Dukelow, 1983; Skinner & Dunbar, 1984; Skinner et al., 1984; Wood et al., 1981). Histopathological findings range from decreased numbers of oocytes or various stage follicles (or both) to decreased ovarian size and the appearance of abnormal cellular masses. The degree and range of these abnormalities was variable across individuals and species (Sacco et al., 1987), and this may be related to individual or species-specific (or both) differences in immune responsiveness to PZP administration (Liu et al., 1989; Mahi-Brown et al., 1985).

The immune-mediated mechanisms whereby PZP has an impact on ovarian function are not well understood; however, it has been suggested that PZP may interfere with communication between developing oocytes and surrounding follicular cells—dogs (Mahi-Brown, Huang, & Yanagimachi, 1982) and rabbits (Skinner et al., 1990)—or that antibodies to ZP attack the developing occyte when certain ZP glycoproteins are secreted early during occyte development, causing oocyte death: guinea pigs (Hasegawa et al., 1992), dogs (Mahi-Brown et al., 1985), nonhuman primates (Sacco et al., 1987), and rabbits (Skinner et al., 1984; Wood et al., 1981).

A review of the literature suggests that, compared to other mammalian species, horses may be relatively insensitive to the adverse effects of PZP on ovarian function. We are unable to conclude that ovulatory failure in Assateague mares was directly related to PZP contraception because untreated controls were not available when this study was conducted. It is possible that antibody titres were still high enough in our currently untreated mares to affect ovarian func-

tion, making them indistinguishable from treated mares in terms of fecal hormone metabolite excretion. Ovulatory failure is relatively common in domestic horses and may be related to a variety of factors (Ginther, 1992). How common this phenomenon is in feral horses not exposed to PZP remains unknown. However, substantial evidence in other mammalian species provides incentive for conducting additional controlled studies in equids to determine the mechanism of action of PZP and its potential for inducing adverse side effects (ovarian pathology). Without such evidence, it is impossible to evaluate the actual potential of PZP for managing reproduction in wildlife species.

Immunocontraception is an attractive option for population management. Vaccines appear to be long acting and effective at stopping reproduction (Kirkpatrick et al., 1996). PZP does not appear to affect activity budgets of mares, their levels of aggression and sexual behavior, or their spatial relationships with the stallion (Powell, 1999, 2000). Despite these benefits, more research is required before PZP immunocontraception can be recommended for widespread use in wildlife. Long-term (up to 7 years) effects of PZP have only been assessed in equids, and these have been based on hormonal analyses only and not on an examination of ovarian histopathology. Behavioral effects have been assessed in a few studies, but these are restricted to ungulates: moose (Heilmann, Garrot, Cadwell, & Tiller, 1998), white-tailed deer (McShea et al., 1997), and feral horses (Powell, 1999, 2000). Clearly, more integrative research in horses is needed to addresses putative changes in reproductive–endocrine patterns, behavior, ovarian histology, and anatomy.

ACKNOWLEDGMENTS

This work was supported by a Smithsonian Institution predoctoral fellowship, the Department of Zoological Research of the National Zoological Park, the Abbott and Nelson Funds of the Smithsonian Institution, the Biology of Small Populations NSF training grant at the University of Maryland (BIR–9602266), Earthwatch Institute, and Sigma Xi. This work was approved by the Animal Care and Use Committee at the University of Maryland and by the Institutional Animal Care and Use Committee at the National Zoological Park. We thank our field staff—Paul Varga, Tim Hadlock, and 63 Earthwatch volunteers—for their assistance with sample collection. Jay Kirkpatrick provided input on this project and administered the contraceptive to some of the horses. We also thank Allison Turner, Jack Kumer, and Carl Zimmerman at the Assateague Island National Seashore for permission to work at the site and for access to records on the horses. Alexa Bach, Ines Castro, Kendall Mashburn, and Astrid Bellem provided assistance with sample preparation and assay. Kaci Thompson provided assistance with data analysis. Devra Kleiman, Jay Kirkpatrick, and Cheri Asa provided helpful comments on this manuscript.

ABSTRACT

Fertility control is a potential method for managing overabundant wildlife populations; however, current technology is limited by duration of treatment efficacy and unacceptable side effects. The objective of this study was to determine the efficacy of a single immunization with gonadotropin-releasing hormone (GnRH) vaccine to suppress reproductive function in pregnant female elk and to evaluate potential behavioral and pathological side effects of treatment. Eighteen captive adult female elk were randomly allocated to one of two experimental groups. Ten females were administered a conjugated and adjuvanted GnRH vaccine intramuscularly, and eight elk received an adjuvant sham vaccine without conjugated GnRH. We compared success of existing pregnancy, neonatal survival, subsequent fertility, reproductive behavior rates, and side effects of treatment between January 2006 and January 2010. The GnRH vaccination did not affect existing pregnancy or calf survival during the year that it was applied; however, it reduced the proportion of pregnant females for 3 yr. Male precopulatory behavior rates exhibited toward GnRH-vaccinated females tended to be greater than those directed at sham-vaccinated females during the second half of the breeding season, when GnRH vaccinates continued to be proceptive. Strong immune and inflammatory responses, including robust GnRH antibody concentrations in GnRH vaccinates, and sterile pyogranulomatous injection site abscesses in both groups, were consistent with vaccination. In conclusion, this GnRH vaccine resulted in prolonged, albeit reversible, impairment of fertility, and is associated with extended reproductive behaviors and partial suppression of hypothalamic-pituitary-gonadal axis function in captive female elk.

INTRODUCTION

Regulating the abundance of elk populations has become a significant issue for natural resource managers in many areas of North America [1]. This is particularly true for protected environments, such as national parks and conservation areas, where unregulated populations, if left unchecked, can have adverse effects on natural and human-dominated systems. Hunting, culling, and trapping have traditionally been used to regulate animal numbers, but there are a growing number of circumstances where these methods pose significant liability [2], and as a result resource managers are seeking alternative approaches to population control [3].

Fertility control offers a potential nonlethal method for controlling the growth of overabundant elk populations, and considerable research has been directed toward the development of different contraceptive technologies [4, 5]. Models have been developed to characterize effects of fertility control on population dynamics of wild ungulates, including elk [6]. Yet, current technologies for altering wildlife fertility suffer from a variety of technical, physiological, and regulatory challenges [4]. As a result, only modest successes have been achieved in developing a safe, practical, and feasible method of controlling reproduction in free-ranging wild ungulate populations.

A potential alternative to current fertility control products, and one that may overcome some of these challenges, involves active immunization against gonadotropin-releasing hormone (GnRH), a small, 10-amino acid neuropeptide produced in the hypothalamus that signals via receptors on gonadotroph cells in the anterior pituitary. Gonadotropin-releasing hormone, along with ovarian- and pituitary-derived endocrine, paracrine, and autocrine signaling, is responsible for gonadotroph function [7, 8], and ultimately gametogenesis [9]. Gonadotropin-releasing hormone is not generally immunogenic but can be made so by conjugation to a large, highly immunogenic carrier protein. When combined with a potent adjuvant, this vaccine stimulates a persistent immune response, resulting in prolonged antibody production against GnRH, the carrier protein, and the adjuvant [4]. Although there are competing theories of action [10], the prevailing hypothesis suggests that antibodies to GnRH induce transient infertility by binding to endogenous GnRH in the hypothalamic-pituitary portal vessels, thus preventing attachment to receptors on gonadotrophs, as well as suppression of pulsatile luteinizing hormone (LH) secretion. Gonadotropin-releasing hormone-antibody titers are correlated with suppression of the reproductive system and infertility in a variety of species [4].

Numerous GnRH vaccines have been developed and are successful in interrupting the hormonal cascade that controls ovulation. These vaccines have been used in physiologic research for decades. However, the use of GnRH vaccines as contraceptive agents in wildlife management has been limited by effective duration, multiple treatments to stimulate adequate antibody response, and deleterious side effects associated with the use of the controversial Freund complete adjuvant (FCA) [4, 5]. Recently, an alternative adjuvant (AdjuVac) containing

mineral oil and mycobacteria derived from a Johne disease vaccine (Mycopar; Fort Dodge Animal Health, Fort Dodge, IA) has been developed and may be as effective as FCA but is associated with fewer lesions [11].

Based on results from studies in captive and free-ranging wild or feral ungulates, a single application of this GnRH vaccine (GonaCon-B) may prove to be a safe and effective multiyear immunocontraceptive agent for free-ranging wildlife. A single application, formulated with the same or a similar GnRH-protein conjugate, has been shown to provide multiple years of decreased fecundity in several ungulate species, including elk [4, 5, 12]. However, few studies have rigorously investigated the secondary effects of this vaccine on social behaviors or ecological consequences in any wildlife species [5].

Elk are polyestrus short-day ovulators, with the peak of breeding season in North America between mid-September and mid-October [13]. Waves of follicle development occur during the ovulatory [14], anovulatory [15], and transitional [16] seasons. Ovulation occurs approximately every 20–21 days [14], and the ovulatory season can persist as late as April, although it is, on average, 142 days, ending in mid-February [16]. Pregnancy rates for mature females (2–12 yr) can approach one calf per female per year in populations that are not forage limited [17]. Approximately 50% of yearling females become pregnant at 16–18 mo of age if an appropriate body mass is achieved (~220 kg, 10% body fat) [13, 17, 18]. Reproductive senescence is not well described, but fertility may decline by 13–17 yr of age [17]; however, effects of body condition are likely more important to fertility than age [18, 19]. Elk are monotocous, and twinning is exceptionally rare [13]. Calving occurs from late May to early July after a gestation of 247–262 days and coincides with spring nutrient flush in most northern latitudes [13, 20].

Application of GnRH vaccine would be most practical during the winter period (December–February), when elk are concentrated in large, primarily single-sex herds [21], and temperatures and snow cover are conducive to chemical or physical capture [22]. At this time, most adult female elk are in midgestation to late gestation, and any contraceptive treatment must be demonstrated to be safe for the developing fetus and health of the neonate [23].

In light of these issues we examined the contraceptive efficacy and potential side effects of GnRH vaccination by testing the following four hypotheses using captive female elk. A single immunization with GnRH vaccine during midgestation in elk will: 1) not affect existing pregnancy; 2) suppress future fertility, with contraceptive effects waning as GnRH antibody concentrations decrease; 3) suppress reproductive behaviors; and 4) be associated with localized inflammatory reactions but not other pathological side effects.

MATERIALS AND METHODS

Animals and Vaccine

This study was reviewed and approved by the Colorado State University (no. 05-187A-01) and the Colorado Division of Wildlife (no. 07-2005) Institutional Animal Care and Use Committees. Animals were housed at the Colorado Division of Wildlife, Foothills Wildlife Research Facility, in Fort Collins, CO (40°35′46″N, 105°9′29″W). Eighteen female elk (1.5–12 yr of age at study onset; 220–275 kg) and two reproductively proven mature male elk (5–7 yr of age; 400–450 kg) were used for this experiment. The majority of experimental elk were long-term residents of the facility, most having been born in captivity. To meet sample size requirements, two free-ranging 3-yr-old females from a local wild population were captured and brought into the captive herd in the spring of 2005. Female elk were trained for repeated handling in isolation pens, alleyways, and a handling chute, and for blood sampling and ultrasound imaging procedures. Female elk were maintained throughout the experiment in two fenced paddocks (5.0 ha) with minimal native forage and were fed a diet of ad libitum alfalfa-grass hay mix, trace mineral blocks, and water, as well as limited pelleted grain supplement. Male elk were similarly maintained in a paddock, physically removed but within sight of females. During breeding seasons (late September–late November), males were maintained with females. All biological samples were collected and hands-on measurements made while female elk were lightly sedated using xylazine hydrochloride (30–250 mg per animal, i.m.; TranquiVed; Vedco Inc., St. Joseph, MO) in a nonsqueeze chute. Tranquilizer effects were reversed after each sampling session with either yohimbine hydrochloride (30 mg per animal, i.v.; Wildlife Pharmaceuticals, Fort Collins, CO) or tolazoline hydrochloride (600 mg per animal, i.m.; Tolazine; Akorn Inc., Decatur, IL).

Experimental vaccines were prepared as previously described [24]. Briefly, the GnRH vaccine consisted of multiple copies of synthetic GnRH peptide linked to hemocyanin protein (Blue Carrier; Biosonda, Santiago, Chile) from the Chilean mollusk (*Concholepas concholepas* [CCH]) and combined with a water-in-oil adjuvant containing killed *Mycobacterium avium* ssp. *avium*. The sham vaccine was similarly prepared but without conjugated GnRH.

Experimental Protocol

Data were collected between January 2006 and January 2010. At the start of the experiment, all 18 females were pregnant (80–100 days), as determined by serum pregnancy-specific protein B assay [25], rectal palpation [26, 27], and/or transrectal ultrasound [28]. One sham-vaccinated female (20 mo of age) aborted her pregnancy by late February 2006.

Approximately half of the females had been previously exposed to a *Brucella abortus* strain 19 vaccine. To avoid potential confounding anamnestic response effects, which may arise from antigenic stimulation with similar intracellular pathogens (*B. abortus* and *M. avium*) [29] or age-related fertility effects [17], we blocked sample units (female elk) with respect to brucella vaccination history and age (1, 2–10, or ≥11 yr of age) and then randomly assigned animals to either the GnRH vaccine (n = 10) or sham vaccine (n = 8) group. The GnRH-vaccinated females were administered 1.5 mg of GnRH-Blue Carrier protein conjugate with adjuvant (1.5 ml) into the left biceps femoris muscle using a handheld 3-ml syringe and a 3.8-cm, 18-gauge needle. Sham-vaccinated females received a similar volume of carrier protein and adjuvant but without conjugated GnRH. Injection site location was similar in all animals, with placement consistently at the leading edge of the cream-colored rump patch and at the same height as the tuber ischii. To facilitate pretreatment ultrasound examination as described below, hair was removed from the injection site and surrounding skin using electric clippers with a no. 40 blade, and the area was cleaned using isopropyl alcohol.

Females were divided into two pens (each pen with five GnRH vaccinates and four sham vaccinates) and placed in separate paddocks. In late September of each year (2006–2009) one male was placed in each pen for 62–65 days. Females remained in the same pen throughout the study, whereas males were rotated between pens each year to minimize effects due to potential random differences in male fertility and individual male-female interactions.

Pregnancy and Ovarian Measurements

We investigated the effects of GnRH immunization on the existing corpora lutea, pregnancy, and calving (2006) by comparing monthly (January–May 2006) serum progesterone concentrations, calving success, and calf survival and growth. Calves were weighed 12–24 h after birth, and then at 2- to 4-wk intervals for the first 3 mo of life. Calves remained with their dams until weaning on 1 September 2006. Subsequent pregnancy rates were determined each January during a 4-yr period (2007–2010) using methods described above. Once pregnancy was confirmed, abortion was induced using two doses of prostaglandin $F_{2\alpha}$ 6 h apart (25 mg, i.m.; Lutalyse; Pharmacia & Upjohn, Kalamazoo, MI) [30, 31].

We measured ovarian follicular and luteal structures in GnRH- and sham-vaccinated females at single time points the first year after vaccination during the early ovulatory (mid-September), late ovulatory (early January), transitional (late February), and anovulatory (late April) seasons using transrectal ultrasound imaging (5-MHz linear array transducer; Televet 1000; Classic Universal Ultrasound, Tequestra, FL) [14–16]. January imaging occurred coincident with pregnancy diagnosis; at all other time points females were not pregnant. Images were saved on a laptop computer for later evaluation. We measured the total number of antral follicles, follicular diameter (mm), and the presence or absence of ovarian structures consistent with luteal tissue. We then grouped follicles into small (<4 mm), medium (4 to <7 mm), and large (≥7 mm) classes, and calculated total follicular volume combining data from both ovaries for each individual.

Analysis of Hormone Concentrations and Antibody Titer

Blood samples (10–30 ml) were collected via jugular venipuncture using a 20-gauge blood collection needle, tube holder, and 10-ml blood tubes without anticoagulant (BD Vacutainer SST; Becton Dickinson and Co., Franklin Lakes, NJ). Blood was allowed to clot at room temperature and was centrifuged for 10 min at 1500 × *g*, and serum was decanted to polypropylene tubes and stored at −80°C until assays were performed. Monthly (January–May 2006) serum concentrations of progesterone were measured by radioimmunoassay [32], a technique previously validated in elk [33]. All samples were run in duplicate in a single batch. The range of the standard curve was 0.39 ng/ml (80% ligand-labeled progesterone) to 15.0 ng/ml (20% ligand-labeled progesterone). Intraassay coefficients of variation were 14.1% for the low reference sample and 7.1% for the high reference sample.

Serum GnRH antibodies were measured prior to vaccination, monthly until calving, and prior to introducing males into female pens each year (September 2006–2009). The concentration of unbound GnRH antibodies was estimated by measuring ^{125}I-GnRH binding capacity in peripheral serum [34, 35]. Serum samples were diluted between 1:2 and 1:100 000 using 0.05 M ethylenediaminetetraacetic acid (EDTA) in 0.01 M PBS with 0.1% gelatin (EDTA-PBS gel). A total of 200 μl of diluted test sera, 100 μl of EDTA-PBS gel, and 100 μl of ^{125}I-GnRH (specific activity ~1850 Ci/mmol; ~60 000 dpm) were added to 5-ml glass tubes. Solutions were vortexed and incubated for 24 h at 4°C. One milliliter of 20% polyethylene glycol solution (6000 mw; diluted with PBS) was added, and tubes were vortexed. Tubes were incubated for 20 min at 4°C, then centrifuged for 30 min at 980 × *g*. Supernatants were decanted and tubes placed in a gamma counter (efficiency ~80%; Micromedic Systems, Horsham, PA) to record radioactivity (cpm). Total radioactivity was measured in 100 μl of ^{125}I-GnRH. Nonspecific binding was measured by adding 100 μl of ^{125}I-GnRH to 300 μl of EDTA-PBS gel and handling similarly to test samples. High antibody titer-positive control sera from rabbits [35] and elk previously vaccinated against GnRH (data not shown) as well as negative control elk sera were included with each batch. All samples were analyzed in duplicate. To provide a similar comparison between animals, we selected the 1:1000 dilution to estimate antibody concentration (pmol/ml) and reanalyzed all samples in a single batch. The intraassay coefficient of variation was 3.5%. Gonadotropin-releasing hormone antibody response is reported as picomoles of ^{125}I-GnRH bound per milliliter of serum.

Pathological Side Effects

Mean serum chemistry and hematology parameters, *M. avium* antibody status, and prevalence of injection site reactions were compared between groups. Blood was collected as described above but with the addition of a 10-ml blood tube with EDTA anticoagulant for hematology. Samples were taken prior to vaccination for each assay and then at 30, 90, and 340 days after vaccination for hematology, chemistry, and *M. avium* assays, respectively. Whole blood and serum were submitted to the Colorado State University Veterinary Diagnostic Laboratory (Fort Collins, CO) for analysis. Hematology parameters measured included: total nucleated cells, segmented neutrophils, lymphocytes, monocytes, eosinophils, platelets (all $\times 10^3$/μl), plasma protein (g/dl), red blood cells ($\times 10^6$/μl), hemoglobin (g/dl), packed cell volume (%), mean corpuscular volume (fl), mean corpuscular hemoglobin concentration (g/dl), and fibrinogen (mg/dl). Chemistry profile parameters included: glucose, creatinine, phosphorus, calcium, magnesium, total protein, albumin, globulin, and total bilirubin (all mg/dl); enzymes, including creatinine kinase, aspartate aminotransferase, gamma-glutamyltransferase, sorbitol dehydrogenase (each IU/L); and electrolytes, including sodium, potassium, chloride, and bicarbonate (each mEq/L). *Mycobacterium avium* antibody concentrations were measured using ELISA (HerdChek ELISA; IDEXX Laboratories, Westbrook, ME) and reported as optical density of the sample.

We used palpation and ultrasonography to evaluate injection sites for evidence of localized inflammation prior to vaccination, at monthly intervals until calving (February–May 2006), and prior to each breeding season (September 2006–2009). Injection sites and surrounding skin were shaved as described above. Qualitative changes in skin temperature, erythema, and swelling were assessed by comparing the injection site with adjacent skin. We used ultrasonography to evaluate muscle tissue for subcutaneous and intramuscular signs of inflammation and injury, including lesions such as hematoma, abscess, scar tissue, cellulitis, and myositis, which are associated with characteristic changes in muscle echogenicity and architecture [36–38]. Longitudinal and transverse ultrasound images of skin, fat, fascia, and muscle at the site of injection were collected using a 5-MHz linear array transducer to a depth of 80 mm with a focal zone at 40 mm and were stored on a computer for future analysis. Ultrasound images were described to indicate qualitative degree of change between prevaccination and postvaccination sampling dates in both muscle echogenicity (e.g., hyperechogenic, hypoechogenic) and architecture (e.g., fiber length, fiber pattern). All ultrasound evaluations were performed and read by a single technician. When images were consistent with a well-defined abscess accessible by percutaneous needle aspiration or if a soft, fluid-filled swelling was palpated, it was aspirated, and aerobic, including mycobacterial, cultures and anaerobic cultures were performed. Two abscesses were lanced, drained, and flushed because the welfare of the animal was a concern.

Each animal was observed for the presence or absence of lameness (e.g., limping, gait alterations, reluctance to stand or bear weight on a limb) each time it was moved from pens to the handling chute. Additionally, caretakers observed each female daily during feeding and noted if swelling or discharge was evident at the site of injection and if there were overt signs of lameness.

During the course of the experiment, three GnRH-vaccinated females died because of handling difficulties (n = 1; February 2006) or chronic wasting disease (n = 2; August 2007). Chronic wasting disease is endemic within the facility and was diagnosed in study animals using immunohistochemistry of rectal mucosa-associated lymphoid tissue, retropharyngeal lymph nodes, and brainstem at the level of the obex [39, 40]. Complete necropsies were performed by a veterinary pathologist, and injection sites along with standard tissues (e.g., representative tissues of each organ system) were removed and preserved in 10% neutral-buffered formalin for histopathological evaluation.

Reproductive Behaviors

We compared rates of reproductive behavior interactions (behavior events per hour) of male and female elk from 25 September–12 November 2006 as previously described [33]. Individually identifiable numeric/color-coded collars were placed on each female in both treatment groups. Behaviors were observed during the morning (0400–0600 h), evening (1600–2000 h), and at night (2200–2400 h) from a tower that provided good visibility of both pens. An infrared night vision monocular was used to observe behaviors during dark hours, and a spotlight was used to confirm collar identification. Four technicians similarly trained in behavior identification and blinded to treatment group performed observations. Based on previously reported elk reproductive behaviors, we identified and recorded 13 different interactions associated with harem tending, proceptivity, receptivity, and mating (Table 1) [21, 33, 41, 42]. Only male-female interactions were recorded. All behaviors were attributed to the individual female displaying or receiving the behavior. If the male displayed behavior directed at more than one female (e.g., herd tending) it was recorded as a separate behavior for each female. Because of small sample size, we grouped these specific behaviors into four general behavior categories: general breeding, male precopulatory, female precopulatory, and copulatory (Table 1). A total of 112 two-hour sampling periods were recorded in 47 days during 38 morning (74.1 h; 35%), 43 evening (81.4 h; 38%), and 31 night (58.5 h; 27%) sampling periods. Length of behavioral interactions was typically short compared with sampling interval, so each interaction was recorded as an event. Behavior rates were calculated as events per female per hour, and estimated mean weekly behavior rates were compared between treatment groups.

Statistical Analysis

Yearly pregnancy data are reported as the proportion of pregnant female elk in each treatment group (number of pregnant females in each treatment group/number of females exposed to bulls from late September to late November each year). Pregnancy proportions were compared with one-tailed Fisher exact tests. The difference in proportions was used to estimate treatment effect. We used normal approximations to binomial distributions to compute confidence limits for the differences between proportions.

To evaluate the probability of pregnancy for a given GnRH antibody concentration, we used simple logistic regression with pregnancy status, breeding season, and treatment group as classification variables, and GnRH antibody concentration as the continuous variable (PROC PROBIT; SAS 9.1; SAS Institute Inc., Cary, NC). The probability of pregnancy after treatment with the GnRH vaccine was calculated for a theoretical sample population with an intrinsic pregnancy rate of 1.0 calf per female per year, and for this study's sham-vaccinated control population, which had an intrinsic pregnancy rate of 0.96 during the four experimental years. Using a cutoff value of $\geq$20 pmol GnRH antibody per milliliter of serum to indicate infertility, we estimated the type 1 (false-positive) and type 2 (false-negative) error rates by calculating the specificity (proportion of correctly classified nonpregnant females) and sensitivity (proportion of correctly classified pregnant females) of using antibody concentration as a diagnostic indicator of pregnancy status. Specificity was calculated as the number of true nonpregnant animals indicated by the antibody concentration divided by the total number of nonpregnant females. Sensitivity was calculated as the number of truly pregnant females indicated by the antibody concentration divided by the number of total number of pregnant females. Pregnancy data were combined over 4 yr for specificity and sensitivity calculations.

Downloaded from www.biolreprod.org.

TABLE 1. Thirteen individual reproductive behaviors and associated behavior categories observed and recorded 8 to 10 mo after immunization in GnRH-vaccinated and sham-vaccinated elk (*Cervus elaphus nelsoni*).

Behavior category	Reproductive behaviors
General breeding	Male behavior related to establishing, maintaining, and defending a group or harem of female elk (i.e., herding, guarding).
Male precopulatory	Male courtship behavior directed toward an individual female to induce or detect estrus (i.e., Flehmen for urine testing, chivy, sniff and/or lick body, rub body, precopulatory mount).
Female precopulatory	Female courtship behavior directed toward dominant male to arouse copulatory behavior (i.e., sniff and/or lick body, rub body, circle, mount, lordosis).
Copulatory	Male behavior directed toward a receptive female (i.e., intromission).

We tested the hypothesis that mean behavior rates between treatment groups were different using a mixed linear ANOVA model to account for both random (individual animal) and fixed (treatment, date, male, and time of day) effects in a repeated-measures structure (PROC MIXED; SAS 9.1). For each of the four behavior categories, a global model was constructed which included treatment group, time of day, and male, along with all of their first-order interactions. Date was included as an additive trend factor. Next, variance structures, heterogeneous versus homogeneous both within and between individual females, were added to the model, and Akaike Information Criterion adjusted for small sample size (AICc) was used to select the best fit model. Similarly, three covariance structures—none, compound symmetry, and spatial power—were analyzed, and AICc was used for model selection. Finally, after fitting variance and covariance structures, six reduced models were run to find the most parsimonious model to estimate treatment effects. Using the best model, mean behavior rates (±SEM) were estimated using least squares analysis, and hypothesis tests were based on type III generalized estimating equations, which account for sample size imbalance.

Similar methods were used to compare mean (±SEM) concentrations of progesterone, as well as ovarian follicle number, size, and volume. Fixed effects in the analyses were treatment status and date, and individual females were evaluated as a random effect. Differences in calf weight during the first 3 mo of life were analyzed in the same way, with dam treatment status, sire, sex, and age as fixed effects. Differences in proportions of small-, medium-, and large-size follicles were analyzed using a chi-square test with treatment status and date as classification variables (PROC CATMOD; SAS 9.1). A paired Student *t*-test (PROC TTEST; SAS 9.1) was used to evaluate differences in mean optical density readings from *M. avium* ELISA. Descriptive statistics were used to explain the similarity of hematology profiles, presence or absence of luteal tissue during early ovulatory and transitional periods, and occurrence of lesions at the site of injection.

RESULTS

Pregnancy and Calving

Gonadotropin-releasing hormone vaccination did not affect calving success in female elk treated at approximately 80–100 days of pregnancy. Serum progesterone concentrations during the second half of gestation did not differ between treatment groups ($P = 0.849$; Fig. 1). Progesterone concentrations varied by month ($P < 0.001$), but there were no treatment by month interactions ($P = 0.619$). All females, except the single 20-mo-old sham vaccinate that had midgestation pregnancy loss, delivered full-term calves. One calf born to a GnRH-vaccinated dam died during parturition due to dystocia. All calves born alive (n = 15) survived the neonatal period and were weaned at approximately 3 mo of age prior to the 2006 breeding season. Dam vaccination exposure did not affect calf weight at any time point prior to weaning ($P = 0.448$; data not shown).

GnRH Vaccine Efficacy and Duration

Pregnancy proportions in GnRH-vaccinated females were lower ($P \leq 0.05$) than in sham-vaccinated females during the first 3 yr of the experiment (Table 2). Treatment effect decreased between Year 1 and Year 4 ($P = 0.009$), from a high of 0.90 in 2007 to a low of 0.12 in 2010 (Table 2). Antibody concentrations in GnRH-vaccinated elk were detectable 1 mo after inoculation, peaked 3–8 mo after vaccination, and waned during the course of the study (Fig. 2). Gonadotropin-releasing hormone antibodies were not detectable in sham-vaccinated females (data not shown). There was a strong inverse relationship between GnRH antibody concentration and the probability of becoming pregnant ($P < 0.001$; Fig. 3). At 30 pmol/ml free GnRH antibody binding capacity in the peripheral serum, the logistic model predicted a pregnancy rate of 0.10 in a population whose intrinsic pregnancy rate approached 1.0 (Fig. 3). Only one GnRH-vaccinated female with lower than 20 pmol/ml concentrations of antibody (approximately 2–17 pmol/ml) did not become pregnant during the first three breeding seasons. Conversely, one female with consistently high serum antibody concentrations (>20 pmol/ml) did become pregnant during the third and fourth breeding seasons. Using a GnRH antibody concentration of 20 pmol/ml during September as the cutoff point, the assay had a sensitivity of 0.85 and specificity of 0.87 to predict whether a female elk would be infertile during the current breeding season.

Reproductive Behaviors

General breeding and male precopulatory behaviors were the most prevalent interactions recorded. Copulatory behaviors were observed too infrequently for meaningful analysis. Although differences in mean male precopulatory behavior rates only approached significance ($P = 0.073$), those directed toward GnRH-vaccinated females (0.45 ± 0.06 behaviors per hour) were 30% greater than those directed toward sham-

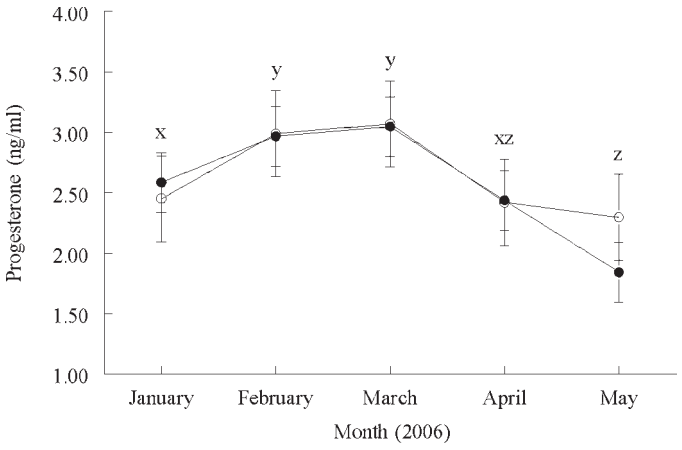

FIG. 1. Mean ± SEM monthly serum progesterone concentrations in GnRH-vaccinated (filled circles; n = 10) and sham-vaccinated (open circles; n = 7) female elk (*Cervus elaphus nelsoni*) between the time of GnRH immunization (January 2006) and parturition (May–June 2006). Means with different letters indicate differences between months ($P < 0.05$).

TABLE 2. Mean yearly pregnancy proportions (no. pregnant/no. exposed to fertile bull) and estimates of treatment effect size (difference in proportions) with 95% confidence intervals for GnRH-vaccinated and sham-vaccinated female elk (2006–2010).

	Proportion pregnant*		Treatment effect
Yr after treatment†	GnRH-vaccinated [n]	Sham-vaccinated [n]	Difference (95% CI)
0	1.0 [10]^{ax}	1.0 [8]^{ax}	0.0
1	0.10 [10]^{by}	1.0 [7]^{ax}	0.90 (0.71–1.0)
2	0.25 [8]^{byz}	1.0 [7]^{ax}	0.75 (0.50–1.0)
3	0.50 [8]^{byz}	1.0 [7]^{ax}	0.50 (0.15–0.85)
4	0.75 [8]^{az}	0.86 [7]^{ax}	0.12 (0.0–0.29)

* Proportions with different superscripts are significant ($P \leq 0.05$). Letters a and b are between treatment groups within a given year; letters x, y, and z are between years.
† Year 0, 2006 (before treatment); Year 1, 2007; Year 2, 2008; Year 3, 2009; Year 4, 2010.

vaccinated females (0.33 ± 0.06 behaviors per hour). This response became apparent after the initial 2 wk of observation (Fig. 4). Individual males were a significant covariate in male precopulatory behavior ($P = 0.002$), as were date and time of day ($P < 0.001$), and there was an interaction between bull and time of day ($P < 0.001$). Female precopulatory behaviors were not different between treatment groups ($P = 0.720$); however, precopulatory behavior of GnRH-vaccinated females persisted throughout the sampling period, whereas this behavior rate dropped to nearly zero in sham-vaccinated females after the first 3 wk of observation (Fig. 4). Date tended to be an important covariate in female precopulatory behavior ($P = 0.055$). There were no differences in mean general reproductive behavior rates between treatment groups ($P = 0.794$). Time of day and date were significant ($P < 0.001$) covariates for general reproductive behaviors.

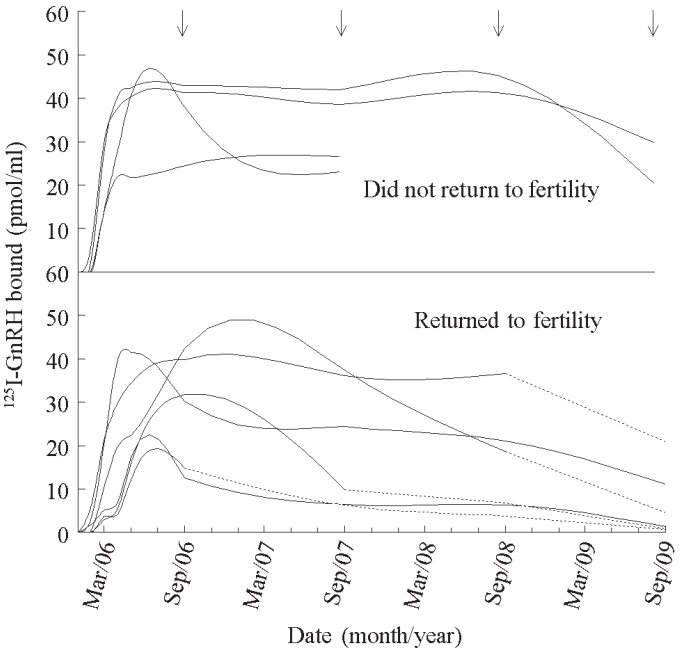

FIG. 2. Persistence of GnRH antibodies measured via ^{125}I-GnRH binding capacity in peripheral blood of GnRH-vaccinated female elk. Top panel shows antibody concentrations in females that did not become pregnant after vaccination (n = 4 of 10) throughout the 4-yr study. Two animals were lost from the study after Year 2. Lower panel shows antibody concentrations from females that either did not experience infertility (n = 1 of 10) or returned to fertility during the study (n = 5 of 10). Solid lines indicate nonpregnant females. Dotted lines indicate pregnant females. Two females became pregnant after antibodies were measured in September 2009. Arrows indicate date when males were placed in female pastures (September 2006–2009).

Pathological Side Effects

Most biochemistry and hematology parameters were within clinically normal ranges for all elk [13]. Two females, one from each treatment group, demonstrated leukocytosis (22×10^3 to 26×10^3 nucleated cells per microliter) 1 mo after injection, which was attributable to neutrophilia (9×10^3 to 12×10^3 per microliter) and lymphocytosis (9×10^3 to 11×10^3 per microliter). The GnRH-vaccinated female demonstrated mild hyperfibrinogenemia (300 mg/dl) and thrombocytopenia (57×10^3 per microliter). An additional four GnRH-vaccinated females had mild hyperfibrinogenemia (300–400 mg/dl). Although all globulin levels were within the clinically normal range (1.9–4.3 mg/dl), serum globulins increased between 0.1 and 0.6 mg/dl at 4 mo after inoculation in every female in both groups.

All animals were seronegative for Johne disease prior to vaccination. One year after injection *M. avium avium* ssp. *paratuberculosis* (MAP) antibody concentrations tended to be greater than zero ($P = 0.059$) in both treatment groups. With one exception, all females showed an increase in MAP antibody concentrations, indicated by an increase in optical density, and 3 (18%) of 17 females had sufficiently robust responses to be classified as seroconverted and Johne disease positive.

Estimated mean (±SEM) number of follicles was greater in GnRH-vaccinated females (5.6 ± 0.44) than sham-vaccinated females (2.46 ± 0.48; $P = 0.005$). Mean size of all imaged follicles in GnRH vaccinates (2.35 ± 0.29 mm; range, 0.3–12.6 mm) was smaller than that of sham vaccinates (4.73 ± 0.84 mm; range, 1.2–16.9 mm; $P = 0.014$). There was no difference in total follicular volume between groups ($P = 0.240$). Date was not a significant covariate ($P \geq 0.05$) in any of the analyses, and there were no date by treatment interactions. The GnRH-vaccinated females had more small follicles (<4 mm) but fewer medium (4 to <7 mm) and large (≥7 mm) follicles ($P < 0.001$) than sham vaccinates. Corpora

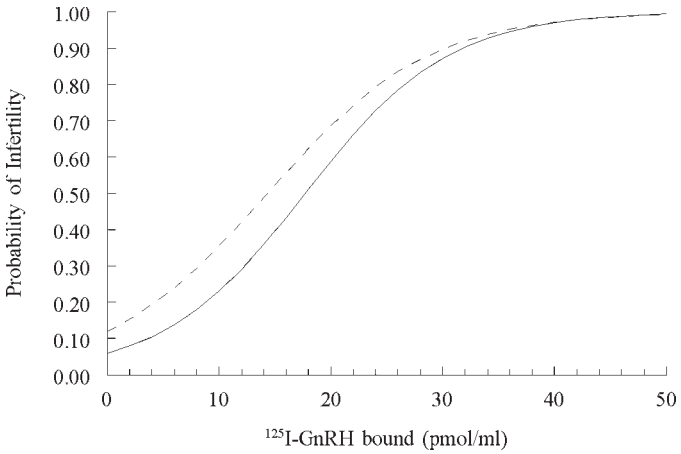

FIG. 3. Predicted relationship between ^{125}I-GnRH binding capacity (antibody concentration) and the probability of infertility in GnRH-vaccinated female elk, modeled with (dashed line; probability of pregnancy if untreated = 0.96) and without (solid line; probability of pregnancy if untreated = 1.0) intrinsic infertility.

Downloaded from www.biolreprod.org.

lutea were observed in 6 (27%) of 22 images collected from sham-vaccinated females during early ovulatory and transitional season periods. In contrast, corpora lutea were never observed in GnRH-vaccinated females during the same time periods. Luteal tissue was not observed in any study animal during anestrus.

Between 15 and 52 mo after injection, 6 (35%) of 17 females (n = 4 GnRH vaccinated and n = 2 sham vaccinated) developed clinically apparent abscesses (e.g., large soft swelling with purulent material) at the site of injection. No aerobic, including mycobacterial, or anaerobic bacterial growth was detected in cultures (n = 4). Two of the four GnRH-vaccinated animals described above died of causes unrelated to vaccination (i.e., chronic wasting disease) 19 mo after vaccination. Both possessed large (~500 ml), purulent, multiloculate, encapsulated abscesses at the site of injection. Histopathology revealed pyogranulomatous inflammation and multiple acid-fast bacilli within the capsule and surrounding muscle tissue. The acid-fast bacilli were consistent with mycobacteria. We did not observe lameness at any time point in study animals.

Muscle architecture and/or echogenicity was altered in 10 (~60%) of 17 females (n = 5 from each treatment group). The earliest changes in echogenicity were observed 2 mo after injection; however, the most severe changes, including images consistent with abscessation were seen 5 to 30 mo after vaccination. Regardless of treatment group, there was a wide variation in severity of change, from muscle fiber disruption and diffuse fiber hyperechogenicity to large, hypoechogenic multiloculated areas within the muscle or between fascial planes. All of the animals with clinical abscesses had evidence of muscle fiber disruption in one or more ultrasound images prior to observing external manifestations of the abscess.

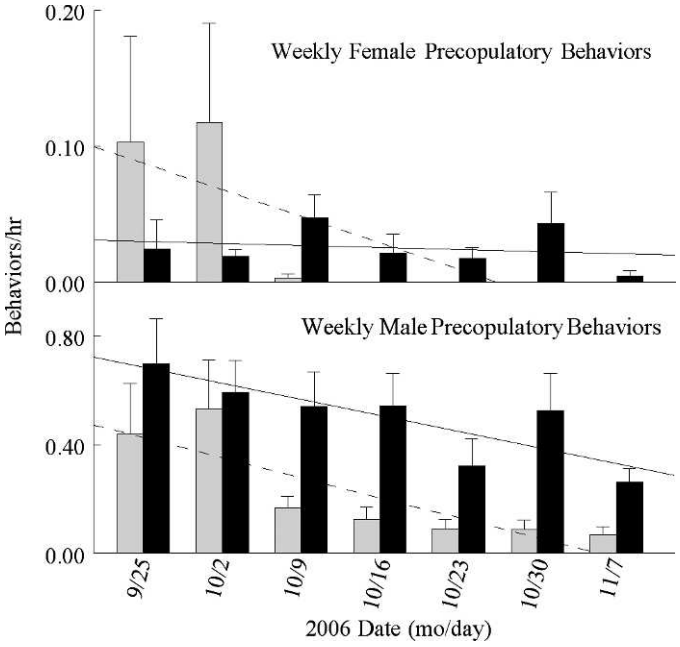

FIG. 4. Mean ± SEM weekly female precopulatory behavior rates demonstrated by GnRH-vaccinated (black bars and solid lines; n = 10) and sham-vaccinated (gray bars and dashed lines; n = 7) female elk (top panel) and mean weekly male precopulatory behavior rates received by female elk (n = 10 GnRH vaccinated; n = 7 sham vaccinated; bottom panel) during the 2006 breeding season (25 September–12 November). Regression lines illustrate persistence of precopulatory behaviors demonstrated and received by GnRH- and sham-vaccinated females.

DISCUSSION

A single vaccination against GnRH during midgestation did not disrupt pregnancy but did decrease the proportion of pregnant female elk for 3 yr after treatment. The efficacy of the GnRH vaccine decreased each year following treatment. These findings supported our predictions that this GnRH vaccine delivered to pregnant female elk reduced fertility, with decreasing efficacy over time. These findings were also consistent, in part, with those reported for nonpregnant female elk treated with GnRH vaccine using keyhole limpet hemocyanin as the carrier molecule rather than CCH [12]. However, in contrast to our measurements, Killian et al. [12] showed a weak inverse relationship between contraceptive efficacy of the vaccine and antibody levels: increasing effectiveness with decreasing antibody titers. Their result is difficult to explain biologically in light of our observations and others [24, 43] that support a strong positive association between infertility and antibody levels. Their finding may be an artifact of small sample size. Despite the association between antibody titer and contraception, we did not identify a GnRH antibody concentration cutoff that predicted contraceptive effects with high sensitivity and specificity. The most useful diagnostic assays have wide separation between negative and positive cutoff values [44, 45]. Because there was overlap in pregnancy status at given antibody concentrations, GnRH antibody concentration as a diagnostic test may be a good indicator of herd or population level of infertility, but a less reliable predictor of individual animal fertility.

The wide variation in antibody concentrations observed in our study was not surprising, given that individual humoral responses to a foreign antigen are known to be influenced by many physiological factors, including nutrition, previous exposure to the same or similar antigens, age, persistence of the antigen, current immune stimulation by other immunogens, and genetics [44]. We attempted to control for the first four potentially confounding factors; however, the latter two factors were not measured or controlled and may have influenced individual responses. Of more interest was the persistence of GnRH antibody concentrations during the course of 4 yr in GnRH-vaccinated animals. Most commercially available vaccines require an initial series of two or three vaccinations with annual revaccination to maintain significant serum antibody concentrations [44]. Previous wildlife immunocontraceptive vaccines have required similar vaccination strategies [46–48]. Only recently have single-dose applications been effective at inducing long-term antibody production and corresponding infertility [43, 49, 50]. It has been suggested that a combination of depot effect produced by a nonbiodegradable oil in water-based emulsion along with an optimized concentration of immunostimulatory killed mycobacteria is responsible for the prolonged antibody effect in GnRH-vaccinated deer [24, 51]. Our finding of extensive localized inflammation at the site of injection nearly 4.5 yr after vaccination supported this hypothesis of a depot effect, particularly given the retained and apparently dead mycobacteria within the sterile lesions. Additionally, *M. avium* antibody concentrations that were often sufficiently elevated to indicate disease status seroconversion supported the assertion that a generalized and robust humoral immune response to the vaccine was critical to its efficacy.

Both GnRH-vaccinated and sham-vaccinated groups had follicles ranging in size from less than 2 mm to more than 12 mm in diameter during the early ovulatory, transitional, and anestrous seasons. Additionally, during transitional seasons ultrasound evidence of luteal tissue was only observed in sham-

Downloaded from www.biolreprod.org.

vaccinated females. Although we did not intensively measure follicular development and document ovulation, these data suggested that 12–18 mo after vaccination with GnRH, at least some females had large preovulatory-sized follicles that likely did not ovulate. The range of follicular size was consistent with earlier data from untreated elk in the transitional and anestrous periods [15, 16]. Although a full range of follicular sizes was observed in our study, mean follicular size was smaller but antral follicles were more numerous in GnRH-vaccinated compared with sham-vaccinated females. Our observations are similar, although less extreme, than those of Seekallu et al. [34]. Those authors found complete cessation of follicular waves and development of large-sized follicles in domestic sheep after a series of two vaccinations against GnRH. Differences in experimental methodology may account for this inconsistency. Our measurements were made 12–18 mo after immunization after a single vaccination, whereas they made measurements 26–66 days after booster vaccination. Their more intensive vaccination and monitoring schedule may explain the more complete hypothalamic-pituitary-gonadal axis suppression observed.

Our data indicated fewer follicles developed to the preovulatory stage, which was likely due to incomplete gonadotropin support. Attenuation of follicle development into large antral stages likely resulted in less negative feedback from dominant follicles secreting inhibin and estradiol. An increase in small follicle recruitment due to less negative feedback from dominant follicles and early regression due to incomplete gonadotropin support could account for the increase in numbers of small follicles observed in GnRH-vaccinated elk. Although follicles were on average smaller in GnRH-vaccinated females, antral follicle development persisted and suggested that gonadotropins, particularly follicle-stimulating hormone (FSH), continued to stimulate early follicular development. Although LH secretion is closely regulated by GnRH [52, 53], FSH synthesis is only partially controlled by the interaction of GnRH with its receptor [54–56]. The primary regulator of FSH synthesis is negative feedback from estradiol and inhibin, and secretion is primarily constitutive [54, 56]. It has been suggested that a component of basal LH secretion is similarly free from GnRH regulation [57]. In the current study, antral follicle development was consistent with FSH stimulation and possibly basal LH signaling, albeit at a decreased level. Absence of observed luteal tissue in GnRH-vaccinated females was consistent with a probable lack of sufficient estradiol to initiate an LH surge and ovulation. Experiments to intensively measure individual animal follicular dynamics and concurrent gonadotropin concentrations are required to test these speculative hypotheses.

Contrary to our prediction, reproductive interactions during the breeding season were not eliminated in vaccinated females. Estrous behavior in domestic ruminants is influenced not only by the presence or absence of progesterone and estradiol, but also the concentration and timing of these steroid hormones [58]. Continuous, high concentrations of progesterone (e.g., during pregnancy) usually inhibit expression of estrous behavior regardless of estradiol concentrations [58]. In contrast, sexual receptivity can be triggered by estradiol alone in most species, albeit often in the pharmacological range, as long as progesterone is not inhibitory [59, 60]. In this study, despite the apparent absence of ovulation, both female attractiveness, measured by male precopulatory behaviors, and female proceptivity, measured by female precopulatory behaviors, were maintained throughout the first breeding season after immunization in GnRH-vaccinated, and consequently nonpregnant, animals.

Interestingly, domestic male cattle will spend equal time with young nulliparous females in estrus or in the luteal phase, finding them equally attractive [61]. Male elk may similarly investigate nonpregnant females regardless of estrous status. A combination of low progesterone due to lack of ovulation, and the presence of limited estradiol due to altered follicular development, may have contributed to the continued expression of precopulatory behaviors in female elk. These mechanisms could account for pregnancy status being a stronger indicator of reproductive behavior than vaccination status. Because we observed too few copulatory behaviors to evaluate differences between treatment groups, it is unclear if vaccinated females were receptive to copulation or were only displaying proceptive behaviors. Because GnRH-vaccinated animals did not likely experience progesterone priming prior to estradiol exposure, which is important for the display of full estrous behaviors in domestic sheep [60, 62], we speculate that copulation failed to occur in nonpregnant GnRH-vaccinated animals. Regardless, it is apparent that in the relatively small captive environment of this experiment, with intensive male-female interactions, GnRH vaccination was associated with persistent breeding behaviors. Although these observations may be an artifact of captivity, the consequences in free-ranging populations are unclear but could be significant and deserve further investigation into potential ecological consequences prior to use in a management application.

In accordance with our hypothesis regarding physiological side effects, GnRH vaccination did not significantly affect blood chemistry or hematology parameters, but it did result in considerable injection site reactions. Two females showed evidence of a systemic inflammatory response, and four additional animals had mildly elevated fibrinogen, an indicator of inflammation. Every animal had increased serum globulins. These findings indicated a robust immune response to both the GnRH conjugate and sham vaccines. Abscesses were confirmed in 35% of females, which was consistent with others using a similar formulation of this vaccine in white-tailed deer [43, 63]. However, ultrasound changes indicative of myositis, trauma, and abscessation [36–38] suggested a higher incidence of injection site inflammatory lesions. It was unclear whether the pyogranulomatous inflammation at the site of injection would have resolved with time. Evaluation of the long-term physiological consequences of injection site reactions in animals treated with this vaccine will be essential for managers making choices based on animal welfare concerns.

In addition to antibodies produced in response to GnRH, antibodies were also produced to other elements of the vaccine. Mycobacteria and their cellular components are particularly immunostimulatory [64]. Antibodies produced in response to *M. avium* ssp. *avium* appear to cross-react well with commercial assays for Johne disease, a gastrointestinal disease of domestic cattle and occasionally wild ruminants, such as elk [65]. Vaccination with GonaCon-B and/or the adjuvant components increased mycobacterial antibodies in nearly every animal and induced clinical seroconversion in 18% of animals. Managers concerned with regulatory issues or Johne disease management should be aware of this finding prior to using this vaccine in free-ranging ungulates.

In conclusion, a single vaccination during midgestation with the described GnRH vaccine decreased pregnancy rates for 3 yr after treatment without compromising the existing pregnancy. This result extended potential practical use of contraception by providing multiple years of decreased fertility when applied to either pregnant or nonpregnant female elk. Hematology and serum chemistry parameters were typically normal, and vaccinated females appeared clinically healthy. Furthermore,

Downloaded from www.biolreprod.org.

the vaccine appeared to be safe for the developing fetus and neonates born to vaccinated females. By contrast, the vaccine prolonged reproductive behaviors during the breeding season, a finding that has potential ecological effects that require further study. The most apparent pathological side effect of the vaccine was related to the development of sterile abscesses at the site of injection. Although lameness was never observed, most GnRH and sham-vaccinated females showed some level of tissue inflammation or abscess. Finally, we demonstrated that GnRH vaccination inhibited, but did not eliminate, follicular development despite the absence of pregnancy, possibly because of continued FSH secretion, indicating continued partial function of the hypothalamic-pituitary-gonadal axis. Our findings extend both the fundamental and practical understanding of GnRH vaccination in pregnant elk, which may assist wildlife managers in their pursuit of science-based population management.

ACKNOWLEDGMENTS

The authors thank the Colorado Division of Wildlife for providing the resident elk and handling facilities used in this investigation. We offer thanks to U.S. Department of Agriculture/Animal and Plant Health Inspection Service, National Wildlife Research Center (L. Miller, J. Rhyan, and K. Fagerstone) for the generous donation of the GnRH vaccine. We are particularly grateful to T. Davis, A. Mitchell, M. Fisher, J. Spaak, and I. LeVan for technical assistance in animal handling, sample collections, and husbandry. We are thankful for the many hours D. Germann, K. Kearl, and M. Paulek spent recording elk behaviors, for histopathological examination provided by T. Spraker, and for the endless logistical support provided by C. Broomfield and T. Powers. A special thanks to M. Allen and C. Magee, who trained multiple people in the art of radioimmunoassay, and to A. Graham and A. Latimer for laboratory assistance. Thank you to G. Sargeant, who provided statistical advice and improved our figures. This manuscript was significantly improved by the review and comments of M. Phillips and T. Shenk of the Colorado Division of Wildlife. A special thanks to M. Wild for supporting our pursuits of excellent research and professional development.

became pregnant. The records prior to treatment showed that in 24 doe-years, 34 fawns were born (1.4 fawns/doe-year). In contrast, during 54 doe-years posttreatment with SpayVac®, only one fawn was born (0.019 fawns/doe-year). SpayVac has also been proven to provide multi-year efficacy with a single dose in Fallow Deer (*Dama dama*), White-tailed Deer (*Odocoileus virginianus*), horses (*Equus caballus*), and Gray Seals (*Halichoerus grypus*).

Field Evaluation of the Immunocontraceptive, GonaCon-B, in Free-ranging Horses (*Equus caballus*) at Theodore Roosevelt National Park

D. L. Baker, J. G. Powers, M. Oehler, J. Ransom, J. P. Gionfriddo, and T. M. Nett

From Colorado State University, Animal Reproduction and Biotechnology Laboratory, Fort Collins, Colorado, USA (Baker, Nett); National Park Service, Biological Resource Management Division, Fort Collins, Colorado, USA (Powers, Ransom); Theodore Roosevelt National Park, Medora, North Dakota, USA (Oehler); and USDA/National Wildlife Research Center, Fort Collins, Colorado, USA (Gionfriddo)

Unchecked free-ranging horse populations can have adverse effects on native plant communities and ecosystem processes, and may lead to conflict regarding appropriate resource allocation between sympatric grazing ungulate species. In response, many land management agencies have reduced free-ranging horse populations through periodic roundups and adoption or sale of excess animals. These methods are time and resource intensive, and can result in injuries to animals and humans. Consequently, more efficient, effective, and humane approaches are desired. One alternative is controlling the fertility of female horses through immunocontraception. We are currently in the final year of a 3-year study at Theodore Roosevelt National Park (ND) to evaluate the effects of the gonadotropin-releasing hormone vaccine, GonaCon-B, on fertility, behavior, and injection site reactions in female horses. In October 2009, park horses were captured via helicopter round-up. All mature mares and band sires were retained to avoid disrupting existing herd dynamics, whereas foals, yearlings, and most satellite males were removed. Mares were blocked according to age and pregnancy status and randomly assigned to a treatment ($n = 29$; 2.0 ml GonaCon-B) or control ($n = 28$, 2.0 ml 0.9% NaCl) group. During March and July 2010 there was no difference between treatment groups in the number of foals observed with mares ($P = 0.65$). During the same time period in 2011 treated mares were three times less likely to have a foal by side than control mares (odds ratio 0.11–1.01, 95% CI). Estimated foaling rate in 2011 was higher ($P = 0.04$) in control mares (0.74, 0.56–0.88) than treatment mares (0.48, 0.31–0.66). Between 25 and 280 days posttreatment nearly 80% of treated mares had visible swelling at the site of injection and a purulent draining abscess was observed in one animal. By 380 days posttreatment approximately half of these swellings were no longer visually detectable. No treatment effects were observed on mare activity budgets, and sociosexual behavior data are currently being analyzed. Our preliminary examination of the data indicate that vaccination with GonaCon-B during gestation does not affect foaling success, decreases fertility for one year posttreatment, is associated with injection site swelling, and does not affect general activity budgets in free-ranging female horses.

Effects of Gonadotropin-releasing Hormone Vaccination (GonaCon-B) on Fertility in Free-ranging Female Rocky Mountain Elk (*Cervus elaphus nelsoni*)

J. G. Powers, D. L. Baker, R. J. Monello, T. S. Spraker, T. M. Nett, J. P. Gionfriddo, and M. A. Wild

From the National Park Service, Biological Resource Management Division, Fort Collins, Colorado, USA (Powers, Monello, Wild); Colorado State University, Animal Reproduction and Biotechnology Laboratory, Fort Collins, Colorado, USA (Baker); Colorado State University, Veterinary Diagnostic Laboratory, Fort Collins, Colorado, USA (Spraker); and the USDA/National Wildlife Research Center, Fort Collins, Colorado, USA (Gionfriddo)

Fertility control is one method, among a suite of management tools, which may assist in mitigating conflicts associated with locally overabundant wildlife. Rocky Mountain elk (*Cervus elaphus nelsoni*) are resilient, adaptable cervids that can have ecological as well as socio-political impacts on the coupled human-natural environment. We evaluated the safety and efficacy of the gonadotropin-releasing hormone vaccine, GonaCon-B, in free-ranging elk. In January 2008, 120 mature (>2 yr) female elk were captured in Rocky Mountain National Park (CO) and randomly assigned to treatment ($n = 60$; 1.5 ml GonaCon-B) or control ($n = 60$; 1.5 ml 0.9% NaCl) groups. All injections were given with hand-held syringes in the biceps muscle. Location of the injection was recorded in reference to anatomic landmarks. Transrectal palpation and pregnancy specific protein B analyses were used to diagnose pregnancy at the time of application. During the following three winters females were recaptured and euthanized in conjunction with park management culling operations (2009, $n = 20$; 2010, $n = 25$; 2011, $n = 34$). At necropsy pregnancy status was determined. Tissues were collected and preserved from organs associated with the hypothalamic-pituitary-gonadal (HPG) axis. Injection sites were relocated, muscle tissue collected, and microbial culture performed when gross evidence of inflammation was present. There were no differences in pregnancy rates between groups at the time of treatment ($P = 0.558$). In the following three years saline administered control females ($n = 36$) had a mean pregnancy rate of 0.83 (0.71 - 0.95, 95% CI). Pregnancy rate in the treatment group was 0.0 (0.0 - 0.22, $P = 0.0001$) year one, 0.33 (0.12 - 0.61, $P = 0.05$) year two, and 0.65 (0.43 - 0.83, $P = 0.17$) year three. Study animals showed no evidence of lameness or external swelling at the injection site prior to euthanasia; however, at the time of necropsy all females in the treatment group had pyogranulomatous inflammation at the site of injection.

Abstract

Gonadotropin-releasing hormone is intermittently released from the hypothalamus in consistent patterns from before birth to final maturation of the hypothalamic-pituitary-gonadal axis at puberty. Disruption of this signaling via GnRH vaccination during the neonatal period can alter reproduction at maturity. The objective of this study was to investigate the long-term effects of GnRH-antibody exposure on reproductive maturation and function in elk calves passively exposed to high concentrations of GnRH antibodies immediately after birth. Fifteen elk calves (eight males and seven females) born to females treated with GnRH vaccine or sham vaccine during midgestation were divided into two groups based on the concentration of serum GnRH antibodies measured during the neonatal period. Those with robust (>15 pmol ^{125}I-GnRH bound per mL of serum) titers (N = 10; four females and six males) were designated as the exposed group, whereas those with undetectable titers (N = 5; three females and two males) were the unexposed group. Onset of puberty, reproductive development, and endocrine function in antibody-exposed and unexposed male and female elk calves were compared. Neonatal exposure to high concentrations of GnRH antibodies had no effect on body weight ($P = 0.968$), endocrine profiles ($P > 0.05$), or gametogenesis in either sex. Likewise, there were no differences between groups in gross or histologic structure of the hypothalamus, pituitary, testes, or ovaries. Pituitary stimulation with a GnRH analog before the second potential reproductive season induced substantial LH secretion in all experimental elk. All females became pregnant during their second reproductive season and all males exhibited similar mature secondary sexual characteristics. There were no differences between exposure groups in hypothalamic GnRH content ($P = 0.979$), pituitary gonadotropin content ($P > 0.05$) or gonadal structure. We concluded that suppressing GnRH signaling through immunoneutralization during the neonatal period likely does not alter long-term reproductive function in this species.

1. Introduction

Episodic secretion of GnRH from the hypothalamus and signaling at gonadotropic cells of the anterior pituitary gland is required for normal steroidogenesis and gametogenesis in reproductively mature mammals [1]. Increases in pulse frequency mark the shift from reproductive quiescence to activity during puberty and tran-

sition from anestrus to breeding condition in seasonal breeders [2]. The hypothalamic-pituitary-gonadal (HPG) axis is functional and active during the neonatal period in domestic ruminants [3,4], but is not fully mature until the prepubertal period [5–8]. There is a biphasic increase in gonadotropins during prepubertal maturation in female sheep and cattle [9]. Similar to females, prepubertal males have a critical period of HPG axis maturation during the neonatal period [10,11]. Attainment of reproductive maturity can be hastened by administration of GnRH during early postnatal life [12]. Alternatively, puberty can be delayed by inhibiting GnRH secretion during this early period of development [13,14]. Gonadotropin-releasing hormone signaling during the postnatal/prepubertal time period is important for final maturation of the HPG axis in domestic ruminants.

Vaccination against GnRH is one method of functionally removing the hormone and its effects in vivo. The effects of GnRH exclusion on reproductive system function have been investigated using active and passive GnRH vaccination in mature [15,16] and juvenile [17,18] ruminants. In adults, reproductive function generally returns as antibody titers wane [19,20]. In contrast, immunization of neonatal or prepubertal animals can have a prolonged effect on reproductive function, despite progressive decline in GnRH-antibodies [21–25]. In fact, Brown and colleagues [22,23] reported that active vaccination against GnRH during the neonatal period caused permanent suppression of reproductive function in a subset of mature domestic sheep of both sexes, despite a lack of measurable GnRH antibodies after the prepubertal period. Few studies have investigated the long-term (>1 yr) reproductive effects of GnRH vaccination during the neonatal or prepubertal period.

Gonadotropin-releasing hormone vaccination has been proposed as a method of wildlife contraception [26]. In a previous study, we actively vaccinated midgestation female elk to evaluate the safety, efficacy, and duration of a recently registered GnRH vaccine (GonaCon, National Wildlife Research Center, United States Department of Agriculture, Fort Collins, CO, USA) intended for use in wild ungulates as a contraceptive [27]. Calves born to these females experienced neonatal passive transfer of GnRH antibodies. Before management application of this vaccine, it is imperative to understand the first-generational effects of vaccination in pregnant females to prevent unintended population-level consequences [28].

The purpose of this study was to investigate the long-term reproductive effects of maternal passive transfer of GnRH antibodies to male and female elk calves after birth. Passive vaccination during the neonatal period may delay the onset of puberty and could permanently suppress function of the HPG axis, leading to decreased fertility during adulthood.

2. Materials and methods

2.1. Animals and experimental approach

This study was reviewed and approved by Colorado State University (#07–146A–01) and the Colorado Division of Wildlife (#09–2007) Institutional Animal Care and Use Committees. All animals were housed at the Colorado Division of Wildlife, Foothills Wildlife Research Facility in Fort Collins, CO, USA (40°352046“ N, 105°92029”W). This work builds upon a previous study investigating the effects of active vaccination against GnRH in mature female elk during midgestation [27]. The current study used calves born during the previous work. Fifteen elk calves (N = 8 male; N = 7 female) born to females immunized with GnRH vaccine or a sham vaccine (carrier and adjuvant but no GnRH) during midgestation (approximately 100 days of 255 ± 7 days gestational period [29]) were divided into two groups, based on the presence of serum GnRH antibodies measured during the neonatal period (1–30 days). Dam vaccination status was not necessarily indicative of calf GnRH antibody exposure status, due to nursing from multiple females early in the neonatal period. Calves with robust (>15 pmol ^{125}I-GnRH bound per mL of serum) neonatal titers (N = 10; six males and four females) were designated as the exposed group, whereas those with undetectable titers (N = 5; two males and three females) the unexposed group. Calves were dam-raised in mixed exposure groups until 3 to 4 mo of age when they were weaned (September 1, 2006). One male calf exposed to GnRH antibodies was <30 days at weaning and was euthanized due to welfare concerns. At weaning, calves were separated into same sex groups, maintained in fenced paddocks (approximately 5 hectares), and fed a diet of ad libitum alfalfa-grass hay mix, limited supplement, trace mineral blocks, and water. Before experiments, calves were trained to repeated handling, blood sampling, isolation pens, alleyways, and a handling chute. All biological samples, with the exception of semen collection which required complete immobilization, were collected while elk were standing and lightly sedated using xylazine hydrochloride (30–150 mg per animal im; TranquiVed; Vedco, Inc., St. Joseph, MO, USA) in a nonsqueeze handling chute. Tranquilizer effects were

Author's personal copy

reversed after each sampling session with either yohimbine hydrochloride (30 mg per animal iv; Wildlife Pharmaceuticals, Fort Collins, CO, USA) or tolazoline hydrochloride (600 mg/animal im; Tolazine; Akorn, Inc., Decatur, IL, USA). During the experiment (May 2007), one male calf in the GnRH antibody-exposed group died because of a venomous snake bite. The study was conducted from birth (May to August 2006) to approximately 3 yr of age (March and April 2009).

2.2. Antibodies and growth rates

To measure maternal antibody transfer to calves, blood was opportunistically collected from calves before first nursing (N = 2; one from each exposure group) and from every calf 24 h after birth, then at approximately 2-wk intervals for the first 2 mo and monthly until 6 mo. Calves were weighed (kg) at the same time points. Thereafter, similar measurements were made sporadically, but not less than once every 6 mo. Final antibody concentration measurements were made before the 2008 reproductive season (mid September to mid November). Blood samples (10 to 30 mL) were collected via jugular venipuncture using a 20-gauge blood collection needle, tube holder, and 10-mL blood tubes without anticoagulant (BD Vacutainer SST; Becton, Dickinson, and Co., Franklin Lakes, NJ, USA). Blood was allowed to clot at room temperature, centrifuged for 10 min at 1500 × *g*, and serum was decanted to polypropylene tubes and stored at −80 °C until assays were performed. Peripheral GnRH antibody concentrations (pmol of ^{125}I-GnRH bound per mL serum at 1:1000 dilution) were measured using a modified radioligand binding assay, as described previously [27].

2.3. Puberty and fertility

2.3.1. Males

We measured and compared mean monthly serum concentrations of testosterone (ng/mL) between exposure groups from 14 to 21 mo [30]. Blood was collected as described above at single time points at the beginning of each month between August 2007 and March 2008. In addition, we measured secondary sexual characteristics, including antler length (cm), scrotal circumference (cm), and neck girth (cm) at monthly intervals from 9 to 21 mo (March 2007 to March 2008) as well as before the 2008 reproductive season (August 2008). Finally, we measured antler complexity (number of branch points), and weight (g) before the first and second potential breeding seasons (August 2007, 2008) when hardened antlers were removed for herd management purposes. Antlers were consistently removed (using a Giglis wire saw) 1 cm above the ridge of bone where the antler and pedicle meet.

To estimate fertility and confirm pubertal maturation, we collected semen samples at monthly intervals from August 2007 to March 2008 (14 to 21 mo). Semen samples were collected via electroejaculation [31] using a 60-mm diameter rectal probe (Pulsator III, Lane Manufacturing, Inc., Denver, CO, USA) while elk were chemically immobilized (18 to 23 mg butorphanol tartrate, 15 to 19 mg azaparone tartrate, and 6 to 8 mg medetomidine hydrochloride im; Wildlife Pharmaceuticals). An endotracheal tube (20 mm internal diameter) was placed during the procedure to prevent laryngeal collapse and hypoxemia. No supplemental oxygen was administered. Sedative effects were reversed when procedures were completed (10 mg atipamazole hydrochloride im; Pfizer Animal Health, Exton, PA, USA; and 500 mg tolazoline hydrochloride im). Total and progressive sperm motility (%), as well as components of velocity (straight line [VSL], curvilinear [VCL], and average path [VAP]; μm/sec), were evaluated immediately using computer assisted sperm analysis (IVOS, Hamilton, Thorne Biosciences, Beverly, MA, USA) [32,33]. If necessary, samples were diluted with semen extender (E-Z Mixin "BF", Animal Reproduction Systems, Chino, CA, USA) before motility analysis. Undiluted semen was smeared, stained with eosin-nigrosin (Hancock Stain; Animal Reproduction Systems), and slides were stored at room temperature for future evaluation. Sperm morphology (% normal) was evaluated by a single technician according to standards used for bovine semen [34].

2.3.2. Females

Onset of puberty was estimated in females by measuring peripheral serum progesterone concentrations (ng/mL) every 10 days (estrous cycle length = 21 to 22 days, luteal phase = 13 to 17 days [35–38]) from August 2007 to April 2008. Serum concentrations of progesterone ≥1.0 ng/mL were considered indicative of a functional CL and signified females were postpubertal [35,39]. Female fertility was evaluated by assessing pregnancy after exposure to proven herd sire males for 63 days during their second potential breeding season (September to November 2008) at 2.5 yr. Pregnancy status was determined using pregnancy specific protein B assay [40], transrectal palpation [41], and transrectal ultrasound [42] 45 days after bulls were removed from paddocks. For management purposes, when pregnancy was confirmed, abortion was induced using two doses of prostaglandin $F_{2\alpha}$ 6 h apart (25 mg

Author's personal copy

im; lutalyse, Pharmacia & Upjohn, Kalamazoo, MI, USA) [43,44].

2.4. Hypothalamic-pituitary-gonadal axis

Pituitary responsiveness to GnRH was measured before the second breeding season (August 2008). All elk were fitted with nonsurgical indwelling jugular catheters (14-gauge 14 cm Abbocath; Abbott Laboratories, Abbott Park, IL, USA) and administered the GnRH analog d-Ala^6-GnRH-Pro^9-ethylamide (1 μg/50 kg body weight iv; Sigma, Chemical Co., St. Louis, MO, USA). Blood samples were collected before treatment then at hourly intervals for 8 h [36,45]. Blood was handled as described above and serum was stored at −20 °C for subsequent analysis of LH [46]. All blood samples collected from males were also analyzed for testosterone [30]. Progesterone was measured in pretreatment serum samples collected from females [47]. Gonadotrope response to GnRH analog challenge was assessed in two ways: (1) mean maximum concentration of LH over all time points (ng/mL); and (2) total amount of LH secreted (ng/mL per min), estimated by calculating the area under the curve for LH response [36]. To avoid confounding female pregnancy estimates, stimulation with GnRH analog was repeated in males but not females during the breeding season (early November 2008).

In addition to challenge with GnRH, we evaluated potential changes to the HPG axis by collecting hypothalamus along with the median eminence, pituitary, and gonads on March 25 (males) and April 14, 2009 (females). We assessed morphologic and morphometric differences in gonads between exposure groups. Gonad mass (g) was determined for each animal. Transverse sections of testes were cut, weighed, and frozen until sperm per gram of testes was measured [48]. Remaining testes tissue and all ovarian tissue was preserved in Bouin's fixative (Polysciences, Inc., Warrington, PA, USA). Pituitary and hypothalamus were hemisectioned through the midsagittal plane. One half of each brain was preserved in 4% paraformaldehyde and the other half wrapped in aluminum foil and frozen at −80 °C. Frozen sections of hypothalamus were assayed for total GnRH content (ng) [49]. Frozen pituitary sections were processed as described by Hart and colleagues [49], and analyzed for LH and FSH content (mg/g tissue) [46,50]. Fixed tissues were trimmed, placed in cassettes, maintained in 10% neutral buffered formalin, and sectioned using standard histology techniques at the Colorado State University Veterinary Diagnostic Laboratory. Hematoxylin and eosin stains were used for histologic examination. A veterinary pathologist (Spraker) qualitatively examined sections of gonad, pituitary, and hypothalamus (magnification × 2 to × 40) for pathologic changes and evidence of differences in morphology.

2.5. Hormone assays

Concentrations of progesterone [47], testosterone [30], LH [46], FSH [50], and GnRH [49] were measured using RIA. Samples were assayed in duplicate in single batches for each hormone at each time point. Intra-assay coefficients of variation for the upper and lower reference standards (20% and 80% ligand-labeled hormone-bound, respectively) were 4% to 15% for progesterone, 3% to 17% for testosterone, 3% to 11% for LH, 3% and 6% for FSH, and 5% and 10% for GnRH. Interassay coefficients of variation were 2% for progesterone, and <20% for testosterone and LH. Both FSH and GnRH were measured in single assays. Mean limits of detection for each hormone (1 SD of the assay) are as follows: progesterone, 5 pg; testosterone, 2.5 pg; LH 30 pg; FSH 0.2 ng; and GnRH 0.5 pg.

2.6. Statistical analysis

Dependent response variables, including body weight, concentrations of progesterone, testosterone, and LH measured at multiple time points, sperm parameters measured after electroejaculation, and secondary sexual characteristics were analyzed using one-way ANOVA models for a nonrandomized design with a repeated measures structure (SAS 9.2, Proc MIXED; SAS Institute, Cary, NC, USA). The independent variables exposure status, sire, date, and time, were included as fixed effects. Sex was also treated as a fixed effect if a response variable was measured in both sexes. Individual animal was included as a random effect. We first modeled the variance-covariance structure for each dependent variable using the restricted maximum-likelihood method, with the most global model of fixed effects (response variable = exposure status + sire + date or time as categorical variables ± sex). We modeled the following variance-covariance structures appropriate for unequal time intervals; variance components (VC), compound symmetric (CS), and spatial power [SP(POW)]. We selected the most appropriate variance-covariance structure using Akaike's Information Criterion with correction for small sample sizes (AICc) and then used the top-ranked structure for subsequent modeling of fixed effects. The best structure for all models had constant variance within an exposure group; some models allowed heterogeneous variance between exposure groups, whereas others were homogeneous for all study

Author's personal copy

animals. The best covariance structure for all variables except body weight was variance components, which implies no covariance between repeated measurements. The best covariance structure for body weight was spatial power. Because date and time were the only significant fixed effects in the model describing total LH released after GnRH analog stimulation, a Student *t* test was used to compare differences between sexes and between months for males.

Single time point concentrations of LH, FSH, and GnRH at necropsy, as well as gonad mass, and sperm per gram of testis were analyzed using generalized linear ANOVA models (Proc GLM), with exposure status, sire, and sex (if appropriate) as classification variables. Arcsine transformation was performed for all data expressed as percent. Means and standard errors were estimated using least squares analysis and tests for differences between GnRH antibody-exposed and unexposed groups were based on type III generalized estimating equations. Descriptive statistics were used to explain concentrations of GnRH antibody.

3. Results

3.1. Antibody concentrations and growth

Antibodies to GnRH were measured in exposed calf serum between 1 and 200 days after birth (Fig. 1). Antibodies were undetectable before nursing in blood samples taken from two calves, one with a GnRH vaccinated dam and the other with a sham-vaccinated dam. Maximum antibody concentrations (± SEM) in exposed calves were often higher (37.7 ± 4.1 pmol/mL; range, 15.2 to 54.1 pmol/mL) than those previously measured in the GnRH vaccinated dam cohort at similar time points (May 2006) (28.8 ± 3.8 pmol/mL; range, 12.2 to 42.3 pmol/mL [data not shown]). Antibodies declined exponentially over time in exposed calves with a half-life of approximately 7 days (Fig. 1). Exponential antibody decay was represented by the following equation: $[A] = 67.1e^{-0.1(d)}$ where A = serum GnRH-antibody concentration and d = calf age in days ($r^2 = 0.64$).

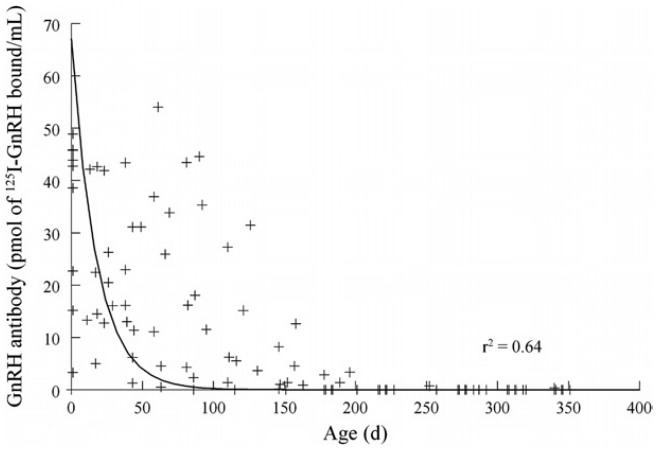

Fig. 1. Persistence of maternal antibody from birth to 1 yr in elk calves (N = six to eight males, two died August 2006 and May 2007; N = 4 females) exposed to colostral transfer of GnRH antibodies during the first 24 h of life. Calves unexposed to GnRH antibodies had undetectable antibody titers (data not shown).

There was no effect of neonatal exposure to GnRH antibodies on body weight (P = 0.968) between birth and 3 yr. Although males were heavier than females at birth (P = 0.024) and at 3 yr (P < 0.001), neither sex (P = 0.905) nor sire (P = 0.913) were significant variables in the model. Age was the most important variable describing body weight (P < 0.001) and there was an age by sex interaction (P = 0.001) with males gaining weight faster than females. Males gained approximately 0.83 kg per day during the first 100 days and then gained more slowly at 0.2 kg per day between 200 and 800 days. Females gained an average of 0.75 kg per day during the first 100 days but decreased their growth rate to 0.1 kg per day between 200 and 800 days.

3.2. Puberty and fertility

3.2.1. Males

There was no effect of exposure on mean monthly concentrations of testosterone (P = 0.659) between 15 and 21 mo. Likewise, sire did not affect concentrations of testosterone (P = 0.275); however, concentration did vary by month (P = 0.001; Fig. 2). Highest concentrations occurred in October and November. With the exception of one calf exposed to GnRH-antibodies, which had a maximum concentration of 1.7 ng/mL during November, all males had at least one testosterone measurement ≥2 ng/mL.

Similar to endocrine results, in male calves neither neonatal antibody exposure nor sire had an effect on semen parameters or most secondary sexual characteristics, including antler mass, neck girth, and scrotal circumference (Table 1). Date was an important variable describing differences in antler length (P = 0.002), antler mass (P = 0.007), neck girth (P = 0.0003), and scrotal circumference (P < 0.0001), but not semen parameters (P > 0.05). Only antler length was affected by exposure status (P = 0.037) with a single male exposed to GnRH antibodies contributing most of the variance. This animal had an unusually short antler, which may have been physically damaged, during his

Author's personal copy

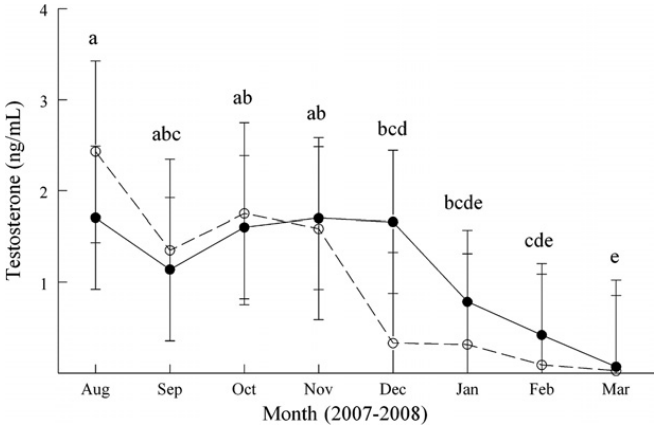

Fig. 2. Mean monthly testosterone concentrations with 95% confidence intervals, between 14 and 21 mo, in male elk exposed (N = 4; ● solid line) and unexposed (N = 2; ○ dashed line) to neonatal GnRH antibodies. Letters denote differences between months ($P < 0.05$); there were no differences between exposure groups within months.

second reproductive season but had a similar number of branch points (five) as other males (five or six per antler). Regardless of exposure group, all males had at least one semen sample which met criteria for adequate progressive motility (≥30%) and morphology (≥70%) of sperm in yearling male domestic cattle [34] and was consistent with acceptable sperm parameters from red deer (*Cervus elaphus*) (>40% motility, >40% normal morphology) [51]. Scrotal circumferences were consistent with those reported for 2-year-old elk [31].

3.2.2. Females

Monthly serum concentrations of progesterone in females were not affected by presence of neonatal antibody titer ($P = 0.727$) or sire ($P = 0.805$); however, concentrations varied by month ($P = 0.002$). All females had evidence of CL formation and regression, based on progesterone profiles, suggesting puberty had been reached by November 2007 (Fig. 3A). All had cyclic changes in serum concentrations of progesterone with multiple samples >1 ng/mL until March 2008 (Fig. 3B). Females were exposed to proven herd sire bulls between September and November 2008 at 28 to 32 mo. All seven females were pregnant when examined in January 2009. Transrectal palpation, ultrasound examination, and pregnancy specific protein B results were concordant.

3.3. Hypothalamic-pituitary-gonadal axis function and structure

In August 2008, before their second potential reproductive season, both males and females responded to GnRH analog stimulation with an acute LH release that peaked between 2 and 5 h and approached baseline levels within 8 h. Although mean maximum concentration of LH was not different between sexes ($P = 0.069$), females (16.1 ± 2.3 ng/mL) had nearly twice the maximum release of LH as males (9.4 ± 2.4 ng/mL; Figs. 4 and 5). Exposure to GnRH-antibodies during the neonatal period did not affect total secretion of LH ± SEM (ng/mL per min) in either males (33.3 ± 7.9 exposed, 35.3 ± 4.1 unexposed; $P = 0.668$) or females (69.7 ± 8.5 exposed, 61.2 ± 8.8 unexposed; $P = 0.333$). Neither mean maximum concentrations of LH nor testosterone were different between months ($P > 0.05$) for males; however, total LH and testosterone released amongst all males in August (42.3 ± 9.2 and

Table 1
Measures of semen quality and secondary sexual characteristics in male elk between 15 and 22 mo of age.

Response variable	Exposed (N = 4)			Unexposed (N = 2)		
	Mean	SEM	Range	Mean	SEM	Range
Normal morphology (%)	59.0	1.6	15–86	67.5	2.4	35–91
Total motility (%)	60.9	1.5	7–98	83.0	1.8	48–98
Progressive motility (%)	39.1	1.3	1–79	64.7	1.5	32–81
Sperm velocities (um per sec)						
VAP	74.5	10.0	31–116	97.6	11.1	76–116

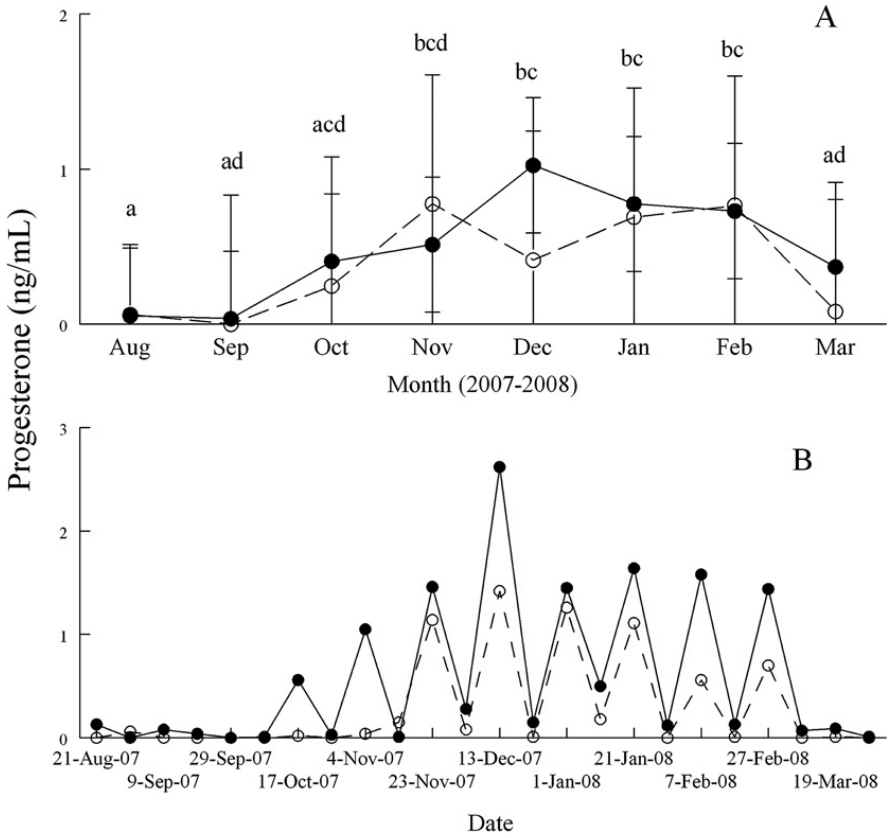

Fig. 3. Top panel (A): Mean monthly progesterone concentrations with 95% confidence intervals, from August 2007 to March 2008, in female elk calves exposed (N = 4; ● solid line) and unexposed (N = 3; ○ dashed line) to GnRH antibodies during the neonatal period. Letters denote differences between months ($P < 0.05$); there were no differences between exposure groups within months. Bottom panel (B): Representative progesterone profiles from female elk calves exposed (● solid line) and unexposed (○ dashed line) to GnRH antibody during the neonatal period. Sampling occurred at approximately 10-day intervals between 15 and 22 mo.

81.8 ± 7.7 ng/mL per min, respectively) was greater than in November (25.6 ± 3.2 and 56.7 ± 6.3 ng/mL per min; $P < 0.001$). A single male with unusually high concentrations of LH (14–22 ng/mL) accounted for most of the variability. Concentrations of progesterone in all females were below the limit of detection at the time of GnRH stimulation in August 2008 indicating lack of luteal tissue.

Endocrine profiles in serum and tissue at the time of necropsy were similar between exposure groups and sexes. There was no effect of exposure to GnRH antibodies on pituitary concentrations of LH ($P = 0.525$) or FSH ($P = 0.349$) in either sex (Table 2). Content of GnRH in hemihypothalmi was not different between exposure groups ($P = 0.979$) or sexes ($P = 0.980$). Serum concentrations of testosterone in males and progesterone in females were nearly undetectable and did not differ between exposure groups ($P > 0.05$). Gonad mass (g) did not vary by exposure status or sire ($P > 0.05$; Table 2).

There were no observed differences in gross or histologic structure of the hypothalamus, pituitary, testes, or ovaries between antibody-exposed and unexposed elk. There was no evidence of overt inflammation or change in structure in the median eminence of any study animal (data not shown). Although gonadotropes were not specifically identified, adenohypophesial structure was similar between exposure groups and was within normal limits for ruminant pituitaries. All ovaries and testes had evidence of gametogenesis. Ovaries had primordial through Graffian follicles, and testes had seminiferous tubules which contained spermatocytes. The only sign of inflammation was infiltration of atretic follicles with eosinophils in four of seven (N = 2 from each exposure group; approximately 60%) females.

4. Discussion

4.1. Antibody effects

Passive transfer of maternal GnRH-antibodies to elk calves shortly after birth did not affect long-term reproductive development in our study elk. There were no significant differences in growth, time of pubertal

Author's personal copy

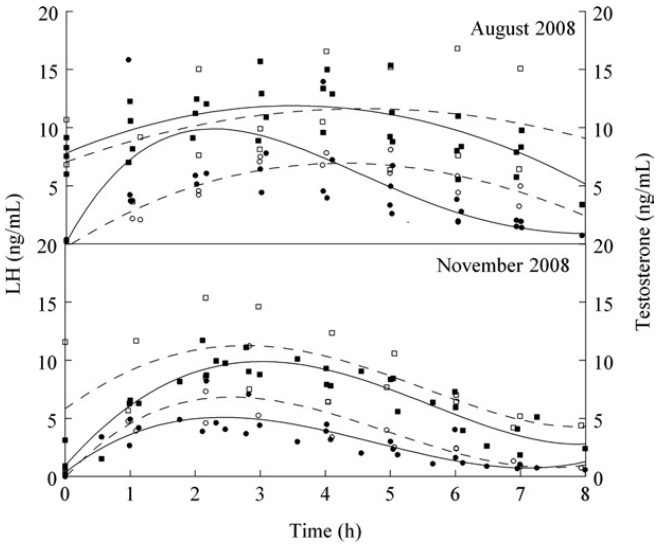

Fig. 4. Serum LH (○ ●) and testosterone (□ ●) concentrations after GnRH agonist treatment at time zero, in male calves (27 to 30 mo) exposed (filled solid line, N = 4) and unexposed (open dashed line, N = 2) to GnRH antibodies during the neonatal period. Total hormone released (ng/mL per min) represented by the area under the curve.

Gonadotropins and GnRH were measured in both sexes, testosterone in males, and progesterone in females.

onset, or structure and function of the HPG axis between exposure groups in males or females. Therefore, we inferred that the presence of high concentrations of passively transferred GnRH antibodies during the first 60 days of life did not permanently alter the reproductive function of elk. However, because our sample sizes were small, particularly for the unexposed male group, we must be somewhat circumspect about our results. Due to small sample variation, a repeated experiment with relatively large sample sizes (e.g., ≥30) would be more likely to find differences, if they existed. Nevertheless, we consider our results relevant because there are multiple time points per elk for most response variables, and for at least one of those time points, each animal produced a reproductively mature response.

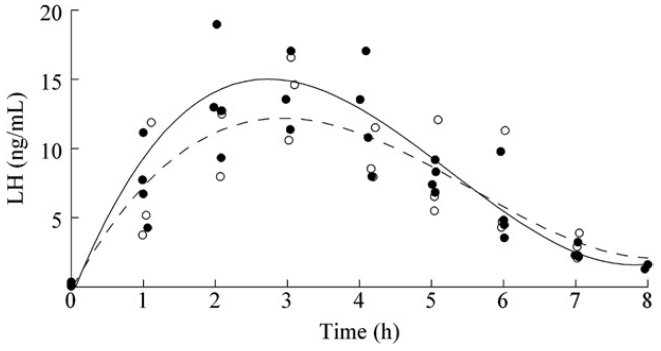

Fig. 5. Serum LH concentrations, after GnRH agonist treatment at time zero, in female elk calves (27 to 28 mo) exposed (● solid line, N = 4) and unexposed (○ dashed line, N = 3) to GnRH antibody during the neonatal period. Total LH released (ng/mL per min) represented by the area under the curve.

Our results were partially in contrast to findings in domestic sheep actively vaccinated against GnRH at 2 wk [21–23] and male rats passively immunized 5 days after birth [24,25]. Clarke et al. found that active vaccination against GnRH during the neonatal period caused permanent HPG axis suppression during adulthood, in a subset of vaccinated males and females, despite a lack of GnRH antibodies. This was caused by decreased GnRH secretion, rather than a decrease in GnRH content of the median eminence [21]. Vogel et al. [24] and Bercu and Jackson [25] found permanent suppression of rat testes development after neonatal passive vaccination, despite normal postpubertal gonadotropin concentrations during adulthood. They suggested that there is a critical window of testes development in rodents at this time that is permanently altered without the timely support of gonadotropins. In our study, we investigated both the potential for passive neonatal vaccination to permanently decrease GnRH secretion and the potential for transient removal of GnRH signaling to alter the structure or function of the pituitary or gonad, even if long-term GnRH secretion was unimpaired during adulthood. We found neither of

these mechanisms altered reproductive function in elk from this study.

Gonadotropin-releasing hormone is secreted from hypothalamic neurons originating within the blood-brain barrier, but terminating near blood vessels of the hypothalamic-pituitary portal system outside of the blood-brain barrier. After active GnRH vaccination in male pigs at 10 and 18 wk and subsequent necropsy at 26 wk, Molenaar and colleagues found lesions, including fibrosis and scar tissue formation within the median eminence which were positively correlated with GnRH-antibody titer and testes atrophy [52]. They suggested that T-cell-mediated autoimmune reactions directed at GnRH neurons or retrograde transport of GnRH antibodies might result in destruction of the neurons or their processes. They demonstrated inflammatory lesions of the median eminence, consistent with the speculation that anti-GnRH immunoglobulin G, in addition to interleukin cytokines, may be responsible for permanent changes to function of GnRH neurons. Their study was different from ours in two important ways. First, the lesions they described were present in animals which had concurrently high concentrations of GnRH antibodies, which may have indicated the inflammatory processes were in progress at the time of death, but the lesions could have been transient. Second, pigs were actively vaccinated with Freund's complete and incomplete adjuvants, potent stimulants of both humoral and cell-mediated components of the immune response [53]. In contrast, elk in our study did not have detectable antibody concentrations by 6 mo and most response variables were measured between 9 and 30 mo. More importantly, elk in the current study were passively immunized with maternal antibodies, rather than stimulating in vivo humoral and cell-mediated immune responses. Although concentrations of GnRH antibodies were certainly higher in our study 24 h after birth, due to reporting inconsistencies, it was not possible to compare concentrations of antibody between the two studies at later time points. Regardless, our elk were not exposed to a full complement of humoral and cell-mediated components of the immune response, whereas pigs exposed to Freund's complete adjuvant along with GnRH conjugated to keyhole limpet hemocyanin (KLH) likely had robust stimulation of the entire immune system. Although we did not examine the histologic structure of the median eminence to the same degree of Molenaar et al. [52], there was no apparent evidence of inflammation or fibrosis in hypothalmi and there was no clinical evidence of HPG axis dysfunction in our elk. Therefore, we inferred that elevated antibody titer alone was not sufficient to induce a permanent decrease in GnRH secretion.

In altricial species, such as the rat, maturation of the HPG axis is incomplete at birth [54]. In precocious species, such as sheep and likely elk, the fetal HPG axis is functional by midgestation [3]; however, hypothalamic signaling is required for development of gonadotrophic cells during the last month of gestation and puberty is reliant on an adequate gonadotrope population [55]. It is unknown exactly when the permanent structure or function of the HPG axis is complete in elk, but we inferred that elimination or at least a decrease in GnRH signaling during the first 60 to 180 days after birth does not delay the process. Because we did not measure gonadotropin secretion during the neonatal period, we do not know if there were adequate concentrations of GnRH antibodies to completely remove GnRH signaling. In our previous study in adult female elk with similar or lower concentrations of GnRH antibodies, there was suppression of fertility, but not complete inhibition of final stages of follicular development, indicating a partially intact HPG axis [27]. Alternatively, ewes with lower concentrations of GnRH antibodies, but with a more aggressive active vaccination schedule, had complete cessation of follicular wave development [56]. It is likely that antibody concentrations were sufficient to influence GnRH signaling in the current study. This finding added strength to our speculation that antibodies alone do not account for long-term suppression of the HPG axis documented in previous studies.

4.2. Comparative reproductive ecology

Our investigation of endocrine changes, direct and indirect measures of fertility, and development of secondary sexual characteristics through puberty in male elk provided results similar to those in untreated and closely related red deer. For male red deer, the highest mean testosterone concentrations occur in late summer and early fall when antlers are hard and velvet has been shed [57–59]. Conversely, in the spring, at the time of antler casting, testosterone is nearly undetectable and testes are at their smallest [58,59]. Male elk in this and other studies [31] appeared to follow a similar seasonal pattern, with testosterone concentrations increasing to a peak in late summer/fall (September to October) then gradually declining through the winter period (December through March). Scrotal circumference mirrored testosterone concentrations, being minimal in late spring and attaining maximum size in late summer. However, as expected, scrotal circumference did not

Author's personal copy

regress to prepubertal dimensions. Male elk pituitary response to stimulation with GnRH analog before and during the second reproductive season was similar to that reported in red deer stags [57,58]. Maximum concentrations of both LH and testosterone, induced by GnRH stimulation, were higher in August than in November. Interestingly, the single outlier male with an unusually large maximum concentration of LH had a relatively modest corresponding maximum concentration of testosterone. This pattern of large LH release with little secretion of testosterone, was characteristic of the nonreproductive season in red deer [57]. It was our observation that this individual was socially the least dominant male and did not produce a satisfactory semen sample until December 2007.

In elk populations that are not nutrient-limited, males are generally reproductively competent at 14 to 16 mo [31] with similar fertility rates as those seen in older more mature bulls [60]. Although we did not directly measure fertility of males in this experiment, there were no significant differences in semen quality or secondary sexual characteristics associated with fertility between exposure groups. Sperm motility, velocity, and morphology parameters met or exceeded standards for domestic bulls [34] and were similar to findings in red deer [33]. Semen evaluation and sperm analysis have remained elusive as a reliable indicator of fertility in domestic animals [61,62]; however, these assays may be more useful in wild species where strong artificial selection pressures for increased fertility are not in effect [63]. Swimming velocity and sperm morphology account for differences in fertility rates of Iberian red deer (*Cervus elaphus hispanicus*) [33]. Additionally, antler size and complexity are associated with testes size and sperm velocity [64]. Finally, despite seasonal testicular atrophy, all males in our study had maturing spermatocytes within the seminiferous tubules during the early spring at approximately 33 mo. Therefore, we inferred that all males were reproductively mature and likely fertile by the end of their first reproductive season at 15 to 21 mo.

Puberty and ultimately fertility in female elk is a function of body condition. In that regard, 50% of yearling females are fertile at 16 to 18 mo if a minimum body mass (approximately 220 kg, 10% body fat) is achieved [65–67]. The first estrous cycle of the reproductive season often has a short interovulatory interval [68], followed by regular ovulations every 20 to 24 days [38]. In our study, every female had regular increases in serum progesterone concentrations at approximately 20-day intervals. Most females had evidence of functional CL by mid-October and all were cycling by early November. This is later than that reported for mature female elk in North America [68], but is within the range observed in other studies with 2-yr-old females [66]. Three of seven females continued to display elevated concentrations of progesterone into late March when sampling was terminated. This was in accordance with previous research which demonstrated estrous cycling in mature females can occur as late as March but typically ends in late February [68]. Pituitary stimulation with GnRH analog before the breeding season induced an LH release similar to that in nonpregnant mature female elk during the reproductive season [36]. In our confirmatory test of fertility, all females became pregnant. These results provided further evidence for the lack of an effect of GnRH antibody exposure on maturation of the HPG axis or fertility in female elk calves in this study.

4.3. Conclusion

There was no apparent effect of exposure to high concentrations of maternally transferred GnRH-antibodies on the long-term structure or function of the hypothalmo-pituitary-gonadal axis of male or female elk. The elk HPG axis is likely structurally mature at birth and transient disruption in GnRH signaling through antibody neutralization was not sufficient to permanently change function in our study elk. Our findings provide important knowledge to inform wildlife management decisions regarding the application of fertility control in free-ranging populations of elk. Additionally, we have advanced the understanding of the mechanism(s) of how GnRH vaccination may affect long-term fertility in ruminant species. The presence of neonatal antibodies alone did not appear to account for changes in fertility later in life.

Acknowledgments

We thank the Colorado Division of Wildlife, Foothills Wildlife Facility Staff for excellent animal care and handling (I. Levan, J. Spaak, M. Fisher, T. Davis, and A. Mitchell). We also thank M. Allen, A. Latimer, A. Graham, and A. Lothridge for laboratory assistance with RIA procedures, and P. Moffett for assistance with semen collection and evaluation. Quantifying Equid Behavior—A Research Ethogram for Free-Roaming Feral Horses

By Jason I. Ransom and Brian S. Cade

Introduction

Feral horses (*Equus caballus*) are globally distributed in free-roaming populations on all continents except Antarctica and occupy a wide range of habitats including forest, grassland, desert, and montane environments. The largest populations occur in Australia and North America and have been the subject of scientific study for decades, yet guidelines and ethograms for feral horse behavioral research are largely absent in the scientific literature. The U.S. Geological Survey (USGS) Fort Collins Science Center conducted research on the influences of the immunocontraceptive porcine zona pellucida (PZP) on feral horse behavior from 2003–2006 in three discrete populations in the American west (see Ransom and others, 2007; Ransom, 2009). These populations were the Little Book Cliffs Wild Horse Range in Colorado, McCullough Peaks Herd Management Area in Wyoming, and Pryor Mountain Wild Horse Range in Montana; the research effort included over 1,800 hours of behavioral observations of 317 adult free-roaming feral horses. The following ethogram was developed during the course of this study to facilitate accurate scientific data collection on feral horse behavior, which is often challenging to quantify. By developing this set of discrete behavioral definitions and a set of strict research protocols, scientists were better able to address both applied questions, such as behavioral changes related to fertility control, and theoretical questions, such as understanding social networks and dominance hierarchies within social groups of equids.

Background

Feral horses in North America are descendents of animals that escaped domesticity or were intentionally released by settlers, explorers, and military personnel, and because of their highly adaptive nature were able to thrive in a multitude of environments. In the United States most feral horses are federally protected by the Wild Free-Roaming Horses and Burros Act of 1971, which refers to them as "living symbols of the historic and pioneer spirit of the West," stating that "they contribute to the diversity of life forms within the Nation and enrich the lives of the American people" (Public Law 92-195, 85 Stat. 649, as amended). Roughly 30,000 feral horses are distributed across 10 western States in the United States on 21.4 million ha of federally designated horse range. With annual population growth rates reported at 15–25 percent (Eberhardt and others, 1982; Wolfe and others, 1989; Garrott and Taylor, 1990; Garrott and others, 1991) and very limited natural depredation, the influence of feral horses on native flora, fauna, and ecosystem processes varies greatly (see Smith, 1986; Fahnestock and Detling, 1999; Coughenour, 2002; Levin and others, 2002; Beever and Herrick, 2006; Beever and others, 2008). Understanding animal behavior can be an important tool in addressing a species' influences and roles in an ecosystem and can lead to better management and conservation practices (Sutherland, 1998; Buchholz, 2007). Additionally, when management practices such as fertility control alter natural biological processes, it is important to consider the ethical implications, such as influences on animal behavior and social structure (Nettles, 1997; Asa and others, 2005; Porton, 2005).

Social Organization

Feral horses arrange themselves in family groups known as bands, which range in size from 2 to 20 or more animals. Band size is variable and may be a response to both the environment the horses inhabit and population density. Animals can reduce risk of predation by living in groups (Pusey and Packer, 1997), and in open habitats without cover in which to hide, animals may form larger groups (Molvar and Bower, 1994). The latter was found to be true in the USGS study,

where mean band size in the sage steppe habitat found at McCullough Peaks was 8.01 ± 0.38 (SE) horses, while habitats with trees and dense vegetation had smaller mean band sizes—4.45 ± 0.16 horses at Little Book Cliffs and 4.16 ± 0.17 horses at Pryor Mountain.

Feral horse bands typically consist of a single polygynous stallion, adult females, foals of the year, and yearling males and females. Bands with multiple stallions do occur and were first reported by Denniston (1979) and Miller (1979). Miller (1979) found that multiple stallions were present only in bands consisting of greater than 9.3 horses. This finding was supported by the USGS study, during which multiple-stallion bands were recorded only at McCullough Peaks; multiple stallions occurred in five bands of horses consisting of 9–18 animals each. At 2 years of age, subordinate males typically disperse the band into bachelor groups of two to several horses, but occasionally 2- and 3-year-old males remain with the band if the stallion does not drive them away. Rutberg and Keiper (1993) found that the age at which male horse dispersal occurs is strongly correlated with the number of peers in the natal group.

Feral horse bands are not geographically territorial and home ranges overlap with those of other bands in the population. This geographically non-territorial, harem-type social structure is known as Type I organization and also is used by the Przewalski horse (*Equus ferus przewalskii*), Plains zebra (*Equus burchellii*), and Mountain zebra (*Equus zebra*) (Klingel, 1975; Rubenstein, 1989). The other organizational structure found in equids, Type II organization, involves adult males establishing geographic territories and females moving between them. Type II organization is used by the Grevy's zebra (*Equus grevyi*), African wild ass (*Equus africanus*), and Asiatic wild ass (*Equus hemionus*). While feral horses do not exhibit geographic territoriality, the USGS study did document resource-oriented territoriality whereby stallions (with the entire band present) defended mineral sources repeatedly and often with elevated agonistic interactions when other bands approached.

Ethological organization within horse bands is characterized by a dominance hierarchy, but the literature has conflicting functional explanations for hierarchical structures in equids. Houpt and others (1978) found that body weight affected social rank but age did not; however, other researchers (Keiper and Sambraus, 1986; Rho and others, 2004; Heitor and others, 2006) found age to be linearly correlated with social rank. Reproductive status of females has been shown to influence their social dominance in a band, as well as their rate of interchange between bands (van Dierendonck and others, 2004). Most studies, however, indicate that agonism is strongly correlated with dominance rank among females (Houpt and others, 1978; Waring, 1983; Keiper and Receveur, 1992; Weeks and others, 2000). The USGS study found that the most dominant members of feral horse bands were female, and stallion rank varied by band. This ethological structure is reported in much of the existing literature (Houpt and Keiper, 1982; McCort, 1984; Keiper and Sambraus, 1986; Klimov, 1988; and Keiper and Receveur, 1992). Lack of stallion dominance has been attributed to the amount of time stallions spend away from the band while recruiting new females or engaging in agonistic interactions with other stallions; females in a band, however, can establish stronger hierarchical relationships because they continuously remain in close proximity to one another (Keiper and Receveur, 1992). Social rank in bachelor groups, which are often unstable, has only been attributed to individual temperament (Tilson and others, 1988).

Ethological Data Collection and Analyses

It is possible to quantify behavior through the systematic enumeration of discretely defined categorical behaviors in terms of counts of occurrence or proportions of time exhibited. Collection of ethological data may be accomplished through several techniques, and the ultimate decision rests on the precisely defined research objectives. The reader is referred to Altmann (1974) for a definitive overview of sampling methodology for observational data. In the last 30 years, many insights have contributed to refining these methods, such as how to determine the appropriate time period between sampling when using the instantaneous scan sampling method and a better research design to capture infrequent behavioral expressions. In sampling feral horse behavior, the USGS study found that instantaneous scan sampling (the method of recording the categorical behavior of each focal animal at precise moments in time) at 1-min intervals was ideal for quantifying time budget data. Continuous sampling is an alternative to this technique and involves recording a focal animal's behavior continuously and noting the point in time that a new behavior begins. Continuous sampling was impractical for our study due to the number of animals and observers involved. Mitlohner and others (2001) found no significant difference between behavioral data recorded with instantaneous scan sampling versus continuous sampling when intervals were 15 minutes or less, and found a high correlation between the techniques when using 1-min intervals.

Collecting data on time budgets using instantaneous scan sampling is fairly straightforward, but behaviors that are infrequent and expressed briefly are not likely to be captured adequately (Houpt, 1991; Doran, 1992). Two relatively good options exist for collection of such data: the all-occurrence method and focal sampling. All-occurrence data collection records every behavior every time it is observed (Altmann, 1974) and can be a good technique when the number of animals in the focal band is not too large and the behaviors of interest are easy to detect. Although less efficient in terms of data collection, the focal sample method may be more reliable since the observer's focus is directed at only one animal (Altmann, 1974; Houpt, 1991). This method involves randomly selecting one individual in the band and continuously observing and recording all behavioral expressions. In feral

horse research, capturing briefly occurring expressions is most important for reproductive, social, and agonistic behaviors. Feeding, resting, and locomotion typically occur in periods long enough to be captured by most techniques.

Ethological protocols must be established prior to data collection and should be defined by research objectives. The discrete behavioral categories presented in this ethogram do not preclude the exhibition of simultaneous behaviors. For example, it is typical in feral horses for a comfort behavior such as masturbation to occur while the animal is feeding, so a protocol should be explicitly defined stating which behavior takes precedence in the data record. If the objective of your research is to determine the amount of time horses are feeding in relation to some covariate, then feeding is the appropriate category, and if expression of comfort behavior is the focus, then it should be recorded as such (or in this case, one might wish to subdivide comfort into several behaviors, since comfort is generally a short-duration behavior with many specific expressions). Regardless of the approach, notations of simultaneous occurrences are invaluable in retrospect.

Simultaneous behavioral expressions are not the only observational data collection pitfall. Some behaviors, such as olfactory investigation, can be ascribed to several categories. This behavior may fall under comfort, reproduction, or harem social behavior, but the correct categorization of such expressions is not subjective: each expression does have an absolute definition. In such cases, the context of the behavior will define its true characterization. When such potentially confusing behaviors are prevalent, they are addressed specifically in the ethogram.

Considerably more in-depth analyses of behavior are possible when covariates associated with individual focal subjects are collected reliably. Many factors may influence behavior, such as age, body condition, dominance rank, presence of dependent foal, climate, and habitat. Fortunately, many feral horses have unique natural markings, making identification of individual animals possible without the use of radio-collars or numbered tags. Pelage color; facial patterns such as snips, strips, blazes, and stars; and leg markings such as coronet bands, socks, and stockings collectively make cataloging and referencing study animals feasible (Sponenberg and Beaver, 1992; Gower, 2000; Green 2001). Properly cataloging and identifying individual horses in a research effort can provide the foundation from which to build in-depth covariate data and thus lead to a better understanding of animal behavior.

Analyses of behavioral data may incorporate many traditional statistical methods, but time budget data presents a particularly challenging dilemma. These analyses must consider the compositional nature of a time budget: models exhibiting strong support for one behavioral category must also be considered for each other category. Proportions of time spent in behavioral categories are compositional dependent variables because the sum of the proportions in all behavioral categories sum to 1. In other words, there is a unit sum constraint (Aitchison, 1986) by which more time spent in one or more behavioral categories must be associated with less time spent in one or more other behavioral categories. These compensatory shifts in estimates are absolute, leading to a dependent relationship among behaviors constituting the time budget being analyzed (Elston and others, 1996). Many compositional data-analysis procedures have been developed (for example, log-ratio procedures; Aitchison, 1986, 1992), but few are appropriate for data that exhibit real values of 0 or 1. It may be important that the amount of time an animal exhibits a given behavior is truly 0 percent or 100 percent. Many methods, such as log-ratio analysis, require data transformations that eliminate values of 0 and 1 by assigning very small or very large values (greater than 0 or less than 1) (Bakeman and others, 1992; Clark and Messina, 1998). This process ultimately alters the distribution of data and may adversely affect conclusions drawn about individual behaviors in the composition (Bingham and Brennan, 2004). Once transformed, the common method of log-ratio analysis also produces only quantitative statements about the overall distribution of the composition in comparison to another and the sampling distribution of the difference; it does not specify explicit contributions of each piece of the composition to those differences (Aitchison, 1986). If your data are not composed of real values of 0 and 1, log-ratio analyses may be appropriate. It is best suited for compositions with only two elements since conclusions about the change in allocation may be drawn easily (Elston and others, 1996), but most behavioral studies aim to address multiple behaviors. Some extensions of the algebra of log-ratio compositional measures have been made by Billheimer and others (2001), but currently these procedures are limited to three-part compositions and still suffer the restriction of not allowing zero proportions.

One solution to the problem of comparing time-budget compositions with several behaviors and true values of 0 and 1 is the use of a multi-response permutation procedure (MRPP; Mielke and Berry, 2007). This method does not require data-transformation and analyzes compositional differences by approximating probabilities of a test statistic based on average Euclidean distances for detecting distributional differences. In other words, the test is focused on differences in multivariate cumulative distributions rather than means. This approach may yield useful results for drawing conclusions about how different animals or treatment groups allocate their time, but it still does not provide insightful conclusions about specific behaviors within the composition of interest. No standardized way to approach this problem currently exists, but one solution is simply to model each behavior to query further covariates and relationships of interest: analyze each part of the behavioral composition as a univariate dependent variable. For such results to be interpretable, however, the same models must be applied and presented for all individual behaviors in the composition.

In simple compositions with few behaviors, the trade-off in time allocation may be evident. It is likely, however, that such clear trade-offs will not always be evident and multiple models must be presented for each behavior. For example, consider a simple composition of three horse behaviors

(Y_f = feeding, Y_r = resting, and Y_l = locomotion, where $Y_f + Y_r + Y_l = 1.0$). If Y_f has a strong linear increase with the predictor variable X_1 (for example, 0/1 indicator variable of sex) and a weak linear increase with predictor variable X_2 (for example, herd size), then Y_r, Y_l, or both must decrease with X_1, but the actual magnitude of that decrease will depend on both behaviors and the degree to which they also are influenced by X_2 (model 1 is $Y = f(X_1 + X_2)$). It could easily be that the strongest model for Y_r might include X_2 and another predictor (say X_3, and model 2 is $Y = f(X_1 + X_3)$). Thus, it is possible for model 1 to be strongly selected for analyzing the Y_f part of the Y compositional vector of behaviors but model 2 to be strongly selected for the Y_r part of the composition. Likewise, one model may be strongly supported for several behaviors and a complement model may be strongly supported for the remaining behaviors in the composition (see Ransom, 2009); however, because the behavioral composition really induces a relationship among the parts of the composition, statistical model results will be uninterpretable if a selected model is not considered to apply to all parts of the behavioral composition (for example, Y_f, Y_r, and Y_l).

The increasing use of maximum-likelihood and Bayesian approaches for solving complex problems may ultimately lead to the development of more lucid guidelines for many problems indicative of behavioral data. These methods can provide powerful tools for analyzing scientific data and can lead to a deeper understanding of the processes and errors involved (Hobbs and Hilborn, 2006). Regardless of the statistical approach, the path toward proper model selection for individual dependent behaviors in a composition has not been described in the literature. The use of model weights and model averaging may assist in drawing coherent conclusions about parameters of interest (Burnham and Anderson, 2002), but all supported models must be considered simultaneously for all dependent compositional variables to avoid violating the inherent statistical assumptions. A reasonable approach to assessing strength of evidence for compositional models, without violating assumptions of dependence, is to sum the minimum Akaike's Information Criteria (AIC: Burnham and Anderson, 2002) scores for the individually-modeled constituent behaviors in a composition; subsequently, each sum then forms an aggregate AIC score for each compositional model. The strength of evidence for the overall composition may then be assessed using AIC weights as Burnham and Anderson (2002) describe for individual models.

Ethogram

This ethogram was developed to investigate the influences of fertility control on feral horse behavior; thus, the behavioral groupings are broad in some contexts, such as feeding behavior, and much more detailed in areas of specific interest to the research objectives, such as agonism. Behavioral researchers often consolidate an array of behavioral expressions into broad categories since data collection on every specific behavior expressed is usually impractical and makes analyses excessively difficult. Therefore, this ethogram divides behavioral expressions into 13 discrete categories that cover the range of expressions a feral horse may exhibit in free-roaming conditions. Two additional categories (human awareness and out-of-sight) are used to account for biased observations. These 13 categories can easily be further aggregated *a posteriori* if desired, but categorizing these behaviors separately *a priori* allows for a wider range of possible analyses while still being practical for data collection. An example of a broader aggregation of these categories is the consolidation of grooming, comfort, standing attentive, and elimination into *maintenance*; herding, reproduction, harem tending, harem social, agonism, and submission into *social*; and human awareness and out-of-sight (unavailable to the observer) into *unknown* (fig. 1). At any given time during the course of observation, a focal animal will be exhibiting behavior that can be described by one of these categories. Developing a research ethogram from the several hundred behavioral expressions documented in equids can be a daunting task; therefore, this basic ethogram for feral horses is presented as a starting point for behavioral studies. For an excellent ethogram resource detailing complete equid behavior expressions, the reader is referred to McDonnell (2003). For a comprehensive work on equine behavior, the reader should also see Waring (1983).

Feeding

Feeding behavior occupies roughly half of the daily time budget of feral horses (fig. 1) and usually entails grazing. Grazing occurs as a horse bites off and ingests grasses and forbs close to the ground (fig. 2). The feeding category also includes browsing on woody plants and trees, eating snow, drinking, mineral licking, coprophagy (eating feces), and pawing at food resources. The latter is critical in defining feeding as a mutually exclusive category in that a horse may be pawing at soil, plants, or snow, but if the action is directly related to acquiring and ingesting a food resource, then it should be considered as feeding behavior. Also, horses move as they graze; therefore, as long as the horse is feeding while it is moving, it should be considered as feeding rather than locomotion.

Resting

The second largest amount of time in the daily time budget of feral horses is allocated to resting, which may occur during 25–35 percent of the daylight hours (fig. 1). Resting behavior is characterized by a general lack of attention and relaxed state and may occur in a standing position or in recumbency (fig. 3). This includes both relaxation and sleeping. Horses are able to sleep standing up due to the stay apparatus that allows their body to be supported without active muscular control (Dallaire, 1986). This behavior is typically observed

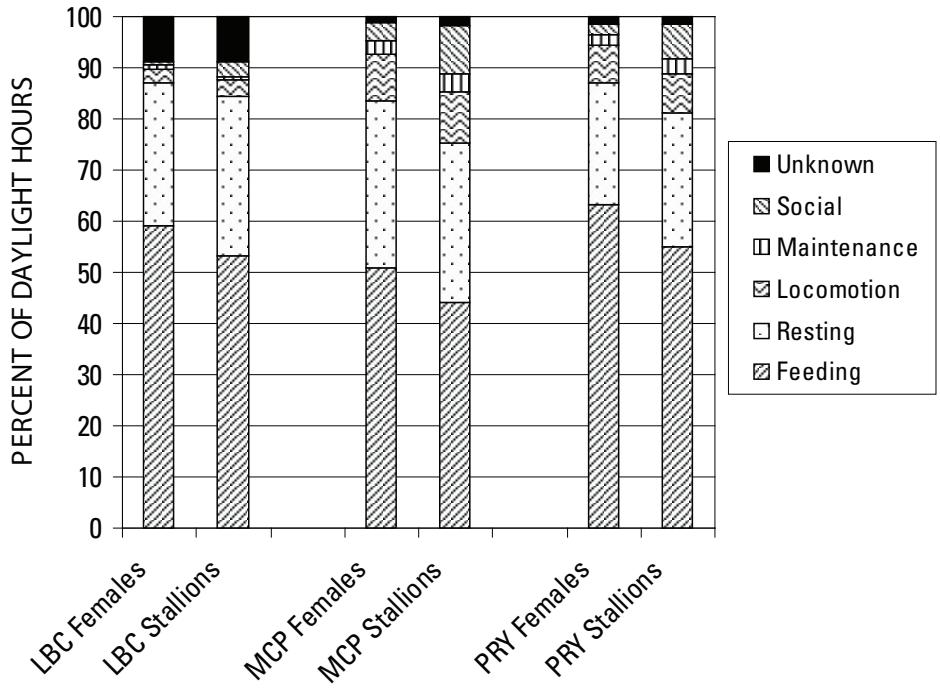

Figure 1. Observed daytime activity budgets of adult control female feral horses (n = 207, mean age = 7.79 yrs ± 0.33 SE, range = 2–21 yrs) and harem stallions (n = 110, mean age = 11.63 yrs ± 0.43 SE, range = 5–26 yrs) at Little Book Cliffs Wild Horse Range in Colorado (LBC), McCullough Peaks Herd Management Area in Wyoming (MCP), and Pryor Mountain Wild Horse Range in Montana (PRY), 2003–2006.

Figure 2. Feral horses grazing, the most typical *feeding* behavior.

Figure 3. *Resting* behavior in a band of feral horses is often characterized by huddling. Aside from the physical protection received by this behavior, the head-to-tail orientation of band members in this type of resting behavior also facilitates grooming. This allows for insect control around the head by the tail-swishing effect of neighbors.

as a body position with the head lowered, eyes closed, and one rear foot slightly elevated. Resting behavior in a band is often characterized by huddling, which facilitates insect control by the tail-swishing of close neighbors. Recumbent rest can be sternal or lateral. The comfort behavior of sun-basking is expressed in a laterally recumbent state, so a protocol must be defined *a priori* characterizing this state as rest or comfort, based on research objectives.

Locomotion

The third largest amount of the daily time budget is spent on locomotion. This behavior includes walking, trotting, cantering, galloping, jumping, and swimming and in feral horses is typically used for moving from one resource to another (fig. 4). Since most feral horse populations in North America occupy arid or semi-arid environments, movement to the few and scattered water sources is often the impetus for daily occurrences of extended locomotion (typically every 12 to 24 hrs). Otherwise, feral horses do not expend vast amounts of energy in locomotion, with the exceptions of brief social interactions between bands, stallion agonistic expressions, and female recruitment efforts by stallions. In this ethogram, locomotion integral to reproductive, harem tending, or comfort behaviors is considered part of its respective behavioral expression and not recorded as locomotion.

Maintenance

Grooming

Grooming behavior occupies a relatively small but important part of the daily time budget of feral horses and is often observed as rolling. Rolling occurs both on land and in water and is thought to assist with pelage health and insect control (fig. 5) (Waring, 1983). Other grooming behaviors include shaking, nibbling or licking on self, tail-swishing, rubbing, and periodic stomping to displace flies and biting insects. Allogrooming (also known as mutual grooming) in this ethogram is not considered categorically as a grooming behavior since it is also a social interaction that involves more than one animal. Depending on the nature of the research, it may be appropriate to consider allogrooming as part of the grooming category.

Figure 4. *Locomotion* is most typically expressed as walking from one place to another, as seen in this feral horse stallion. The higher energy-expense gaits of trotting, cantering, and galloping are observed far less frequently.

Figure 5. *Rolling* by this feral horse mare is a grooming behavior associated with pelage hygiene and insect control.

Comfort

Comfort behavior takes on a wide variety of forms in feral horses and includes any type of self-enjoyment expression, such as play, investigation, and stimulation (fig. 6). Some examples of comfort behavior are sun-basking, shelter seeking, masturbation, sexual play, object play, locomotor play, play fighting, and some olfactory investigations. Olfactory investigations also may be indicative of reproductive behavior or social behavior and should be included in the appropriate category for data collection based on specific research objectives. This ethogram also includes yawning and stretching as comfort behaviors, though it would not be inappropriate to include those expressions as a form of resting behavior.

Standing Attentive

When horses receive a stimulus that causes alertness, they react by exhibiting a rigid body posture with head upright, ears pointed forward, and eyes open and alert (fig. 7). This may be momentary in the case of a sound or smell causing alertness, but such standing attentive behavior also occurs for extended periods of time when a female is standing guard over a sleeping foal or a predator is nearby. In this ethogram, standing attentive does not include instances when the behavior is a result of human presence (fig. 8). In those cases, human awareness is considered its own category so that the biased data may be properly addressed during analyses.

Elimination

Elimination in horses is expressed as urination or defecation (fig. 9), though depending on research objectives, it should be determined whether any such expression will be included in this category or whether elimination with social implications is considered elsewhere. Socially, feral horse stallions create fecal middens known as stud piles and repeatedly defecate on them. These middens are thought to facilitate communication or ownership status of certain resources (Feist and McCullough, 1976; Rubenstein and Hack, 1992). When female feral horses urinate or defecate, it is common for the harem stallion to cover it with his urine for similar reasons. It has been reported that female horses do not cover the urine of other females in this fashion (McDonnell, 2003), though this was documented periodically during our study and may have implications in the female dominance hierarchy.

Figure 6. A typical *comfort* behavior for feral horse males is masturbation, which is expressed when a horse flexes his erect penis against his abdomen. This behavior is not expressed in conjunction with a nearby female and should not be confused with the penis drop observed when a male is reproductively tending a female.

Figure 7. Feral horse mares are focused on an external stimulus (in this case, a foal distress vocalization in the distance) and are exhibiting *standing attentive* behavior. Note the directionally pointed ears, rigid body position, and focused eyes characteristic of this expression. This behavior should not be confused with *human awareness*.

Figure 8. *Human awareness* is an important behavior to record when conducting any behavioral research so that biased data can be properly omitted from analyses of naturally occurring behaviors. Here, an entire band has paused because they noticed the photographer in the distance.

Figure 9. A female feral horse is exhibiting *elimination* by urination. Urination behavior in horses is sexually dimorphic: female horses urinate in a posterior direction and male horses urinate in an anterior direction.

In this ethogram, random urination and defecation are considered elimination, whereas systematic covering of urine or feces from the female by a harem stallion is considered as a harem tending behavior. The systematic covering of urine from a female by a female in the same harem is considered harem social behavior.

Social

Harem Social

Harem social behavior is considered to be social interaction among band members that is not specifically indicative of reproductive, harem tending, or agonistic behavior. Allogrooming is considered a harem social behavior in this ethogram (fig. 10), as is olfactory investigation (from one horse to another, fig. 11, or the systematic smelling of urine deposits among band members) and pair-bonding among juveniles (fig. 12).

Herding

When a feral horse stallion actively drives females of his harem together, it is considered herding behavior. This involves the stallion moving systematically behind the females, posturing with his head held low and ears laid back, and controlling the direction and movement of the band members (fig. 13). Waring (1983) termed this motion with the stallion's head moving side-to-side as snaking. Some researchers may choose to consider this as an agonistic behavior, but it is considered here as its own category since the function of the behavior is maintaining the harem rather than aggression toward specific females.

Harem Tending

Harem tending consists of stallion behaviors that are directed at maintaining the harem and include the defense and recruitment of females. The defense of females is expressed as a stallion positioning himself between his harem females and a perceived threat (typically another stallion) (fig. 14). It is also expressed by covering a female's urine or feces with his own, or by depositing feces on a stud pile (fig. 15). Recruitment, or stealing, of females by a harem stallion from another stallion is also considered harem tending behavior in this ethogram.

Reproduction

Reproductive behavior in feral horses is characterized by a series of stallion-initiated behaviors and a series of mare-initiated behaviors. The stallion reproductive sequence often

Figure 10. One of the most common *harem social* behaviors is allogrooming (also known as mutual grooming). It is expressed by the lateral parallel body position of two horses that allows for nibbling along the back or withers of each horse. While this behavior can be considered grooming, it is also thought to facilitate pair-bonding and dominance structure between band mates (Waring, 1983).

Figure 11. Olfactory investigation in the *harem social* behavior context is often observed as prolonged olfactory engagement of a female and her foal in a bonding regimen. This also may include licking and nudging.

Figure 12. Pair-bonding among juveniles within a band is also a common *harem social* behavior. In this example, female foals are closely engaging each other, which is thought to facilitate development of the female-female ethological relationships critical to band structure and stability later experienced as reproductive members of a family group (Crowell-Davis and others, 1986).

Figure 13. A feral horse stallion (leftmost horse) is *herding* females in his band by posturing and actively driving his females back into a cohesive group. Herding is the most common social behavior expressed by the dominant male toward females in his harem.

Figure 14. The blue roan stallion (foremost) is *harem tending* by expressing a posturing behavior and positioning himself between his harem females (several additional females out of the photo to the left) and an intruding male (right). Depending on the persistence and signals of the intruder, this behavior may develop into *agonism*.

Figure 15. Male feral horses also express *harem tending* by maintaining fecal middens, or stud piles, in which feces are aggregated at strategically located positions within the band's home range.

(but not always) begins with herding or reproductive tending behavior. Reproductive tending is the close following of a female by the male, without the directional driving observed in herding behavior. Following this tending behavior, the stallion often vocalizes and exhibits the olfactory response known as flehmen (fig. 16) (Stahlbaum and Houpt, 1989). He then proceeds by rubbing his head on the female's flanks and (or) resting his chin on her back, and extends his penis out of the prepuce (fig. 17). Some of these behaviors out of sequence are not necessarily associated with a stallion reproductive sequence; therefore, protocols to determine how to categorize the observed behavior are specified in figure 18.

Female reproductive behavior is signified by estrous, which can sometimes be challenging to detect from typical field observation distances. A mare initiates her reproductive sequence by presenting herself facing away from the stallion, lifting her tail, and vocalizing (though sometimes the female faces the stallion first). These behaviors alone do not necessarily signify estrous, since the female could simply be vocalizing and preparing to defecate. If in estrous, it is typically accompanied by posturing her body with hind legs slightly apart (an apparent squat) and often turning her head toward her posterior. The mare also will frequently emit small streams of urine, a behaviour that is often concurrent with rhythmic 'winking' of her vulva: winking can be observed by the periodic flashes of pink from the inner coloration of her vaginal membranes (McDonnell, 2003). These contrasting pigments can be seen in the rolling female in figure 5, simply because of her posture. The urine emitted from female horses in estrous consists of specific variations of urinary volatile compounds that may facilitate chemical communication during reproductive behavior (Ma and Klemm, 1997). Female horses may express estrous behavior during the anovulatory period (typically winter) as well as during pregnancy (Crowell-Davis, 2007). Such anomalies to our conventional understanding may lead to misinterpretation of estrous behavior in the field and care should be taken to correctly and systematically identify this behavior.

Once both male and female are exhibiting reproductive behaviors, copulation may occur with the stallion mounting the female from behind, neck arched over her back and forelegs resting on her sides (fig. 19). Several events could occur in this situation and should be categorized separately if reproductive behavior is a focus of the research. These include successful copulation, unsuccessful copulation (the stallion cannot adequately mount the female for some reason), mare acceptance, mare rejection (the mare kicks and moves away from the stallion), and forced copulation (the mare is not presenting or accepting the stallion's advance, but he relentlessly mounts her anyway).

Figure 16. Flehmen response in this feral horse stallion is displayed by the elevated head, and raised, inverted upper lip. This posture is a response to particularly exciting chemicals and olfactory signals that are detected by the main olfactory epithelium and concentrated directly into the vomeronasal organ, which in part controls sexual activity (Estes, 1972; Mills and Nankervis, 1999).

Figure 17. A feral horse stallion is exhibiting penis extension and rubbing of the female's flanks as part of the male reproductive behavior sequence.

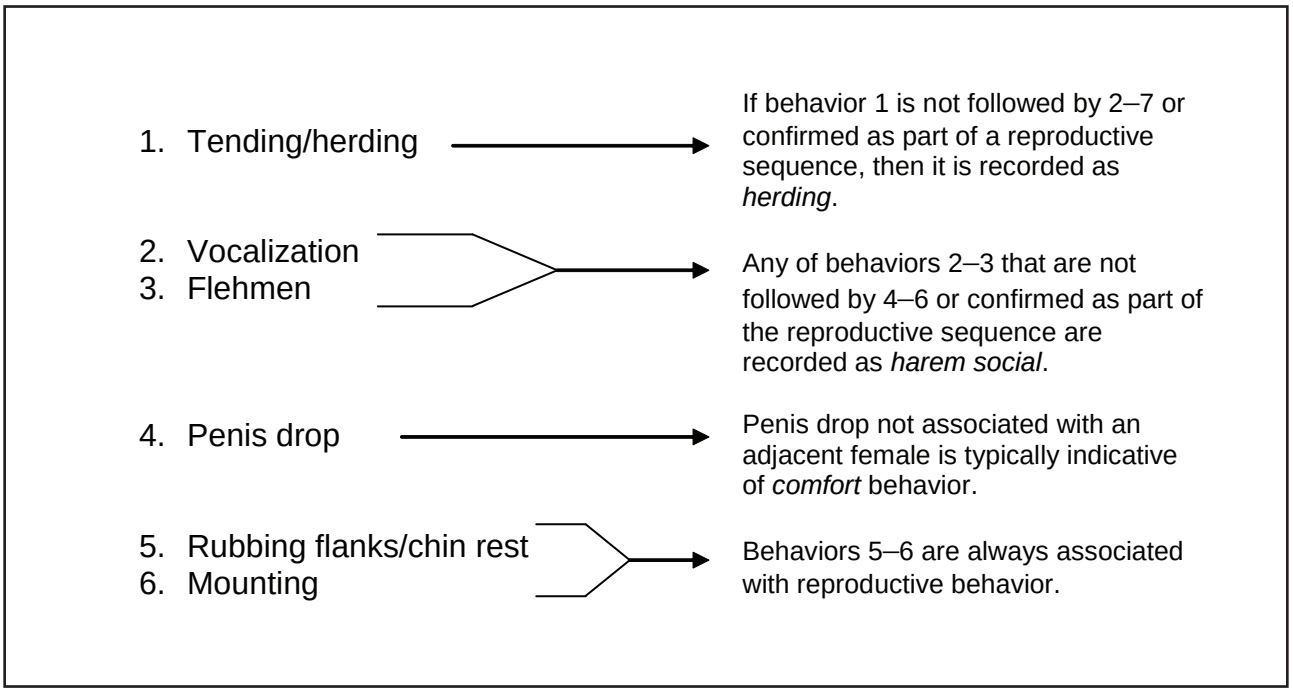

Figure 18. Basic guidelines for distinguishing reproductive and non-reproductive behaviors in stallions.

Figure 19. *Successful copulation* is occurring between this feral horse male and female. This reproductive behavior is characterized by a maintained mounting position on the female for the male and a relatively stationary, relaxed position for the female. *Unsuccessful copulation* is often a result of *mare rejection*, with the female expressing *agonistic* behaviors such as kicking toward the male and a brief mounting position for the male.

Parturition may also be included in the reproductive category or designated as its own behavioral category, depending on research focus.

Agonism

Agonism in feral horses is exhibited by a wide range of behaviors and in this ethogram is put into seven categories arranged by increasing intensity of the interaction. Note that any or all of the following behaviors may be exhibited in play by young animals, in which case they should be considered comfort behavior rather than agonism. The first four categories of agonism may occur between males only, females only, or between males and females, but the remaining levels of agonism are typically observed only between males.

The most common and least intense form of agonism is the threat. Threats are characterized by laterally pinned back ears, arched neck, and (or) a movement of the head toward the opposing horse, but with no physical contact (fig. 20). Most conflicts and dominance interactions among feral horses are resolved by these gestures alone.

The next agonistic expression is the bump or push, which is expressed by the aggressor making forceful contact with another horse using its head, neck, or shoulder (fig. 21).

As agonism escalates, the aggressor may chase its adversary at a gallop to displace the animal from the immediate area or with the intent of engaging the animal in more agonistic behavior (fig. 22). Chasing behavior is typically brief (seconds) or may last several minutes; however, the USGS study documented this behavior occasionally persisting over long time periods (greater than 1 hour) and great distances (greater than 3 km).

The fourth level of agonism involves biting an opponent or kicking with the hind legs (fig. 23). This level involves physical contact, though serious injury is rare.

Rearing occurs when the horse lifts its forelegs off the ground and elevates its body into a more vertical position, thus looking larger to the opponent (fig. 24). While technically only a threat, this body position typically signifies a more intense agonistic interaction and provides the initial position for commencement of stomping, striking, boxing, and dancing behaviors.

Figure 20. *Agonism* is expressed by both of these feral horses in the form of a *threat*. This is the most common form of agonism between feral horses and is most easily recognized by the laterally positioned, posterior pointing direction of the ears (shown in both animals here).

Figure 21. *Pushing* is an agonistic expression shown here by the foremost horse pushing toward the more distant horse.

Figure 22. *Chasing* is a moderately intense form of agonism and is shown here along with an expression of imminent biting behavior.

Figure 23. *Biting* is a common expression of agonism in equids and is expressed here between feral horse females to assert dominance.

Figure 24. *Rearing* is an expression often signifying a potentially intense agonistic interaction, typically between feral horse stallions.

Figure 25. *Striking* or *stomping* is being expressed by the feral horse stallion on the left. This behavior is typically indicative of highly agonistic expression and is expressed by the directed extension and downward motion of one or both front feet.

Stomping and striking occur when a horse uses one or both front feet to attack an opponent by extending the legs out and downward. This behavior has the potential to seriously injure the recipient (fig. 25).

The most intense form of agonism between feral horse stallions is boxing and dancing. These behaviors involve the engagement of the agonists in vertical body positions and the use of the front legs in striking (boxing) or closer engagement that results in head and neck biting (dancing) (fig. 26). On very rare occasions, feral horse stallions have been observed engaging in prolonged fights resulting in considerable injury and sometimes fatal outcomes.

Submission

Submission is exhibited by the loser of the agonistic encounter. This may be expressed by simply running away, but also may be expressed with laid down ears (distally or posteriorly), lowered head posture, lowering of the hindquarters, and sometimes jaw snapping (especially in juveniles) (fig. 27).

Acknowledgments

Thanks to Linda Coates-Markle, the late Dr. Francis J. Singer, and the many field technicians who voiced their opinions on how to aggregate these behaviors in the most meaningful way for its original research purpose. Many thanks to Hanem Abouelezz, Laura Caldwell, Melissa Esser, Marty Felix, Kayla Grams, Patti Grigsby, Susan Hahn, Billie Hutchings, Georgia Manus, Jane Nibler, Christina Petrandis, Phyllis Preator, Jennifer Severude, and Gerald Thygerson for the thorough notes and explanations in the margins of datasheets, which inevitably became as valuable for understanding equid behavior as did the rigidly collected and analyzed data points. J. Roelle, J. MacLeay, L. Zeigenfuss, and A. Kane provided useful and critical insights in their reviews of this manuscript. Thank you to S. McDonnell for expertise in helping us accurately define stallion reproductive behaviors. All photographs are courtesy of Jason I. Ransom. The National Park Service, U.S. Bureau of Land Management, and U.S. Department of Agriculture Animal and Plant Health Inspection Service provided administrative support and oversight during all USGS feral horse research efforts.

Figure 26. *Boxing* and *dancing* between these two stallions is illustrative of the highest level of agonism that feral horses typically express.

Figure 27. *Submission* is being expressed by a young male horse (grullo [dark grey] horse in center) and directed toward the larger, dominant male (foremost), who is displaying *threat* behavior associated with dominance.

ABSTRACT Locally abundant feral horses (*Equus caballus*) can rapidly deplete available resources. Fertility control agents present promising nonlethal tools for reducing their population growth rates. We tested the effect of 2 forms of the immunocontraceptive porcine zona pellucida (PZP) on foaling rates in 3 populations of feral horses in the western United States. A liquid form requiring annual boosters was administered at Little Book Cliffs Wild Horse Range, Mesa County (CO), and Pryor Mountain Wild Horse Range, Bighorn County (WY) and Carbon County (MT), and a time-release pellet form designed to produce 2 yr of infertility was administered at McCullough Peaks Herd Management Area, Park County (WY). Average foaling rates (foals born/mare-yr) from direct observation of untreated and treated female horses (mares), 2004–2008, were 60.1% ($n = 153$ mare-yr) versus 6.6% ($n = 91$ mare-yr) at Little Book Cliffs, and 62.8% ($n = 129$ mare-yr) versus 17.7% ($n = 79$ mare-yr) at Pryor Mountain, respectively. At McCullough Peaks, mean annual foaling rates from 2006 to 2008 were 75.0% ($n = 48$ mare-yr) for untreated mares and 31.7% ($n = 101$ mare-yr) for treated mares. Controlling for age of mares and pretreatment differences in fertility, PZP reduced foaling rates in all 3 herds. The pellets used at McCullough Peaks (produced by cold evaporation) were less effective than pellets used in a previous trial and produced by heat extrusion. Immunocontraception with PZP may be a useful tool in reducing fertility rates in some western United States feral horse herds, but population growth reduction will depend on timely access to mares for inoculation and the proportion of mares that can be successfully treated. Published 2011. This article is a U.S. Government work and is in the public domain in the USA.

KEY WORDS *Equus caballus*, feral horse, fertility control, immunocontraception, PZP, western United States, wildlife contraception.

Tools for regulating animal populations are needed when habitat and resources are inadequate to sustain local abundance. Traditionally, regulation of wildlife populations has focused on lethal methods. Fertility control has emerged as an increasingly viable alternative to such methods and may be a particularly valuable tool when managers are faced with regulating protected species that are locally overabundant (Hobbs et al. 2000, Porton 2005). Such is the case with rapidly reproducing feral horses (*Equus caballus*) that roam large areas of public land in the western United States that are managed by the Bureau of Land Management (BLM) and U.S. Forest Service (Eberhardt et al. 1982, Garrott et al. 1991).

Many fertility control techniques have been proposed or tested for managing feral horses in the United States, ranging from hormone implants (Plotka et al. 1992) and intrauterine devices in females (Daels and Hughes 1995, Killian et al. 2008) to testosterone propionate treatment of males (Turner and Kirkpatrick 1982). These efforts produced tools that were publicly unacceptable, expensive to use, or impractical on a large scale (Kirkpatrick and Frank 2005). In recent decades, immunocontraceptive vaccines incorporating antigens such as porcine zona pellucida (PZP) or gonadotropin-releasing hormone (GnRH) have been used to limit reproduction in feral horses (Killian et al. 2008, Kirkpatrick and Turner 2008, Gray et al. 2010). Manager interest in these agents increased because of the relative ease of their application, expected efficacy and duration, and anticipated lack of side-effects.

Porcine zona pellucida acts as a vaccine against pregnancy by stimulating the production of zona pellucida antibodies in female mammals (Sacco 1977, Liu et al. 1989). These antibodies provide a barrier that prevents sperm from binding to the surface of an ovum and results in limited penetration of

[1]*E-mail: ransomj@usgs.gov*

the zona pellucida and subsequent limited pregnancy in horses (Liu et al. 1989, Kirkpatrick et al. 1990). The most widely used formulations of PZP include a liquid form with a reported effectiveness of 7–10 months (Liu et al. 1989, 2005; Lyda et al. 2005), a time-release, heat-extruded (H/X) pellet form with a reported 22-month effectiveness (Turner et al. 2008), and a liposome-encapsulated liquid form known as SpayVac® (Immunovaccine Technologies, Halifax, NS, Canada), targeted for multiple-year effectiveness (Brown et al. 1997, Killian et al. 2008).

Detected physiological side-effects of PZP treatment have included a decrease in ovarian function when treatment is applied for >3 yr (Kirkpatrick et al. 1995), and injection-site reactions that appear to be nondebilitating in feral horses (Roelle and Ransom 2009). Reproductive behaviors were also found to be affected during the breeding season (Ransom et al. 2010) and band fidelity and reproductive behaviors were found to be affected outside of the breeding season (Nuñez et al. 2009).

Access to animals for timely inoculation and other management constraints may affect the utility of PZP as a management tool for western feral horse populations. We hypothesized that effectiveness of the treatments would be less than that previously demonstrated clinically. To evaluate this hypothesis, we applied PZP in liquid and pellet form in 3 western feral horse populations managed by BLM and assessed the effectiveness of the agent on individual female horses (hereafter, mares) from 2002 to 2008. Our objectives were to quantify the effectiveness of multiple years of contraception with liquid PZP and a single application of PZP pellets produced by an alternate, and more efficient, method (cold evaporation; Turner et al. 2008) on individual free-roaming mares in the context of age-specific foaling rates and actual management constraints.

STUDY AREAS

We inoculated mares with PZP at the Little Book Cliffs Wild Horse Range, the McCullough Peaks Herd Management Area, and the Pryor Mountain Wild Horse Range. The Little Book Cliffs Wild Horse Range, located in Mesa County, Colorado, USA (latitude 39°12′N, longitude 108°25′W), consisted of approximately 14,600 ha of sloping plateaus, sagebrush (*Artemisia* spp.) parks, and steep shale and sandstone cliffs dissected by 4 major canyon systems. Elevations ranged from 1,500 m to 2,250 m. The study area also exhibited dense stands of Colorado piñon (*Pinus edulis*) and Utah juniper (*Juniperus osteosperma*). Population size varied from 122 to 204 horses during the course of this study. Snow accumulation limited access to much of this study area during winter months, though horses that migrated into lower canyons could sometimes be accessed. The horses could only be approached close enough to dart (<60 m) when they were in open sagebrush parks.

Located in Park County, Wyoming, USA (latitude 44°35′N, longitude 108°40′W), the McCullough Peaks Herd Management Area consisted of 44,400 ha of open sagebrush park with badlands along the western edge. Vegetation consisted of large expanses of small shrubs, grasses, and forbs. Elevations ranged from 1,200 m to 1,964 m. Population size was as high as 495 horses before a large management removal in 2004, and ranged from 112 to 194 in subsequent years. The horses in this population did not allow humans to approach within darting range and remote delivery of PZP was deemed impractical at this site at the time of study.

The Pryor Mountain Wild Horse Range, located in Bighorn County, Wyoming and Carbon County, Montana, USA (latitude 45°04′N, longitude 108°19′W), consisted of slightly >16,000 ha of low desert, foothill slopes, forested montane slopes, steep canyons, and isolated grassy plateaus. Elevations ranged from 1,190 m to 2,625 m. Three undeveloped roads intersected the study area and were impassable from late autumn to early spring due to snow accumulation and seasonal erosion. Horses in this population were more conditioned to humans and could be approached at close range (<40 m) with little or no evasive behavior throughout the summer and when located at accessible low elevations in winter.

METHODS

Vaccine Preparation

We used the liquid form of PZP at Little Book Cliffs and Pryor Mountain and the cold-evaporation (C/V) pellet form at McCullough Peaks. Personnel from the Science and Conservation Center at ZooMontana (Billings, MT) prepared the liquid agent according to the methods of Dunbar et al. (1980) and delivered both agent and adjuvant to us. We emulsified PZP and adjuvant in alcohol-sterilized syringes prior to use, as described by Kirkpatrick et al. (1990). For hand injections, we loaded the emulsion into alcohol-sterilized syringes fitted with single-use sterile needles. For injections by dart, we loaded the emulsion into 1-cm^3 barbless darts (Pneu-Dart®, Williamsport, PA) as they were removed from the manufacturer's packaging and placed a small dab of petroleum jelly on the tip of the dart to prevent leakage. Both primer and booster injections at Little Book Cliffs and Pryor Mountain contained 0.5 mL (100 μg) of PZP. Primer inoculations at Little Book Cliffs also contained 0.5 mL of Freund's complete adjuvant (FCA; Claassen et al. 1992, Kensil et al. 2004), whereas those at Pryor Mountain contained 0.5 mL of either FCA or Freund's modified adjuvant (FMA). Freund's complete adjuvant can produce false-positive tuberculosis test results in treated animals and has been known to contribute to abscessed injection sites (Broderson 1989); therefore, FMA was substituted for FCA after research indicated no difference in efficacy between the 2 adjuvants (Lyda et al. 2005). Booster inoculations were identical except that we substituted Freund's incomplete adjuvant (FIA). Additional details on darts and delivery methods can be found in Roelle and Ransom (2009).

Personnel at the Medical College of Ohio (now the College of Medicine, University of Toledo) prepared the time-release pellets using the cold-evaporation process described by Turner et al. (2008). All pellets contained a saponin adjuvant, QA-21 (Virbac Corporation, Brussels, Belgium), and were

designed to release PZP in bolus fashion at 1 month, 3 months, and 12 months. The 1-month and 3-month pellets each contained 100 μg of PZP and 200 μg of adjuvant; the 12-month pellets contained 250 μg of PZP and 500 μg of adjuvant. The PZP used in these pellets was obtained from ZooMontana.

Contraceptive Treatments

We initiated treatments at each of the 3 study areas in conjunction with gathers (roundups) conducted by BLM (Pryor Mountain in Sep 2001, Little Book Cliffs in Jul 2002, and McCullough Peaks in Oct 2004) and collected all data in accordance with Colorado State University Animal Care and Use Committee Standards (protocol 03-107A-02). Age classes and numbers of horses treated were in accordance with local plans developed by BLM managers. At Little Book Cliffs and McCullough Peaks, these management decisions were based on the number of mares in each class that needed to be contracepted in order to meet specific population growth goals, as predicted by the WinEquus model (Jenkins 1996). Managers at these sites randomly selected mares within each age class to be treated, and we randomly assigned control status to mares within bands to ensure that each band of horses being observed for a concurrent study of PZP effects on behavior contained both treated and untreated mares (Ransom et al. 2010). Treatment decisions at Pryor Mountain were not random across age classes, but rather all animals in given cohorts were treated, as discussed below. We gave all injections intramuscularly in the hip, regardless of delivery method.

We treated mares of all ages ≥1 yr at Little Book Cliffs. The primer dose was administered by hand to gathered mares while they were restrained in a squeeze-chute. Additional ungathered mares received the primer by dart in order to make up the desired sample size because an insufficient number of mares were captured. We delivered a booster inoculation by dart when the animals could be relocated (never sooner than 24 days), followed by annual boosters by dart. We recorded delivery distance of dart applications using Leica Rangemaster 1200 Scan laser rangefinders (Leica, Solms, Germany). We attempted to schedule the annual boosters such that mares would be continuously immunized. Duration of effectiveness of PZP has not been studied in detail, especially for multiple years of treatment.

At the time we initiated our experiments, available evidence indicated that PZP antibody titers would be maintained at contraceptive levels in many mares for 10 months following a first booster and that duration of efficacy may be extended following subsequent boosters (Liu et al. 1989, Kirkpatrick and Turner 2002). Based on these studies and consultation with the manufacturers of the drug, we assumed 10 months duration of efficacy for the first booster, 11 months for the second, and 12 months for all subsequent boosters. Using this schedule as a guide, most mares at Little Book Cliffs were treated for 4 consecutive yr, though a few were lost to the study for various reasons and 4 mares received 5 booster inoculations. We did not add young animals to the treatment group as they reached 1 yr of age, but we did add them to the control group when they reached 3 yr of age. Precise age (observed as a foal) was available for 73.9% of 88 mares (both treatment and control) studied at Little Book Cliffs. Remaining mares were aged by tooth eruption and wear patterns (American Association of Equine Practitioners 2002).

At Pryor Mountain, treatments were similar to those at Little Book Cliffs except that we inoculated mares 1–2 yr of age (2002–2004) and older mares (≥15 yr, 2002–2004; ≥11 yr after 2004). These age classes were selected by managers to address public input concerning welfare of young and old females. Animals were, thus, added to the treatment group as they reached 1 yr of age (2002–2004) or 15 yr of age (11 yr of age after 2004), and controls consisted of middle-age animals that had never been treated. Treatments at Pryor Mountain also differed from those at Little Book Cliffs with respect to the timing of the first booster. At Pryor Mountain, management constraints (e.g., public appeals timeframe for Environmental Assessments) and weather forced us to deliver a number of first boosters only 14–16 days after the primer, instead of the 3–4 weeks used in previous studies (Kirkpatrick et al. 1997). Of the 83 treated or control mares at Pryor Mountain, ages of 64 (77.1%) were known (observed as a foal) from a long-term demography study (Roelle et al. 2010). We estimated ages of the remaining mares as at Little Book Cliffs.

At McCullough Peaks, we administered all inoculations in October 2004 while gathered mares were individually restrained in a squeeze-chute. We gave each mare a primer inoculation of liquid PZP (FMA as adjuvant), followed immediately by the time-release pellets, which were delivered by jabstick or hand-held trocar syringes and designed to act as boosters. Treated mares were of all ages ≥1 yr. We did not add mares to the treatment group in subsequent years, but we did add recruited mares to the control group when they reached 3 yr of age. We collected foaling data for 1 yr beyond the expected contraceptive effect in order to detect a possible residual effect, as was reported in the only similar study of time-release PZP (Turner et al. 2007). Precise ages were known for 34.4% of the 64 mares studied at McCullough Peaks (born during our study). We estimated ages of the remaining mares as at Little Book Cliffs.

Field Observations

U.S. Geological Survey (USGS) and BLM employees and volunteers recorded all field observations from the ground using optical equipment (binoculars, telescope) as necessary. These observers had completed undergraduate degrees in equine science, veterinary or preveterinary medicine, or biology, or had extensive experience working with equines. All mares and foals were identified and cataloged individually on the basis of pelage color, natural markings, and band association. Observers were trained in identifying individuals using these attributes and were provided with a photo database containing images of each individual for reference.

We located >99% of all mares and foals (when present) at least weekly from April to October of each year, and most

were relocated several times per week. Of those not located weekly, 4–6 mares annually at Little Book Cliffs were difficult to access, but were located at least monthly. Likewise, 1 mare at Pryor Mountain (2004) and 2 mares at McCullough Peaks (2007) were also not found weekly, but were observed at least monthly. Observations during the remainder of the year were opportunistic and largely dictated by weather. It is possible that some foals were born and died without being observed; however, given the intensity of observations, we believe that this rarely occurred. We matched foals with dams based on observations of attachment (e.g., nursing, general proximity) during the early days and weeks of a foal's life (Waring 2003); foaling rate was, thus, defined as the frequency of live births per cohort as detected by direct observation.

Data Analysis

The average gestation period for a horse is 335–342 days (Card and Hillman 1993); thus, mares are often pregnant when they receive a contraceptive agent, and the effect of contraception is not seen until the second foaling season following immunization. For example, a pregnant mare immunized in December of one year will give birth to a foal in the following spring, will be infertile for the subsequent breeding season, and the effect of that contraception will be seen in the next foaling season. We subsequently divided mares into 3 groups: untreated (control) animals that were never immunized; pretreatment animals that had been immunized, but the immunization had not yet taken effect; and treated animals that had been immunized and the immunization had presumptively taken effect. These strata were based on the date of booster treatment for each individual and the presumed duration of efficacy discussed previously.

We modeled foaling probability of mares with mixed-effects logistic regression, where individual mare was included as a random effect on the intercept term to account for the repeated observations (multiple yr) of individuals over time. This was necessary to account for variation that may be present among individuals who were sampled repeatedly, though not always equally over time. Such variation may arise from physiology, behavior, or any number of external factors that may affect conception, pregnancy, and parturition. We used the lmer(·) function in the lme4 package in R version 2.10.0 (The R Foundation for Statistical Computing 2009) to obtain mixed-effects model estimates. If the variance estimate for the random effect of individual mare converged to zero, we re-estimated the model as a simpler fixed-effects logistic regression using the glm(·) function. Foaling rates of feral horses often increase for the first few years after mares reach sexual maturity, remain high through middle age, and decrease in older mares (Garrott and Taylor 1990, Roelle et al. 2010). We, therefore, included linear and quadratic effects of age in all models. We rescaled age in the quadratic effect by subtracting the mean age of horses (8.89 yr across all populations), so that the intercept term of the model corresponded to probability of foaling at mean age. We fitted separate models for each study area.

To assess effects of the immunocontraceptive, we compared untreated mares to pretreatment mares and untreated mares to treated mares. In both comparisons we used only years in common between the 2 groups so that any environmental effects were constant. We used the first comparison (untreated vs. pretreatment) to isolate any preexisting differences associated with potential nonrandom selection of individuals that could have arisen from allocation of controls per band rather than across the population. We modified the estimated odds ratio of foaling rates in the second comparison (untreated vs. treated mares) by the estimated odds ratio associated with the preexisting differences. The odds ratio of producing foals associated with the immunocontraceptive was then equal to $\exp(\hat{\beta}_{\text{treated}} - \hat{\beta}_{\text{pretreatment}})$ where $\hat{\beta}_{\text{treated}}$ was the estimated difference between treated and untreated mares and $\hat{\beta}_{\text{pretreatment}}$ was the estimated difference between pretreatment and untreated mares. We estimated variance for the combined odds ratio using simple formulas for linear combinations of uncorrelated random variables (Neter et al. 1996:1318). Because the estimated differences for pretreatment and treated groups used the same horses, the assumption of uncorrelated estimates was violated to some degree (le Cessie et al. 2008). Other models combining all 3 treatment groups, which ignored our desired balance across years, suggested that the estimated differences between untreated and pretreatment mares and between untreated and treated mares were positively correlated. Excluding a positive covariance in our variance estimates for the combined odds ratio produced a wider interval than would have resulted had we been able to account for the positive covariance. Thus, we consider our variance estimates for the combined odds ratios assuming zero correlation to be conservative. We estimated degrees of freedom for use with a t-distribution for constructing confidence intervals based on Satterthwaite (1946) as provided in Buckland et al. (1993:89).

At Little Book Cliffs and Pryor Mountain, mares received varying numbers of annual boosters: darts did not always function properly (Roelle and Ransom 2009), and it was not always possible to meet the schedule outlined above for keeping mares continuously contracepted. We used mixed-effects logistic regression to estimate probability of foaling among presumptively treated mares as a function of these variables. We included number of boosters received as a continuous variable and assigned a value for dart function (good or poor) based on physical examination of the dart after it was recovered. Darts were classified as poor if the vaccine did not fully discharge from the dart, pieces of the dart separated, or the needle broke on impact, and classified as good if the dart fully discharged and was structurally intact. We assigned a value for booster timing (good or poor) based on the number of days between injections. Consistent with the planned injection schedule for keeping mares continuously contracepted, we considered timing to be poor if >300 days (approx. 10 months) elapsed between the first and second boosters, >330 days (approx. 11 months) between the second and third, and >365 days (12 months) between all subsequent boosters. We also considered timing to be poor if the first booster was delivered during the

breeding season, which we defined based on foaling dates for untreated mares and an average gestation period (approx. 11 months). At Little Book Cliffs, 82.1% of births to untreated mares ($n = 117$ mare-yr) occurred in March–May, so we defined the breeding season as April–June. At Pryor Mountain, 93.5% of births to untreated mares ($n = 108$ mare-yr) occurred in April–June, so we defined the breeding season as May–July. We included linear and quadratic effects of age as in the previous comparisons.

At Little Book Cliffs and Pryor Mountain, we hypothesized that method of primer injection (dart or syringe) might affect foaling rate of treated mares in the first year of contraception. Also, at Pryor Mountain we hypothesized 2 additional factors might have an effect on foaling rate of treated mares in the first year of contraception: adjuvant used with the primer (FCA or FMA) and time between the primer and first booster (good or poor). We considered time between the primer and first booster to be poor if the booster was delivered <21 days after the primer. We examined foaling rates of treated mares as a function of these factors using fixed-effects logistic regression, again incorporating linear and quadratic terms for age of the mare.

RESULTS

At Little Book Cliffs, 25 individual mares composed the treatment group (received a primer inoculation and ≥1 booster inoculation, and were ≥3 yr of age at the time of expected parturition), and the untreated group (≥3 yr of age at the time of expected parturition) comprised 63 mares. At Pryor Mountain, 40 mares were treated (one additional mare was included in pretreatment analyses but died before a treatment effect could be detected) and 42 were untreated. At McCullough Peaks, 36 mares received the pellet form of the vaccine and 28 were untreated. Most mares were observed for foaling in multiple years and, unless otherwise noted, sample sizes reported hereafter represent mare-years.

Mares at Little Book Cliffs demonstrated a cumulative behavioral aversion to darting with first darts being delivered at an average of 28.6 ± 1.5 m (SE) linearly increasing to fourth darts being delivered at an average of 39.4 ± 3.3 m. Pryor Mountain horses were more conditioned to human presence and most received no >2 dart applications. Behavioral aversion to darting was not evident at this site; these horses received first darts at an average of 17.67 ± 2.1 m and second darts at an average of 12.2 ± 1.6 m.

At both Little Book Cliffs and Pryor Mountain, the original protocol called for boosters to be timed such that mares would always be effectively contracepted. This protocol was followed reasonably well at Little Book Cliffs, but at Pryor Mountain other management considerations and weather often intervened, and 72 of 79 boosters (91.1%) were delivered in August, September, or October, irrespective of when the previous booster was delivered. Delivering vaccinations by dart was seldom possible from November through February at either Little Book Cliffs or Pryor Mountain because seasonal access to roads and trails was impeded by drifting snow.

Of the 6 foals born to treated mares at Little Book Cliffs, 3 were born to a single mare. At McCullough Peaks, 20 of the 32 foals born to treated mares were attributed to 4 mares that produced a foal in each of the 3 treatment yr and another 4 mares that produced a foal in each of 2 treatment yr. At Pryor Mountain, 4 of the 14 foals born to treated mares were accounted for by 2 mares that produced 2 foals each. Though the number of foals born to treated mares was relatively small, the timing of these births provides some quantitative evidence that second and subsequent boosters may have a longer contraceptive effect than does the first booster (Fig. 1).

In all 6 comparisons of treatment groups (untreated vs. pretreated and untreated vs. treated at 3 study areas) mare age affected foaling (either the linear or quadratic term, or both; $P < 0.05$). Across all populations in our study, there was a nonlinear relationship ($R^2 = 0.80$, $n = 972$ mare-yr) between age of control and pretreatment mares and foaling rate (Fig. 2). After controlling for mare age, foaling rate of untreated mares as compared to pretreatment mares was lower at Little Book Cliffs, and slightly higher at McCullough Peaks and Pryor Mountain; however, the difference only approached significance ($P = 0.09$) at Little Book Cliffs (Table 1).

The combined odds ratios indicate that PZP treatment reduced the foaling rate at all 3 study areas ($P < 0.05$; Table 1); however, effectiveness of the treatment varied by area. At Little Book Cliffs, the mean foaling rate observed among treated animals was 6.6% (range = 0.0–10.0% over 5 yr), whereas the mean annual foaling rate observed at Pryor Mountain was 17.7% (range = 0.0–35.0% over 5 yr). The mean annual foaling rate observed at McCullough Peaks was even higher (31.7%); interestingly, however, foaling rate in the third year of treatment effect at McCullough Peaks

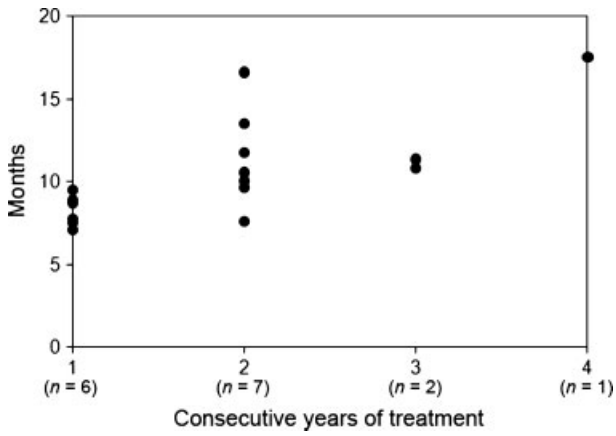

Figure 1. Foals born to feral horse (*Equus caballus*) females treated with the immunocontraceptive porcine zona pellucida (PZP) as a function of time (months) from booster inoculation to conception (calculated from parturition date) and the number of consecutive annual treatments received. Females inhabited Little Book Cliffs Wild Horse Range (Mesa County, CO) and Pryor Mountain Wild Horse Range (SE Carbon County, MT), USA, from 2002 to 2008, and received 1–4 booster inoculations containing a 1-cm^3 emulsion of PZP and Freund's incomplete adjuvant.

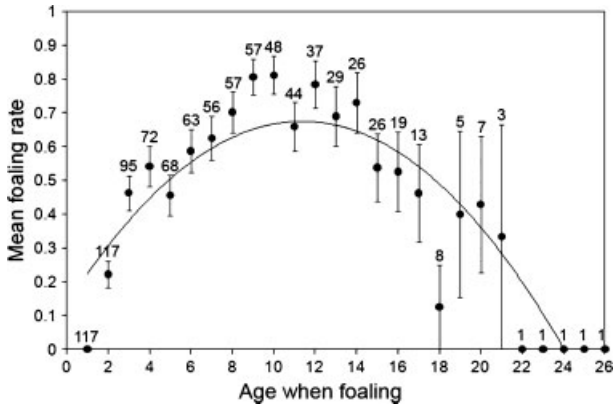

Figure 2. Mean foaling rates (±SE of the mean) for all ages of untreated and pretreatment feral horse (*Equus caballus*) females (*n* given at the top of each error bar) at Little Book Cliffs Wild Horse Range (Mesa County, CO, USA) 2002–2008, McCullough Peaks Wild Horse Management Area (Park County, WY, USA) 2003–2008, and Pryor Mountain Wild Horse Range (SE Carbon County, MT, USA) 2002–2008.

(29.0%, $n = 31$ mares) was nearly identical to that in the first year (27.8%, $n = 36$ mares), even though the pellets used at McCullough Peaks were designed for only 2 yr of efficacy.

When combined in a mixed-effects model with linear and quadratic effects of age and a random effect of individual mare, neither dart function ($z = 1.30$, $P = 0.20$), consecutive years of treatment ($z = 0.49$, $P = 0.62$), nor booster timing ($z = 1.04$, $P = 0.30$) affected foaling at Little Book Cliffs ($n = 91$; Table 2). Similarly, none of these covariates had an effect at Pryor Mountain (dart function, $z = 0.71$, $P = 0.48$; consecutive years of treatment, $z = -0.04$, $P = 0.97$; booster timing, $z = -0.32$, $P = 0.75$; $n = 79$). When combined in a fixed-effects model with linear and quadratic effects of age, time between the primer and first booster also had no effect ($z = 0.38$, $P = 0.70$) at Pryor Mountain, nor did adjuvant used with the primer ($z = 0.15$, $P = 0.88$; $n = 40$ mares). There was no random effect of individual mare in this model because we considered only the first booster for each mare. Lack of significance for the primer adjuvant term, despite the relatively large difference in foaling rates (FCA = 7.4%, FMA = 46.2%; Table 2) may be explained by the fact that all (17) of the mares ≤6 yr of age, most of which would have a low foaling rate in the absence of contraception, received FCA as the primer adjuvant, and none produced foals. An exact Chi-square test on the remaining 23 mares (all ≥12 yr of age) also showed no effect of the primer adjuvant (FCA, 2 of 10 mares foaled; FMA, 6 of 13 foaled; $P = 0.38$). No models could be properly fitted for foaling rate in response to method of primer delivery because of the uneven distribution of delivery methods at each site (Table 2).

DISCUSSION

Feral horses treated using 2 different forms of the immunocontraceptive PZP exhibited decreased foaling rates compared to untreated mares. Fertility was strongly related to age of mares and proved to be critical in understanding the effectiveness of treatment. Both the liquid and C/V forms of PZP were robust in terms of timing and the various management constraints encountered during application periods, though we suspect the difference in foaling rates between the 2 sites where liquid PZP was used relate to such challenges. Few treated mares produced foals in our study, but there is some evidence that repeated annual boosters increased the effective duration of each treatment.

Several investigators have noted that individual mares vary greatly in their ability to raise antibody titers against PZP and that some mares may simply not respond (Liu et al. 1989,

Table 1. Logistic regression comparisons of foaling rates (%) for untreated, pretreatment, and treated females at mean age in 3 feral horse herds in the western United States, 2002–2008. Contraceptive treatments consisted of liquid porcine zona pellucida (PZP) followed by annual boosters at Little Book Cliffs Wild Horse Range (Mesa County, CO) and Pryor Mountain Wild Horse Range (SE Carbon County, MT), and a liquid primer plus time-release PZP pellets at McCullough Peaks Herd Management Area (Park County, WY).

Comparisons and parameter values	Little Book Cliffs	Pryor Mountain	McCullough Peaks

Turner et al. 2002, Lyda et al. 2005). Our results, particularly at Little Book Cliffs and McCullough Peaks, where multiple births to individual mares accounted for a high proportion of the foals born to treated animals, seem to confirm this conclusion. Early investigations also showed that application of PZP does not affect pregnancies in progress (Liu et al. 1989, Kirkpatrick et al. 1990). Our results support this conclusion; foaling rates among pretreatment mares at all 3 study areas were greater than or equal to foaling rates among untreated mares.

Our results at Little Book Cliffs (6.6% observed foaling rate) for mares treated with liquid PZP are similar to those reported previously. Turner and Kirkpatrick (2002) reported that 34 of 340 mares (10.0%) that received a primer followed by annual boosters produced foals on Assateague Island National Seashore, Maryland, USA. Later in the same multiyear study, the authors reported a foaling rate of 3.9% ($n = 861$) among treated mares (Kirkpatrick and Turner 2008; table 1). In a composite sample from multiple western horse herds, Turner et al. (2002) found an 8% foaling rate ($n = 376$) among treated mares. In contrast to the multiyear study on Assateague Island, however, mares in these western herds received only a single booster inoculation.

At Pryor Mountain, the foaling rate observed among treated mares (17.7%) was somewhat higher than that found at Little Book Cliffs and reported in other studies (Turner and Kirkpatrick 2002, Turner et al. 2002, Kirkpatrick and Turner 2008). Although none of the covariates we included in the models were significant at either Little Book Cliffs or Pryor Mountain, we suspect that timing of the boosters, especially in the first and second years, may be responsible for the higher foaling rate at Pryor Mountain. In the only other multiyear study of PZP efficacy in feral horses (Assateague Island), researchers delivered boosters in the spring to maximize the probability that anti-PZP titers would remain high and mares would remain contracepted throughout the following breeding season, rather than attempting to keep mares contracepted throughout the year (Kirkpatrick et al. 1990). At some (unspecified) point in time, however, investigators at Assateague began delivering boosters in August or September if the mares had already been contracepted for ≥2 yr (Turner and Kirkpatrick 2002). Delivery of the booster in August or September allowed more efficient access to the mares and apparently did not affect efficacy of the treatments (Turner and Kirkpatrick 2002). Actual booster timing at Pryor Mountain was, thus, similar to the revised approach at Assateague, except that mares received boosters in August–October irrespective of the number of years contracepted. If the first PZP booster is effective for only 7–10 months (Liu et al. 1989, 2005; Lyda et al. 2005), then first boosters delivered in August–October may not result in effective contraception throughout the following breeding season. The same may be true for second boosters, for which duration of efficacy is not well-known. Apart from this potential effect at Pryor Mountain, however, effectiveness of the liquid form of PZP appears to have been quite robust with respect to timing of boosters.

Foaling rates among mares at McCullough Peaks treated with the C/V pellets were higher than those reported in the only other study where a presumptive multiple-year, time-release form of PZP was used on horses. Using H/X pellets on the Clan Alpine herd in Nevada, USA, investigators found foaling rates of 5.2% ($n = 58$) in the first year of treatment, 14.9% ($n = 68$) in the second year, and 31.6% ($n = 19$) in the third year (Turner et al. 2007:table 4). Foaling rates in the first 2 yr were significantly different

from rates among untreated mares ($P < 0.001$), and investigators felt that there was some residual, though statistically nonsignificant, effect in the third year (31.6% foaling, $n = 19$; Turner et al. 2007). Observed foaling rate in the third year of our study (29.0%) was remarkably similar, suggesting no advantage of the C/V pellets in terms of increased duration of efficacy.

Differences between our results and those from Clan Alpine appear to be related to the pellet formulation (C/V vs. H/X). Subsequent to the initiation of our study, Turner et al. (2008) reported that C/V pellets performed poorly in vitro; >80% of the total PZP was released before the desired window. In white-tailed deer (*Odocoileus virginianus*), C/V pellets were also less effective in the first year (2 of 8 F produced fawns) than H/X pellets (0 of 9 F produced fawns), though sample sizes were small (Turner et al. 2008).

The primer doses for both liquid and pellet applications contained either FCA or FMA, which are widely recognized as being highly immunogenic (Kensil et al. 2004): the PZP dosage in the liquid boosters and the 1-month and 3-month pellets was equal and the 12-month pellet contained 2.5 times more PZP. However, whereas the booster doses of liquid PZP contained FIA, the pellet doses contained QA-21. The adjuvant dosage was much higher for QA-21 than for FIA, and QA-21 is also highly immunogenic (Kensil et al. 2004), but it is possible this difference in booster adjuvants could have contributed to the effectiveness of treatment observed.

Our study also illustrated the importance of considering age-specific differences in foal production when evaluating the effects of a contraceptive. In most previous studies of which we are aware, age has been addressed by selecting only mares in prime reproductive status, usually ages 6–15. This is a reasonable approach in situations where investigators are able to select specific mares for treatment; however, this is not the case in most western United States feral horse populations, where treatments necessarily span a broader range of ages. Age was a significant covariate in all of the models we used to compare treatment groups. Furthermore, we might well have reached an incorrect conclusion regarding importance of the primer adjuvant had we not included mare age in our comparisons. Equivalence of FCA and FMA in raising antibody titers has also been demonstrated in vitro (Lyda et al. 2005) and in vivo at Assateague Island, where the switch from FCA to FMA has apparently not affected effectiveness of the treatments.

Liquid doses of PZP can be delivered by dart or by hand injection. Pellet forms of PZP can currently only be delivered by hand injection in conjunction with gathers, but researchers are developing the technology to apply pellets via dart. The liquid form of PZP appears to reduce foaling rates more effectively than the C/V pellet form, but considerable time can be expended in delivering the drug by dart, depending on wariness of the animals. The additional challenge of cumulative behavioral aversion to dart application may be a long-term concern for repeated vaccinations in areas where horses are not accustomed to human presence. Feral horses in the western United States are often inaccessible at the optimal time for an annual inoculation (late winter); therefore, if PZP is applied remotely in the liquid form, scheduling boosters such that mares are continuously contracepted appears to be a more effective strategy than a static annual date of inoculation.

To date, time-release (pellet) technology appears to offer the greatest promise for a multiyear immunization using PZP and, based on the 2 studies completed thus far, pellets produced by the H/X process appear to be superior to those produced by the C/V process. Both types, however, significantly reduced foaling in treated mares as compared to controls. Pellets produced by a third process referred to as pressure-molding have not yet been tested in vivo in feral horses (Turner et al. 2008). The liposome-encapsulated form of PZP, SpayVac®, may also be useful as a multiyear contraceptive agent, but to date has been tested in only a small number of horses (Killian et al. 2008, Gray et al. 2010).

MANAGEMENT IMPLICATIONS

In herds where feral horse mares can be accessed annually for booster inoculations, the liquid form of PZP delivered by dart can reduce foaling rates and the effective duration of each treatment may increase with repeated annual applications. However, a multiyear contraceptive agent would be preferable for use in most cases, even if horses can be accessed for annual boosters, because of increased efficiency in application and decreased problems with behavioral aversion to treatment and ability to locate individual animals on the range. Ultimate success in limiting population growth will depend not only on the efficacy of the agent, but also on the proportion of mares that can be accessed for treatment (Garrott 1991, 1995; Kirkpatrick and Turner 2008) and the age of mares treated. Porcine zona pellucida appears to be a robust form of fertility control in feral horses and able to withstand a wide array of application challenges in the field, though effectiveness may vary considerably by drug form and application strategy. Managers must also consider the scope and magnitudes of potential side-effects associated with use of the drug and weigh the known effects against the benefit of reducing population growth.

ACKNOWLEDGMENTS

We thank the many field technicians who spent long hours searching for, darting, and monitoring horses under difficult conditions: H. Abouelezz, L. Caldwell, M. Esser, M. Felix, K. Grams, P. Grigsby, S. Hahn, B. Hutchings, G. Manus, J. Nibler, C. Petrandis, P. Preator, J. Severude, and G. Thygerson. Logistical support was provided by the BLM's Grand Junction, Cody, and Billings Field Offices as well as the National Park Service (NPS) Bighorn Canyon National Recreation Area. In particular, we thank D. Bolstad, J. Dollerschell, A. Shepherd, and T. Hatle from the BLM, and R. Lasko and C. Bromley from NPS, for coordination and technical support. The late F. J. Singer coauthored the Wild Horse and Burro Strategic Research

Plan and resulting Fertility Control Field Trial Plan from which this work originated. K. Frank, J. Kirkpatrick, and R. Lyda at ZooMontana provided vaccine and technical support, as did J. Turner, Jr., at the University of Toledo. This research was funded by the USGS Wildlife Program and conducted through a cooperative effort between the USGS Fort Collins Science Center, the BLM Wild Horse and Burro Program, the U.S. Department of Agriculture Animal and Plant Health Inspection Service, NPS, and Colorado State University. Abstract

Abiotic inputs such as photoperiod and temperature can regulate reproductive cyclicity in many species. When humans perturb this process by intervening in reproductive cycles, the ecological consequences may be profound. Trophic mismatches between birth pulse and resources in wildlife species may cascade toward decreased survival and threaten the viability of small populations. We followed feral horses (*Equus caballus*) in three populations for a longitudinal study of the transient immunocontraceptive porcine zona pellucida (PZP), and found that repeated vaccinations extended the duration of infertility far beyond the targeted period. After the targeted years of infertility, the probability of parturition from post-treated females was 25.6% compared to 64.1% for untreated females, when the data were constrained only to females that had demonstrated fertility prior to the study. Estimated time to parturition increased 411.3 days per year of consecutive historical treatment. Births from untreated females in these temperate latitude populations were observed to peak in the middle of May, indicating peak conception occurred around the previous summer solstice. When the post-treated females did conceive and give birth, parturition was an estimated 31.5 days later than births from untreated females, resulting in asynchrony with peak forage availability. The latest neonate born to a post-treated female arrived 7.5 months after the peak in births from untreated females, indicating conception occurred within 24–31 days of the winter solstice. These results demonstrate surprising physiological plasticity for temperate latitude horses, and indicate that while photoperiod and temperature are powerful inputs driving the biological rhythms of conception and birth in horses, these inputs may not limit their ability to conceive under perturbed conditions. The protracted infertility observed in PZP-treated horses may be of benefit for managing overabundant wildlife, but also suggests caution for use in small refugia or rare species.

Introduction

Phenology of nearly all biological phenomena is influenced by natural abiotic events and is reflected in traits evolving to maximize fitness [1]. Births of many large mammal species, for example, occur in annual pulses that are regulated by seasonal cues such as photoperiod and temperature [2]. Increasing sunlight and temperature that accompanies the transition from winter to spring can trigger a physiological response in the pineal gland that initiates reproductive receptivity (Figure 1) [2–4]. This ultimately influences when females may conceive and thus when offspring are born. For example, feral horses (*Equus caballus*) in the northern hemisphere typically begin reproductive cyclicity in early spring and continue until late autumn; consequently, we may posit that conception should naturally peak near the longest day of sunlight (summer solstice) and parturition should peak 335–342 days later (duration of equine gestation [5]). This pattern should result in synchrony of the birth pulse with spring, when climate and forage availability for the dam can contribute to increased neonate survival.

Human actions have the potential to perturb such phenology. Resource managers are increasingly considering transient contraceptives to help limit growth of wildlife populations when species become locally overabundant and risk depleting resources or altering natural communities [6,7]. These agents are especially appealing to managers of protected species and small populations because fertility of treated individuals may return when the transient contraception wears off [8]. However, the transient nature of many fertility control agents and variation of individual responses to those agents introduces uncertainty toward persistence of infertility and the timing of births thereafter. Cascading trophic asynchrony between birth pulses and seasonal resource peaks can have profound effects on the population ecology of wildlife species [9–12]. Observed changes in such phenology and their implications have garnered much attention in climate change science [13,14], but more direct anthropogenic influences, such as fertility control, remain almost completely unstudied. Unintended

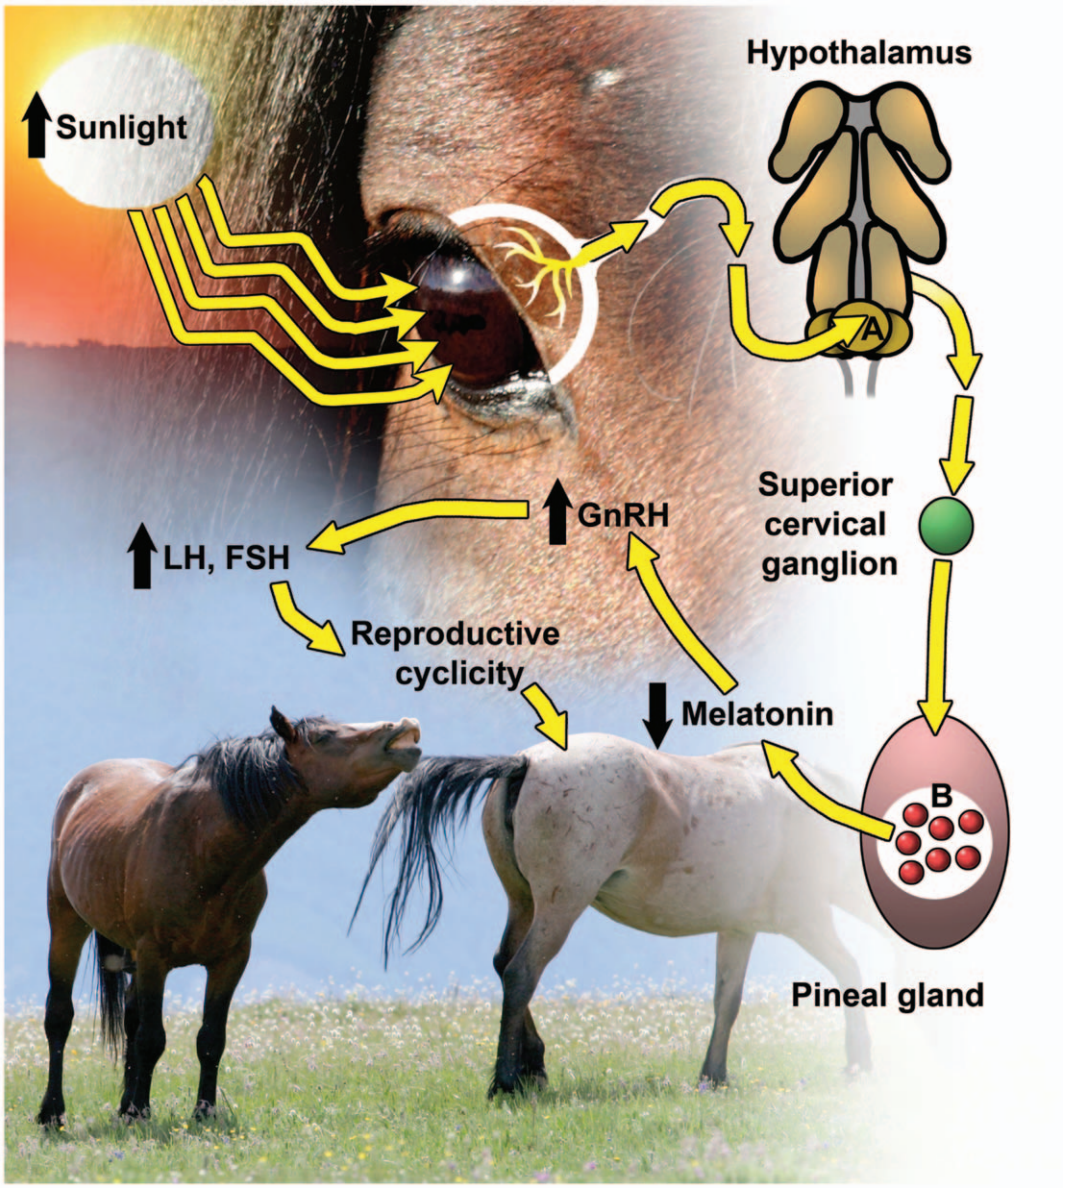

Figure 1. The physiological pathway from photoperiod to reproductive cyclicity in the horse (*Equus caballus*). Increasing sunlight toward the long days of summer strikes the retina, which transmits a neural signal to the suprachiasmatic nuclei (A), across the hypothalamus, and ultimately synapses to the pineal gland to stimulate release of inhibitory neurotranmitters toward the pinealocytes (B). Melatonin production then diminishes, thus increasing release of gonadotropin releasing hormone (GnRH), which increases luteinizing hormone (LH) and follicle stimulating hormone (FSH), and ultimately induces reproductive cyclicity.
doi:10.1371/journal.pone.0054972.g001

persistence of contraception, and consequent phenological changes in births, may compromise the ability of populations to recover after catastrophic stochastic events and threaten viability of small refugia populations.

The immunocontraceptive porcine zona pellucida (PZP) is becoming an increasingly popular management tool and has been used in at least 76 animal species worldwide [6]. This transient contraceptive may last 10–22 months per application, depending on the formulation and species [6,15,16]. The management appeal of PZP is that it is expected to be reversible, is relatively easy to apply, and has few known contraindications for individuals [17,18]. Population-level contraindications are more uncertain, but some evidence suggests decreased fecundity among untreated females, decreased fidelity in social groups, and increased adult survival can occur in populations containing PZP-treated females [19–22].

The individual-level efficacy and behavioral implications of PZP were previously investigated in three free-roaming feral horse populations in the western U.S. [16,23]. We have now followed each individual female in these same populations past their targeted infertile years to further evaluate return to fertility, phenology of births, and neonate survival. We hypothesized that duration of residual infertility would be a function of cumulative historical treatments. We also hypothesized that due to the expected individual response variability to treatment and the unknown and variable duration of infertility, post-treated females would give birth later in the year compared to untreated females, and those births would be asynchronous with forage availability.

We expected that parturition timing would be constrained by photoperiod and temperature and that offspring born toward the end of this temporal window would have decreased survival.

Materials and Methods

Ethics Statement

All data for this study were collected in accordance with the Colorado State University approved Animal Care and Use Committee protocol 03-107A-02. All data collection was conducted with the permission of the Bureau of Land Management (BLM) on public lands they administer, and involved routine observations of feral horses, which are protected under The Wild Free-Roaming Horses and Burros Act of 1971 (U.S. Public Law 91–195, as amended).

Study Areas

The Little Book Cliffs Wild Horse Range, located in Mesa County, Colorado, U.S.A. (latitude 39°12′N, longitude 108°25′W), consisted of approximately 14,600 ha of sloping plateaus, sagebrush (*Artemisia* spp.) parks, and 4 major canyon systems. Elevations ranged from 1,500 m to 2,250 m. The study area was characterized by dense stands of Colorado piñon (*Pinus edulis*) and Utah juniper (*Juniperus osteosperma*). Population size varied from 131–179 horses during 2005–2011 and was distributed in bands of 2–9 horses. Mean annual temperature was 11.5°C (minimum = −26.7, maximum = 41.1°C). Mean total annual precipitation was 235.4 mm (range = 184.4–300.2 mm), typically falling in a monsoonal pattern of late summer rains.

McCullough Peaks Herd Management Area in Park County, Wyoming, U.S.A. (latitude 44°35′N, longitude 108°40′W), consisted of 44,400 ha of primarily open sagebrush steppe. Elevations ranged from 1,200 m to 1,964 m. Population size ranged from 169–236 horses in bands of 2–17 individuals during 2007–2011. Mean annual temperature was 8.0°C (minimum = −30.0, maximum = 37.8°C) and mean total annual precipitation was 271.2 mm (range = 168.9–389.1 mm).

The Pryor Mountain Wild Horse Range, located in Bighorn County, Wyoming and Carbon County, Montana, U.S.A. (latitude 45°04′N, longitude 108°19′W), consisted of roughly 16,000 ha of low desert, foothill slopes, forested montane slopes, steep canyons, and isolated grassy plateaus. Elevations ranged from 1,190 m to 2,625 m. Vegetation types varied greatly from lower to higher elevations of the range with lower elevations dominated by sagebrush communities, mid elevations dominated by curl-leaf mountain mahogany (*Cercocarpus ledifolius*) and Utah juniper communities, and high elevations dominated by limber pine (*Pinus flexilis*), subalpine fir (*Abies lasiocarpa*), and alpine bluegrass (*Poa alpina*). Mean annual precipitation was 161.4 mm (range = 96.7–233.4 mm) and mean annual temperature was 7.1°C (minimum = −33.9, maximum = 40.0°C). The population ranged 171–233 during the study and was arranged in bands of 2–12 individuals.

Treatments

Free-roaming female feral horses were formerly treated with PZP for 1–5 years at all three study sites [16]. The conventional liquid form of PZP was designed to provide infertility through only a single year per inoculation, and this form was used at Pryor Mountain beginning in 2001 and at Little Book Cliffs beginning in 2002. The date of annual inoculation ranged from Jan. 5–Dec. 4, which reflects the time of year when each female was initially vaccinated, perpetuated by annual efforts to locate and re-vaccinate them remotely. These re-vaccination times varied for each horse and year due to occasional difficulties in accessing the sites as well as individual variation in horses' tolerance of humans.

The time-release form of PZP consisted of a single inoculation of liquid PZP simultaneously applied with 3 pellets designed to release PZP in a bolus fashion at 1, 3, and 12 months, for a total of 22 months of targeted infertility [16]. All females in the treatment group at McCullough Peaks received time-release PZP in October 2004. No females were re-treated with PZP unless they had produced a foal during post-treatment. All females that were re-treated were omitted from our study at that time.

We defined post-treatment for this study as beginning two full parturition seasons after the final inoculation of conventional PZP or after the single inoculation using PZP time-release pellets. For example, if a female received a conventional PZP inoculation in autumn 2004, then she was presumably contracepted in 2005. This meant she should not produce an offspring, but could conceive at some time in 2006. The first post-treatment year would then be 2007. If that 2004 inoculation was time-release PZP, then the first post-treatment year could have been as early as 2007.

Data Collection

We observed post-treated females from 2005 at Little Book Cliffs and Pryor Mountain and from 2007 at McCullough Peaks until they died, were removed, were treated again by managers, or the end of 2011, whichever came first. We omitted data for one female from the Little Book Cliffs and six females from McCullough Peaks because they produced offspring in every treatment year and thus were never effectively contracepted. Females that produced offspring during treatment years, but not in every year, were retained because contraception could have occurred. The untreated female group consisted of all individuals in each population that had never been inoculated with PZP and were at least 4 years old at the first year of this study period. The minimum age of post-treated females at the first year of this study period was 4 years old. The resulting data arose from observations of 88 post-treated females (age 4–24 years) and 119 untreated females (age 4–23 years) (Table 1).

Observation protocols followed Ransom et al. [16] for all three sites. For the Pryor Mountain site in 2010–2011, we also used data provided by the Pryor Mountain Mustang Center, WY, USA; these were collected under the same protocols. Throughout the study, 96.1% of all females and offspring (when present) were located at least weekly from April to October of each year. At Little Book Cliffs, 6–8 females were difficult to access weekly, but were located at least once per month. A single band containing two females at McCullough Peaks was not located weekly, but was observed at least monthly during 2007–2010. In 2011, that band was found only once and both females were observed with neonates. At Little Book Cliffs, we also used motion-activated infrared trail cameras at remote water points to provide supplemental observations. Observations during the winter were irregular and sometimes constrained by weather. It is possible that some offspring were born and died without being observed during the course of this study; however, given the intensity of observations, we believe this rarely occurred. We matched all neonates with dams based on observations of attachment (e.g., nursing, general proximity) during the early days and weeks of a neonate's life [24]. We did not attempt to assess pregnancy in females that may have visually appeared pregnant but did not produce a viable offspring. Parturition probability was thus estimated from the frequency of live births per cohort as detected by direct observation.

Table 1. Parturition data from untreated and porcine zona pellucida (PZP) treated female feral horses (*Equus caballus*) at Little Book Cliffs Wild Horse Range, CO, Pryor Mountain Wild Horse Range, MT, and McCullough Peaks Herd Management Area, WY, USA.

	Little Book Cliffs WHR (2005–2011)	Pryor Mountain WHR (2005–2011)	McCullough Peaks HMA (2007–2011)
Number of untreated females	41	44	34
Number of untreated females never producing offspring	6	11	15
Age of untreated females	4–23 yr	4–15 yr	4–21 yr
Number of post-treated females	22	38	28
Number of post-treated females never producing offspring	15	18	15
Age of post-treated females	6–21 yr	4–24 yr	4–20 yr
Observed parturition range for untreated females	Feb. 23–Sep. 1	Feb. 21–Sep. 3	Jan. 15–Sep. 7

Estimated difference in peak parturition date (95%CI)	105.9 (69.7–142.1) days	34.8 (17.0–52.3) days	None

doi:10.1371/journal.pone.0054972.t001

We visually classified the body condition of each dam when we first detected her neonate in the field. This body condition score increased discretely from 1 to 9 as fatness increased [25]. Neonate data were collected concurrently and the general activity state of each neonate was categorized as vigorous, lethargic, or immobile. If neonates were resting when first observed, they were continually observed until the band became active again and neonate activity could be classified. Neonate date of birth was estimated subjectively by observing presence of an umbilicus, level of activity, and time elapsed since the dam was previously observed pregnant. The median time elapsed before a neonate was detected was only six days during the post-treatment observation years ($n = 328$ neonates).

Data Analyses

Model structure. We used mixed-effects regression models to estimate parturition probability, phenology, and offspring survival in the maximum likelihood framework [26]. Individual female was used as a random effect on the intercept term to account for the repeated observations (multiple years) of individuals over time. This was necessary to account for variation that may be present among individuals who were sampled repeatedly, though not always equally over time. Such variation may arise from the many biotic and abiotic factors that may affect conception, pregnancy, parturition, and neonate care. We also used population as a random effect on the intercept term to account for variation attributed to location and treatment regimen. We used the lmer(·) function in the lme4 package in R version 2.14.1 (R Development Core Team 2011) to obtain all mixed-effects model estimates.

Parturition probability. Parturition history for each female was known (binomial response of the female producing at least one offspring in the past or not) from direct observation of all females <12 years old at Little Book Cliffs and Pryor Mountain, and all females <9 years old at McCullough Peaks. All older females were documented giving birth at least once within that same time period. Parturition rates of feral horses typically increase for the first few years after females reach sexual maturity, remain high through middle age, and decrease in old age [16]; therefore, we included linear and quadratic effects of age in models of parturition probability. We rescaled age in the quadratic effect by subtracting the mean age of horses (9.98 yr across all populations), so the intercept term of the model corresponded to probability of parturition at mean age.

Total annual precipitation for the biological year prior to parturition (spring of conception through spring of parturition) was used as a proxy for forage abundance, and thus potential body condition at the year of conception. Daily surface climate data were obtained from the National Climate Data Center (http://www.ncdc.noaa.gov) for Grand Junction, CO (Station 53488, about 13 km southwest of Little Book Cliffs), Cody, WY (Station 481840, about 32 km west of McCullough Peaks), and Lovell, WY (Station 485770, about 21 km south of Pryor Mountain) for all years of the study. The complete model of parturition probability included the fixed effects of age, treatment, conception year total precipitation, and parturition history. We ran a secondary linear model (lm(·) function) for only the post-treated females that produced offspring in order to investigate the influence of age at first treatment and number of treatments received (1–5 annual inoculations). This secondary model only applied to horses at Little Book Cliffs and Pryor Mountain, where repeated inoculations of conventional liquid PZP were applied.

Parturition phenology. We hypothesized that photoperiod and temperature were critical factors influencing phenology of conception, and thus phenology of parturition. Consequently, the model of parturition phenology included treatment and temperature at the approximate conception date as fixed effects, and individual and population as random effects on the model intercept. A supplemental model was considered for post-treatment females at Little Book Cliffs and Pryor Mountain to assess the interaction of last treatment date and number of consecutive annual treatments as a fixed effect, also using individual and population as random effects. Because only one treatment was applied at McCullough Peaks and the actual decay rate of the time-release pellets was unknown, we could not apply this supplemental model for that site.

Survival. Survival was a binomial response attributed to persistence of a neonate from parturition until the following year April observation or death during that time period. Managers removed 30 neonates from the range during their birth year, and those animals were not included in modeling survival. We hypothesized that survival was a function of treatment, dam age,

dam body condition, mean winter temperature (Nov. 1–Mar. 31), and the temporal difference between birth date and spring peak available forage. We used Normalized Difference Vegetation Index (NDVI) data obtained from the National Aeronautics and Space Administration (http://modis.gsfc.nasa.gov) and reconciled using ArcGIS software (Esri, Redlands, California) to assess temporal variation in forage availability. The phenology product from Tan et al. [27] was used to generate date of mean maximum NDVI in each year across each study area. Mean NDVI was used as a temporal indicator of forage availability, but not forage abundance because tree presence and distribution can strongly influence magnitude of this metric.

Results

Parturition Probability

During the years of observation, 15–44% of untreated females and 47–68% of post-treated females never produced offspring (Table 1). Of all post-treated females in the study, 81% had successfully produced offspring prior to treatment and the remaining 19% were <4 years old when first inoculated. Likewise, 97% of all untreated females in the study had successfully produced offspring prior to or during the study period. The probability of producing offspring was strongly related to treatment ($z = -6.90$, $P<0.001$) and age ($z = -2.93$, $P = 0.003$), and weakly influenced by total annual precipitation during year of conception ($z = 1.79$, $P = 0.074$). At mean age and mean conception-year precipitation, the estimated parturition probability for post-treated females was 25.6% (95% CI = 17.8–35.2%) and for untreated females was 64.1% (53.1–73.9%) if they had produced offspring in any year prior to the study. The estimated parturition probability was only 2.1% (1.3–3.2%) for post-treated females and 10.7% (7.0–15.9%) for untreated females that had never previously produced offspring. Parturition probability increased 0.497% (0.494–0.500%) per year of age for all females until age 10; after which it declined at the same rate. Population contributed to a small amount of variation in the model ($\sigma = 0.33$) but individual identity was more influential ($\sigma = 0.82$).

Of the 52 females that received 1–5 annual injections of conventional PZP (Little Book Cliffs and Pryor Mountain), 27 produced at least one offspring post-treatment. The length of time between last inoculation and first parturition ranged from 565–2,971 days and was strongly influenced by the total number of years a female was treated ($t = 5.18$, $P<0.001$). Estimated time to parturition increased 411.3 (246.5–576.0) days per year of consecutive treatment (Figure 2). Neither age at first treatment ($t = -1.04$, $P = 0.309$) nor fertility history ($t = 0.01$, $P = 0.991$) influenced the length of time to parturition. The secondary model was not run for McCullough Peaks, where all 36 females were treated with the 22-month time-release PZP pellets on the same day. Thirteen post-treated females in that population produced an offspring during the 5 years of observation and the observed length of time between inoculation and first parturition ranged from 530–2,000 days.

Parturition Phenology

Births from all untreated females increased in frequency toward the summer solstice and decreased toward the winter solstice, and those trends corresponded with temperature and forage availability (Figure 3). Parturition from untreated females was similar between populations and ranged from Jan. 15–Sep. 7 (Table 1). Parturition from post-treated females ranged from Feb. 20–Dec. 22, and the estimated peak was 31.5 (17.0–46.0) days later than births from untreated females, after controlling for temperature at conception date. The latest neonate born to a post-treated female arrived 7.5 months after the peak in births from untreated females, indicating conception occurred within 24–31 days of the winter solstice. Among the post-treated females that gave birth late and then did not produce a neonate the next year, there was some evidence that subsequent births began to shift back toward the phenology observed for untreated females (Figure 3).

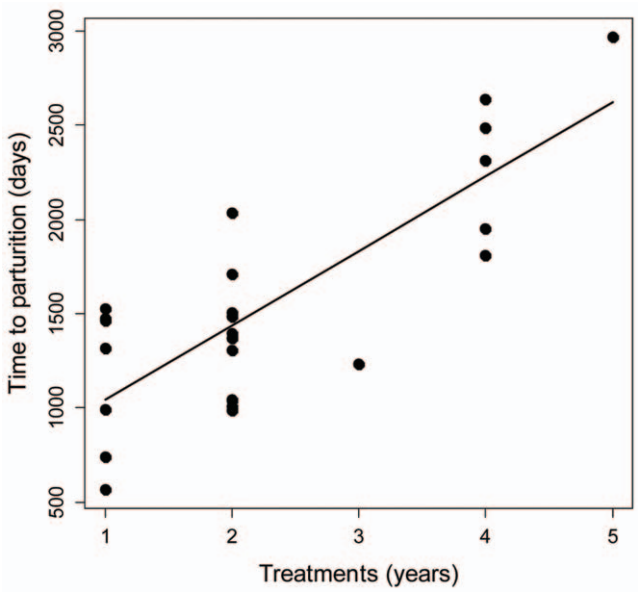

Figure 2. Time between final contraceptive inoculation and first parturition from feral horse (*Equus caballus*) females. Births shown are from horses at Little Books Cliffs Wild Horse Range, CO, USA and Pryor Mountain Wild Horse Range, MT, USA as a function of consecutive annual porcine zona pellucida (PZP) inoculations, 2005–2011.
doi:10.1371/journal.pone.0054972.g002

Survival

Nearly every neonate born was observed in a vigorous activity state, with the exception of four that were immobile (one to a post-treated female) and two that were lethargic (none to post-treated females). All six of those neonates died before the following spring. Body condition of dams at first observation of neonates ranged 3–9 (mean = 5.73, 5.61–5.84). Eighty-five percent of neonates were observed alive in the spring following their birth. The estimated survival probability of a neonate born to a dam in mean body condition at spring peak greenness was 79.9% (67.9–85.4%). This probability decreased 11.4% (10.7–12.0%) with each 1-unit decrease in dam body condition. Survival declined 1.4% (1.4–1.5%) for every 10 days after peak greenness that parturition occurred.

Treatment ($z = -1.49$, $P = 0.137$), band size ($z = 0.67$, $P = 0.500$), dam age ($z = -1.16$, $P = 0.247$), and mean winter temperature ($z = 0.89$, $P = 0.372$) did not influence survival in this model; however, the treatment and winter temperature effects were disparate between sites. At Little Book Cliffs and Pryor Mountain, treatment weakly influenced survival ($z = -1.78$, $P = 0.075$), whereas at McCullough Peaks it clearly had no influence ($z = 0.01$, $P = 0.993$). Likewise, mean winter temperature influenced survival ($z = -2.16$, $P = 0.031$) at Little Book Cliffs and Pryor Mountain, but not at McCullough Peaks ($z = 1.00$, $P = 0.320$).

Discussion

Parturition Probability

The probability of post-treated females producing offspring was 38.5% lower than for untreated females, after controlling for differences due to age, precipitation during conception year, and fertility history. The return to fertility rates observed were highly variable and this may in part be due to the disparate abilities of individual females to raise therapeutic-level antibodies against PZP and the length of time those antibodies persisted above threshold concentrations [15,28,29]. A similar result was reported for horses at Assateague Island National Seashore, MD and VA, USA, where 68.8% of 32 female horses treated for three consecutive years with PZP became pregnant 1–4 years after the last treatment [8]. Only 3 horses were vaccinated for four consecutive years in that study: one became pregnant 3 years after the last treatment, another became pregnant after 4 years, and the third became pregnant after 8 years. In a similar, but critically endangered species, *E. ferus przewalskii*, only 45% of 20 females that had been inoculated with PZP for 3 consecutive years demonstrated fertility after 6.7 post-treatment years [30]. More surprisingly, 4 of 9 females in that study that had only received a single treatment (one primer injection followed by one booster injection) never produced any offspring after 4–8 years of observation. While the mechanism for explaining this protracted infertility in *E. ferus przewalskii* is unknown, some of the Assateague horses were found to have experienced ovulatory failure [31]. This is not the targeted physiological response of PZP vaccination, and the effect was highly variable between individuals due to the episodic nature of ovulatory failure, as opposed to a chronic condition. Studies of non-equid species have demonstrated atrophic changes in ovarian morphology, folliculogenesis, and reproductive endocrine function, indicating that prevention of sperm binding may not be the only mechanism acting on fertility in PZP-inoculated animals [32–35].

Parturition Phenology

Parturition phenology for North American feral horses has been shown to peak during May [36–38]. We estimated parturition from untreated females peaked May 10–19 across the 3 populations, which was 22–43 days before spring forage availability began to decline, and placed conception roughly 7–15 days before the longest day of sunlight (or 323–332 days from previous summer solstice). This phenology appears synchronized with the most abundant forage during the parturition period while females' metabolic needs should be elevated from late term pregnancy and lactation [39]. Our findings for PZP-inoculated females demonstrated a markedly different phenology. The estimated peak in parturition from post-treated females at two sites (Aug. 24 at Little Book Cliffs and Jun. 18 at Pryor Mountain) occurred as forage availability was declining; however at Little Book Cliffs where births were latest, the monsoonal rains provided a bimodal distribution in greenness (Figure 3A). The second peak in forage availability arrived Nov. 1, which was 69 days after estimated peak in parturition from post-treated females.

This protracted birth phenology resulted in parturition dates spanning 305 days for post-treated females as compared to 229 days for untreated females. Across all females in the 3 populations, the parturition season ranged nearly the entire year (341 days). This indicates surprising plasticity in birth phenology of temperate latitude horses given the physiological mechanisms thought to be driving reproductive cyclicity. At Shackleford Banks, North Carolina, USA, female feral horses exhibited estrus beyond the normal breeding season after being vaccinated annually with PZP for 1–6 years [38]. Based on the observed birth phenology in our study, this phenomenon occurred in our subjects as well; however, we recorded 81.4% of 328 documented births between March 1 and June 21. This suggests that photoperiod and temperature remain fundamentally important in regulating birth phenology, but several other mechanisms may be acting to help explain the wide range of birth dates observed. Follicular activity of the estrous cycle during the first half of the breeding season is characterized by more numerous large follicles and greater incidence of anovulatory waves [40]. Gestation length is variable and has been attributed to seasonal variations that influence nutrition of females [41]. The annual rhythm of luteinizing hormone (LH) secretion is partially regulated by photoperiod, but also has a strong endogenous component [42]. Age and fertility history of females can strongly influence the occurrence of a winter anovulatory period [43], as can melatonin sensitivity of individuals [2]. This litany of influences is compounded by the known variations in PZP immunocontraception efficacy and duration, as well as the uncertain mechanism of action that may be confounded with ovarian pathologies.

The protracted breeding season of PZP-vaccinated females found in our study, as well as by Nuñez et al. [38], indicates that horses that would normally conceive during their first or second reproductive cycle of the year continue to cycle throughout the year and then only conceive when contraception sufficiently decays. This inherently extends the breeding season and challenges the physiological constraints assumed to be regulating fertility. The 'self-correcting' trend we observed provides additional empirical support for the importance of such abiotic factors in birth phenology, but also illustrates that phenological shifts associated with the uncertainties surrounding immunocontraception may be short term. The long term effects of PZP treatment on population ecology are less clear given the behavioral components that can affect social networks, as well as fitness of untreated females in social groups [19,21–23].

It should be noted that the protracted phenology detected at Little Book Cliffs and Pryor Mountain was not observed at McCullough Peaks, where the final bolus release of PZP is assumed to have occurred around July. This should have led to infertility persistence through the following July but appears to have persisted much longer in many individuals. Some variation in parturition phenology likely arose from the unique immune response of each female to the vaccine, but this was not compounded by the widely disparate vaccination dates experienced at the other two sites, and thus a more consistent phenology was observed.

Survival

The ultimate consequence of altered birth phenology is survival. Collectively, survival of all neonates in our study was consistent

with the mean survival rate (73.9%) derived from 12 historic studies on feral horse neonates [44]. Survival probability for neonates in our study was 79.9%, at mean body condition of the dam and at spring peak NDVI. This probability predictably decreased with decreasing dam body condition and with temporal distance between date of birth and spring peak NDVI. Treatment did not influence survival in the global model, but was influential at the two sites where unseasonably late births were observed. The treatment effect on survival at Little Book Cliffs was somewhat ameliorated by the secondary peak in forage availability following the monsoons. Such fine scale ecosystem effects may be important considerations when assessing the potential for fertility control applications on specific populations.

Conclusion

Humans are increasingly attempting to manage the planet's wildlife and habitats with new tools that are often not fully understood. The transient nature of the immunocontraceptive PZP can manifest into extraordinary persistence of infertility with repeated vaccinations, and ultimately can alter birth phenology in horses. This persistence may be of benefit for managing over-abundant wildlife, but also suggests caution for use in small refugia or breeding facilities maintained for repatriation of rare species. These results introduce ethical questions toward regulating populations with tools that may alter ecology of the species, but also offer quantitative insights that can be weighed with the depth of management need. The growing need for humane, non-lethal, population control measures also led us to empirical evidence that illustrates the physiological flexibility of horse reproduction in the race for fitness. Photoperiod and temperature are powerful inputs driving the biological rhythms of conception and birth in horses, but do not limit the ability of horses to conceive under perturbed conditions.

Acknowledgments

This work could not have been completed without the field technicians who searched relentlessly for every individual horse, every week: H. Abouelezz, L. Caldwell, M. Esser, M. Felix, K. Grams, P. Grigsby, S. Hahn, B. Hutchings, G. Manus, J. Nibler, C. Petrandis, P. Preator, J. Severude, and G. Thygerson. M. Dillon at the Pryor Mountain Wild Mustang Center provided additional data for 2010–2011. Thanks to T. Fancher, D. Ignizio, and C. Talbert for compiling and analyzing the MODIS data and T. Mask for invaluable data compilation assistance. D. Baker, R. Boone, J. Manning, and J. Roelle provided much appreciated critical reviews of earlier versions of this manuscript. Thanks to the BLM, U.S. Geological Survey, and the Animal Plant Health Inspection Service for administrative and technical support throughout this project.

REVIEW

Ecological feedbacks can reduce population-level efficacy of wildlife fertility control

Summary

1. Anthropogenic stress on natural systems, particularly the fragmentation of landscapes and the extirpation of predators from food webs, has intensified the need to regulate abundance of wildlife populations with management. Controlling population growth using fertility control has been considered for almost four decades, but nearly all research has focused on understanding effects of fertility control agents on individual animals. Questions about the efficacy of fertility control as a way to control populations remain largely unanswered.

2. Collateral consequences of contraception can produce unexpected changes in birth rates, survival, immigration and emigration that may reduce the effectiveness of regulating animal abundance. The magnitude and frequency of such effects vary with species-specific social and reproductive systems, as well as connectivity of populations. Developing models that incorporate static demographic parameters from populations not controlled by contraception may bias predictions of fertility control efficacy.

3. Many population-level studies demonstrate that changes in survival and immigration induced by fertility control can compensate for the reduction in births caused by contraception. The most successful cases of regulating populations using fertility control come from applications of contraceptives to small, closed populations of gregarious and easily accessed species.

4. Fertility control can result in artificial selection pressures on the population and may lead to long-term unintentional genetic consequences. The magnitude of such selection is dependent on individual heritability and behavioural traits, as well as environmental variation.

5. *Synthesis and applications*. Understanding species' life-history strategies, biology, behavioural ecology and ecological context is critical to developing realistic expectations of regulating populations using fertility control. Before time, effort and funding are invested in wildlife contraception, managers may need to consider the possibility that many species and populations can compensate for reduction in fecundity, and this could minimize any reduction in population growth rate.

Key-words: behaviour, demography, ecological process, fertility control, fitness, immunocontraception, population dynamics, population ecology, wildlife contraception, wildlife management

Controlling reproductive capacity of wildlife

Humans have been attempting to control the abundance of animals for over 13,000 years (Diamond 2002). Although regulating the herd size of domestic animals has been a feature of human economies for millennia, people have also sought to regulate populations of wild animals using hunting and culling techniques. Recent societal trends have motivated wildlife managers to seek nonlethal strategies of regulating births using fertility control (Hobbs, Bowden & Baker 2000; Porton 2005). This trend may be attributed to an increasingly mutualistic societal view arising from abundance of wildlife in suburban and urban areas (Teel & Manfredo 2009). In such circumstances, perception of wildlife species may focus less on

their role as a natural resource and more on how they are part of our social environment (Leong 2010). This may lead humans to be more aware of, and concerned about, the welfare of these species. The balance of human perception and wildlife abundance is precarious because as highly adaptive species increase in density, wildlife–human conflicts increase, and society can then be confounded with the dichotomy of desire for wildlife protection and relief from wildlife conflict (Knuth *et al.* 2001; Lauber & Knuth 2004; Lauber *et al.* 2007; Hadidian 2009).

The practice of using fertility control to manage reproduction in wildlife emerged over 40 years ago (Asa & Porton 2005). Wildlife managers have been attracted to fertility control as a means to regulate overabundant wildlife when animals threaten people's lives, livelihoods or property; when they cause declines in more desirable species; and when their densities are high enough to increase disease transmission or disrupt ecosystem function (Caughley 1981; Hone 2007). The vast majority of empirical knowledge about wildlife fertility control comes from individual-level studies of drug safety and efficacy (Garrott 1995; Kirkpatrick, Lyda & Frank 2011). As a consequence, we know relatively little about how fertility control influences population ecology. It remains uncertain whether findings of research on the efficacy of fertility control at the individual level can allow inferences to populations. There may be compensation in vital rates that allow individuals to maintain fitness, thus offsetting the effects of fertility control agents. If such compensation occurs, then it may be infeasible to control some wildlife populations using fertility control.

Types of fertility control applied to wildlife include products that disturb normal reproductive hormone cascades or interfere with conception, such as immunocontraceptive vaccines, pharmaceuticals, hormone derivatives, agonists, antagonists, mechanical devices and surgical techniques (Asa 2005). All of these methods may prevent births, but they also may induce unintended changes to behaviour and physiology (Nettles 1997; Gray & Cameron 2010). It is not surprising that hormonal derivatives such as melengestrol and levonorgestrel affect behaviour (Gray & Cameron 2010), but it is surprisingly uncertain how variable such behavioural changes can be, even within similar taxa. Stump-tailed macaque *Macaca arctoides* females, for example, can become markedly more aggressive towards conspecifics when treated with a synthetic progestin (Linn & Steklis 1990), but hamadryas baboon *Papio hamadryas* females can become more passive when treated with a similar progestin (Portugal & Asa 1995).

Any fertility control application that changes the reproductive capacity of an individual has the potential to induce individual behavioural changes that can alter family group structure, influence interspecific and intraspecific interactions and ultimately shape population dynamics in unforeseen ways. Fertility control in free-roaming wildlife populations has been associated with changes in immigration (Ramsey 2005; Merrill, Cooch & Curtis 2006), decreased group fidelity (Nuñez *et al.* 2009; Madosky *et al.* 2010), increased survival (Caughley, Pech & Grice 1992; Kirkpatrick & Turner 2007; Williams *et al.* 2007), altered reproductive behaviour (Nuñez, Adelman & Rubenstein 2010; Ransom, Cade & Hobbs 2010) and shifted phenology (Ransom, Hobbs & Bruemmer 2013). Understanding and predicting these sometimes subtle and incremental shifts is difficult, and the challenge of separating the influences of multiple population growth controls can be daunting (Sibly & Hone 2002). To exacerbate these problems, the longitudinal studies needed to detect and quantify long-term population-level effects of fertility control treatments are expensive and time-consuming.

Insights into population-level effects of fertility control have largely been accomplished through efforts that simulate population dynamics (Caughley, Pech & Grice 1992; Hone 1992; Hobbs, Bowden & Baker 2000; Davis & Pech 2002; Merrill, Cooch & Curtis 2006). Simulation models can be useful tools for screening management alternatives; however, widespread behavioural and demographic changes induced by fertility control may subvert the underlying assumptions of demographic parameters in models that fail to consider these changes. The assumptions of many fertility control population models could be wrong if the vital rates informing them are based on the wealth of *a priori* ecological knowledge about species and systems before fertility control was applied.

Here, we synthesize findings from studies on population-level effects of wildlife fertility control and compare some of those outcomes with those from individual-level studies. We specifically investigate the demographic and behavioural components from wildlife fertility control studies, seeking to understand feedbacks that might be influencing population-level outcomes of fertility control strategies. We attempt to identify some of the underlying processes to help inform modelling efforts and future design for empirical population-level fertility control studies, and ultimately try to determine whether, in fact, nature can overcome control efforts at a scale that makes fertility control ineffective as a wildlife management tool.

The feedback dilemma

Considering animal behaviour in broad ecological and conservation contexts is critical to understanding population ecology (Sutherland 1998; Buchholz 2007); yet, a lack of rigorously quantified behaviour data often inhibits our ability to assess the magnitude of its importance. At the individual level, wildlife contraceptive studies have illuminated a wide array of behavioural changes attributed to fertility control applications (Nettles 1997; Gray & Cameron 2010). Studies on captive animals incorporate more experimental control than is usually possible with free-ranging wildlife, but the artificial environments inherent in captive studies often preclude the insights towards ecological feedbacks that studies of free-ranging wildlife

contribute. Consideration of results from both types of studies is needed to understand the potential population-level effects of fertility control acting through birth, survival, immigration and emigration. Feedbacks on population growth may be negative or positive, and the nature of feedback direction may vary with the ecology of the species in question.

Fertility control is designed to reduce the probability that an individual gives birth, so it should be expected that fecundity of treated animals will be less than that of untreated animals; however, indirect effects make the broader influence of treatment on birth rates less clear. Unintentionally protracted contraception has been attributed to physiological changes in ovarian function after fertility control treatments (Kirkpatrick *et al*. 1995; McShea *et al*. 1997; Nettles 1997; Powell & Monfort 2001; Stoops *et al*. 2006). Such residual infertility was observed in feral horses *Equus caballus* and Przewalski horses *E. ferus przewalskii* repeatedly treated with porcine zona pellucida (PZP) and was further complicated by shifts in the seasonal birth pulse when fertility resumed (Nuñez 2009; Feh 2012; Ransom, Hobbs & Bruemmer 2013). Increased frequency of reproductive behaviour has been observed in females treated with PZP vaccines and has the potential to focus attention of breeding males away from fertile females and towards the attractive, but sterile, females (Shumake & Wilhelm 1995; McShea *et al*. 1997; Heilmann *et al*. 1998; Nuñez, Adelman & Rubenstein 2010; Ransom, Cade & Hobbs 2010). Similarly, both elk *Cervus elaphus* and mule deer *Odocoileus hemionus* males demonstrated increased reproductive behaviour towards females treated with gonadotropin-releasing hormone vaccine (GnRH) or leuprolide (a GnRH agonist) after the untreated cohort became pregnant (Baker *et al*. 2002, 2004; Conner *et al*. 2007; Powers *et al*. 2011). All of these studies represent a potential mechanism for decreased fitness in males and could result in a higher net contraceptive effect at the population level (Ransom 2012).

In contrast, fecundity of untreated female mice *Mus domesticus* increased when fertility-controlled females were present, attenuating the contraceptive effect (Chambers, Singleton & Hinds 1999). Many species have been reported exhibiting a compensatory reproduction response when a subset of the population has been perturbed, such as might be the case with large-scale fertility control application (Swenson 1985; Kirkpatrick & Turner 1991; Boyce, Sinclair & White 1999; Williams 1999). How such effects originate through changes in social networks is unknown. Likewise, the effects of fertility control on biochemical and olfactory communication are virtually unknown, but have been implicated in disrupting intraspecific interactions in a primate (Crawford, Boulet & Drea 2010) and could lead to greater uncertainty about fecundity at the population level.

Fidelity to family groups has decreased in conjunction with fertility control applications (Fayrer-Hosken *et al*. 2000; Nuñez *et al*. 2009; Madosky *et al*. 2010), and time spent with conspecifics or potential mates has also changed (Bertrand *et al*. 1996; Poiani *et al*. 2002; Harrenstien *et al*. 2004). Territoriality increased for pikas *Ochotona curzoniae*, and the increase was related to decreased litter size (Liu *et al*. 2012). These types of changes can affect time budgets such that basic maintenance behaviours of feeding and resting decrease, resulting in lower body condition in animals receiving contraception (see Ji, Clout & Sarre 2000; for example). Similarly, female elk treated with leuprolide had comparable maintenance behaviours as untreated elk, but retained less body fat than untreated, pregnant females, possibly due to decreased anabolic hormone exposure during their infertile year (Conner *et al*. 2007).

Increased or decreased agonism between conspecifics has also been attributed to some contraceptive applications (Linn & Steklis 1990; Portugal & Asa 1995; Penfold, Patton & Jochle 2005; Snape, Hinds & Miller 2011). These behaviours can alter dominance hierarchies and thus access to resources (Dublin 1983; Schulte *et al*. 2000; Creel 2001). More directly, some deer treated with hormonal applications lost body condition or stopped eating altogether (Bell & Peterle 1975; White, Warren & Fayrer-Hosken 1994). Low body condition arising from any of these processes can enhance the fertility control effect by changing the ability of individuals to meet the nutritional requirements needed to support pregnancy and lactation (Cook *et al*. 2004; Rhind 2004).

Apart from the many potential direct and indirect effects of fertility control on births, some applications may also influence survival. Body condition and longevity can increase when the costs associated with reproduction decrease. For example, feral horses treated with a PZP vaccine had higher survival probability than untreated controls (Turner & Kirkpatrick 2002; Ransom 2012). Similarly, survival was higher among fertility-controlled rabbits *Oryctolagus cuniculus* (Twigg *et al*. 2000; Williams *et al*. 2007), coyotes *Canis latrans* (Bromley & Gese 2001) and foxes *Vulpes vulpes* (Saunders *et al*. 2002). These results show that reductions in recruitment caused by fertility control can be offset at least in part by enhanced survival of females, thereby attenuating the effect of fertility control on population growth rate.

Feedbacks amplifying the effect of fertility control can also occur. Disease transmission was 28% higher in populations of possums *Trichosurus vulpecula* with sterile females, illustrating the potential for decreased survival in fertility-controlled populations (Caley & Ramsey 2001). Phenological shifts in birth patterns among females that formerly received contraception may also have implications for survival of both females and their neonates if births occur asynchronously with forage resources (Ransom, Hobbs & Bruemmer 2013).

Perhaps, the most challenging impediment to predicting population-level effects of fertility control occurs when populations are open to immigration and emigration, processes that can be accelerated by feedbacks from the

application of fertility control. Male possums, for example, increased in frequency at sites where females received contraception (Ji, Clout & Sarre 2000), and in one study, the rate of immigration equalled the rate of reduction in births attributed to fertility control (Ramsey 2005). A similar feedback was also observed in deer (Merrill, Cooch & Curtis 2006). Home ranges of fertility-controlled female rats *Rattus argentiventer*, koalas *Phascolarctos cinereus* and white-tailed deer were larger than those of fertile females (Jacob, Matulessy & Sudarmaji, 2004; Gilman *et al*. 2010; Hynes *et al*. 2011). This was explained by an absence of range-limiting dependent young, and in deer, this larger home range was positively correlated with increased mortality rates (Gilman *et al*. 2010).

For nearly all of the collateral effects discussed here, there are almost as many cases where no collateral effects were detected when a different fertility control method was used or a different species was studied (Gray & Cameron 2010: Fig. 2). Such variation in individual and species responses emphasizes the need for careful consideration of species biology, reproductive system, physiology, behavioural ecology, population biology and ecological context when considering fertility control management for a population.

Population-level effects of fertility control

Scientific progress towards understanding population-level effects of fertility control has been slow despite an articulate call for population-level research of wildlife contraception nearly two decades ago (Garrott 1995). We reviewed 479 papers in the scientific literature on wildlife fertility control from 1980 to 2011 and found that 90% focused on individual-level effects (Fig. 1). Half of the papers were published in the last decade, reflecting an increasing interest in wildlife fertility control. There was an increasing trend in population-level studies, but still only 10% of the papers reviewed addressed population-level effects.

Only 6·5% of all papers we reviewed considered behavioural or indirect demographic effects in population-level assessment of fertility control (Table 1), and only half of those quantitatively considered such effects in modelling population dynamics with fertility control (Table 2). This is surprising given that such a large number of individual-level studies describe the potential for indirect effects to influence fertility control efficacy at the population level (Nettles 1997; Gray & Cameron 2010). The number of studies that empirically tested fertility control management for achieving long-term reduction in population size was too small for us to conduct a meaningful quantitative meta-analysis. It is worth noting, however, that the studies evaluating fertility control in open populations of promiscuous breeders did not sufficiently reduce population size for long time horizons (Twigg *et al*. 2000; Ramsey 2005; Jacob, Singleton & Hinds 2008), and a study of an open population of deer had mixed results (Merrill, Cooch & Curtis 2006). Efforts to manage relatively small, closed populations of feral horses, deer, elephants and feral cats using fertility control were much more successful (Rudolph, Porter & Underwood 2000; Delsink *et al*. 2006; Rutberg & Naugle 2007; Kirkpatrick & Turner 2008; Mendes-de-Almeida *et al*. 2011; Ransom 2012).

A broad consensus among both empirical and simulated studies is that in most free-roaming wildlife populations, a majority of the individuals in one or both sexes must be infertile to realize meaningful reduction in population growth. Reduction in abundance can require aggressively maintained treatment for long periods of time (Hobbs, Bowden & Baker 2000). This can mean that >50% of females must be treated in closed populations of long-lived, low-fecundity species to achieve moderate reduction in growth (Hone 1992; Hobbs, Bowden &

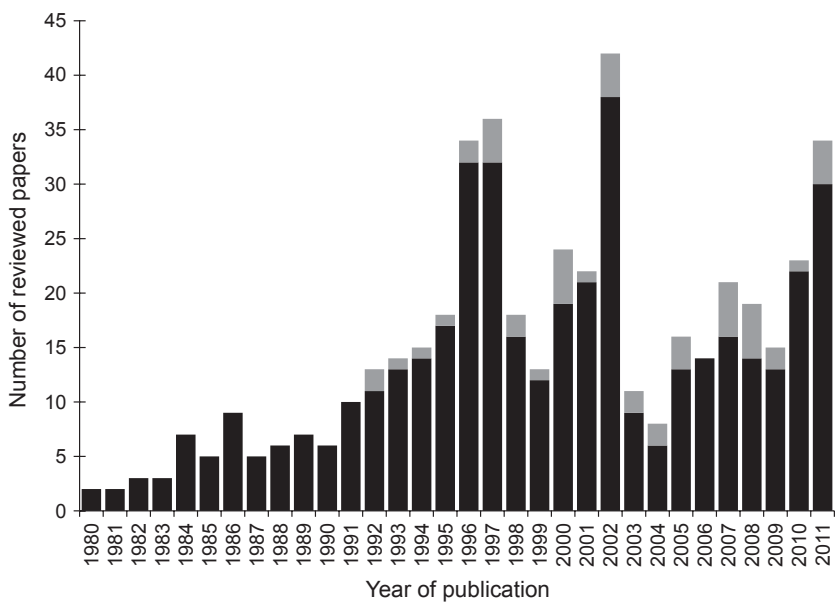

Fig. 1. Trends in publication (n = 479 papers) for research on fertility control in wild and feral fauna from 1980 to 2011. Proportion of each bar in grey depicts investigations that included empirical or simulated population-level effects.

Table 1. Number of reviewed scientific publications from 1980 to 2011 that included population-level effects of fertility control on wild or feral animals in theoretical, simulation or empirical contexts and the number of those publications that considered behavioural or indirect demographic feedbacks on population-level effectiveness of the application

	Type of study			Feedback on fertility control efficacy		
Fauna type	Theoretical	Simulation	Empirical	Negative	Positive	Not considered
Ungulate	1	10	6	4	0	13
Rodent	2	2	6	6	1	3
Marsupial	0	1	3	4	0	0
Pachyderm	2	2	1	2	0	3
Carnivore	0	3	1	0	0	4
Fish	1	0	0	1	0	0
Non-specific	4	3	0	4	0	3
Total	10	21	17	21	1	26

Baker 2000), and perhaps, >90% of females must be treated in open populations where immigration can compensate for birth reductions (Merrill, Cooch & Curtis 2006). Controlling populations of short-lived, high-fecundity animals is even more daunting because the high recruitment rates require fertility control treatments to be applied frequently (Singleton *et al*. 2002; Williams *et al*. 2007; Jacob, Singleton & Hinds 2008). In some applications, the lag time between treatment and effect on birth rates can result in too many new fertile females being recruited into the population for treatment strategies to be efficiently applied, even in long-lived, low-fecundity species (Nielsen, Porter & Underwood 1997; Whyte, van Aarde & Pimm 1998). Achieving population goals using fertility control for highly promiscuous breeders may not be feasible (Caughley, Pech & Grice 1992).

Some simulations have concluded that the response of a population to fertility control is nonlinear, and if survival increases as fecundity declines, then the survival is more influential on population growth than births (Hone 1992; Sinclair 1997; Hobbs, Bowden & Baker 2000; Merrill, Cooch & Curtis 2003). The logical conclusion to this is that fertility control is generally more effective at maintaining populations than actually reducing them, and thus, effective use of fertility control to maintain a population at reduced abundance may require culling to get the population to the desired level within a manageable time frame (Hone 1992; Barlow, Kean & Briggs 1997; Hobbs, Bowden & Baker 2000). Perhaps, most alarming is that many of these simulations assume 100% sterility, which is generally only achieved using surgical applications. Physically treating such large numbers of animals may be prohibitive due to the labour, time and expense necessary for capture, handling and application.

In contrast to these discouraging results, there is some evidence that fertility control can reduce and maintain populations at desired targets for abundance. Female feral horses have a long lifespan and can potentially produce offspring annually for up to 20 years of their life. A fertility control study at Assateague Island, the USA, reported zero population growth in only 2 years, with 42–76% of adult female feral horses treated annually with PZP (Kirkpatrick & Turner 2008). Population decline began 8 years after treatment began, and by year 11, the population had decreased nearly 23%. This sharply contrasts most simulation predictions, but may be explained by the indirect effects of treatment, the population parameters, life-history strategies of the species and the continual accessibility to individuals for treatment. This example reflects a relatively small, closed population of a polygynous species with strong social hierarchies. Thus, the lack of immigration and potentially reduced fecundity in subordinate females may act to supplement the effects of fertility control at the population level. Residual effects of treatment and decreased birth rate among untreated females contributed to a 33% difference in expected and realized births in another study of PZP in feral horses (Ransom 2012). Survival, however, appears to have increased in older females in both studies, which partially offsets the effects of fertility control. This complex system of feedbacks demands a deeper understanding of the influences acting on vital rates in populations proposed for control, and before we categorically dismiss the use of fertility control to functionally reduce populations, we must carefully consider how those feedbacks are operating.

Implications towards fitness

The genetic consequences of controlling any individual's fertility could have long-term effects on population fitness. Such artificial selection can theoretically occur in two ways. First, by purposeful or inadvertent non-random selection of animals targeted for contraception, managers may prevent reproduction in wildlife in ways that change gene flow in a population. This would have genetic effects similar to those that may arise from traditional means of wildlife management, such as non-random lethal removal of individuals from the gene pool. The second and far more uncertain mechanism is that inferred by the animal itself. Behavioural decisions unique to individuals shape their fitness, especially among males (Smith & Blumstein 2008). Such may be the case when polygynous males divert reproductive behaviour or when agonism increases or decreases in response to fertility control in the

Table 2. Population-level effects of fertility control in simulated (S) and empirical (E) studies that explicitly incorporated demographic feedbacks into analyses

Source	Taxa	Data	Individual treatment efficacy	Percent of population treated	Population effect	Feedback	Mechanism
Caughley, Pech & Grice (1992)	Gregarious, stratified by dominance structure	S	Non-specific: 100%	0–100% in social groups of up to 5 females	If female loses dominance at treatment, productivity increases	Negative	Increased births from subordinate females
Hone (1992)	a: long-lived, low fecundity b: short-lived, high fecundity	S	Non-specific: 100%	20–100% of original fecundity of females	Curvilinear response: for b, 80% fertility reduction ≈ 50% abundance reduction	Negative	Increased survival
Seagle & Close (1996)	White-tailed deer (*Odocoileus virginianus*)	S	Non-specific: 100%	0–100% of females	No reduction at <50% of females treated in open population	Negative	Increased immigration
Barlow, Kean & Briggs (1997)	a: monogamous and, b: polygamous	S	Non-specific: 100%	0–100% of females and/or 0–100% of males	Greatest effect in (a) with both sexes treated; less effect in (b)	Negative	Increased survival; increased births in b
Twigg *et al.* (2000); Williams *et al.* (2007)	European rabbit (*Oryctolagus cuniculus*)	E	Tubal ligation: 100%	0%, 40%, 60%, 80% of females	After 4 years, no difference in population size between treatments	Negative	Increased survival, increased immigration, decreased emigration
Singleton *et al.* (2002)	House mouse (*Mus domesticus*)	E, S	Tubal ligation & ovariectomy: 100%	67% of females	75% density reduction after 11 weeks, but compensation by 20–24 weeks	Negative	Increased births per female
Davis & Pech (2002)	Based on red fox (*Vulpes vulpes*)	S	Non-specific: 100%	0–100% of females	Absent density dependence, density increased with up to ~50% treatment	Negative	Increased survival
Merrill, Cooch & Curtis (2006)	White-tailed deer (*Odocoileus virginianus*)	S	Non-specific: 100%	30%, 45%, 60% of females	No population reduction if movement rates were >25% of observed and treatment was <45%	Negative	Increased immigration

Table 2. (continued)

Source	Taxa	Data	Individual treatment efficacy	Percent of population treated	Population effect	Feedback	Mechanism
Ramsey (2005)	Brushtail possum (*Trichosurus vulpecula*)	E	Tubal ligation: 100%	0%, 50%, 80% of females	60% recruitment for 50% treated/74% for 80% treated: no population effect	Negative	Increased immigration, increased survival
Kirkpatrick & Turner (2008)	Feral horse (*Equus caballus*)	E	PZP: 0–8% birth rate in females	42–76% of females	Population decreased 22·8% in 11 years	Negative	Increased survival
Jacob, Singleton & Hinds (2008)	Ricefield rat (*Rattus argentiventer*)	E	Tubal ligation, progesterone: 100%	Up to 76% of females	No population effect in open population	Negative	Increased births, increased survival
Budke & Slater (2009)	Feral cat (*Felis catus*), closed population	S	Surgical or contraception: 100%	0–30% of females	91% of adult females need to be sterile to stop population growth	Negative	Increased survival

population. The age of individuals also interacts with demographic parameters of the population, as well as environmental variation, to influence fitness (Gaillard *et al*. 2000).

Individual physiology introduces a special consideration in the case of immunocontraceptives, and some authors have questioned the soundness of using a wild animal's immune system to select for the ability to reproduce (Nettles 1997; Cooper & Herbert 2001; Cooper 2004; Cooper & Larsen 2006). Immunocontraceptives are typically <100% effective at preventing pregnancy because they impose their effects through stimulation of the immune system. Depending on the magnitude of heritability, it is possible to select for decreased immune function and likely decreased fitness in relatively few generations. For example, if 10% of females in a population fail to mount a significant antibody response to an immunocontraceptive vaccine, and that phenotype has 80% heritability, then approximately 20% of female progeny will likewise not respond (Cooper & Larsen 2006). Thus, the trait has doubled in a single generation, assuming all females within the population were vaccinated. This has the potential to lead to immune incompetence and resistance to immunocontraception in the population. If immune responses responsible for contraception are mediated through the same or similar genetic pathways as those responsible for responding to pathogens and disease states, it is possible and even likely to select for decreased population fitness.

Alternatively, if a large proportion of the variation in contraceptive response is attributable to the environment, then even intense selection will have little effect on the phenotype of future generations (Magiafoglou *et al*. 2003). Difficulties in estimating heritability and finding reliable, accurate and sensitive indicators of changes in phenotype of immune function, given multigene effects on the system, pose significant challenges to resolve this question. However, there is evidence from studies with mice, chickens and pigs that strongly suggest that antibody production, delayed type hypersensitivity and phagocytic activity are heritable traits (Mouton, Sant'Anna & Biozzi 1988; Sarker *et al*. 1999; Wilkie & Mallard 1999; Pinard-van der Laan 2002). Significant changes in both humoral and cell-mediated immune responses can be achieved in as few as three generations in controlled environments (Sarker *et al*. 1999). Genetic variability in phenotype can change in response to environmental conditions (Hoffman 1999). This emphasizes the need for both laboratory and field studies of immunocontraceptives when investigating variance in immune response.

The proportion of the population targeted for fertility control will also influence selection pressure applied by non-response. From a practical standpoint, managers are likely to treat as many animals as possible when beginning a fertility control programme, particularly in extensively managed populations that are above management objectives. This will maximize non-response selection

pressure (Garrott 1995). Targeting for contraception may be more discriminating in intensively managed feral horse herds by selecting only a proportion of the population and ensuring that each female contributes an offspring to the population prior to contraception (Nuñez, Adelman & Rubenstein 2010). This strategy would result in decreased selection for non-response. Additionally, immigration and emigration will affect gene flow in the population and dilute the selection pressure. Treatment application intensity, non-response rate, change in fitness and migration will all influence the strength of artificial selection. This is one aspect of fertility control that wildlife managers have little, if any, valid data with which to make an informed decision. A cross-disciplinary approach involving immunologists, reproductive scientists, population or conservation geneticists and wildlife biologists may begin to answer these questions.

CONCLUSION

Study of individual effects of fertility control applications is an important step towards technology development of potential tools for managing wildlife, but understanding their ecological effects is a critical prerequisite for using them. Natural systems and processes are strained under anthropogenic pressures and ever-fragmenting landscapes, and resources to address these challenges are often lacking. Actions such as population-level fertility control demand that practitioners weigh not only the biological and ecological costs, but also the economic, political and regulatory costs involved for implementation.

Definitive generalizations about the biological and ecological conclusions of fertility control across taxa and biomes remain elusive. Primary empirical studies are still needed to evaluate population-level effects of fertility control on large wildlife populations over long time periods. Given the resources necessary to conduct such studies, it is likely that most future insight will arise from adaptive management applications. As such, fertility control as a management tool must be applied in thoughtful, calculated ways to achieve the greatest likelihood of success at reducing or maintaining population numbers. Current evidence suggests that population-level management of wildlife using fertility control is more likely to be successful if it is applied to populations (i) that are relatively small, (ii) that have little or no opportunity for an influx of new animals, (iii) that are comprised of a species that exhibits a relatively long gestation period and (iv) where a large proportion of individual animals can be accessed and aggressively treated. Fertility control management of non-native species might be more successful than management of native species because non-natives have not evolved in the ecosystem of concern, and the system is not dependent upon the species for natural function. For these reasons, alterations to life history, natural selection or behaviour may be also more publically acceptable, as long as they do not affect the conservation of native wildlife species. This hypothesis has not been tested to date. Likewise, applications to wildlife species occupying highly disturbed ecosystems may be effective because there may be disproportionately large influences from anthropogenic sources (i.e. where ecosystem drivers are more dependent on human actions than on natural processes), and the effects of fertility control on natural processes may be relatively minor in comparison.

If the necessary biological and ecological conditions can be met for effective use of fertility control to regulate wildlife populations, it is critical to address regulatory, political and economic concerns through public discourse and debate between agency, academic, political and public stakeholders who value their common wildlife resources for a wide variety of reasons. This includes transparent consideration of laws and regulations governing label and off-label use of drugs and vaccines; the welfare of animals subjected to capture, handling and treatment; and public acknowledgement that the targeted population effect and the ability of a management tool to reach such goals are not absolute. Rigorous economic analysis of the cost-effectiveness of fertility control relative to other management options is necessary to economically justify investing in the control actions (sensu Sebastián-González *et al.* 2011). This requires quantitative evaluation of the population-level and ecosystem-level benefits of the proposed actions.

Robust quantitative tools are necessary for modelling outcomes due to the disparate responses observed across species, populations and control options. Feedbacks from fertility control application vary widely and can produce quite unexpected results. In some cases, unintended changes to births, survival, immigration or emigration could provide a formidable barrier to effective management of populations using fertility control. Scientists, managers and practitioners are thus faced with understanding the often confounding nature of the actions implemented to achieve goals for populations. Fertility control can lead to complex population-level effects on the target species as well as cascading impacts on ecosystems. Both population-level and ecosystem-level impacts can and should be explored using a range of tools including empirical studies and simulation modelling. Expanding the prevailing birth-centric research theme to more thoughtful data collection and modelling that considers births, deaths, immigration, emigration, gene flow and ecological interactions will improve the quality and utility of fertility control studies.

ABSTRACT

Wildlife management actions can alter fundamental behaviors of individuals and groups, which may directly impact their life history parameters in unforeseen ways. This is especially true for highly social animals because changes in one individual's behavior can cascade throughout its social network. When resources to support populations of social animals are limited and populations become locally overabundant, managers are faced with the daunting challenge of decreasing population size without disrupting core behavioral processes. Increasingly, managers are turning to fertility control technologies to supplement culling in efforts to suppress population growth, but little is quantitatively known about how either of these management tools affects behavior. Gonadotropin releasing hormone (GnRH) is a small neuropeptide that performs an obligatory role in mammalian reproduction and has been formulated into the immunocontraceptive GonaCon-B™. We investigated the influences of this vaccine on behavior of feral horses (*Equus caballus*) at Theodore Roosevelt National Park, North Dakota, USA, for a year preceding and a year following nonlethal culling and GnRH-vaccine treatment. We observed horses during the breeding season and found only minimal differences in time budget behaviors of free-ranging female feral horses treated with GnRH and those treated with saline. The differences observed were consistent with the metabolic demands of pregnancy and lactation. We observed similar social behaviors between treatment groups, reflecting limited reproductive behavior among control females due to high rates of pregnancy and suppressed reproductive behavior among treated females due to GnRH-inhibited ovarian activity. In the treatment year, band stallion age was the only supported factor influencing herding behavior ($P < 0.001$), harem-tending behavior ($P < 0.001$), and agonistic behavior ($P = 0.02$). There was no difference between the mean body condition of control females (4.9 (95% CI = 4.7–5.1)) and treated females (4.8 (95% CI = 4.7–4.9)). Band fidelity among all females increased 25.7% in the year following vaccination and culling, despite the social perturbation associated with removal of conspecifics. Herding behavior by stallions decreased 50.7% following treatment and culling ($P < 0.001$), while harem-tending behavior increased 195.0% ($P < 0.001$). The amount of available forage influenced harem-tending, reproductive, and agonistic behavior in the year following culling and treatment ($P < 0.04$). These changes reflected the expected nexus

between a species with polygynous social structure and strong group fidelity and the large instantaneous change in population density and demography coincident with culling. Behavioral responses to such perturbation may be synergistic in reducing grazing pressure by decreasing energetically expensive competitive behaviors, but further investigation is needed to explicitly test this hypothesis.

1. Introduction

Gregarious relationships can impart individual benefits such as decreased depredation, increased foraging efficiency, and increased fecundity (Pusey and Packer, 1997). When resources to support populations of social animals are limited and populations become locally overabundant, managers are faced with the daunting challenge of decreasing population size without disrupting core behavioral processes. For example, the limited contiguous habitat and finite resources found on public wildlands cannot sustain overabundant populations of large ungulates, and managers continuously seek innovative and publically-acceptable tools for managing these species (Powers et al., 2011). Historically, such populations have been reduced by culling, using either lethal methods such as hunting, or non-lethal methods such as capture and translocation. Limiting fecundity through the use of immunocontraceptives is becoming a more commonly considered tool for controlling wildlife abundance. However, these tools can be accompanied by physiological changes that may alter behavior and ultimately influence population dynamics in unforeseen ways (Ransom et al., 2014). The paucity of quantitative data on natural behavior of wild free-roaming fauna, especially pertaining to those treated with fertility control agents, impairs our ability to understand species' influences and roles in ecosystems and thus our ability to effectively manage populations.

Elk (*Cervus canadensis*) and feral horses (*Equus caballus*) are increasingly targeted for fertility control management in the United States and both species exhibit complex social behavior and polygynous mating systems. Whereas elk congregate seasonally into mating groups (Geist, 1982), feral horses form bands that persist year-round with distinct associations of individuals sometimes lasting a decade or more (Klingel, 1982). These bands are largely maintained by reproductive, herding, agonistic, and defensive behaviors initiated by the polygynous male in the band, as well as hierarchical relationships among females (Ransom and Cade, 2009). Culling can result in discrete changes to population density and demography, which could perturb social organization. Likewise, effective fertility control agents lead to discrete changes in presence of offspring in the population, and thus may influence social behavior.

Approximately 33,000 feral horses roam 13 million ha of public lands in the western United States and managers have historically relied on nonlethal culling through a process of capture, removal, and public adoption to regulate animal abundance (Garrott and Oli, 2013). This process is unsustainable because demand in the U.S. for feral horses as domestic stock is less than half the number of animals removed, which has left as many horses in federally-subsidized pastures as persist in the wild. Several fertility control techniques have been investigated for use in feral horses, but most of these efforts resulted in tools that were publicly unacceptable, expensive to use, or impractical on a large scale. Among the most promising techniques are immunocontraceptive vaccines such as porcine zona pellucida (PZP) and gonadotropin-releasing hormone (GnRH). These agents are relatively easy to apply, are reasonably efficacious, and are not expected to be accompanied by serious contraindications (Kirkpatrick et al., 2011).

Gonadotropin releasing hormone is a small neuropeptide that performs an obligatory role in mammalian reproduction. When combined with a potent adjuvant, the GnRH vaccine stimulates a persistent immune response resulting in prolonged antibody production against GnRH, the carrier protein, and the adjuvant (Miller et al., 2008). The most compelling hypothesis of vaccine effectiveness suggests that antibodies to GnRH likely induce transient infertility by binding to endogenous GnRH, thus preventing attachment to receptors on gonadotropes and suppression of pulsatile luteinizing hormone (LH) secretion (Molenaar et al., 1993). Gonadotropin releasing hormone antibody titers are correlated with suppression of the reproductive system and infertility in a variety of species (Fagerstone et al., 2010). As anti-GnRH antibodies decline over time, concentrations of available endogenous GnRH increase and treated animals usually regain fertility (Powers et al., 2011).

This immunocontraceptive vaccine, known by the trade name as GonaCon-B^{TM}, has been shown to provide multiple years of infertility in several wild ungulate species including horses (Killian et al., 2008; Gray et al., 2010), bison (*Bison bison*) (Miller et al., 2004), elk (Powers et al., 2011), and white-tailed deer (*Odocoileus virginianus*) (Gionfriddo et al., 2009). Given the physiological mechanism of action, GnRH immunocontraception has the potential to reduce fertility and suppress the reproductive behaviors typically associated with copulation; however, in GnRH-vaccinated elk, such behaviors were not entirely diminished likely due to incomplete suppression of the hypothalamic pituitary gonadal (HPG) axis (Powers et al., 2011). Similar to elk, feral horses are polyestrous and fertility control agents that do not suppress these social behaviors can lead to females exhibiting frequent reproductive behaviors that can cascade into altered behaviors from associated band members and nearby males (Nuñez et al., 2009; Ransom et al., 2010).

Rigorous quantitative investigation into the potential effects of GnRH treatment on feral horse behavior is missing from the assessment of this immunocontraceptive as a potential management tool. Such data are

Table 1
Population metrics for feral horses (*Equus caballus*) at Theodore Roosevelt National Park, North Dakota, USA, 2009 and 2010. Normalized Difference Vegetation Index (NDVI) is shown for only the behavior observation period in each year.

	2009	2010
Number of males	64	26
Number of females	74	59
Number of foals	27	31
Mean male age ± SE (range)	5.0 ± 0.45 (1–15)	7.7 ± 0.68 (1–16)
Mean female age ± SE (range)	5.3 ± 0.50 (1–20)	6.4 ± 0.45 (1–18)
Number of bands	19	16
Mean band size ± SE (range)	8.3 ± 0.07 (3–14)	8.7 ± 0.07 (3–19)
Total population size	165	116
Mean NDVI (95% CI)	0.44 (0.324–0.548)	0.43 (0.346–0.504)
Density (number of horses/ha)	0.009	0.006

also absent in regard to culling, which is arguably the most common feral horse management practice worldwide. We investigated the influences of GnRH treatment on behavior of feral horses at Theodore Roosevelt National Park, North Dakota, for a year proceeding and a year following GnRH vaccination and culling. Our objectives were to quantify effects of these two management tools on time budgets of individuals and social interactions between individuals. Based on the assumed mechanism of action of GnRH vaccine, we posited that inoculation would suppress reproductive behaviors in treated females compared to controls and that the sudden decrease in density and social perturbation caused by population reduction would measurably influence social behaviors of all horses.

2. Materials and methods

2.1. Study area

Theodore Roosevelt National Park is located in southwestern North Dakota, USA (45°55′N/103°31′W). The South Unit of the park, where this study was conducted, comprised approximately 19,000 ha and consisted of eroded badlands with gullies and ravines separated by large upland plateaus, and small buttes. The mixed-grass prairie vegetation was predominantly comprised of needle and thread (*Hesperostipa comata*), threadleaf sedge (*Carex filifolia*), western wheatgrass (*Pascopyrum smithia*), blue grama (*Bouteloua gracilis*) and little bluestem (*Andropogen scoparius*) (Butler et al., 1986). Sympatric ungulates included feral horses, pronghorn (*Antilocapra americana*), bison, mule deer (*Odocoileus hemionus*) and elk. Feral horses were confined to the South Unit by a 1.8–2.4 m high woven wire boundary fence and no other feral horse populations were nearby. All individual horses in this population were previously identified and assigned individual identity numbers by managers, and age and reproductive data for each animal have been maintained since 1993 (National Park Service, unpublished data).

2.2. Treatments and study subjects

In spring/summer 2009, when pre-treatment data were collected, 165 horses occupied the park and were organized into 19 bands (Table 1). All bands contained a single adult stallion and adult females and their offspring, with the exception of one band that also contained a second stallion. No females persisted outside of bands; whereas, bachelor males were distributed across the landscape individually or sometimes in small ephemeral bands.

Horses were gathered into permanent corrals and handling facilities using a helicopter during a scheduled management capture in October 2009. Managers attempted to gather all horses in the population at that time, and removed 78 horses based on the agency's specific management needs. Eighty-one percent of the culled animals were foals, yearlings, and 2- and 3-year olds, and 14% were bachelor males not associated with any band. The remaining individuals removed included three females age ≥16 years, and one 6-year old female; none of which were part of our experimental group. These removals inherently skewed the sex ratio of the population between years because so many bachelor males were removed; however, paternity attributed to bachelor males is thought to be low (Bowling and Touchberry, 1990) and all study bands were subjected to competition pressure equally in each year at the population level. Post-treatment data were collected in spring/summer 2010, when 116 horses (including those born in 2010) occupied the park (Table 1).

We selected 58 adult females (2–17 years of age) using a randomized complete block design consisting of a GnRH-vaccinated treatment group and a saline control group. The resulting experimental female population consisted of 29 GnRH-vaccinated females (treatment) and 28 saline-treated (control) females, with one mature female remaining in the population that could not be captured. Females that were not in either treatment group were excluded from behavior analyses. The GnRH vaccine ultimately did not prevent conception in all inoculated horses (Baker et al., 2013); therefore, to more clearly separate the effects of infertility on behavior, we also excluded from analysis observations of 14 treatment females that became pregnant in 2010 and produced offspring in 2011. Females of both treatment groups were dispersed randomly across 16 bands with no difference in proportion of treated and control females between bands (paired t-test for unequal means: $t = 0.116$, $P = 0.909$). The same adults and bands observed in 2009 were observed in 2010, with none of the research cohort or band stallions removed during the culling operation.

Veterinarians blinded to treatment status assessed the general health, pregnancy, and body condition of each

animal at the time of capture. Pregnancy status and approximate stage of gestation were determined using rectal palpation of the reproductive tract and transrectal ultrasound imaging (Bucca et al., 2005). We visually assessed body condition of all females and scored condition using a numerical index that increased 1–9 with increasing fatness (Henneke et al., 1983). Females in the treatment group received an intramuscular injection in the gluteus muscle, by hand-syringe, containing 2000 μg of GnRH vaccine (2 mL, GonaCon-B™ (National Wildlife Research Center, Fort Collins, CO, USA)). Females in the control group were injected in a similar manner with an equal volume of saline solution. All data for this study were collected in accordance with Colorado State University Animal Care and Use Committee standards (protocol 12-3197A).

2.3. Behavioral sampling

Behavioral observations were conducted during three daylight time periods (08:00–12:00 h, 12:01–16:00 h, and 16:01–20:00 h) from April 18, 2009–July 16, 2009 and April 8, 2010–August 19, 2010. Each observation session included collection of a 20 min instantaneous scan sample of time budgets at 1 min intervals for each adult band member (≥1 years old), and all-occurrence data collection for social interactions, exactly as implemented by a synonymous study of PZP in horses (Ransom et al., 2010). We used a feral horse ethogram that categorized specific behaviors into 15 discrete time budget categories; agonism, comfort, elimination, feeding, grooming, harem-social (e.g., allogrooming, pair-bonding, female-female urine marking), harem-tending (e.g. stallion defense of a band female or recruitment of a new female into the band), herding (e.g., driving or snaking behavior by the stallion), interaction-with-humans, locomotion, out-of-sight, reproduction, resting, standing attentive, and submission (Ransom and Cade, 2009). The infrequency and similar nature of several behaviors in the instantaneous scan samples led us to aggregate them into broader categories for time budget analyses. Grooming, comfort, standing attentive, and elimination were combined into *maintenance*; reproductive, harem-tending, harem-social, agonism, submission, and herding were combined into *social*; and interaction-with-humans and out-of-sight were combined into *unknown*. The time spent in the category *unknown* ultimately did not differ between treatment groups or between years.

We also collected social behavior data at every occurrence throughout each observation session because instantaneous scan sampling has the potential to underestimate rare events (Ransom and Cade, 2009). These all-occurrence behaviors included intraband social behaviors associated with herding, reproduction, agonism, and harem-tending and were retained as discrete categories for social behavior analyses. We observed all horses from the nearest distance that did not elicit attention of horses to the presence of the observer, typically 50–300 m. All observations were conducted using a 15–45 × 600 mm spotting scope or 10 × 42 mm binoculars when the distance between horses and observers was too far to allow unassisted detailed observation.

2.4. Statistical analyses

We modeled the frequency of each behavior using mixed-effects linear regression, where individual female identity and sampling time period (time of day) were included as random effects on the intercept term of each model. This accounted for variation that may have been present among individuals who were sampled repeatedly, though not always equally over time, and for temporal variation in behavior when samples were not equally collected across all times of day. We used the lme4 package of R version 2.14.1 (The R Foundation for Statistical Computing 2011) and SYSTAT 12.02.00 (SYSTAT Software, Inc. 2007) to calculate descriptive statistics and obtain mixed-effects model estimates using restricted maximum likelihood (Harville, 1977).

We fitted separate models for each year to assess the fixed effects of treatment (x_1, pre-treatment or pre-control in 2009, treatment or control in 2010), foal presence (x_2, dependent foal < 1 year of age present with the female, or no foal present with the female), female age (x_3), band size (x_4, total number of animals in the group), and band fidelity (x_5, number of times a female changed bands within the sampling year) on time budget behaviors. In the notation of Gelman and Hill (2007), models took the form of $y_{jk[i]} = \alpha_{0j[i]} + \alpha_{1k[i]} + \beta_0 + \beta_{x_1}x_{1[i]} + \beta_{x_2}x_{2[i]} + \beta_{x_3}x_{3[i]} + \beta_{x_4}x_{4[i]} + \beta_{x_5}x_{5[i]} + \varepsilon_{jk[i]}$, where the random effect intercept of $\alpha_{0j[i]} \sim N(\mu = 0, \sigma_j^2)$ represents time period j (08:00–12:00 h, 12:01–16:00 h, 16:01–20:00 h), for $i = 1,\ldots,n$ observations, and the random effect intercept $\alpha_{1k[i]} \sim N(\mu = 0, \sigma_k^2)$ represents $k = 1,\ldots,n$ individual horses for $i = 1,\ldots,n$ observations. This equation identifies the fixed effect intercept as β_0, x = independent variable with parameter β_x, ε = statistical error, and y = dependent variable. All-occurrence social behavior was modeled in the same framework, but because those data involved a given stallion directing a behavior toward a given female, we also included the additional variable of stallion age as a fixed effect.

In order to gain insight into the effects of removal versus fertility control, we also modeled time budget and all occurrence behavior across both years, replacing treatment status with observation year as a fixed effect. This allowed us to look at the broad paradigm change, independent of trying to separate the inherently related aspects of changing sex ratio, density, and competition. We included Normalized Difference Vegetation Index (NDVI) as a fixed effect in this model in order to estimate the temporal influence of forage availability on behavior that could have varied between years. The NDVI data were obtained from the National Aeronautics and Space Administration (http://modis.gsfc.nasa.gov) and reconciled using ArcGIS software (ESRI, Redlands, California). We also included sex as a fixed effect in this model to gain insight into both male and female time budgets in concert with the culling perturbation.

3. Results

The 2009 pregnancy assessment indicated that 89% of the control group and 86% of the treatment group were pregnant at the time of saline- or GnRH vaccine-injection. In the following year, 71% (95% CI = 53.9–89.3%) of control females and 72% (95% CI = 55.1–89.7) of treated females were observed with a dependent offspring. Mean body condition of pre-control females was 5.1 (95% CI = 4.8–5.4) and of pre-treatment females was 4.9 (95% CI = 4.7–5.2) in 2009. Likewise, mean body condition of control females was 4.9 (95% CI = 4.7–5.1) and of treated females was 4.8 (95% CI = 4.7–4.9) in 2010.

We collected behavioral data on 93 feral horses (23 males, 29 pre-treatment females, 27 pre-control females, 14 other females) for 582.4 h in 2009. The median age of observed stallions was 7 years (range = 3–14 years), median age of observed females was 5 years (range = 2–17), and median band size was 8 horses (range = 3–17). In 2010, approximately 5 months after treatment and culling, we observed 77 of the same feral horses (18 males, 29 treated females, 28 control females, two other females) for 1263.90 h. The median age of observed stallions was 9 years old (range 5–15), median age of observed females was 5 years old (range = 3–18), and median band size was eight horses (range = 3–19). The final data used for GnRH treatment analyses arose from 1331 observations of 29 pre-treated and 29-pre-control females in 2009 and 2299 observations of 15 treated and 28 control females in 2010. The final data used for culling analyses arose from 2115 observations of 23 males, 27 pre-control females and 29 pre-treatment females in 2009, and 3274 observations of 18 males, 28 control and 29 treatment females in 2010.

3.1. Time budgets

Band size and foal presence were influential in how females allocated their time during 2009, but there were no differences in behaviors between pre-treatment and pre-control females (Table 2). However, treated and control females spent their time differently in the year following inoculation. Treated females fed more and moved more than control females, and reciprocated by reducing time in resting and maintenance behaviors (Fig. 1). There were no changes in time spent engaging in social behaviors between treated or control females and their conspecifics (Table 2). Band size influenced feeding time, increasing 0.9 ± 0.40 (SE)% with each additional horse in the band in 2009. This effect was not evident in 2010 after the population was reduced. Time of day influenced feeding behavior in both years. Horses fed an estimated 7.3 ± 4.69% (2009) and 7.5 ± 5.01% (2010) less in the morning, as compared to 7.4 ± 5.00% (2009) and 9.0 ± 5.04% (2010) more in the afternoon.

Time spent feeding was largely reciprocated by time resting among both treated and control groups (Fig. 1). There were no differences between pre-treatment and pre-control females in time spent resting ($t_{1270} = 0.459$, $P = 0.646$), but like feeding, this relationship changed after inoculation, and treated females rested less than their control counterparts (Table 2). Foal presence influenced

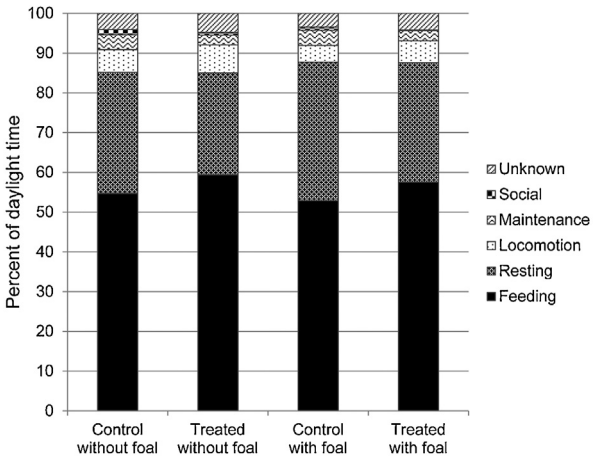

Fig. 1. Mean allocations of daylight time budget behaviors for feral horse (*Equus caballus*) females at median age (5 years old) and median band size (eight horses). Estimates are shown from mixed-effects linear regression considering individual identity and time of day as random effects. Data consisted of 2299 observations of 28 control and 15 treatment females in 2010 at Theodore Roosevelt National Park, USA. Foal presence was defined as a dependent born during the observation year.

resting in both years with independent females resting 4.4 ± 2.27% (2009) and 4.4 ± 1.83% (2010) less than females with a dependent foal (Table 2). Resting occurred temporally opposite of feeding activity, with 7.0 ± 4.43% (2009) and 6.5 ± 4.18% (2010) more resting in the morning and 6.8 ± 4.72% (2009) and 7.2 ± 4.22% (2010) less in the afternoon.

The remainder of horses' time was occupied by locomotion (about 5% of their time), maintenance (about 3% of their time), and social behavior (about 1% of their time) (Fig. 1). Treated females spent less time moving than controls and reciprocated with increased maintenance behavior (Table 2). Age was a statistically significant effect in modeling locomotion in 2010, but because time in locomotion only differed by 0.12% per year of age, this is unlikely to be biologically significant. Foal presence, however, was a strongly supported effect and females with a dependent were on the move 1.5 ± 0.35% more than independent females (Table 2). Maintenance behavior was influenced by band fidelity in 2010 and time spent exhibiting this behavior increased 1.6 ± 0.44% per band change. Six of 43 females (14%) were observed changing bands one to three times during 2010. In contrast, 23 of 58 females (40%) changed bands one to four times in 2009. The decreased band size in 2010 appears to have influenced time spent performing maintenance behavior (Table 2). Like age and locomotion, this effect was statistically significant but with an increase of only 0.1 ± 0.06% per additional band member it is unlikely to have biological meaning. Locomotion, maintenance, and social time budget behaviors were influenced minimally by time of day or individual variation (Table 2).

3.2. Social behaviors

All-occurrence social behaviors associated with herding, harem-tending, reproduction, and agonism from stallions toward females were observed 57% of the time

Table 2

($n = 331$) during 2009 and 51% of the time ($n = 650$) during 2010. Herding by stallions was the most frequently observed social behavior. Band size influenced this behavior in 2009, with herding increasing 0.16 ± 0.56 times per hour (tph) per additional horse in the band (Table 3). In 2010, however, age of the stallion was the only important fixed effect on this behavior and herding increased 0.18 ± 0.038 tph per year of age. At median stallion age, median female age, and median band size, pre-treatment females received herding behavior 2.24 ± 0.743 tph and pre-control females received this behavior 1.98 ± 0.694 tph ($t_{274} = -0.892$, $P = 0.373$); likewise, treated females received herding behavior 1.06 ± 0.415 tph and control females received this behavior 0.99 ± 0.454 tph ($t_{602} = -0.271$, $P = 0.787$). Time of day was not an important influence on herding in either year and variance of this random effect was similar in both years (Table 3).

Harem-tending occurred less frequently than herding in 2009, but at a similar rate as herding in 2010. The supported fixed-effects in models of harem-tending were band size in 2009 and age of stallion in 2010 (Table 3). As band size increased per horse, harem-tending decreased 0.05 ± 0.020 tph in 2009, and as stallion age increased per year, harem-tending decreased 0.11 ± 0.026 tph in 2010. As with herding behavior, time of day did not influence harem-tending occurrence in either year and there was little individual variance in 2009.

Contrary to our prediction that reproductive behaviors would be reduced in GnRH-treated mares compared to controls, we observed almost exactly the same frequency in both years and between treatment groups. At median stallion age, median female age, and median band size pre-treatment females received reproductive behaviors 0.57 ± 0.374 tph and pre-control females received reproductive behaviors 0.40 ± 0.349 tph ($t_{274} = -1.054$, $P = 0.293$); likewise, treatment females received reproductive behaviors 0.59 ± 0.270 tph and control females received reproductive behaviors 0.56 ± 0.297 tph ($t_{602} = -0.177$, $P = 0.860$). The only supported fixed-effect in either year was female age in 2009, which estimated a 0.05 ± 0.024 tph decrease in reproductive behavior per year of age.

Agonism occurred at similar rates as reproductive behaviors in both years and was influenced by stallion age in both years (Table 3). Agonism from males toward females increased 0.03 ± 0.019 tph per year of male age in 2009 and 0.04 ± 0.017 tph per year of male age in 2010. At

	Band fidelity	2.411	0.016	0.201	0.037	0.365		

median stallion age, median female age, and median band size pre-treatment females received agonistic behaviors 0.26 ± 0.251 tph and pre-control female received agonistic behaviors 0.44 ± 0.234 tph ($t_{274} = 1.744$, $P = 0.082$); likewise, treatment females received agonistic behaviors 0.19 ± 0.184 tph and control females received agonistic behaviors 0.36 ± 0.203 tph ($t_{602} = 1.627$, $P = 0.104$). Band fidelity also influenced the 2010 estimate and agonism increased with number of band changes (Table 3). Neither time of day nor individual variance influenced agonism occurrence in either year.

3.3. Population reduction

Horses allocated time differently by sex and by year (Table 4). Males fed less, rested more, moved more and engaged in social interactions more often than females, but all horses fed less, rested more, moved more, and performed less maintenance behavior and engaged in more social behavior in 2010 as compared to 2009 (Fig. 2). Normalized Difference Vegetation Index was highly correlated between years ($R^2 = 0.90$). The finer scale all-occurrence behavioral data revealed that herding by stallions decreased 50.71% from 2009 to 2010, and appeared to increase in frequency concurrent with the seasonal green-up period (and concurrent reproductive season) (Fig. 3A). Harem-tending behavior increased 195.0% from 2009 to 2010, when both were estimated at median stallion age, median female age, median band size, and mean NDVI. Harem-tending also occurred in concert with forage production, but this relationship was more pronounced in 2010, when the frequency of occurrence was markedly escalated (Fig. 3B). Time of day and individual identity contributed little to variance in these models (Table 4).

4. Discussion

There were no differences in any behaviors between treatment groups before GnRH vaccination and culling. Females vaccinated against GnRH managed their time differently than controls. They fed less, rested more, traveled less, and performed more maintenance behaviors than their control counterparts, but engaged in the same amount of social behavior. The estimates across years, however, indicated that pronounced behavioral changes occurred in how stallions engaged with females in social behaviors. Stallions herded all females less and harem-tended more following the changes in population density, demography, and social perturbation that resulted from culling. The date of observation in relation to forage availability explained some differences between years, while the increased mean age of stallions as well as the decreased band size in 2010 also explained some of the differences. None of the models indicated that herding or harem-tending varied due to the treatment status of females, but rather implied that the paradigm shift in competition influenced how band stallions managed their family groups. Because the same stallions were observed in both years, the effect of age potentially reflected the additional year of experience each male possessed, in the context of competition pressure.

The similarity in female social behavior between treatment groups likely related to estrous behavior, a catalyst of other social behavior. Estrous behavior is influenced by the concentration and timing of progesterone and estradiol, the steroid hormones that fluctuate with occurrence of pregnancy (Katz, 2007). During pregnancy, high concentrations of progesterone usually inhibit estrous behavior (Crowell-Davis, 2007; Fabre-Nys and Gelez, 2007). The GnRH-antibodies stimulated by GnRH vaccination should have interrupted the hormonal cascade in females and ultimately suppressed pulsatile luteinizing hormone (LH) secretion, and thus ovulation (Powers et al., 2011). Consequently, we might expect that similar social behavioral expressions (albeit for different reasons) between pregnant females and GnRH-treated females would be observed. However, a similar study in elk concluded that GnRH was not completely suppressed in vaccinated females and thus some LH stimulation occurred and likely allowed limited production of estradiol (Powers et al., 2011). This permitted reproductive behaviors, at a reduced level, in GnRH-treated individuals. It should also be noted that estrous behavior has been observed with low frequency among both pregnant female and anovulatory female horses (Asa et al., 1983; Crowell-Davis, 2007). This is thought to be a bonding mechanism that assists in the maintenance of stable social groups of horses year-round, rather than ephemeral reproductive groups, such as those observed in elk. Also, the complex social behaviors among feral horses do not entirely center on reproductive receptivity, and other behaviors associated with dominance hierarchies, leadership, and gregarious lifestyles may or may not be as directly influenced by fluctuations in progesterone and estradiol.

Regardless of the similarity in social behaviors between treatment groups, treated females still allocated their time budgets differently than controls in 2010. Most GnRH-vaccinated females in the final dataset were likely not pregnant in 2010 because we categorically omitted the treated females that demonstrated unsuccessful response to vaccination by producing offspring in 2011. Pregnancy influences time spent feeding and resting simply due to the metabolic needs of barren females as compared to pregnant females (National Research Council, 2007). The composite nature of time budget behaviors requires that if any one behavior changes, then other behaviors such as locomotion or maintenance must also change; thus, the small differences between treatment groups were unsurprising.

The estimates of time spent per behavior for all horses in our study fell well within the ranges previously reported for daylight time budgets of horses (Mayes and Duncan, 1986; Boyd, 1998; Berger et al., 1999; Ransom et al., 2010). Ultimately, body condition scores of control and treated females were at parity in 2010. This may indicate that the metabolic demands of pregnant and non-pregnant females were compensated for behaviorally, that the body condition scoring system was not sensitive enough to detect finer-scale differences, or that forage abundance was high enough to obfuscate the effects of behavior on body condition. Foal presence influenced resting in both years with independent females resting less than females with a

dependent foal. Band size was also an important effect on some behaviors; most notably, herding and harem-tending behavior in 2009 were significantly related to band size, but this was not the case in 2010. This effect on social behaviors was replaced with stallion age in 2010. These contradictions may be in part due to the change in population size that occurred between years or due to changes in band composition. Even though band size did not change notably between years, some young animals were removed from bands.

Density of bachelor males in the population was likely influential in the large changes in herding and harem-tending behaviors observed between years: the number of bands and band size did not differ greatly between

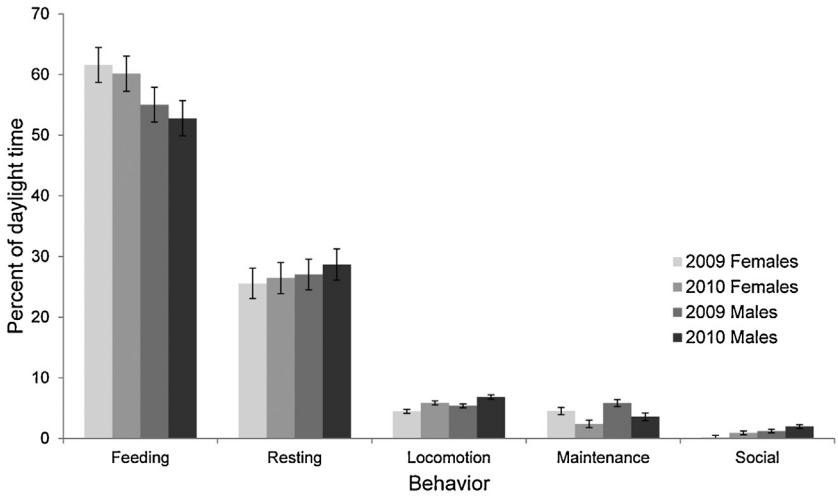

Fig. 2. Comparison of mean ± SE daylight time budget behaviors of feral horses (*Equus caballus*) before (2009) and after (2010) culling and GnRH treatment at Theodore Roosevelt National Park, USA. Estimates are shown at median age, median band size, and mean Normalized Difference Vegetation Index (NDVI) and arose from mixed-effects linear regressions considering individual identity and time of day as random effects.

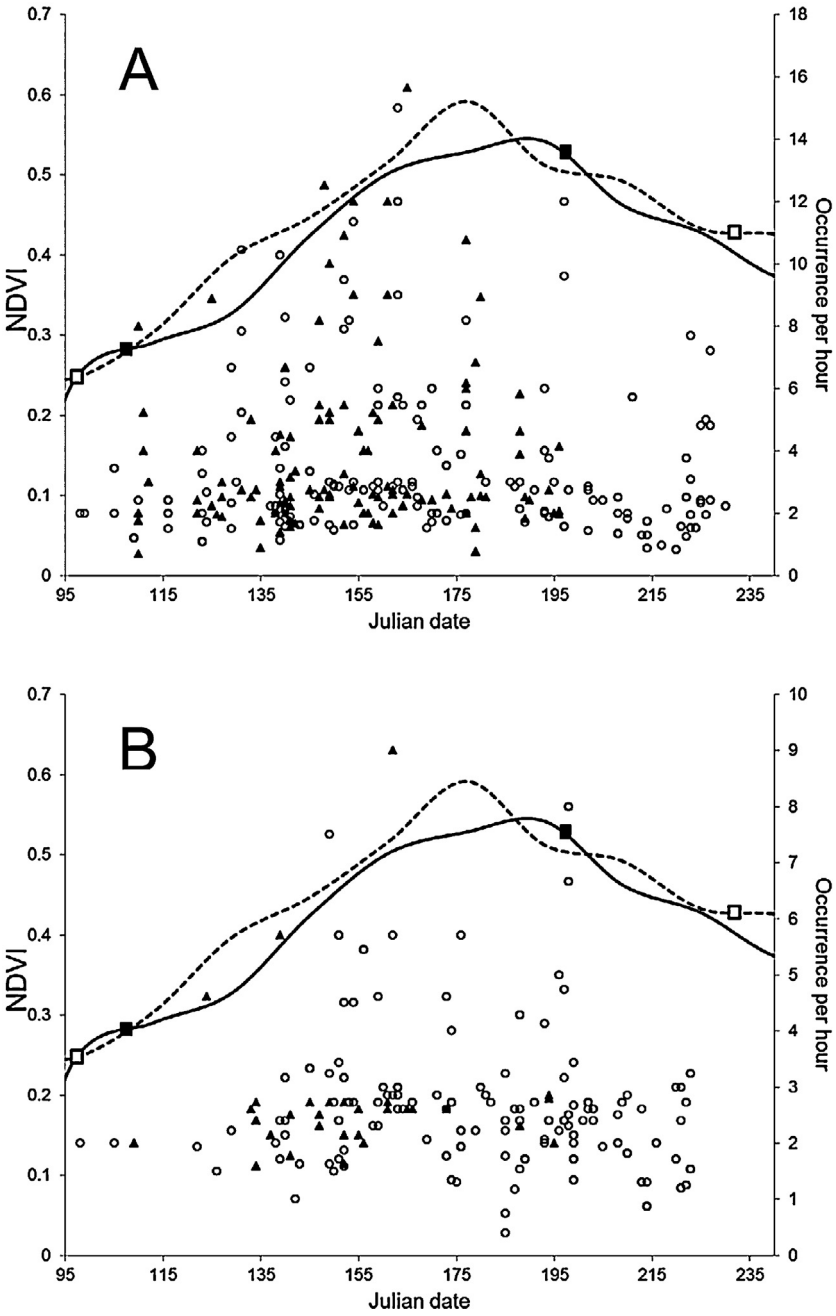

Fig. 3. Temporal occurrence and rate of feral horse (*Equus caballus*) herding (A) and harem-tending (B) behaviors in relation to seasonal trend in forage availability using Normalized Difference Vegetation Index (NDVI) as an index of greenness. NDVI for the pre-treatment year of 2009 is shown as a solid line with behaviors as solid triangles and NDVI for the post-treatment year of 2010 is shown as a dashed line with behaviors as hollow circles. Boxes on the NDVI trend lines designate the beginning and end of each behavior observation season.

years, but the number of available males in the population decreased 41% between years and the mean age of males in the population increased by nearly 3 years or 36%. This combination of effects presents compelling evidence that quickly and non-randomly reducing population density has behavioral implications for individuals and how bands function in the social dynamics of the population.

Herding and harem-tending behavior are important behaviors used by band stallions to maintain bands, but also represent an energetic cost for both the male and female(s) involved. Such costs may have biological meaning in terms of body condition and fidelity of females to the band (Ransom et al., 2010). The decline in herding behavior detected between years is not surprising given the decreased presence of competing males in the

population, which is often what prompts a stallion to actively herd females together (Waring, 2003). This decrease in potential energetic expense lends support for the practice of culling because while it decreases grazing impact by removing animals, it also leads to the remaining animals expending less energy (that would have to be replaced by grazing) by decreasing frequency of behaviors that arise from competition. Consequently, 2.2% less feeding behavior was estimated for stallions in 2010 as compared to 2009 in our study. This is supported by the observed increase in harem-tending behaviors in our study, most of which are likely driven by instinctual behavioral mechanisms more than active presence of a competitor. Such behaviors include stallions marking urine deposits of band members and constructing fecal middens that relate to reproductive status, communication, and band identification (Feist and McCullough, 1976; Rubenstein and Hack, 1992).

Little has been studied on the effects of culling in feral horse populations, and what has been presented in the literature focuses on stress and its effects on reproduction (Hansen and Mosley, 2000; Ashley and Holcombe, 2001). A short term study did collect data on percent of time horses spent feeding, resting, vigilant, traveling, and engaged in agonistic encounters and found no difference between control (horses not gathered or pursued) and simulated (horses that were pursued but evaded capture) groups (Hansen and Mosley, 2000). That study did not investigate the broader effects relating to density and sex ratio changes. We could find no other studies that investigated behavior before and after population removals of feral horses. There are some comparable studies of feral horse behavior in relation to immunocontraception however.

Porcine zona pellucida is the most extensively investigated immunocontraceptive for feral horses, and recent studies have found PZP-treated females exhibit more frequent reproductive behaviors and seasonally prolonged reproductive behaviors than their control counterparts. In a comparable study of three feral horse populations, 54.5% more reproductive behaviors were received by PZP-treated females than by control animals during the breeding season (Ransom et al., 2010). Likewise, in another feral horse population, more frequent reproductive behaviors among PZP-treated females were observed in the non-breeding season (Nuñez et al., 2010). Elevated rates of estrus have been reported in PZP-treated females of other species as compared to control females, which likely explains this increase in observed reproductive behavior (Mahi-Brown et al., 1985; Shumake and Wilhelm, 1995; Heilmann et al., 1998; Curtis et al., 2002). Seasonality of estrus in horses may not be as constrained by abiotic factors as previously thought, so it is possible that any contraceptive that does not completely suppress estrus could be associated with seasonally atypical expressions of reproductive behavior (Ransom et al., 2013). Decreased band fidelity has also been reported among PZP-treated female horses (Nuñez et al., 2009; Madosky et al., 2010), and in our GnRH study the per capita female interchange rate decreased 25.7% from 2009 to 2010. Given that some social reorganization was expected following the culling perturbation, the observed decrease in interchange provides additional evidence that GnRH-vaccinated females were not expressing the frequent reproductive behavior that appears to be coincident with decreased band fidelity.

Studies of the effects of GnRH immunocontraceptive vaccines on behavior of female horses are limited; nevertheless, a few small studies do illustrate some general patterns in responsiveness. In the only other feral horse study reported in the literature, no differences were observed between treatment groups in time spent feeding, resting, or traveling in either the breeding or non-breeding season (Gray et al., 2010). Of the 25 copulations observed in that study, only one was a GnRH-vaccinated female and it occurred during the non-breeding season. Both treated and control females demonstrated reproductive behavior roughly once every 2 h in our study. Our results concur with observations of reproductive behaviors in controlled experiments where captive mares were treated with GnRH vaccine. In those studies, treated mares showed suppressed ovarian activity and ovulation after immunization but continued to show evidence of estrous behavior at irregular intervals and duration (Dalin et al., 2002; Imboden et al., 2006). Similar behavioral responses to contraception induced by GnRH vaccine and GnRH agonist have been reported in other ungulate species as well (Baker et al., 2002, 2004; Conner et al., 2007; Powers et al., 2011). The parity we observed between treatment groups therefore simply reflects the limited reproductive behavior among control females due to high rates of pregnancy and suppressed reproductive behavior among treated females due to GnRH-inhibited ovarian activity. Since GnRH is highly conserved across mammalian species, fertility control technology founded on this hormone may suppress reproduction but does not always prevent the occurrence of sexual behaviors.

Our study was limited to only a pre-treatment and treatment year, and as such inferences should only be extended to the individual level in the short term. Both pregnancy and birth rates between treatment groups in our study were the same, but variation in birth interval among individuals can make longer term trends less certain in terms of births, dependent foals, physiology, and associated behaviors. While some studies have demonstrated females may be less likely to foal in consecutive years, as opposed to alternate years, others have found no differences (Roelle et al., 2010). Probability of foaling can also be strongly related to band size (Roelle et al., 2010), which was equitable between years in our study but may trend downward with effective fertility control over long time periods. For these reasons, the short duration of our study provides some relatively clear inference toward short-term effects of GnRH and culling on individual behaviors; however, long term effects of fertility control on behavior may manifest to all individuals as a population paradigm shifts to lower fecundity, and variable and unknown effects on social structure and dynamics emerge.

5. Conclusion

Our study found only minimal differences in behavior of free-ranging female feral horses treated with GnRH

and those treated with saline. Those differences could be physiologically explained and body condition between the two treatment groups was at parity. Following the same methodological protocols as a similar study of PZP-treatment on behavior of feral horses (Ransom et al., 2010), GnRH appears to lead to fewer behavioral modifications than PZP in this species in the short term. Long term influences of GnRH remain uncertain. The ultimate assessment of any fertility control agent must include the scope and magnitude of all potential contraindications, vaccine efficacy, and weighing the known effects against the benefit of reducing population growth. The differences in how band stallions socially interacted with all females between years provided strong evidence related to the effects of culling. These behavioral responses shed light on the effects of reducing competition and density in a social polygynous species with strong group fidelity. Such perturbation may be synergistic in reducing grazing pressure by decreasing energetically expensive competitive behaviors, but further investigation is needed to explicitly test this hypothesis.

Conflict of interest

We declare no conflict of interest among financial, personal, or other relationships with other people or organizations that could inappropriately influence, or be perceived to influence, our work.

Acknowledgments

Special thanks to Lindsey Eby, Alanna Kirby, Al and Jennifer Schaeffer, Marylu and Henry Weber, and Jan Peterson for enduring the elements to collect these data. Kathy Fagerstone, James Gionfriddo, and Lowell Miller graciously provided GonaCon for treatments. Thanks to Valerie Naylor and Bill Whitworth for their support, assistance, and funding from Theodore Roosevelt National Park. Thanks to Alicia Niery for data entry assistance. This research was funded by the Morris Animal Foundation, Merck-Merial Veterinary Scholars Program, Theodore Roosevelt National Park, U.S. Geological Survey Fort Collins Science Center, and the National Park Service Biological Resource Management Division. No agency administration or funding program had a role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. Wild and Feral Equid Population Dynamics

JASON I. RANSOM, LAURA LAGOS, HALSZKA HRABAR, HANIYEH NOWZARI, DORJ USUKHJARGAL, AND NATALIA SPASSKAYA

Ransom, J.I., L Lagos, H. Hrabar, H. Mowrazi, D. Ushkhjargal, and N. Spasskaya. 2016. Wild and feral equid population dynamics. pages 68-86 in J. I. Ransom and P Kaczensky, eds., Wild equids; ecology, management and conservation. Johns Hopkins University Press, Baltimore, Maryland.

Wild equid populations are shaped by births, deaths, emigration, and immigration, each of which is subject to a suite of biological and ecological inputs across space and time. How these inputs influence population dynamics varies between populations as well as among species. In our rapidly changing world, human actions also increasingly affect wildlife populations (Sanderson *et al.* 2002). Fragmented landscapes, hunting of predators, reintroduction of species, invasive species, competition with humans and their livestock for resources, direct killing, and climate change all can influence population dynamics (see chap. 12). Most wild equids occupy arid or semiarid steppe, grassland, and desert environments, but some feral populations also thrive in forests, montane, and coastal environments, and across hot and cold, xeric and mesic, conditions. The array of factors potentially influencing these populations is great, but some fundamental elements influencing birth, survival, and movement are common to all.

Food can be one of the most important natural factors limiting populations of large herbivores (Fowler 1987; Gaillard *et al.* 1998, 2000; Gaidet and Gaillard 2008). As such, some populations may exhibit density dependence and be limited because of their own impact on forage resources, or because population density itself influences age-specific natality, behavior, or survival (Choquenot 1991; Gaillard *et al.* 1998, 2000; Flux 2001; Linklater *et al.* 2004; Bonenfant *et al.* 2009). When such populations lack resources, body condition of individuals can diminish and disease and parasitism can increase, all with the cumulative effect of reducing fecundity and survival, and ultimately limiting population growth (Eberhardt 1977). Some populations may persist without exhibiting density dependence, changing through time without realized self-imposed resource limitation. Those populations may still be limited by predation or climate events (Ellis and Swift 1988; Georgiadis *et al.* 2003). Over time, any given population may move between exhibiting density dependence and apparent density independence as the influencing factors change. Regardless of the specific paradigm, both deterministic and stochastic mechanisms play important roles in shaping populations (Björnstad and Grenfell 2001).

Attempting to draw broad inferences across equid population states, processes, and inputs is a challenging task, but the wild and feral members of family Equidae are perhaps more similar than not in their equation of life on earth. Some species, notably African wild ass (*Equus africanus*) and kiang (*E. kiang*), are vastly understudied, and considerable gaps persist in our knowledge of even their basic ecology. Other species, such as the feral horse (*E. caballus*), provide rich data sets that can inform us with in-depth ecological perspectives. In this chapter, we have synthesized data from studies on equids across the globe toward understanding the common and diverging natural influences acting to shape their populations. The populations in these studies ranged on 6 continents across >91 degrees of latitude, from savannah to mountains and deserts to islands, and thus were influenced by a diversity of biotic and abiotic factors. We focus here on natality, survival, and population growth. We briefly discuss movement into and out of populations, but largely defer that topic to chapter 13. The influence of humans on these populations is a broad topic that can profoundly affect survival, and we must defer that topic to chapter 12.

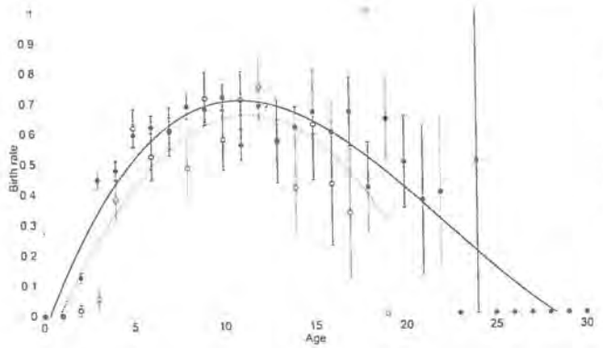

Fig. 6.1 Mean age-specific birth rates of horses ± standard error, as derived from *E. caballus* (feral) in the western United States (solid dots and solid trend line, n = 1,013 births, excluding females that received fertility control treatments) (Ransom *et al.* 2011; J. Ransom, unpublished data), and *E. f. przewalskii* (open dots and dashed trend line, n = 217 births, excluding females in the year of their introduction) (Great Gobi B Strictly Protected Area, Mongolia, unpublished data).

Natality

All species of wild equid appear to follow the same general distribution of age-specific natality that is observed in horses, with primiparous births most typically occurring from females age 2–5 years, and peak birth rates occurring roughly for females age 6–17 (fig. 6.1). There is some evidence that when forage is abundant, female equids are more likely to give birth at an earlier age (Berger 1986; Saltz and Rubenstein 1995; Tatin *et al.* 2009). When forage and water becomes exhausted, age of primiparous birth can increase and birth rates for all females can decline quickly (Ginsberg 1989). The majority of feral asses (*E. asinus*) in Death Valley, USA, for example, were observed giving primiparous birth at age ≥4 years while persisting in an extremely harsh environment (Moehlman 1974). (Note that sexual maturity is reached at 1.5 years; Grinder *et al.* 2006.) In the wild, female plains zebra (*E. quagga*) have been documented giving birth as old as age 18 (Klingel 1969), mountain zebra (*E. zebra*) at age >21 (Joubert 1974*a*), Przewalski's horses (*E. ferus przewalskii*) at age 20 (O. Ganbaatar, unpublished data), and feral horses as old as age 24 (fig. 6.1).

Horses and zebras typically give birth to one offspring annually, though extraordinarily rare cases of twins have been reported (Roelle *et al.* 2010; Vodička 2010). Feral asses have been observed giving birth to either one or two offspring (Grinder *et al.* 2006), as have Asiatic wild asses (*E. hemionus*) (Schook *et al.* 2013). The cases of twins born to Asiatic wild asses all resulted in early mortality of at least one sibling, and it is unknown how frequently twin births occur in the wild. Wild females of all asses are most typically observed with only one offspring of the year. The mean birth rate for equid females ≥2 years old across all species and studies we reviewed ranged from 0.20 in mountain zebras to 0.68 in feral asses, with a mean across species of 0.47 (95% confidence interval, or CI = 0.35–0.59) (table 6.1). Note that the lowest value from individual studies in this range arose from Przewalski's horses in the Gobi Desert following a catastrophic winter climate event (birth rate = 0.04) (Kaczensky *et al.* 2011), and the maximum value occurred in a small Asiatic wild ass (onager) population that started to increase rapidly six years after reintroduction (birth rate = 1.00) (Saltz and Rubenstein 1995). Despite these extremes, however, birth rates among wild equid species are remarkably similar when put in context of the pressures selecting for fitness.

Birth rates in wild populations reflect offspring born and observed, rather than pregnancy rate, which is presumably higher in most cases. Pregnancy rates

Note: Table includes some semiwild populations in managed reserves. Mean rates from each source study were weighted by sample size (number of individuals sampled) and length of study (years) to generate the mean values shown for each species ± standard error. The range of individual study means is given in parentheses after the point estimate. Birth rate is total number of foals divided by all females at least 2 years of age, and survival rate for adults represents individuals ≥2 years of age. Foal survival represents individuals surviving from birth to age 1.

have not been rigorously measured across equid species in the wild, but the feral horses of Kaimanawa, New Zealand, exhibited pregnancy rates of 0.79–0.94, with an average birth rate observed at only 0.49 (Linklater *et al.* 2004). Similarly, feral horses in Idaho, USA, exhibited an average pregnancy rate (across all ages) of 0.68, with only 8% of 1- to 3-year-olds becoming pregnant, increasing to 93% of 10- to 12-year-olds becoming pregnant (Seal and Plotka 1983). Plains zebra pregnancy rates in the Serengeti were reported ranging from 0.69 in 3- to 5-year-olds to 0.88 in 13- to 16-year-olds (Grange *et al.* 2004), but birth rates in similar systems of east Africa were reported as only 0.26–0.51 (Klingel 1969; Georgiadis *et al.* 2003). It is possible that in many studies the reported birth rates may be negatively biased because offspring aborted, stillborn, or depredated immediately after birth were undetected by observers. Abortion is extraordinarily unlikely after three months of gestation in horses, which implies that the environmental conditions early in pregnancy are perhaps most influential in the successful birth of a foal (Roberts 1986).

Interbirth interval (the time between subsequent offspring) among equids can vary depending on individual-level reproductive history and resource availability. Primiparous feral horses, for example, were less likely to foal in the year following their first foal, whereas multiparous females were more likely to foal if they had foaled the previous year (Roelle *et al.* 2010). The interbirth interval among plains zebra, on the other hand, appeared to be longer if the first foal was male (Barnier *et al.* 2012). Feral horses also demonstrated a protracted interbirth interval after producing a male foal under stressed resource conditions (Monard *et al.* 1997).

Both strong physiological and environmental inputs influence the rate and phenology of conception

and subsequent year births in most wild equid populations. Hormones associated with reproduction (such as estradiol, progesterone, and testosterone) fluctuate cyclically through time in both males and females (Kirkpatrick *et al.* 1977; Nuñez *et al.* 2011; Schook *et al.* 2013), reaching an annual apex of reproductive potential when enough sunlight and warm temperatures have stimulated the hormonal cascade (Ransom *et al.* 2013). This mechanism can help regulate birth cycles, and ultimately produces birth pulses that are often synchronized with forage availability. Estrus, birth rates, and birth phenology have been correlated with rainfall in some populations of zebras (Klingel 1969; Joubert 1974*b*; Williams 1998; Sinclair *et al.* 2000; Rubenstein 2010), feral horses (Siniff *et al.* 1986; Berman 1991; Scorolli and Lopez Cazorla 2010; Ransom *et al.* 2013), and Asiatic wild asses (Saltz *et al.* 2006). This synchrony with forage resources may increase female and neonate survival, especially because nutritional requirements of lactating females are elevated and higher-quality forage can result in increased body condition and nutritional support for neonates (Ginsberg 1989; National Research Council 2007). In a study of three temperate populations of feral horses where birth phenology was perturbed, estimated survival of foals decreased 1.4% for every 10 days after peak forage that parturition occurred (Ransom *et al.* 2013).

Environmental pressures can contribute greatly to birth phenology, and in some cases can truncate the birth season to a short, synchronized pulse. Predation, for example, has been posited to influence the timing of births under the premise that neonates are most vulnerable in their first hours or days of life, and as such predators can only harvest a finite number of young in a short period of time; consequently, if all young are born together, more should survive (Darling 1938; Sinclair *et al.* 2000). Parturition season for Asiatic wild asses in the Mongolian Gobi (where wolves prey on them), for example, typically begins mid-June and concludes around mid-July (P. Kaczensky, personal communication), and similarly the same species in Badghyz State Reserve, Turkmenistan (13° latitude farther south), was reported to foal primarily between 14 April and 14 May, but some foals were recorded as early as late as 28 July (Wolfe 1979). In contrast, a Sri Lanka feral ass population located almost on the equator and with no predators present exhibited no birth seasonality, and offspring were born uniformly across every month of the year (Santiapillai *et al.* 1999). Predation pressure may not be the primary driver of length of birthing season, however; length of gestation, birth interval, and duration of resource availability can all be important factors (Williams 1998). Wildebeest (*Connochaetes taurinus*) sympatric with Grevy's zebra (*E. grevyi*) in Kenya, for example, exhibited a birth season constrained to only two weeks, whereas the Grevy's zebra present in the same environmental conditions gave birth over the course of months (Williams 1998). In that system, rainfall was highly stochastic, and thus seasonal forage availability did not exhibit a pronounced peak.

Gestation period is similar among equid species, though environmental inputs can create plasticity (Howell and Rollins 1951). Average gestation length ranges from 327 to 357 days in horses (Howell and Rollins 1951; Card and Hillman 1993; Monfort *et al.* 1994), 321 to 404 days in asses (Grinder *et al.* 2006; Pagan *et al.* 2009; Schook *et al.* 2013), and 364 to 390 days in zebras (Grubb 1981; Penzhorn 1988; Churcher 1993). Gestation period in kiang is the least quantified, with reports ranging from 210 to 365 days (St-Louis and Côté 2009). Given the nearly yearlong gestation across all equid species, we could expect estrus, reproductive behavior, and conception to peak between the spring equinox and the summer solstice, waning thereafter with subsequent parturition occurring roughly at the same time the following year. Where such empirical data were present in the literature, this pattern was evident across equid species, though it is more variable in populations near the equator (fig. 6.2).

While body condition, resource availability, and biological inputs all contribute to conception and birth success, these factors may also influence sex ratio of young born into the population. Female feral horses in poor body condition at the time of conception have been observed producing more female foals (Cameron *et al.* 1999), for example, aligning with the much-debated Trivers-Willard hypothesis, which posits that when populations are experiencing more stress (and thus individuals have decreased body condition), more female offspring will be produced because they can increase fitness more quickly than inputs of male offspring (Trivers and Willard 1973). Sex ratio of foals across all equid species and populations we reviewed is of course quite variable, precisely because of these environmental inputs, but on average we found that the ratio of males to females born did not differ from parity (1.1 males to 1 female; 95% CI = 0.93–1.29:1). The extreme situations were 2.2 males to 1 female in a population of mountain zebra (n = 16 foals; H. Hrabar, unpublished data), and 2.2 males to 1 female in an Asiatic wild ass population that was experiencing a high growth rate (n = 53 foals; Saltz and Rubenstein 1995). In the latter case, it is interesting that while more males were being produced in a density-independent environment

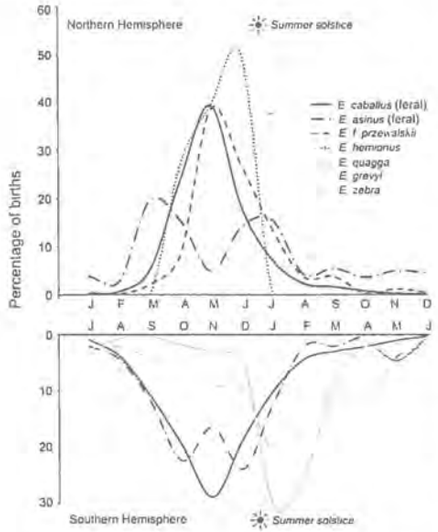

Fig 6.2 Percentage of births by month across equid species. Data are smoothed and shown as the mean across populations. Data for *E. caballus* derived from Tyler 1972, Boyd 1980, Keiper and Houpt 1984, Berger 1986, Berman 1991, Lucas *et al.* 1991, Ashley 2000, Gomes and Oom 2000, Linklater *et al.* 2004, Greyling 2005, Nuñez *et al.* 2010, Scorolli and Lopez Cazorla 2010, Lagos 2013, Ransom *et al.* 2013, and N. Spasskaya, unpublished data; data for *E. asinus* derived from Moehlman 1974, McCool *et al.* 1981, Ruffner and Carothers 1982, and Santiapillai *et al.* 1999; data for *E. f. przewalskii* derived from Chen *et al.* 2008, Prague Zoo 2010 (wild and semiwild populations only), and Usukhjargal and Bandi 2013; data for *E. hemionus* derived from Wolfe 1979 and O. Ganbaatar, unpublished data; data for *E. quagga* derived from Klingel 1965, Smuts 1976*b*, and Sinclair *et al.* 2000, data for *E. grevyi* derived from Dobroruka *et al.* 1987 and Rowen 1992, data for *E. zebra* derived from Joubert 1974*b*, Penzhorn 1985, Westlin-van Aarde *et al.* 1988, and H. Hrabar, unpublished data.

(in concurrence with Cameron and Linklater 2007), the investigators noted that more female foals were being produced by primiparous mothers of age 2 or 3 years as compared to multiparous mothers of age 4 or 5 years. This may reflect an evolutionary disparity in effective maternal investment, but that hypothesis was not specifically tested. The opposite extreme was observed in a resource-stressed population of plains zebra where the sex ratio was 0.27 males to 1 female (n = 19 foals; Hrabar and Kerley 2013) and a feral horse population where the sex ratio of 0.47 males to 1 female was observed (n = 25 foals; Stanley and Shultz 2012).

Survival

Most feral horses, feral asses, and some Przewalski's horses and mountain zebra live in environments without significant predation pressure and exhibit relatively high survival rates across all age classes. Most other wild equid populations are subject to predation from a variety of large predators, and thus experience locally reduced survival rates. Despite this dichotomy of population paradigms, age-specific survival is surprisingly comparable among equid species, with some elevated mortality in foals, relative security in the adult cohort, and then a gradual decrease as senescence prevails (fig. 6.3). The resulting age structure of wild populations is also relatively consistent among species and populations, with foals typically comprising 8–15% of a population, juveniles 13–28% of a population, and adults 71–78% of a population (Berman 1991; Tatin *et al.* 2003; Grange *et al.* 2004; Smith *et al.* 2007). Equids are long-lived animals, and where individuals were followed from birth, known ages for individual wild Przewalski's horses exceeded 25 years old (Prague Zoo 2010) and for feral horses exceeded 29 years old (Ransom 2012). Equids generally live longer in captivity owing to more controlled environmental conditions and applied veterinary care; as such, captive Asiatic wild asses >27 years old have been reported (Volf 2010), as have Przewalski's horses >30 years old (Ballou 1994). Mortalities in wild equid populations arise from a variety of causes. Deaths of adult Przewalski's horses (n = 145) at Hustai National Park, Mongolia, for example, were attributed to blood parasites (2.1%), endoparasites (1.4%), disease (7.6%), stillbirth (9.7%), injury (12.4%), predation (22.1%), starvation (31.1%), and other/unknown reasons (13.8%) (Usukhjargal and Bandi 2013). Nine percent of foal deaths (25 of 278 foals) in the same study were attributed to infanticide by stallions (box 6.1).

Annual foal survival rates reported across the studies we reviewed averaged 0.71 (95% CI = 0.53–0.88), and adult survival rates averaged 0.88 (95% CI = 0.85–0.90) (table 6.1). Much of the variation in annual survival rates of both foals and adults by population may be attributed to localized predation. A large number of predators have been documented killing both young and adult equids, including African lion (*Panthera leo*), leopard (*P. pardus*), cheetah (*Acinonyx jubatus*), and spotted hyena (*Crocuta crocuta*) for feral horses, zebras, and asses in Africa; wolf (*Canis lupus*) and snow leopard (*Uncia uncia*) for Asiatic asses, Przewalski's horses, and kiang in the Middle East and Asia; wolf and brown bear (*Ursus arctos*) for feral horses in Europe; and puma

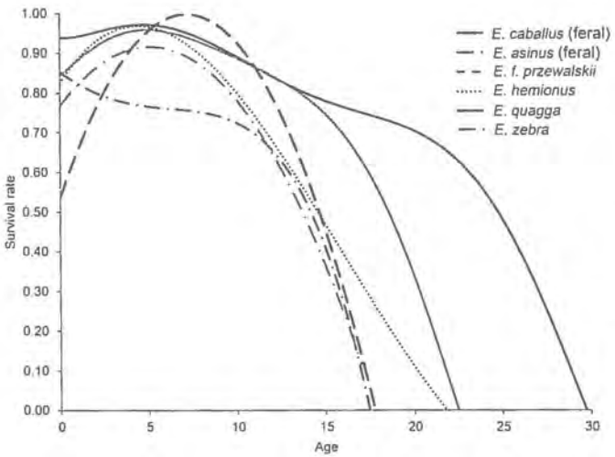

Fig. 6.3 Trend in age-specific survival rates for equid species. Data for *E. caballus* derived from Ransom 2012; data for *E. asinus* derived from McCool *et al.* 1981; data for *E. f. przewalskii* derived from Hustai National Park, unpublished data; data for *E. hemionus* derived from Saltz and Rubenstein 1995 and Lkhagvasuren *et al.* in review; data for *E. quagga* derived from Spinage 1972; data for *E. zebra* derived from Joubert 1974*a*

(*Puma concolor*) and jaguar (*P. onca*) for feral horses and feral asses in the Americas. In one feral horse population in the western United States, foal survival was reported to be only 27%, and 82% of foal carcasses found showed evidence of being killed by puma (Turner *et al.* 1992); however, most feral horse populations coexist with pumas and experience limited depredation. In the Gobi Desert of Mongolia, 23% of wolf scats analyzed contained remains of Asiatic ass (Feh *et al.* 2001), but it is unknown how many of those samples arose from predation as opposed to scavenging.

Analysis of predator diets has provided some evidence of selection for equids, with a wide range of selection to nonselection across species and seasons. Wolves in northwest Spain clearly selected for feral horses (Ivlev index = 0.99–1.00) (Lagos 2013), but a similarly pack-organized canine, African wild dog (*Lycaon pictus*), specifically avoided hunting zebra even when they were relatively abundant (Hayward *et al.* 2006). In Lewa, Kenya, African lions strongly selected Grevy's zebra over plains zebra, even though plains zebra outnumbered Grevy's zebra four to one (Rubenstein 2010). In the Serengeti, Tanzania, 90% of all spotted hyena kills were adult zebra when the available ungulate assemblage was quite diverse (Kruuk 1972). In systems where feral horses and predators most typically coexist, a high percentage of all mortality is attributed to a sole predator as opposed to disease, accident, or other natural causes. Wolves in Peneda-Gerês National Park, Portugal, for example, have been responsible for 89% of horse mortalities, and in nearby Galicia, Spain, that figure rises to 96% (Gomes and Oom 2000; Lagos 2013). In systems with multiple predators or sympatric prey species, the percentage of equid mortality attributed to depredation can be somewhat ameliorated, such as plains zebras in the Serengeti, Tanzania, where 59–74% of all mortality was attributed to African lion and spotted hyena (Schaller 1972), or Przewalski's horses in Hustai National Park, where 13–50% of horse mortalities were attributed to wolves (Van Duyne *et al.* 2009).

At a finer scale, predator species may also select for one sex of prey over the other; thus they may affect prey populations differently at long timescales. Spotted hyenas at Ngorongoro, Tanzania, killed 2.25 female plains zebra for every one male, but lions at Serengeti, Tanzania, killed only 0.83 female plains zebra for every one male (Kruuk 1972). Longitudinal studies indicate that shifts in diet can also occur over time, as in the Serengeti, Tanzania, where 19–20% of spotted hyena diet was composed of plains zebra before the 1970s, but after that time it diminished to <9% (Kruuk 1972). The zebra population remained relatively stable over that time period (Hack *et al.* 2002), but changes in other prey populations or competing predator populations could have contributed to the apparent dietary shift.

Some behavioral traits may also influence survival. Group formation in ungulates has been posited to be a function of open environments where foraging can be optimized because groups of animals are more vigilant for predators than isolated individuals can be (Kie 1999). Equids form groups of various sizes and composition, which may influence predation risk (see chap. 2). Schaller (1972) reported that lions were 13% more successful when plains zebras were alone rather than

BOX 6.1 INFANTICIDE AMONG EQUIDS

Infanticide is not common in equids but has been reported in both captive and wild populations. This unique source of mortality arises when a stallion intentionally kills a foal, an action hypothesized to be a fitness-driven evolutionary behavior (Hrdy 1979). The concept posits that if a novel stallion kills an unrelated foal, then the foal's mother may more quickly return to estrus and be fertilized by the assailant male, thus increasing his fitness faster through reduction of interbirth interval. This concept has been discussed most broadly in the classic case of the African lion (Packer and Pusy 1982), but it has drawn the attention of equine ethologists because of their polyandrous mating systems.

Infanticide among the equids appears to be most prevalent in the harem-forming species and has been reported most frequently in captive conditions where artificial social constructs may elevate frequency (Pluháček *et al.* 2006). In the wild, infanticide has been documented at the highest rates in Przewalski's horses, where 9% (25 of 278 foals born 1993–2011) of all foal mortality in Hustai National Park, Mongolia, was attributed to this phenomenon (Usukhjargal and Bandi 2013). It was also reported in the same species at Kalamaili Ungulate Protected Area, China, where 83.3% of all foal mortalities (7 mortalities out of 24 births) was attributed to infanticide in the 5-year period following reintroduction (Chen *et al.* 2008). Nearly half of those deaths occurred in the first year, lending support to the proximate social stresses presented when novel stallions suddenly become available to social groups.

Infanticide was reported in domestic horses (Duncan 1982) and New Forest ponies (Tyler 1972), and attempted infanticide among feral horses has been documented across populations (Tyler 1972; Berger 1986; Gray 2009). When more than one adult male has been present in a band of feral horses, extraordinary maternal protection has also been reported, potentially minimizing the incidents of infanticide (Cameron *et al.* 2003). While the sample size is limited, there is some evidence that intruding stallions may selectively target male foals (all cases reported by Duncan 1982, with additional cases reported by Berger 1986), which could reflect the potential for reducing future competition from unrelated males, but that hypothesis has never been explicitly tested. Induced abortion has also been documented when novel stallions forcibly copulate with a pregnant female. At the Granite Range, USA, such feticide was reported for 78% of forced copulations by novel feral horse males (Berger 1986).

Harem-forming zebra have also demonstrated infanticide, with three cases being reported in wild mountain zebra (Penzhorn 1975), and multiple cases reported in captive plains zebra (of which several individuals originated from wild populations) (Pluháček *et al.* 2006). In a captive mountain zebra enclosure in Namibia, Joubert (1971) reported an attempted infanticide that failed when the female actively defended her foal, but the stallion then proceeded to kill two sympatric antelope instead. This event illustrates the uncertainties underlying our understanding of mechanisms and motivations related to infanticide (Pluháček *et al.* 2006). It is possible that some cases of infanticide are motivated by a more immediate need: survival. At Hluhluwe Reserve, South Africa, a severely injured plains zebra foal was observed in the center of a band vocalizing continuously and loudly after escaping from a predator attack. All adult members of the band were expressing elevated vigilance behaviors and nervousness, and the band stallion eventually approached and killed the foal with strikes to the head. While the genetic relationship of the stallion and foal was unknown, the silencing of the foal instantly reduced the exposure of the band to local predators (J. Ransom, unpublished data). Infanticide has not been reported for Grevy's zebra, but the territorial organization of this species can result in females not remaining with specific males long enough for the males to benefit from such behavior.

Photo by J. Ransom

in a group. Unlike most equids, where foals closely accompany their dams most or all of the time, Grevy's zebra sometimes leave their foals in aggregated juvenile groups or "kindergartens" (Williams 1998). The source of this behavior may arise from energetic constraints of young, but ultimately it may also place foals at risk of depredation, especially during nocturnal aggregations (Klingel 1974).

Because most equids inhabit arid environments, considerable interannual variance in precipitation and related productivity may also influence survival (Archer *et al.* 1999). One model simulation of zebra populations suggested that survival decreases more rapidly during dry seasons than reproduction increases during wet seasons, which would constrain population growth over time (Georgiadis *et al.* 2003). In contrast, neither wet season nor dry season rainfall at Kruger National Park, South Africa, influenced plains zebra survival in a longitudinal empirical study, though it did affect other ungulates in the system (Owen-Smith *et al.* 2005). Across ungulate species, it appears that interannual variance in precipitation influences juvenile survival more profoundly than it does adult survival (Gaillard *et al.* 1998, 2000). In feral horses, each centimeter of spring rainfall increased foal survival by 1.5%, did not measurably influence survival for animals up to age 19, and then significantly increased survival rates for animals ≥20 years old (Ransom 2012).

Population Growth

Quantifying population dynamics is generally not as simple as adding births and subtracting deaths. Understanding population growth and decline is further complicated by movement into and out of populations, and by catastrophic stochastic events that change rates both instantaneously and longitudinally. In addition to that volume of uncertainty, the size of most wild equid populations is not absolutely known or even estimated robustly (Moehlman 2002). We have reviewed studies where some measure of population growth was reported or could be reasonably derived. To discuss this more clearly, we refer to the theta-logistic model because it accommodates the nonlinear density dependence more indicative of equid populations (Gilpin and Ayala 1973):

$$\frac{dN}{dt} = rN\left(1 - \frac{N}{K}\right)^{\theta}$$

In this model, r is the intrinsic rate of increase, N is the population size, K is the carrying capacity, t is time, and θ is the nonlinear modifying parameter for the ratio of

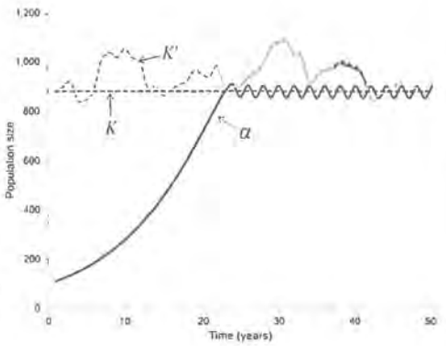

Fig. 6.4 An example of theta-logistic population growth for a simulated equid population over time (black line), where growth rate (r) is fixed and reaches the fixed carrying capacity of K. The same population is simulated with a randomized carrying capacity (K') in gray, illustrating the stochastic effects of resource availability on a single parameter. Point α represents the inflection point where population growth begins to moderate as the population approaches K.

N:K. Conceptually, when $\theta < 1$, r decreases rapidly with population size; likewise, the population will quickly approach K when $\theta > 1$. For equids, this is a steeper curve than the classic logistic sigmoid curve, and the inflection point is much closer to K (fig. 6.4). In this example, a simplified deterministic population trajectory is used to illustrate growth of hypothetical equid population. To add a degree of reality, K is randomized (K') to illustrate how carrying capacity can vary annually with the amount and quality of resources available over time, which in turn can influence the maximum number of individuals that could survive at a given time (fig. 6.4, gray lines). Conceptually, when rapid growth is reported for a population, the theta-logistic model suggests that the population is most likely below α (the inflection point) on the sigmoid curve, and when slow growth is observed, the population might be closer to K at that point in time. Many studies report an instantaneous rate of increase (λ) rather than r. This simply reflects the growth rate of a population from one year to the next as if it had instantly occurred, or $\lambda_t = (N_t / N_{t-1})$ where t represents one year. For synthesis and discussion purposes, we have converted r values from individual studies to λ, using $\lambda = e^r$.

Mean annual population growth (λ) in the studies we reviewed averaged 1.12 (95% CI = 1.04–1.19) across all species (table 6.1). While the reported range of growth rates was similar between species, the average

growth rates for Asiatic wild ass, Grevy's zebra, and plains zebra were notably lower than the other species (1.04, 1.02, and 0.98, respectively). It is unknown whether this finding simply reflects the paucity of data for these species, is an artifact of their different life history strategies, or is indicative of a more complex set of factors. Robust population dynamics metrics for African wild ass and kiang are completely missing from the literature, illustrating critical science needs for better understanding equid ecology.

Some variability in population growth rates over time and between studies and species may be explained by the relationship between abundance and resources. Equids are generally well equipped to persist near K because their longevity and high survival rates, low recruitment rates, and low sensitivity to moderate environmental stressors result in relatively durable populations, barring catastrophic mortality events (Saltz 2002). When mass mortality events occur, equids are quite slow to recover because of their inherently low recruitment rates, but at the longitudinal scale, this is when equids should be most productive. For example, a small, reintroduced Asiatic wild ass (onager) population exhibited its maximum growth rate as abundance expanded to the resources available (Saltz and Rubenstein 1995). In feral horses, heavily managed populations that have persisted near K but then experience a large culling event can be suddenly reduced far below α, prompting a compensatory response in increased growth rate (Choquenot 1990; National Research Council 2013).

Focused predation can impart nonrandom influence on population growth, such as at Pryor Mountain, USA, where predation from specific pumas was increasingly limiting the horse population from 1993 to 2004 to a nadir of $\lambda = 0.97$ before the pumas were killed and the predation pressure was dramatically released (Ransom 2012). In a plains zebra population in South Africa, models of population growth including lion predation were far more supported than models of climate factors, though population growth of only one of the two populations was affected by number of lions present (Grange *et al.* 2012). While food, water, and predation have been widely investigated as agents of population constraint, behavior has also been posited to limit equid populations by reduced fecundity arising from social stress (Linklater 2000; Tatin *et al.* 2009).

Perhaps the most unpredictable natural influence on population growth of equids also carries the greatest magnitude of effect: catastrophic climate events such as extreme drought and storms. Such events can have lasting influence on population dynamics and in some cases can threaten extirpation of populations. The dzud winter (extreme cold with heavy snow) of 2009/2010 in the Mongolian Gobi, for example, suddenly reduced the Przewalski's horse population by 60% in a single season (Kaczensky *et al.* 2011). The population effect from direct mortality was compounded by a severe reduction in per capita births the following year, with only one female foaling. Though not well quantified, the extirpation of Asiatic wild asses from Kazakhstan at the end of the nineteenth century was documented following a similar dzud winter, though hunting by humans and competition with their livestock certainly contributed to the decline (Zhirnov and Ilyinsky 1986). Winter mass mortalities of feral horses in the American West have been documented with a 51% decline in a single winter at Pryor Mountain (Garrott and Taylor 1990) and 12% in a winter at the Granite Range (Berger 1983). The latter study indicated that severe snowstorm mortality might be more common than assumed and also referenced an earlier unpublished event in the Granite Range when 300 horses died (roughly 50% of the population).

Despite the extraordinary capacity of equids to persist in harsh arid environments, drought can still promulgate catastrophe. One severe mass mortality event related to drought was reported for plains zebra at the Tuli Game Reserve in southern Africa in 1983, where 199 carcasses and only 58 live zebra were detected following two years of drought (Walker *et al.* 1987). Hundreds of mountain zebra were reported dead in the Namibian Khomas Hochland during the 1968/1969 drought, with mortalities attributed to starvation, entrapment in mud at waterholes, and behavioral disorientation leading to increased human depredation (Joubert 1971). Large-scale drought-related mortalities are relatively common in the Australian outback, where tens of thousands of feral horses perish during extended drought. Similar events are generally precluded in the United States only by artificial water supplementation.

Severe thunderstorms have also had population-level effects on small equid populations. For example, a thunderstorm overtook Tornquist Provincial Park in Argentina, killing 193 feral horses in 48 hours (28% of the population) (Scorolli *et al.* 2006). Likewise, electrical storms at the high-altitude area of Pryor Mountain have produced fatal lightning strikes to individuals and entire feral horse bands, with an event in 1999 killing 4% of the population with a single lightning strike (US Bureau of Land Management, unpublished data).

Little has been quantified regarding movement of individuals into and out of equid populations in the

context of population growth rate. But one only need consider the migrant case of the plains zebra to understand the ramifications of how migration can quickly influence access to resources and changes in body condition that may influence birth rates, or how such migrations attract predators that might influence survival rates (Naidoo *et al.* 2014). Localized movements of plains zebra in Kruger National Park, South Africa, required travel of 10–15 km every 1–2 days during the dry season for individuals to drink, thus reducing time available for foraging and resting (Cain *et al.* 2012). Feral horses in central Australia also traveled up to 15 km during drought in order to access water, and one population declined 51% in density during a severe drought; it is unknown how many of those animals died as opposed to emigrated from the area (Berman 1991). In a similar xeric environment, feral asses of Death Valley became more prevalent within 1.6 km of a water source in summer (Moehlman 1974). Anthropogenic disturbance at water holes has been implicated in movement of Grevy's zebra, with the energetic costs arising from long-distance movement to and from water being reflected in reduced foal survival (Williams 1998). Whether any of these traveling individuals truly moved from one population to another, affecting population demography, is unknown, but the catalysts for such movement clearly provide an opportunity for immigration and emigration, which ultimately can influence both population dynamics and genetic flow.

Conclusion

The wild and feral equid populations of the world share many common features, and they function similarly for a variety of reasons. Equids can be quite long-lived ungulates and demonstrate relatively low fecundity, meaning that, in the absence of extreme stressors, their populations should be rather stable over time. Unfortunately, this is seldom realized in a changing world where anthropogenic influence permeates nearly all populations (see chap. 12) and climate events can impart severe catastrophes. Recovering from such population decimations requires long timescales for equids. Ultimately, most wild equids persist in a state where extensive conservation measures are needed to prevent extirpation and most feral equids persist at the other end of the curve, where extensive management is necessary to mitigate resource damage.

We aimed in this synthesis to gain a better understanding of equid ecology and what naturally shapes their populations, but such findings are not functionally separate from the effects that humans have on these populations. Direct killing, encroachment, and resource competition remain the largest threats to wild equids and profoundly influence the dynamics of most populations. The scale of human impacts thus confounds attempts to understand the natural influences on these species. What we can conclude, however, is that precipitation and phenological rhythms can strongly influence births, whereas survival is more strongly influenced by predation and mass catastrophe. Equids also exhibit complex social behavior that may drive population dynamics in ways we simply have not quantified or fully understand (see chap. 3). Such uncertainties in both the changing environment and our shortfalls in understanding the depth of equid societies demand forward thinking conservation and careful management for a group of species that nearly all persist on the world's threatened and endangered list.

ACKNOWLEDGMENTS

The authors wish to thank the peer reviewers, who provided helpful and constructive comments that ultimately improved this synthesis. Special thanks are owed to the many colleagues that shared unpublished data and responded promptly to the authors' queries, all toward an open effort to better understand equids.

Wildlife contraception

ABSTRACT

Managers concerned with shrinking habitats and limited resources for wildlife seek effective tools for limiting population growth in some species. Fertility control is one such tool, yet little is known about its impacts on the behavioral ecology of wild, free-roaming animals. We investigated influences of the immunocontraceptive porcine zona pellucida (PZP) on individual and social behavior in bands of feral horses (*Equus caballus*) in three discrete populations and used 14 hierarchical mixed effect models to gain insight into the influences of PZP treatment on feral horse behavior. A model of body condition was the strongest predictor of feeding, resting, maintenance, and social behaviors, with treated females allocating their time similarly to control females. Time spent feeding declined 11.4% from low condition to high condition females ($F_{1,154} = 26.427$, $P < 0.001$) and was partially reciprocated by a 6.0% increase in resting ($F_{1,154} = 7.629$, $P = 0.006$), 0.9% increase in maintenance ($F_{1,154} = 7.028$, $P = 0.009$), and 1.8% increase in social behavior ($F_{1,154} = 15.064$, $P < 0.001$). There was no difference detected in body condition of treated versus control females ($F_{1,154} = 0.033$, $P = 0.856$), but females with a dependent foal had lower body condition than those without a foal ($F_{1,154} = 4.512$, $P = 0.038$). Herding behavior was best explained by a model of treatment and the interaction of band fidelity and foal presence (AIC_c weight = 0.660) which estimated no difference in rate of herding behavior directed toward control versus treated females ($F_{1,102} = 0.196$, $P = 0.659$), but resident females without a dependent foal were herded 50.9% more than resident females with a foal ($F_{3,102} = 8.269$, $P < 0.001$). Treated females received 54.5% more reproductive behaviors from stallions than control mares ($F_{1,105} = 5.155$, $P = 0.025$), with the model containing only treatment being the most-supported (AIC_c weight = 0.530). Treated and control females received harem-tending behaviors from stallions equally ($F_{1,105} = 0.001$, $P = 0.969$) and agonistic behaviors from stallions equally ($F_{1,105} < 0.001$, $P = 0.986$). Direct effects of PZP treatment on the behavior of feral horses appear to be limited primarily to reproductive behaviors and most other differences detected were attributed to the effects of body condition, band fidelity, or foal presence. PZP is a promising alternative to traditional hormone-based contraceptives and appears to contribute few short-term behavioral modifications in feral horses.

1. Introduction

The size and distribution of human populations has rapidly increased over the last several decades, leading to shrinking habitats and limited resources for many large vertebrates around the world. Managers seek effective tools for limiting population growth in some of these species. Attempts to regulate populations have historically emphasized controlling survival, but more recently, fertility control has emerged as an alternative to lethal methods of population control (Hobbs et al., 2000; Porton,

2005). Little is known about impacts of fertility control on the behavioral ecology of wild, free-roaming animals; yet, understanding animal behavior can be an important tool in addressing a species' influences and roles in an ecosystem and can lead to better management and conservation practices (Sutherland, 1998; Buchholz, 2007). The ethical considerations of potentially altering animal behavior and social structure through the use of fertility control agents on free-roaming wildlife are also a growing concern among managers and the public, as are concerns for animal welfare, such as potential negative physiological reactions to treatment (Nettles, 1997; Asa et al., 2005; Porton, 2005).

Large populations of ungulates (white-tailed deer (*Odocoileus virginianus*), elk (*Cervus canadensis*), and feral horses (*Equus caballus*)) are targeted for fertility control management in the United States. Feral horses exhibit the Type I mating system found in the family Equidae, which is characterized by family groups (bands) typically consisting of a polygynous male with females and their young (Klingel, 1975). Such social groups are largely maintained by a suite of behaviors consisting of reproductive, herding, agonistic, and defensive expressions initiated by the polygynous male in the band, as well as hierarchical dominance relationships among females (Feist and McCullough, 1976; McCort, 1984; Klimov, 1988; Pickeral et al., 1993; Linklater et al., 1999). With such complex social organization, artificial changes to behavior may have far-reaching implications for the treated individual and other members of the family group, as well as the social dynamics of the entire herd. An ideal fertility control agent for free-roaming populations of such animals would have little influence on behavior. The immunocontraceptive porcine zona pellucida (PZP) has been proposed as such an agent.

PZP acts as a vaccine against pregnancy by stimulating the production of zona pellucida antibodies in female mammals (Sacco, 1977; Liu et al., 1989). These antibodies provide a barrier that prevents sperm from binding to the surface of an ovum and results in limited penetration of the zona pellucida and subsequent limited pregnancy in many taxa (Kirkpatrick and Turner, 1991; Kirkpatrick et al., 1996). PZP treatment has been shown to reduce fertility in horses with only 0–19% of treated mares producing foals (Liu et al., 1989; Kirkpatrick et al., 1996). Unlike most conventional contraceptives, this immunocontraceptive does not appear to affect ovarian function of the inoculated female horse when used for up to 3 years; however, additional treatments have been reported to decrease ovarian function (Kirkpatrick et al., 1995). Some additional potential side-effects of PZP treatment have also been investigated in feral horses: formerly treated mares have successfully returned to fertility (Kirkpatrick and Turner, 2002) and injection site reactions were minimal and non-debilitating (Roelle and Ransom, 2009). It remains unclear how PZP treatment influences the behavior of feral, free-roaming horses.

Many wild ungulate species have complex mating systems maintained by dominance hierarchies within family groups, active recruitment and defensive behaviors by polygynous males, and resource driven behavioral patterns. PZP treatment is not expected to have a direct effect on these behaviors in horses because ovarian function remains intact and artificial hormones are not administered. However, horses are polyestrous and females may exhibit estrous behavior during both ovulatory and anovulatory phases of ovarian follicular development, which is thought to facilitate social structure (Crowell-Davis, 2007). PZP treatment of females has the potential to elevate the exhibition of repetitive estrous behavior beyond that which stallions are accustomed to. We hypothesize that such polyestrous cycling in individual mares may elicit excess reproductive behaviors by both the cycling female and nearby males, prompt more frequent herding and harem-tending behaviors by stallions, and elevate frequency of agonism between stallions and females. We also posit that if individuals allocate more time to reproductive and social behaviors, less time is available for critical feeding and maintenance behaviors and could present long-term concerns for animal health.

Current research on this topic has been limited to a few island populations where time budgets of PZP-treated females were found to be comparable to control females (Powell, 1999; Rogers, 2001); however, it has recently been shown that band fidelity can decrease and rates of reproductive behavior can increase in association with PZP treatment (Nuñez et al., 2009). These results are somewhat conflicting and present concern that animals in disparate populations may exhibit different behavioral responses to PZP treatment, possibly due to percent of females treated, population size, or density. Approximately 37,000 feral horses roam on 13 million ha of public lands in the western United States and represent the vast majority of feral horses in the US. We investigated influences of PZP immunocontraception on the behavior of feral horses in three discrete free-roaming western populations over a 4-year period. Our objective was to quantify effects of immunocontraception on time budgets of individuals and social interactions within family groups, differentiating between control females and effectively contracepted females.

2. Methods

2.1. Study areas

Three study areas, Little Book Cliffs Wild Horse Range, McCullough Peaks Herd Management Area, and Pryor Mountain Wild Horse Range were chosen to represent the wide variety of habitats occupied by feral horses in the western United States. These populations use a mosaic of habitats, including desert, sage steppe, piñon-juniper woodland, coniferous forest, and montane environments (Table 1). A small number of unimproved roads traversed these areas, but the majority of land at all three locations was designated as Wilderness Study Area and closed to motorized vehicles throughout the period of this study.

Little Book Cliffs managers removed 68 horses from the population in 2004 and Pryor Mountain managers removed seven horses in 2003 and 19 horses in 2006, but none of these animals were members of the focal bands

Table 1
Geographic, biologic, climatic, and population data for conditions present during behavioral observations of feral horses (*Equus caballus*) at Little Book Cliffs Wild Horse Range (LBC), McCullough Peaks Herd Management Area (MCP), and Pryor Mountain Wild Horse Range (PRY), USA, April–October, 2003–2006. The number of treated females comprises all individuals vaccinated with the immunocontraceptive porcine zona pellucida (PZP).

Study area	Location	Elevation (m)	Size (ha)	Terrain	Dominant vegetation	Precipitation (% of obs.)	Temperature (mean (°C) ± SE)	No. of treated females	Population size	Band size (mean ± SE)
LBC	39°12′N; 108°27′W	1500–2250	14,614	Sloping plateaus, sagebrush parks, steep shale and sandstone cliffs, 4 major canyon systems	Sagebrush (*Artemisia tridentata*), grasses, Colorado piñon (*Pinus edulis*), Utah juniper (*Juniperus osteosperma*)	4.88	25.12 ± 1.32	27	120–204	4.45 ± 0.16, range = 2–9
MCP	44°35′N; 108°40′W	1200–1964	44,440	Flat, open sagebrush park, rugged badlands along western edge	Sagebrush, grasses, small stands of cottonwood (*Populus* sp.) and willow (*Salix* spp.)	3.78	26.62 ± 1.80	36	112–495	8.01 ± 0.38, range = 2–19
PRY	45°04′N; 108°19′W	1175–2670	16,046	Lowland desert, foothill slopes, forested montane slopes, steep canyons, grassy plateaus	Sagebrush (*A. tridentata*), grasses, Utah juniper, Douglas fir (*Pseudotsuga menziesii*) and limber pine (*Pinus lexilus*)	5.25	20.63 ± 1.17	54	142–168	4.16 ± 0.17, range = 2–11

used in our study. Managers removed 379 animals from the McCullough Peaks population in October 2004. Due to management need, 1-year-old females, and 1- and 2-year-old males were removed from the focal bands used in this study, but all reproductive animals in these bands were captured and released as intact family units. Hansen and Mosley (2000) reported no changes in feeding or reproductive behavior and no effect on fecundity following such removals.

2.2. Study subjects

Horses in the treatment group at all three study areas were given primer injections consisting of 0.5 mL (100 μg) PZP and 0.5 mL (100 μg) Freund's complete adjuvant or Freund's modified adjuvant. Subsequent booster injections at Little Book Cliffs and Pryor Mountain consisted of 0.5 mL (100 μg) PZP and 0.5 mL (100 μg) Freund's incomplete adjuvant. These injections of liquid PZP were designed to provide approximately 1 year of infertility, with annual boosters extending the period of contraception. In addition to the primer dose given to horses at McCullough Peaks, a second (simultaneous) injection delivered booster doses via three time-release PZP pellets (bolus release at 1, 2, and 12 months) designed to provide 2 years of infertility (Turner et al., 2008). A full description of these procedures is described in Roelle and Ransom (2009).

Most female horses were pregnant at the time of their first injection of PZP and some did not exhibit infertility after receiving treatment; therefore, to clarify behaviors associated with effective fertility control, all analyses considered animals to be in the treatment group only when they had received at least the primer and one booster dose, and exhibited non-pregnancy. Three females that received PZP but continued to produce young were omitted from analyses. Observations of treated animals that occurred after prescribed treatment had concluded were omitted from analyses because post-treatment PZP titer levels could not be verified; it was thus unknown if contraception persisted or return to fertility had occurred. Animals in the control group were not injected with PZP and exhibited pregnancy as it naturally occurred.

During the course of this study, 27 horses were treated at Little Book Cliffs, 36 were treated at McCullough Peaks, and 54 were treated at Pryor Mountain, with the number of treatments received by any individual horse varying from 1 to 4. The percentage of treated females >1 year of age in each population therefore varied by year, but averaged 36.0% at Little Book Cliffs, 80.6% at McCullough Peaks, and 25.7% at Pryor Mountain. All focal animals at each site were monitored by trained technicians one to five times per week from April to October each year, 2003–2006. Pregnancy and parturition were primarily determined by visual assessment, with supplemental pregnancy data opportunistically gained through fecal assays of estrone conjugates and progesterone metabolites (Kirkpatrick et al., 1991) or blood estrone sulfate/progesterone analyses (Munro and Stabenfeldt, 1984; Stabenfeldt et al., 1991). All data for this study were collected in accordance with the Colorado State University Animal Care and Use Committee standards (protocol 03-107A-02).

2.3. Behavioral sampling

Eight to ten feral horse bands were chosen in each of the three populations from a stratified random sample consisting of bands with at least one stallion, one treated mare and one control mare, though natural interchange dictated that band compositions were plastic throughout the study. Behavioral observations were separated into three daylight time periods: 08:00–12:00 h, 12:01–16:00 h, and 16:01–20:00 h. We collected behavioral data for 3133 horse hours (total band observation hours times the number of focal animals in each band) at Little Book Cliffs, 4221 horse hours at McCullough Peaks, and 2592 horse hours at Pryor Mountain. Each observation session included collection of climatic (temperature, precipitation, cloud cover, wind speed), geographic (UTM coordinates and elevation), and temporal (time and date) data, a 20-min instantaneous scan sample of time budgets (Altmann, 1974) at 1 min intervals for each band member, and all-occurrence data collection for social interactions (Altmann, 1974).

In order to accurately record behaviors, we defined an ethogram that categorized specific behaviors into a suite of 15 discrete time budget categories (*see* Ransom and Cade, 2009). These categories were agonism, comfort, elimination, feeding, grooming, harem-social (e.g., allogrooming, pair-bonding), harem-tending (e.g., stallion defense of a harem mare or recruitment of a new mare into the harem), herding (driving or snaking behavior by the stallion), interaction-with-humans, locomotion, out-of-sight, reproduction, resting, standing attentive, and submission. The relative infrequency and similar nature of several behaviors in the instantaneous scan samples motivated us to aggregate them into broader categories for time budget analyses. Grooming, comfort, standing attentive, and elimination were combined into *maintenance*; reproductive, harem-tending, harem-social, agonism, submission, and herding were combined into *social*; and interaction-with-humans and out-of-sight were combined into *unknown*. The time spent in the category *unknown* ultimately did not differ between treatment groups in any population.

Instantaneous scan sampling has the potential to underestimate rare events (Houpt, 1991; Doran, 1992); thus, we also collected social behavior data at every occurrence throughout each observation session. These all-occurrence behaviors included intraband social behaviors associated with herding, reproduction, agonism, and harem-tending and were retained as discrete categories for social behavior analyses. We conducted all observations from distances that did not elicit attention of horses to the presence of the observer. McCullough Peaks horses were relatively reactive to the presence of humans and observations were generally conducted approximately 100 m away unless terrain allowed an observer to remain concealed at a closer distance. Horses at Little Book Cliffs and Pryor Mountain were less reactive to human presence and observations were conducted at approximately 50 m or more. All observations utilized 10 mm × 50 mm binoculars or a 16–45 mm × 60 mm spotting scope in situations where unaided observations were not adequate.

2.4. Model covariates

We initially considered age, climate, time of day, band fidelity, presence of dependent young, size of the band, body condition score, and experience of the dominant male within a band as factors that might help explain variation in horse behavior beyond the effects of treatment. We also considered sampling year in the event that behaviors varied temporally due to an effect we did not otherwise explicitly include in our analyses. Age was absolutely known from parturition records for 88.4% of all individuals at Pryor Mountain, 42.1% of all individuals at Little Book Cliffs, and 34.2% of all individuals at McCullough Peaks. An experienced veterinarian estimated ages for the remainder of animals in this study using dental assessments during scheduled management captures. This method provides only approximate age due to the many external factors effecting tooth wear (Martin, 2002).

Climatic data (temperature, cloud cover, wind speed, and precipitation) was relatively homogeneous across locations and observations so we did not further consider climate in behavior analyses. Behavioral observations were distributed equally across daylight time periods so we did not further consider time of day. The total number of all horses present in the band at the time of the observation constituted the band size. Band composition data collected every 7 days, from April to October of each year, determined band fidelity: females were considered transient if they left their band and went to another band at least once during the season and resident if they never left during the season. Presence of young was recorded as a dependent foal from birth to the end of that sampling season or documented death that season. Body condition of individuals was determined using a 10-step index similar to the system of Henneke et al. (1983); however, since these scores were assigned solely by visual assessment (rather than palpation) in the field, the scale was adapted to a 0.0–5.0 score with half-step intervals similar to that described by Rudman and Keiper (1991). This scale facilitated more consistent estimation of body condition in the field. Tenure of males as band stallions in this study was unknown, so we assumed age was a reasonable indicator of band stallion experience. Age range of the observed band stallions was 4–26 years, with mean age = 11.88 (95% CI: 10.43–13.33).

2.5. Statistical analyses

Some horses were born into focal bands, died, or immigrated/emigrated to/from focal bands during the study; therefore, some horses were observed repeatedly over the course 4 years while others were only observed in a single year. As a result, samples were not equally distributed across individuals or across years. Repeated measures of individuals were accounted for by averaging data for each individual or unique pair of individuals per year and including the influence of individual identification on the random effect intercept of each model. This design allowed analyses to include a measure of variability among individuals as well as among years. Observations of individual horses were not averaged over the entire 4-year

period because potentially important variables such as age, band fidelity, presence of a dependent foal, and treatment status often varied annually. Five extreme outlier values were detected in the residual values for time budget behaviors and these observations were omitted from analyses. The final dataset considered in all analyses consisted of 184 control female and 103 treated female observations that were comprised of 99 individual control horses (32 at Little Book Cliffs, 34 at McCullough Peaks, 33 at Pryor Mountain) and 56 individual treated horses (18 at Little Book Cliffs, 16 at McCullough Peaks, 22 at Pryor Mountain).

We formulated a candidate set of 14 hierarchical mixed effects models, which, in the notation of Gelman and Hill (2007), took the form of $y_{hjk[i]} = \alpha_{0hj[i]} + \alpha_{1hk[i]} + \beta_0 + \beta_x x_{[i]} + \varepsilon_{hjk[i]}$, where the random effect intercept of $\alpha_{0hj[i]} \sim N(\mu = 0, \sigma^2_{hj})$ for treatment h (treated or control) in population j (Little Book Cliffs, McCullough Peaks, or Pryor Mountain), for $i = 1, \ldots, n$ observations, and the random effect intercept $\alpha_{1hk[i]} \sim N(\mu = 0, \sigma^2_{hk})$ for h in $k = 1, \ldots, n$ individual horses for i observations. This equation identifies the fixed effect intercept as β_0, with ε = statistical error, and y = dependent variable. The candidate model set included models with the fixed effect parameter (β_x) for fixed effects (x) of age (model 1), treatment (model 2), body condition (model 3), foal presence (model 4), band fidelity (model 5), band size (model 6), sampling year (model 7), and the interactions of treatment and band fidelity (model 8), treatment and body condition (model 9), band fidelity and body condition (model 10), band fidelity and foal presence × treatment (model 11), age and treatment (model 12). Social behavior involved pairs of animals, and the fixed effect of stallion age (model 13) and average distance between the stallion and focal mare (model 14) were also considered for those analyses.

Analyses of individual time budget behaviors and social behavior data were performed using the Hierarchical Linear Mixed Model function of SYSTAT 12® (SYSTAT Software Inc., 2007) with estimates obtained by restricted maximum likelihood (Harville, 1977). We also analyzed body condition as a dependent variable using the candidate model set, excluding Models 3, 9, and 10 because they contained body condition as an independent variable. Probabilities for all tests are reported with a 95% level of confidence.

We used minimum corrected Akaike's Information Criteria (AIC_c) to evaluate the strength of evidence for all mixed models (Burnham and Anderson, 2002). Models achieving the greatest AIC_c weight were considered the best model for the predicted behavior, and all models exhibiting a ΔAIC_c of <2 were considered plausible (Burnham and Anderson, 2002). Time budget behaviors were modeled individually to investigate the influences of fixed effects on each behavior; however, the strength of evidence for each model was ultimately evaluated based on the composition of all behaviors in the time budget (feeding, resting, locomotion, maintenance, and social). This was performed by summing the minimum AIC_c scores from each individually modeled constituent behavior and using the aggregate AIC_c score ($aAIC_c$) as strength of evidence for the overall composition (Ransom and Cade, 2009). This procedure allowed detailed analyses of the individual behaviors without violation of the inherent compositional dependence. Time budgets were analyzed as mean percent of time allocated to each behavior in the composition, per horse, per year and social behavior models were evaluated individually because the data represent frequency-of-occurrence.

3. Results

3.1. Time budgets

Feeding behavior for all horses occupied the largest percent of daylight time budgets and there was no difference detected between treatment groups, with control females feeding an estimated 57.7% ± 3.2 SE of daylight hours and treated females feeding an estimated 55.0% ± 3.3 SE of daylight hours ($F_{1,154} = 0.351$, $P = 0.554$). The most-supported model for feeding behavior was Model 3 (body condition) with an AIC_c weight of 0.947, and no other models were considered plausible. This model estimated an 11.4% decrease in time spent feeding as body condition score increased from 1.0 to 4.0 (Fig. 1, Table 2).

Resting behavior occupied an estimated 27.1% ± 2.0 SE of control female daylight time budgets and 27.9% ± 2.2 SE of treated female daylight time budgets ($F_{1,154} = 0.075$, $P = 0.785$). Models 3 (body condition) and 4 (foal presence) were both plausible for explaining resting behavior, with Model 3 carrying an AIC_c weight of 0.705 and Model 4 an AIC_c weight of 0.209. Body condition in model 3 estimated an increase of 6.0% in time spent resting as body condition increased from 1.0 to 4.0, which partially compensated for the negative trend detected in feeding behavior (Table 2). Model 4 estimated that foal presence best explained resting behavior with independent females resting an average of 29.3% ± 1.6 SE of the time and females with a dependent foal resting 12.9% less ($\bar{x} = 25.5\% \pm 1.6$ SE).

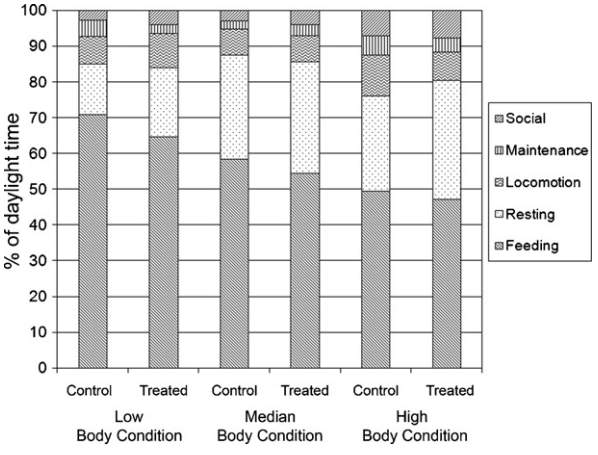

Fig. 1. Mean allocations of daylight time budget behaviors as a function of low (<2.5), median (3.0) and high (>3.5) body condition scores for repeated observations of 99 control female and 56 treated female feral horses (*Equus caballus*) at Little Book Cliffs Wild Horse Range, McCullough Peaks Herd Management Area, and Pryor Mountain Wild Horse Range, USA, 2003–2006.

Table 2
Hierarchical linear mixed model estimates of the difference in means for each fixed effect in the most-supported models of daylight time budget behaviors (feeding, resting, locomotion, maintenance, social) and all-occurrence social behaviors (reproductive, herding, harem-tending, agonism) for repeated observations of 99 control and 56 treated feral horses (*Equus caballus*) at Little Book Cliffs Wild Horse Range, McCullough Peaks Herd Management Area, and Pryor Mountain Wild Horse Range, USA, 2003–2006. Random effect variance is denoted as σ_p^2 for the horse population and σ_i^2 for the individual horse.

[a] This variable produces a vector of interaction estimates, as described in the text.

Locomotion occupied a relatively small amount of female daylight time budgets, and while model 2 (treatment) best explained this behavior (AIC_c weight = 0.461), it estimated no difference between treatment groups (Table 2). Control females in this model were in locomotion an estimated 6.6% ± 1.6 SE of the time and treated females were in locomotion an estimated 6.4% ± 1.6 SE of the time. Model 4 (foal presence) was also plausible for explaining locomotion behavior and was supported by 25.0% of the AIC_c weight. The effect of foal presence was weak and the model estimated females with a dependent foal were in locomotion an average of 6.2% ± 1.1 SE of the time and independent females were in locomotion an average of 6.8% ± 1.1 SE of the time (Table 2).

Maintenance behavior was expressed by control females an estimated 1.7% ± 0.8 SE of the time and by treated females an estimated of 2.4% ± 0.8 SE of the time ($F_{1,154} = 0.420$, $P = 0.518$). This behavior was best explained by Model 3 (body condition) and while the effect was significant, the amount of time spent in expression of maintenance behavior only increased 0.8% as body condition increased from 1.0 to 4.0 (Table 2). Likewise, social behavior was also best explained by Model 3 (body condition) and this behavior increased 1.8% as body condition score increased from 1.0 to 4.0. No other models were supported for maintenance or social behaviors.

Body condition was clearly the most-supported effect for explaining daylight time budget behaviors, with an $aAIC_c$ weight of 0.996 among the candidate models. Body condition scores of the animals observed ranged from 1.0 to 4.0 with a median score of 3.0. Model 2 (treatment) and Model 4 (foal presence) were the most plausible models for predicting body condition, with AIC_c weights of 0.390 and 0.285, respectively. There was no difference detected in body condition of control females ($\bar{x} = 2.99 \pm 0.08$ SE) compared to treated females ($\bar{x} = 2.97 \pm 0.08$ SE) ($F_{1,154} = 0.033$, $P = 0.856$) in Model 2; however, females with dependent foals in Model 4 exhibited lower body condition ($\bar{x} = 2.91 \pm 0.04$ SE) than females without dependent foals ($\bar{x} = 3.02 \pm 0.03$ SE) ($F_{1,154} = 4.512$, $P = 0.038$). The estimated decrease in time feeding was compensated by an increase in resting, maintenance, and social behavior as body condition increased (Fig. 1); however, body condition data exhibited considerable variation suggesting that other factors we did not measure may also influence time budget behaviors.

3.2. Herding behavior

Herding was the most commonly observed intraband social behavior at all three sites. Stallions were observed herding females at Little Book Cliffs at a mean rate of 0.20 (95% CI: 0.16–0.25) times per hour (tph), McCullough Peaks 0.17 (95% CI: 0.13–0.22) tph, and Pryor Mountain 0.68 (95% CI: 0.52–0.85) tph. Band fidelity contributed strongly to the models of herding behavior and models containing this variable totaled 79.7% of the AIC_c weight. The most-supported model for herding behavior was Model 11 (treatment + the interaction of band fidelity and foal presence), and it attained an AIC_c weight of 0.660 with no other candidate models being plausible.

The effect of treatment in Model 11 was not significant and was accompanied by considerable variation, but the interaction effect of band fidelity and foal presence was strong (Table 2). Resident females without a foal were herded by stallions 0.57 tph ± 0.15 SE whereas resident females with a dependent foal were herded by stallions 50.9% less at an average of 0.29 tph ± 0.15 SE. Transient females without foals were herded by stallions least often, at an average of 0.18 tph ± 0.15 SE, and transient females with a dependent foal were herded similarly to resident females with a foal at an average of 0.27 tph ± 0.16 SE.

3.3. Reproductive behavior

Reproductive behavior was the second most frequently observed intraband social behavior at all three sites. Little Book Cliffs stallions were observed exhibiting reproductive

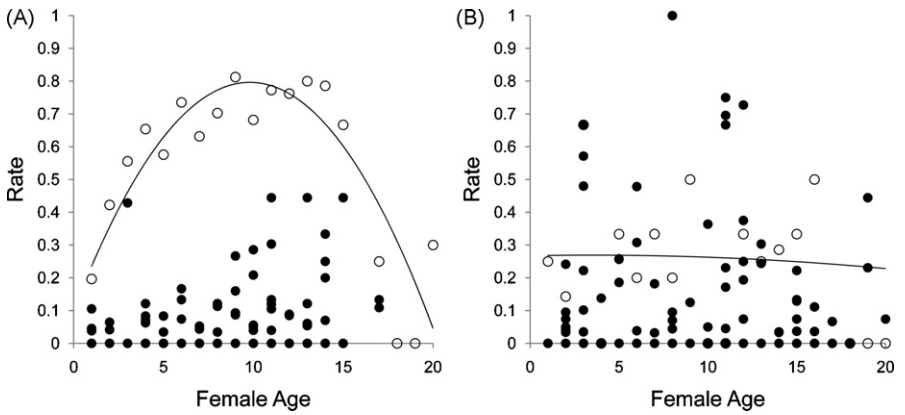

Fig. 2. Rate of feral horse (*Equus caballus*) reproductive behaviors exhibited per hour (●) as a function of female age, and mean rate of viable foal production (○) as a function of female age at conception, for repeated observations of 99 control females (A: $y = -0.007x^2 + 0.142x + 0.101$, $R^2 = 0.89$) and 56 treated females (B: $y = -0.0002x^2 + 0.001x + 0.267$, $R^2 = 0.002$) at Little Book Cliffs Wild Horse Range, McCullough Peaks Herd Management Area, and Pryor Mountain Wild Horse Range, USA, 2003–2006.

behavior toward females at a mean rate of 0.05 (95% CI: 0.02–0.09) tph, with McCullough Peaks stallions exhibiting the same rate of 0.05 (95% CI: 0.03–0.08) tph. Pryor Mountain stallions exhibited this behavior toward females at the rate of 0.10 (95% CI: 0.07–0.13) tph. Copulation (successful and unsuccessful) comprised 34.2% of the reproductive behaviors observed and pre-copulatory behaviors such as reproductive tending, flank-rubbing, chin-resting, flehmen response, and penis extension comprised 65.8% of the observations. The most-supported model for reproductive behavior was Model 2 (treatment), with an AIC_c weight of 0.530, and no other candidate models were plausible.

The effect of treatment was highly significant with control females receiving an average of 0.05 ± 0.02 SE reproductive behaviors from stallions per hour and treated females receiving 54.5% more reproductive behaviors at an average of 0.11 ± 0.02 tph (Table 2). The rate of reproductive behavior expressed toward females generally followed the relationship between viable foal production and age of the female at the time of conception (Fig. 2A), but this relationship deteriorated in the treatment group and the rate of reproductive behaviors expressed was both higher than control females and exhibited no clear pattern among age cohorts (Fig. 2B).

3.4. Harem-tending behavior

Harem-tending behavior was observed with greater frequency at Pryor Mountain than at the other two sites, but was still relatively infrequent in all populations. Stallions exhibited harem-tending behavior toward females at Pryor Mountain 0.17 (95% CI: 0.12–0.22) tph, whereas this was observed at Little Book Cliffs only 0.04 (95% CI: 0.03–0.05) tph and at McCullough Peaks only 0.02 (95% CI: 0.01–0.03) tph. Model selection among harem-tending models revealed body condition as an important effect, with Model 3 attaining 93.0% of the AIC_c weight. Harem-tending behaviors by stallions toward females increased 14.1% as body condition increased from 1.0 to 4.0 (Table 2). There was no difference detected in harem-tending behaviors by stallions toward control females ($\bar{x} = 0.08$ tph ± 0.04 SE) as compared to treated females ($\bar{x} = 0.08$ tph ± 0.05 SE) ($F_{1,105} = 0.001$, $P = 0.969$).

3.5. Agonism

Agonistic behaviors from stallions toward female band members were observed 0.03 (95% CI: 0.01–0.05) tph at Little Book Cliffs, 0.01 (95% CI: 0.01–0.02) tph at McCullough Peaks, and 0.04 (95% CI: 0.03–0.06) tph at Pryor Mountain. In order of increasing intensity, 67.7% of these agonistic expressions were in the form of a threat, 1.7% were bumps or pushes, 26.8% were kicks or bites, and 3.8% were chases. Model 6 (band size) best explained the observed agonistic expressions and was supported by 92.5% of the AIC_c weight. The effect of band size was statistically significant, but only resulted in agonistic behavior decreasing 0.7% as band size increased from 3 to 14 horses. There was no difference in rates of agonistic behavior exhibited by stallions toward control females ($\bar{x} = 0.03$ tph ± 0.01 SE) compared to treated females ($\bar{x} = 0.03$ tph ± 0.01 SE) ($F_{1,105} < 0.001$, $P = 0.986$). Agonism between females occurred too infrequently to conduct meaningful analyses.

4. Discussion

Previous research indicated that immunocontraception with PZP did not lead to behavioral changes in feral horses (Kirkpatrick et al., 1996; Powell and Monfort, 2001); however, more recent work by Nuñez et al. (2009) refuted these assertions with evidence that PZP immunocontraception led to a decrease in band fidelity and an increase in reproductive behaviors during the non-breeding season. Our findings are similar to those of Nuñez et al. (2009), indicating that PZP treatment can affect behavior in feral horses. We found that treated females received significantly more reproductive behaviors from stallions than did control females, and the most-supported model of this behavior was that of treatment. Models containing the fixed effect of treatment were also supported for

locomotion and herding behavior, but no differences were detected between treatment groups. All other behaviors investigated were better explained by models of body condition, foal presence, or band size.

4.1. Time budgets

Estimates of daylight time budget allocations for all age and treatment groups fell within the broad ranges previously reported for equids (Mayes and Duncan, 1986; Boyd, 1988; Berger et al., 1999). The differences detected in time budget behaviors were primarily a function of body condition and are comparable to expected differences in time budgets between barren and pregnant/lactating females. Boyd (1988) found pregnant female horses spent more time feeding than barren females, which corresponds to the respective metabolic needs of animals in these conditions (Henneke et al., 1984; National Research Council, 2007).

These results largely concur with Powell's (1999) finding of no difference in time allocation between PZP-treated and control horses; however, data were not completely comparable because control females in Powell's study were previously treated and PZP titer levels were unknown. Rogers (2001) found that PZP had no effect on time spent walking, grooming, or standing in feral horses. Likewise, Heilmann et al. (1998) found no differences in time spent moving or idling between PZP-treated and untreated free-ranging female elk. Our results are consistent with those from these studies, and it appears that the complex social organization of feral horses does not greatly influence the time allocated to these basic maintenance behaviors. McShea et al. (1997) did note that PZP-treated female white-tailed deer spent more time running or walking than untreated females, but we did not detect this effect in horses.

Models that were most strongly supported for time budget compositions attributed primary differences between treatment groups to body condition and foal presence effects. Body condition contributed to individual time budget behavior with females in lower body condition feeding more than those in higher condition. Few animals exhibited extremely low or high body condition in our study and investigation into this effect may require a wider range of conditions to elucidate more in-depth results. Social dominance in relation to body condition has been attributed to food gain and energy expenditure (Hogstad, 1987; Cuthill and Houston, 1997; Fischoff et al., 2007) and stochastic climate events could cause depressed or elevated states of body condition and lead to greater differences between treatment groups. Turner and Kirkpatrick (horses: 2002) and McShea et al. (white-tailed deer: 1997) found that contracepted females exhibited higher body condition than control females, and Conner et al. (2007) found a seasonal difference in winter body condition of females, but no overall difference between fertility control treatment groups. Likewise, we found no difference in body condition of treated versus control females in our study.

van Dierendonck et al. (2004) reported that mares without foals spent less time resting and a greater percent of time in social interaction than either pregnant or post-partum mares. One plausible model of resting behavior in our study exhibited support for the effect of foal presence, but with contrary results. Mares with dependent foals rested less than their barren counterparts. This conflicting result may be attributed to the social structure (absence of stallions) in van Dierendonck et al.'s (2004) study, compared to the free-roaming natural populations that experienced threats of predation and competition among stallions in our study. Females with dependent young simply had to be more vigilant when faced with these natural constraints on their time.

4.2. Social behavior

Frequency of some social behavior was heterogeneous across the populations we studied, likely resulting from local densities of bands on the landscape. This proximity of groups to one another introduces different levels of social pressure between bands and illustrates that some populations may be more sensitive to fertility control management strategies than others. All-occurrence analyses of social behavior detected 54.5% more reproductive behaviors were received by treated females than by control animals. This is not surprising given the higher rates of estrous reported in PZP-treated females of other species as compared to control females (Mahi-Brown et al., 1985; Shumake and Wilhelm, 1995; Heilmann et al., 1998; Curtis et al., 2002). Nuñez et al. (2009) reported more frequent reproductive behaviors exhibited and received by treated female horses outside of the breeding season; likewise, Heilmann et al. (1998) found that PZP-treated female elk exhibited higher rates of sexual interaction outside of the breeding season than did untreated females. Powell (1999) also found that reproductive tending and mating duration by stallions lasted longer as a result of mares continuing their estrous cycles into the fall, which he proposed may contribute to a disruption in band stability. Similarly, McShea et al. (1997) found that the breeding season behavior of white-tailed deer males was extended, and started earlier in the subsequent year after females were treated. Our study examined only the frequency of reproductive behaviors and did not examine seasonality. The difference between treatment groups in pattern and relationship to age-specific fecundity we detected appears to directly correspond to the treatment applications across age cohorts and efficacy of the vaccine. It may be important to consider additional research to assess the scope of this potential effect as it could have implications for stallion body condition and consequent lifetime fitness.

Herding behavior may be important because of the high energetic cost of locomotion for both the male and female(s) involved and may have biological meaning in terms of stallion body condition and fidelity of females to the band. We detected no significant difference in herding between treatment groups, but there was a strong effect of the interaction between band fidelity and foal presence in predicting this behavior. Rogers (2001) found that the percentage of time females were herded was different between treatment groups and detected significant effects of foal presence and band fidelity. Even when generalized

across 3 populations, we also detected this difference and found that absence of a dependent foal was associated with an increase in herding behavior. Linklater et al. (1999) found that transient mares had poorer body condition than resident mares as a result of greater harassment by stallions and Nuñez et al. (2009) found that immunocontracepted female feral horses exhibited a decrease in band fidelity during the non-breeding season. These findings suggest further investigation into the effects of fertility control on band fidelity would help determine the scope and extent of this relationship in immunocontracepted female horses during the breeding season.

Harem-tending and agonistic behaviors by stallions did not differ among treatment groups, but stallions invested more harem-tending behaviors in mares with higher body condition. Optimality theory may explain this finding by the perceived fitness pay-off the stallion would receive from investing in animals more likely to contribute offspring (MacArthur and Pianka, 1966), but the true nature of this relationship has not been explained by our analyses. Stallions also expressed no difference in frequency of agonistic behaviors toward control and treated females. This is not surprising since agonistic expressions within feral horse bands are often expressed between females in order to establish and facilitate dominance (Houpt et al., 1978; Waring, 1983; Keiper and Receveur, 1992; Weeks et al., 2000). The stallion is generally not the most dominant member of the band, perhaps as a result of greater time spent away from the group while defending or recruiting females (Keiper and Receveur, 1992).

While few studies have investigated the relationship of agonism and contraception in feral horses, agonism related to presence of a foal and band fidelity has been described. Estep et al. (1993) found no change in agonistic behaviors associated with presence or absence of a dependent foal, and Rutberg and Greenberg (1990) found that frequency of aggression did not vary between females of transient and resident status. Our study concurs with these results as the covariates of interest were not present in the most-supported models of agonistic behavior, and they were not significant effects in the candidate models that contained them.

5. Conclusion

Our study found that reproductive behavior was the only acute short-term response attributable to PZP treatment. Most behaviors we measured were better explained by body condition and those findings are consistent with the metabolic needs of barren versus pregnant/lactating females. Foal presence was also an important effect in some behaviors, and while no differences in treatment groups were detected, the efficacy of treatment inherently influences this effect making it important in the long-term consideration of fertility control use. The long-term influence of changes to band fidelity and foal presence on band structure, social networks, dominance hierarchies, pair-bonding, and socialization requires further study. Such effects have broader implications than the results presented in this study and may imply more dynamic changes to the ecology of feral horses.

Acknowledgments

Thank you to the guiding forces of the research advisory team that provided oversight for this project: F. Singer, J. Roelle, A. Kane, L. Coates-Markle, D. Bolstad, and A. Shepherd. F. Singer and L. Coates-Markle were instrumental in developing the field trial plan, treatment strategies and initiating the larger fertility control study. Thanks to W. Andelt, P. Cryan, T. Holcombe, J. MacLeay, J. Roelle and two anonymous referees for reviewing earlier versions of this manuscript. Special thanks to T. Hatle and J. Dollerschell with the US Bureau of Land Management (BLM) and C. Bromley with the National Park Service for logistical assistance on the ranges. A generous thank you to the outstanding field technicians that made this work a reality: H. Abouelezz, L. Caldwell, M. Esser, M. Felix, K. Grams, P. Grigsby, S. Hahn, B. Hutchings, G. Manus, J. Nibler, C. Petrandis, P. Preator, J. Severude, and G. Thygerson. This study was funded by the U.S. Geological Survey Wildlife Program, in collaboration with the BLM, USDA Animal and Plant Health Inspection Service, and Colorado State University. Any use of trade, product, or firm names is for descriptive purposes and does not imply endorsement by the U.S. Government or Colorado State University.

Potential Demographic and Genetic Effects of a Sterilant Applied to Wild Horse Mares

By James E. Roelle and Sara J. Oyler-McCance

Abstract

Wild horse populations on western ranges can increase rapidly, resulting in the need for the Bureau of Land Management (BLM) to remove animals in order to protect the habitat that horses share with numerous other species. As an alternative to removals, BLM has sought to develop a long-term, perhaps even permanent, contraceptive to aid in reducing population growth rates. With long-term (perhaps even permanent) efficacy of contraception, however, comes increased concern about the genetic health of populations and about the potential for local extirpation. We used simulation modeling to examine the potential demographic and genetic consequences of applying a mare sterilant to wild horse populations. Using the VORTEX software package, we modeled the potential effects of a sterilant on 70 simulated populations having different initial sizes (7 values), growth rates (5 values), and genetic diversity (2 values). For each population, we varied the treatment rate of mares from 0 to 100 percent in increments of 10 percent. For each combination of these treatment levels, we ran 100 stochastic simulations, and we present the results in the form of tables and graphs showing mean population size after 20 years, mean number of removals after 20 years, mean probability of extirpation after 50 years, and mean heterozygosity after 50 years. By choosing one or two combinations of initial population size, population growth rate, and genetic diversity that best represent a herd of interest, a manager can assess the likely effects of a contraceptive program by examining the output tables and graphs representing the selected conditions.

Introduction

As the primary agency responsible for management of wild horses (*Equus caballus*) on public lands in the United States (U.S.), the Bureau of Land Management (BLM) has a need for a long-lasting, non-lethal method to control population growth rates. Given the protection afforded by The Wild Free-Roaming Horses and Burros Act of 1971 (P.L. 92–195 as amended) and general lack of natural predators, wild horse populations commonly increase at rates of 15–25 percent per year (Eberhardt and others, 1982; Garrott and others, 1991a) and quickly exceed the carrying capacity of their ranges. In the past, BLM has managed excess horses through a gather, removal, and adoption program, with unadopted horses held in short- and long-term holding facilities until the end of their natural lives. The sustainability of this strategy has recently been called into question, however (U.S. Government Accountability Office, 2008; Garrott and Oli, 2013; National Research Council, 2013). Therefore, BLM has increased efforts to develop a contraceptive that will reduce population growth rates in wild horse herds and thus reduce the number of excess animals that must be removed and cared for.

The contraceptive SpayVac has recently demonstrated the potential for long-lasting efficacy (at least 4 years) in wild horses (Killian and others, 2008). Maximizing the duration of contraceptive effectiveness is especially important in managing wild horses, which in most cases must be captured in order to successfully administer the drug. With extended efficacy (or perhaps even permanent sterility), however, comes increased concern for both the genetic health of a horse herd and the possibility of extirpation. Simulation modeling can be a useful tool in understanding the likely consequences of alternative management actions. We used the VORTEX software package (Lacy and others, 2014; Lacy and Pollak, 2014) to simulate the effects of treating various proportions of mares with a permanent sterilant. Response variables included population size, number of animals removed, average heterozygosity, and probability of local extirpation. (The VORTEX manual (Lacy and others, 2014) uses the term "extinction" rather than "extirpation." We believe that extirpation is more appropriate in this case, as we are simulating local populations, not the entire species.) We chose the VORTEX software because it can be used to simulate both demographic and genetic effects, and because it has been useful in simulating management of the horse population on Assateague Island (Ballou and others, 2008).

VORTEX is an individual-based model in which events happen or fail to happen on the basis of probabilities for each modeled individual. For example, if 100 females are of breeding age, each of which can produce at most one offspring, and fecundity is set to 80 percent, there is no guarantee that exactly 80 offspring will be born. Rather, for each female of breeding age, a random number chosen from a uniform distribution between 0 and 1 is compared to the probability of producing an offspring (in this example, 0.8). If the random number is less than 0.8, then the female is tagged in the model to give birth but otherwise does not. Thus, no two simulations are identical even when they use the same demographic parameters, and multiple iterations must be run in order to examine the possible range of outcomes. In general, we present results in the form of mean values for the multiple simulations; however, it is important to remember that extreme values can also be of interest. In addition, it is important to note that these simulations represent the results of management prescriptions applied consistently through time, without adaptation based on monitoring of results. In the real world, there would be many opportunities to adjust management strategies based on previous results.

Model Parameters

Parameter values and VORTEX options used in our simulations are summarized in table 1 and described in some detail in the sections that follow. Our knowledge of the biology and demography of horse populations and the efficacy of SpayVac and other forms of contraception is incomplete; what is applicable to one herd may not be applicable to all herds. In light of that fact, in cases where specific parameter values were in question, we tried to select the value or option that would have the largest effect on one or more of the response variables. For example, we don't know that SpayVac is a sterilant, but it may be. Furthermore, BLM is considering the use of other techniques (for instance, ovariectomy) that definitely will be permanent. So, for modeling purposes, we assume a permanent sterilant; once a mare is treated and the treatment works, she is infertile for life. This assumption is likely to minimize the number of animals tagged for removal during a simulation, while at the same time maximizing any decline in heterozygosity. We were similarly conservative in our choice of other parameter values and options, always choosing those that were likely to have the most detrimental effect on population demography and genetics.

Table 1. Parameter values and options used in simulations of the effects of a mare sterilant applied to wild horses.

[H_o, observed heterozygosity; ≥, equal to or greater than; BLM, Bureau of Land Management]

Parameter or option	Value selected for simulations
Mating system	Long-term polygyny
Age of first reproduction	Females = 3 years, males = 5 years
Maximum age (life span)	25 years
Maximum age of reproduction	20 years
Basic time cycle	1 year
Maximum litters per year	1
Maximum progeny per litter	1
Density-dependent reproduction	Not used
Reproductive rates	See tables 2 and 3
Mortality or survival rates	See tables 2 and 3
Sex ratio at birth	50 percent males
Mate monopolization	Mean of 3.0 mates per successful sire
Initial population size	100, 250, 500, 750, 1,000, 1,250, or 1,500
Initial age distribution	Stable age distribution calculated from age-specific schedules in table 2 and 3
Carrying capacity	Arbitrarily set at 5× the initial population size, but the contraception and removal programs prevent carrying capacity from having any effect
Initial heterozygosity	Actual allele frequencies at 13 microsatellite loci from the Lost Creek herd in Wyoming (high diversity, $H_o = 0.78$) or the Cibola-Trigo herd in Arizona (low diversity, $H_o = 0.49$)
Removals	When the simulated population reaches ≥150 percent of the initial population size, try to remove enough animals to get back to the initial population size. BLM's age-class removal criteria are used, but are constrained such that no more than 90 percent of any age and sex class are removed.
Efficacy of treatment	Treatment is efficacious in 90 percent of all newly treated mares
Duration of efficacy	If treatment is efficacious, female remains contracepted for life
Proportion of females treated	0 percent–100 percent, in 10 percent increments
Standard deviation due to environmental variability	$S_{EV} = 0.12$ for fecundity; $S_{EV} = 0.06$ for mortality
Concordance	Yes. Breeding and mortality are affected simultaneously.
Probability of catastrophe	10 percent annually
Impact of catastrophe	Reduce reproduction to 50 percent of normal; reduce survival to 75 percent of normal
Distribution of litter sizes	Not used; litter size in horses is virtually always 1
Number of iterations per simulation	100
Number of years per iteration	20 years for population size and removals; 50 years for heterozygosity and probability of extirpation
Number of populations in each simulation	1
Definition of extirpation	The population is considered to be extirpated when it no longer has individuals of both sexes.

Demographic Parameters

Mating System

VORTEX models breeding systems as monogamous or polygamous and short-term or long-term. With monogamous breeding, a male is needed for every breeding female; males may therefore become a limiting factor restricting breeding. In polygamous models, only one male is needed for all females to have an opportunity to breed. However, another parameter (see the section Mate Monopolization) can specify that only a subset of males has an opportunity to breed. For example, a polygynous system can be created in which successful males control harems of, say, five females on average, while the remaining males are excluded from breeding.

If a short-term option is chosen, then VORTEX assumes that mates are randomly reshuffled each year and that all available individuals have an equal probability of breeding. If a long-term option is chosen, then once harem relationships between stallions and mares are formed, those relationships remain intact across years of the simulation until a member dies or disperses to a different population. Demographically, it does not matter whether long-term relationships or rearrangement of harems each year is chosen. Genetically, there may be a small effect on the rate of loss of genetic diversity from the population, with greater loss of diversity expected in populations with higher harem fidelity.

We realize that wild horses do not necessarily mate for life (mares do move between harems) but, of the two choices available in VORTEX, long-term polygyny comes closer to representing the mating system of wild horses. We therefore used long-term polygyny as the mating system in all of our simulations. This is a conservative assumption, in the sense that it represents the greatest opportunity for loss of genetic diversity. Any additional interchange that does occur in the real world will tend to ameliorate effects and result in higher genetic diversity than predicted by our models.

Age of First Reproduction

VORTEX describes reproduction in terms of the age when the first offspring are born, not the age at onset of sexual maturity or the age at first conception. The program also assumes that breeding (and, for that matter, all other events) takes place at discrete intervals, usually years. Thus, age at first reproduction is entered as an integer value. The value used should represent something like the median age of first reproduction, not the earliest age ever observed, because the earliest observed age may not be typical of the population. We therefore used 3 years as the age of first reproduction in females and 5 years as the age of first reproduction in males (Garrott and Taylor, 1990; Garrott and others, 1991b; Roelle and others, 2010).

Maximum Age and Maximum Age of Reproduction

If the species being modeled does not reproduce throughout its entire adult life, the age when the species ceases to reproduce must be specified. For example, humans typically reach reproductive senescence before they die. If the typical life expectancy is 70 years but reproduction ceases at 50 years, then 50 years would be the maximum age of reproduction. VORTEX requires that the maximum age be the same for both sexes, but allows the maximum age of reproduction to vary by sex. Establishing the maximum age of reproduction is difficult because old animals are hard to age (unless they were marked or identified in the year of birth) and because sample sizes of old animals are typically small. Garrott and others (1991b) present information showing that some mares can reproduce at greater than 20 years

of age, whereas Roelle and others (2010) found no evidence of reproduction by females older than 16 years. Roelle and others (2010) also found that very few harems are held by stallions older than age 20. On the basis of available evidence, we used 20 years as the maximum age of reproduction and 25 years as the maximum age.

Maximum Number of Progeny per Year

VORTEX provides a great deal of flexibility in specifying the maximum number of progeny that can be born to a given female in a year (or other time interval), thus allowing species that produce multiple clutches or litters to be modeled. However, most of this flexibility is not needed for modeling a horse population. Given that horses produce only a single litter per year (the average gestation period is 335–342 days; Card and Hillman, 1993) and that twins are virtually unknown, we used 1 for the maximum number of litters per year, 1 for the maximum number of progeny per litter, and a year (365 days) as the basic time cycle.

Density-Dependent Reproduction

VORTEX allows the reproductive rate of the population being modeled to change with changing population size. For example, reproduction could be low when the population is small owing to a difficulty in finding mates (Allee effect) or, conversely, reproduction could drop off when the population is large (more specifically, at high density) owing to limited resources or territories, intraspecific competition, crowding, or stress.

Density-dependent reproduction, also known as compensatory reproduction, has been reported for wild horses (Kirkpatrick and Turner, 1991; Jenkins, 2000; Roelle and others, 2010), but quantifying the magnitude of the effect is difficult, and the information available is insufficient to allow generalization or calculation of some average function. In addition, many of our simulated populations differed only about 50 percent (that is, between N and 1.5 × N) because of the way we implemented the removal function (see section Removal and Contraception Programs). In our estimation, reproductive rates are not likely to change substantially owing to density in that relatively small range. We therefore did not use density-dependent reproduction in our simulations.

Reproductive and Mortality Rates

VORTEX models reproductive rate as the proportion of adult females giving birth each year (or other time interval), where an adult female is defined by the age of first reproduction (see previous discussion). Similarly, mortality rates are modeled as the proportion of animals dying in each age and sex class. From age 0 to the age of first reproduction, each age and sex class can have a different mortality rate; after the age of first reproduction, all animals are considered adults, and the mortality rate can vary only by sex.

While these parameters are fundamental to modeling population dynamics, values are well known for perhaps only a handful of wild horse populations. In our estimation, however, wild horse managers are more likely to have at least some idea of the annual population growth rate multiplier for a herd (λ, lambda), which is just a different way of expressing the growth rate itself. We therefore modeled a set of scenarios in which $\lambda = 1.05$, 1.10, 1.15, 1.20, or 1.25 (that is, annual growth rates of 5 percent, 10 percent, 15 percent, 20 percent, or 25 percent in the absence of contraception). To produce these growth rates, we used reproductive and survival rates (table 2) derived largely from Garrott

(1991a). We arrived at the values for λ = 1.25 by experimenting with parameters in the model. Table 3 provides an example of how we translated these parameters into VORTEX.

Table 2. Annual survival and reproductive rates used to simulate various annual population growth rates.

Population growth rate (percent)	Juvenile survival rate (percent)	Adult survival rate (percent)	Mares foaling (percent)
5	80	91	50
10	80	92	65
15	80	97	65
20	80	99	80
25	90	99	92

Table 3. Translation of the annual rates shown in table 1 into VORTEX parameter values for an annual population growth rate of 20 percent (λ = 1.20).

[λ, annual population growth rate multiplier for a herd; <, less than; ≥, equal to or greater than]

Reproduction		Female Mortality		Male Mortality	
Mare age (years)	Mares foaling (percent)	Age (years)	Rate (percent)	Age (years)	Rate (percent)
1	0	<1	20	<1	20
2	0	1 to <2	1	1 to <2	1
≥3	80	≥2	1	2 to <3	1
				3 to <4	1
				4 to <5	1
				≥5	1

We believe that, in the absence of contraception, growth rates of most wild horse herds will fall within the range shown in table 2. Rather than having to specify reproductive and mortality rates, a manager will need only to choose one or perhaps two values for the annual population growth rate to use the output from the model.

Sex Ratio at Birth

While foal sex ratio can differ from 50:50 in small herds in a given year (Roelle and others, 2010), over time the ratio tends to be fairly even in most herds. For example, Garrott (1991b) found that for a 12-year period 65 of 74 (88 percent) herds sampled in Nevada, Oregon, and Wyoming had a foal sex ratio that did not differ from 50:50. We therefore used 50 percent males in the foal crop in our simulations.

Mate Monopolization

As noted in the previous section, we ran our simulations using a polygynous breeding system. In order to do so, VORTEX requires that one of the following three parameters be specified: percentage of males in the breeding pool, percentage of males successfully siring offspring, or mean number of mates per successful sire. The remaining two parameter values are calculated from the one that is supplied based on the assumptions that some males are excluded from the breeding pool and that breeding

success among males in the pool of available breeders is described by a Poisson distribution. Only the first parameter (percentage of males in the breeding pool) is used by VORTEX.

Of the three ways in which mate monopolization can be described in VORTEX, mean number of mates per successful sire is the one most commonly discussed in the literature on feral horses, but comparisons among studies are hampered by inconsistencies in defining what constitutes a potential mate (that is, the age classes of mares). Roelle and others (2010) defined potential mates as all mares 2 years of age and older, and found a mean harem size of 2.2 mares (range 1.9 to 2.7) during 12 years. Using the same age criteria, Kaseda and Khalil (1996) found average harem sizes of 1.8 to 5.3 mares in many years.

Potential effects of using different values for the mean number of mates per successful sire are not intuitive; to a first approximation, however, one might expect that varying this parameter would affect genetics more than demography. We explored sensitivity of model results to mean number of mates per successful sire in a series of simulations with initial population size = 500, proportion of mares treated = 0.5, lambda = 1.05 (in the absence of contraception and removals), and initial heterozygosity = 0.77. We varied mean number of mates per successful sire systematically between 1.5 and 5.0. The fairly low growth rate and fairly high proportion of mares treated consistently kept the simulated population after 50 years at 200–250 animals; however, final heterozygosity ranged only from 0.74 to 0.75. Given the apparent lack of sensitivity of the model, we decided to set the value of mean number of mates per successful sire to 3.0 for all simulations.

Initial Population Size

Horse herds managed by BLM vary considerably in size, and the size of the herd is potentially very important relative to demographic and genetic results of contraception. We approached this problem by simulating herds with initial populations of 100, 250, 500, 750, 1,000, 1,250, and 1,500 animals. These initial populations should encompass the appropriate management level (AML; population goal) for many herds. We recommend a more detailed, site-specific analysis before a sterilant is applied to any herd with fewer than 100 animals. In addition, we implicitly assume that a herd is at its appropriate size before the results of these simulations can be used to evaluate a fertility control program. For example, the results of the simulations having an initial population and appropriate management level of 500 animals cannot be used if the population in fact contains, say, 1,000 animals.

Initial Age Distribution

VORTEX allows two options for specifying the initial age distribution used in a simulation. A specific age distribution (the number of individuals in each sex and age class) can be entered, or VORTEX can calculate the stable age distribution (proportion of animals) that would result from the age-specific schedules of reproduction and mortality described previously. We used the latter option, and the proportions were applied to the initial population size to determine the number of animals initially in each sex and age class.

Carrying Capacity

Carrying capacity (K) describes a theoretical upper limit to the size of a population. In VORTEX, if the actual population, N, exceeds K at the end of a particular year, then additional mortality is applied equally across all age and sex classes to reduce the population such that N = K. While carrying capacity is an important theoretical construct, values for K are difficult to estimate. We

somewhat arbitrarily set the value for K at 5 times the initial population size. With the contraception and removal programs specified as described in subsequent sections, simulated populations never reach carrying capacity.

Genetic Parameters

VORTEX allows inbreeding depression to be incorporated into the population model as a reduction in first-year survival among inbred individuals. Although some diploid species that have been studied show depressed fitness when inbred (O'Brien and Evermann, 1988; Quattro and Vrijenhoek, 1989), the rate at which inbreeding affects survival and reproduction is not well understood for most species. Therefore, we elected not to use this function in the wild horse model. A better approach for investigating the potential genetic consequences of contraception and gathers (round-ups) is to track the degree of genetic diversity, which can be loosely linked to fitness and an ability to adapt to environmental change.

VORTEX tracks changes in genetic diversity using heterozygosity (the frequency of two different alleles at a given gene) as a metric. Heterozygosity ranges from 0 (all individuals are homozygous and the same at all genes) to 1 (all individuals are heterozygous with different alleles at all genes). It is generally believed that higher levels of heterozygosity are associated with more genetic variation and lower probability of inbreeding depression.

VORTEX can track heterozygosity in two ways. Because VORTEX includes a detailed simulation of genetic change in the populations, one way to measure changes in heterozygosity is to start with maximum heterozygosity (1) by assigning each founder individual two unique alleles at a number of loci (genes). Each offspring is randomly assigned one of the two alleles from each parent at each locus. This method tracks relative loss of heterozygosity through time. Perhaps a more realistic way to examine loss of heterozygosity is to mimic real populations by starting with individuals that have a known level of heterozygosity. VORTEX allows this option by allowing real allele frequencies to be used as a starting point for model simulations. Thus, if we know the level of heterozygosity for a population, we can enter real allele frequencies such that the starting point of the simulations will have exactly that level of heterozygosity. We used the latter of these two approaches and ran the simulations for two different initial levels of heterozygosity (high and low) as reported for two real-world herds (Gus Cothran, Texas A&M University, unpublished reports prepared for BLM). Actual allele frequencies at 13 microsatellite loci were taken from the Lost Creek herd in Wyoming (high genetic diversity, $H_o = 0.78$; report prepared in 2010) and the Cibola-Trigo herd in Arizona (low genetic diversity, $H_o = 0.49$; report prepared in 2008). Absent site-specific information, we typically expect larger herds to have higher genetic diversity.

Removal and Contraception Programs

Removals

Given the limitations of available contraceptive methods, and facing population sizes that greatly exceed the desired number of animals in many herd management areas, BLM currently views contraception as a means of reducing the number of animals that must be removed, and perhaps increasing the interval between gathers, rather than as a replacement for gathers. We therefore simulated a gather-and-removal program that is as similar as possible to the program that BLM uses in the field. We modeled a gather-and-removal event in any year in which the simulated population was 150 percent or more of the initial population, and we attempted to remove sufficient animals to return the population

to its initial size. We removed animals from age classes according to BLM's removal criteria, which specify the following order: ages 4 and under, followed by ages 11–19, followed by ages 5–10. We constrained the number of animals removed, however, such that no more than 90 percent of any group was taken (because it would rarely be possible or desirable to remove every animal from a given age class). Our response variable is the total number of animals removed in 20 years averaged for 100 iterations.

Contraception

We implemented a simulated contraception program using capabilities in VORTEX called "population state" variables and "individual state" variables. Briefly, we used these variables to define the proportion of previously untreated females that are treated in each application and the probability that the treatment works if it is given (efficacy). In most cases, animals in BLM herds need to be gathered in order to apply a fertility control agent; we therefore treated mares following every gather and removal. Killian and others (2008) found that 17 percent of mares treated with SpayVac were pregnant in years 2 through 4 of their study, which implies efficacy of 83 percent. The most aggressive assumption would be that the treatment is 100 percent efficacious. However, it is probably also fair to assume that some mares will not respond to an immunocontraceptive such as SpayVac. We therefore assumed efficacy of 90 percent for all simulations. We also assumed that once a mare is successfully contracepted, she remains contracepted for life without further treatment (we assumed permanent sterility). We varied the proportion of mares treated from 0 to 100 percent in increments of 10 percent to illustrate the range of possible contraceptive effects. For example, when the proportion of mares treated is set at 20 percent, each mare not successfully treated in the past has a 20 percent chance of being caught and treated, and there is a 90 percent chance that the treatment will be effective. Note that high treatment rates (90–100 percent, for example) would likely be very difficult to achieve in the real world because some animals are difficult or impossible to gather.

Random Variation

Environmental Variation in Breeding and Mortality

In addition to the variability inherent in an individual-based model, VORTEX allows specification of variability (standard deviation) in the proportion of females breeding and in the proportion of both sexes dying due to factors external to the population (such as weather, predation, parasite loads). Estimates of variability in these parameters are generally not available for wild horse herds, but sufficient information was available to calculate standard deviations in fecundity and mortality for the Pryor Mountain herd (Roelle and others, 2010).

The standard deviation due to environmental variability, s_{ev}, for either fecundity or mortality, can be expressed as $s_{ev} = \sqrt{s_{tot}^2 - s_{ds}^2}$, where s_{tot}^2 is the total variance in the parameter for all years and s_{ds}^2 is the sampling (binomial) variance for all individual rates. From the Pryor Mountain data set (Roelle and others, 2010), we calculated $s_{ev} = 0.12$ for fecundity and $s_{ev} = 0.06$ for mortality. We combined ages and sexes for both of these calculations and used the resulting values in all simulations.

Concordance of Environmental Variation in Breeding and Mortality

Factors such as those already described (weather, predation, parasite loads) can affect reproduction and survival independently or simultaneously. Simultaneously means that good years for

reproduction are also good years for survival. We know of no information that can be brought to bear on this subject in regard to wild horse demography, but it seems logical that demographic effects would be most pronounced if these parameters vary simultaneously. We therefore opted for concordance in environmental variation.

Number and Types of Catastrophes

The VORTEX software allows specification of catastrophes (floods, forest fires, epidemic diseases) through particular effects on reproduction and survival. Perhaps the most common such event on western ranges is drought, and although droughts occur fairly frequently, we know of no specific information relating drought to reproduction and survival in wild horses. Nevertheless, we felt that it was important to include some form of catastrophe in our simulations. We therefore specified that drought would have a 10 percent probability in any year and that it would reduce reproduction to 50 percent of the normal level and survival to 75 percent of the normal level.

Distribution of Litter Sizes

VORTEX allows for one additional form of random variation if females can produce litters of different sizes. Because wild horses almost never produce more than one offspring, we did not use this parameter.

Simulation Control

Number of Iterations

As noted in the previous section, VORTEX uses a random number generator to simulate random events in an organism's life cycle. Therefore, no two runs or iterations of the model are identical even with a single set of input data. To obtain a more complete picture of demographic behavior, multiple iterations are required. We explored changes in the standard deviation of both mean population size and heterozygosity after 50 years while varying the number of iterations from 25 to 1,000. Because of the complexity of the removal and contraception functions, no consistent pattern emerged in the standard deviations of these parameters. More particularly, increasing the number of iterations to more than 100 did not consistently lead to lower variance about the mean. We therefore chose 100 iterations for all of our simulations.

Number of Years per Iteration

Initial simulations with some basic data indicated that significant changes in heterozygosity are rare in less than 50 years. On the other hand, significant demographic changes can occur in as little as 20 years. We therefore evaluated mean population size and removals at the end of 20 years of simulation, but we used 50 years to evaluate heterozygosity and probability of extirpation.

Number of Populations

VORTEX can be used to model a single, isolated population or a complex metapopulation composed of as many as 50 populations with interchange of animals between them. Although it is clear that some animals move between certain populations of wild horses, we know of no information on

rates of such movement. We therefore modeled only a single population without introduction of animals from outside, which is the worst case from the perspective of genetic diversity.

Extirpation Definition

VORTEX offers several methods for defining extirpation of a population. We used the definition that says a population is extirpated when it no longer contains individuals of both sexes.

Interpreting Model Output

Appendix A contains output from 70 sets of simulations representing two levels of genetic diversity (low or high), seven initial population sizes (100, 250, 500, 750, 1,000, 1,250, or 1,500 animals), and five population growth multipliers (1.05, 1.10, 1.15, 1.20, or 1.25). Each set of simulations is represented by a figure, and each figure contains five graphs and a table of supporting data. The order of the figures varies first by annual growth rate, then by population size, and then by genetic diversity. Thus, figure 1 has low genetic diversity, an initial population size of 100, and a growth multiplier of 1.05, and is followed by figure 2 with low genetic diversity, an initial population size of 100, and a growth multiplier of 1.10, and so on. In each figure, the first four (black and white) graphs and the table represent the same set of simulations, and the graphs and table have identical values. Due to a nuance in the way VORTEX operates, however, the final (color) graph represents a different set of simulations having the same parameter values but differing slightly due to random variation as already discussed. Thus, the value for average population size at 20 years on the color graph will not in general be identical to that in the table, but the two values will usually be very similar.

The black and white graphs present mean values (that is, averaged for 100 iterations) of four response variables on the vertical axes: mean population size after 20 years, mean number of removals after 20 years, mean probability of extirpation after 50 years, and mean heterozygosity in the herd after 50 years. In all cases, the horizontal axis is the percentage of previously untreated mares that are treated following each gather, varying from 0 percent to 100 percent. The colored graph represents the mean trajectory of the population size for a subset of the treatment levels (0 percent, 20 percent, 40 percent, and so on) depicted as lines of different color. It is very important to understand that there is some information that cannot be conveyed by mean values. For example, there are many cases where the table and black and white graphs show that animals were removed, but the colored graph lines never plot higher than 1.5 × the initial population. The appropriate interpretation is that on average the population stayed below the threshold (1.5 × the initial population), but in some individual iterations the population grew sufficiently to trigger a removal.

As an example application of model results, suppose a manager wants to know what proportion of mares can be treated with a sterilant in a herd having low genetic diversity, an initial population size of about 750, and a population growth multiplier of 1.15. This set of conditions is represented by figure 18 in appendix A. The first thing to notice about figure 18 is that no treatment level has any real effect on either mean probability of extirpation after 50 years or mean heterozygosity after 50 years. The graph of mean population size after 20 years, however, shows that treatment levels greater than 50 percent of the mares result in populations somewhat less than 750. We also see that if 50 percent of the mares are treated, the mean number of removals after 20 years is around 900, or about 500 fewer than in the scenario where no mares are treated. The number of removals can be further reduced by treating a higher proportion of mares, but only if average population levels below 750 are acceptable. The average trajectory of the population size through time can be examined by looking at the last (color) graph in the

figure 18, which also shows that treatment rates more than about 50 percent will result in populations that are commonly below the starting point of 750 animals.

Finally, uncertainties about level of genetic diversity, population size, or growth rate can be addressed by examining figures representing nearby values in the parameter space. Thus, in the example in the preceding paragraph, a manager might also wish to look at the figures representing 500 and 1,000 animals in the population and growth multipliers of 1.10 and 1.20 to gain some understanding of how sensitive model results are to these assumptions.

Conclusions

We believe that simulation results presented herein represent a useful starting point for evaluating a management program involving a contraceptive technique that is permanent (or nearly so). In particular, the results show that only in the most extreme circumstances (such as low initial genetic diversity, low population growth rate, high proportion of mares treated, no change in management for 50 years) would there likely be any noticeable effect on genetic diversity or a significant probability of extirpation of a herd. Monitoring and adaptive management would reduce the probability of unacceptable results even further. For example, a simple exchange program in which an animal or two were moved between herds periodically would help to maintain genetic diversity, and the contraceptive program could always be modified or discontinued in the event that the reduction of population was greater than anticipated. In short, we see nothing in our results that should steer wild horse managers away from permanent contraceptive techniques, as long as results are monitored and adjustments are made if necessary.

Injection-Site Reactions in Wild Horses (*Equus caballus*) Receiving an Immunocontraceptive Vaccine

By James E. Roelle[1] and Jason I. Ransom[1]

Abstract

The U.S. Geological Survey and the Bureau of Land Management are conducting research on the efficacy of the immunocontraceptive agent porcine zona pellucida (PZP) in reducing fertility of wild horses (*Equus caballus*). As an antigen, PZP stimulates antibody production when injected into many mammalian species. These antibodies bind to the external surface of the ovum, preventing fertilization. By itself, PZP is only weakly immunogenic and is therefore delivered with an adjuvant, most commonly one of the Freund adjuvants, designed to further stimulate antibody production. Freund's complete adjuvant (FCA) in particular is known to be very effective, but may also be associated with undesirable side effects such as formation of abscesses at injection sites. Such reactions may be exacerbated when accompanied by the additional trauma of a remotely delivered dart. Because horses in our three study herds were individually identifiable by color markings and harem association, we were able to monitor mares for injection-site reactions (abscesses, nodules, swelling, and stiffness) following inoculation with PZP.

In 100 injections delivered by hand we observed a single nodule, two instances of swelling, and no other reactions. In two herds that received remotely delivered (dart) injections, the frequency of reactions was about 1 and 6 percent for abscesses, 25 percent for nodules (both herds), 11 and 33 percent for swelling, and 1 and 12 percent for stiffness. Abscesses were too infrequent to allow meaningful analysis of the relation to covariates, but for the other types of reactions we used logistic regression to examine the relation of occurrence to the delivery method (rifle or CO_2-powered blowgun), adjuvant (FCA, Freund's modified adjuvant, and Freund's incomplete adjuvant), dart trauma (normal or abnormal), and age of mare. Abnormal dart trauma included cases where the dart hit bone or the needle broke off. We found strong evidence (odds ratio = 5.023, $P = 0.001$) for a higher probability of occurrence of swelling when darts were delivered by blowgun. We found some evidence (odds ratio = 8.729, $P = 0.07$) that abnormal dart trauma led to a higher frequency of nodule formation. Nodules were the most common reactions observed and often persisted for a year or more, but in our observations they did not appear to change any animal's range of movement or locomotor patterns and in most cases did not appear to differ in magnitude from naturally occurring injuries or scars. We were unable to perform histological examinations of these nodules, but they may be similar to granulomas reported by other investigators following administration of Freund's adjuvant.

Introduction

The Wild Free-Roaming Horses and Burros Act of 1971 (P.L. 92–195, as amended) declared that "wild free-roaming horses and burros are living symbols of the historic and pioneer spirit of the West" and that these animals "shall be protected from capture, branding, harassment, or death." Responsibility for management of wild horses (*Equus caballus*) and burros (*Equus asinus*) on western lands was vested in the Bureau of Land Management (BLM) and the U.S. Department of Agriculture Forest Service (FS). BLM, our partner in the research described here, currently manages wild horses and burros on 199 Herd Management Areas (HMAs) encompassing over 13.9 million hectares. Given the protection afforded by the Act and largely unchecked by natural predators, wild horse populations can increase rapidly, often 15–25 percent per year (Eberhardt and others, 1982; Garrott and Taylor, 1990; Garrott and others, 1991) and can quickly exceed the capacity of the range to support them. Historically, BLM has managed excess animals by gathering them (every 3–5 years on most HMAs) and offering them for adoption or sale to good homes. More recently, BLM has sought to diversify its management program through the use of contraception to slow population growth.

In 2001, BLM and the U.S. Geological Survey (USGS), Fort Collins Science Center, initiated research to study the efficacy of the immunocontraceptive agent porcine zona pellucida (PZP) in limiting the fertility of mares in three horse herds in the Western United States: Little Book Cliffs Wild Horse Range (LBC) in Colorado, McCullough Peaks Herd Management Area (MCP) in Wyoming, and Pryor Mountain Wild Horse Range (PRY) in Montana and Wyoming. (See Kirkpatrick and Frank [2005] for a recent review of contraception in equids and other free-ranging animals.) PZP is produced from

[1]U.S. Geological Survey, Fort Collins, Colorado.

pig ovaries and acts as an antigen when injected into other species. PZP stimulates production of antibodies that bind to the zona pellucida, or external surface of the ovum, of the host species and interfere with fertilization (Asa, 2005). PZP by itself is only weakly antigenic and is usually delivered with an adjuvant to further stimulate the host immune system to produce antibodies. The adjuvant of choice for PZP applications in equids, at least for the first inoculation, has most often been Freund's complete adjuvant (FCA) (see, for example, Kirkpatrick and others, 1990; Turner and others, 1996, 1997, 2001). While very effective, FCA can have undesirable side effects, including the formation of abscesses and granulomas at the injection site, which appear to depend on the species, delivery method (hand injection or dart), injection location, and injection route (for example, intramuscular, subcutaneous) (Mahi-Brown and others, 1985; Broderson, 1989; Claassen and others, 1992; Leenaars and others, 1994, 1998; Lyda and others, 2005). In addition, accidental exposure to FCA can be hazardous to those administering the injections (Chapel and August, 1976).

In view of the potential for such adverse reactions, quantification of their occurrence is desirable. However, followup observations of injection sites is not often possible with free-ranging animals because individual animals are not easily identified unless they are marked (for example, with brands or ear tags) when treated (but see Naugle and others [2002] for an example involving individually recognizable white-tailed deer [*Odocoileus virginianus*]). In our three study herds, however, horses were individually recognizable through color markings and band (harem) associations, thus offering an opportunity to observe reactions at contraceptive injection sites. Here, we report the results of those observations; information on contraceptive efficacy will be presented elsewhere.

Study Areas

The Little Book Cliffs Wild Horse Range is located in Mesa County, Colorado, about 13 km northeast of Grand Junction and consists of 14,614 ha of sloping plateaus, sagebrush parks, steep-walled shale and sandstone cliffs, and four major canyon systems. A Wilderness Study Area (WSA) comprises 10,734 ha of the range and limits access by motorized vehicle. During our study, the herd was distributed across the entire range. Some horses traveled seasonally between the lower canyons and the higher elevations, and others did not move seasonally. Locating individual horses was often complicated by the predominance of Colorado piñon (*Pinus edulis*) and Utah juniper (*Juniperus osteosperma*) in association with the rough terrain. Once located, horses were generally approachable to within adequate observation distance using binoculars or spotting scopes; however, certain horses exhibited restless behavior when observers were present in wooded areas and would flee before detailed observation data could be collected.

The McCullough Peaks Herd Management Area is located in Park County, Wyoming, 32 km east of the town of Cody. It consists of 44,440 ha of predominantly flat, open sagebrush steppe, with rugged badlands along the western edge. A WSA occupies 9,943 ha of the range. There was no single seasonal congregation area for horses, though the majority of the population resided in the southern half of the range during our study. Horses on this portion of the range were generally quite visible due to the nature of the terrain and vegetation, but they were not approachable. Observation of injection sites was thus difficult, even with the aid of a spotting scope.

The Pryor Mountain Wild Horse Range is located 21 km north of Lovell, Wyoming, and lies within northern Bighorn County, Wyoming, and southeastern Carbon County, Montana. The range includes BLM land, portions of Custer National Forest and Bighorn Canyon National Recreation Area, and private lands, and consists of 16,046 ha of lowland desert, foothill slopes, forested montane slopes, steep canyons, and grassy plateaus. Three WSAs occupy the majority of PRY, limiting motorized access to the sparse road system. Vegetation types vary greatly from lower to higher elevations of the range, with lower elevations dominated by big sagebrush (*Artemisia tridentata*), mid-elevations dominated by curl-leaf mountain mahogany (*Cercocarpus ledifolius*), Utah juniper, and various grasses, and high elevations dominated by limber pine (*Pinus flexilis*), subalpine fir (*Abies lasiocarpa*), and alpine bluegrass (*Poa alpina*). Most horses moved from lower and mid-elevations in winter to high elevations in summer. Thus, horses were usually easy to observe in summer when they were in open subalpine and alpine meadows, but difficult to observe in spring and fall on forested montane slopes. Horses at PRY did not generally react to humans and, once located, could be closely approached for detailed observation.

Methods

We initiated treatments at each of the three study areas in concert with gathers scheduled by BLM (PRY in 2001, LBC in 2002, MCP in 2004). Ages and numbers of horses treated were in accordance with local plans developed by BLM (U.S. Department of the Interior, Bureau of Land Management, 2001, 2002, 2004). At LBC and MCP, mares of all ages ≥1 year were included. At PRY, however, we treated only mares 1–2 years old or >15 years old. At LBC and PRY, mares that were gathered received an initial inoculation (primer) by hand-held syringe or jabstick while restrained in a squeeze-chute, ungathered mares (sufficient to make up the total number of desired treatments) received the primer injection by remotely delivered dart, and all mares received a second inoculation (booster) by dart. At MCP, all inoculations were given in a squeeze-chute by hand-held syringe, jabstick, or hand-held trocar. All inoculations, regardless of delivery method, were given in the hip.

At LBC and PRY, primer injections consisted of 0.5 mL (100 μg) PZP and 0.5 mL (100 μg) FCA or Freund's modified adjuvant (FMA), and boosters consisted of 0.5 mL (100 μg)

PZP and 0.5 mL (100 μg) Freund's incomplete adjuvant (FIA). Adjuvants and PZP were provided by the Science and Conservation Center at ZooMontana in Billings. Darts were propelled from a Dan-Inject® (Dan-Inject of North America, Knoxville, Tenn.) CO_2-powered blowgun, a Dan-Inject® CO_2 rifle, or a Pneu-dart® (Pneu-Dart, Williamsport, Pa.) 193 rifle. The CO_2 delivery systems allowed user-defined power in pounds of pressure per square inch. The Pneu-dart rifle used .22 caliber CCI® (CCI, Lewiston, Idaho) green power-level charges that were individually weighed to ensure consistent delivery force. Abnormally light and abnormally heavy charges were discarded. Darts used in all delivery systems were 1-cc Pneu-dart darts with 3.8-cm barbless needles. These injections of liquid PZP at LBC and PRY were designed to provide 1 year of infertility, with annual boosters extending the period of contraception.

Treatment at MCP consisted of a primer injection (same composition as for the other two herds with FCA as the adjuvant) delivered by either hand-held syringe or jabstick and a second (but simultaneous) injection delivered by trocar and consisting of three pellets designed to release PZP in bolus fashion at 1, 3, and 12 months postinjection and provide 2 years of infertility. Pellets were developed at the Medical College of Ohio (now the College of Medicine, University of Toledo) and were formed using an organic solvent to mix polymer with PZP and the saponin adjuvant QA–21. The polymer was a mixture of polylactic acid and glycolic acid (both approved for use in humans by the Food and Drug Administration), with the ratio of the two components dependent on the desired release time. Subsequent evaporation of the solvent resulted in a polymer/PZP/adjuvant mixture viscous enough to be formed into pellets that were cut to the desired mass and loaded into a trocar for delivery (J. Turner, Jr., University of Toledo College of Medicine, written commun., 2005).

Liquid vaccine was provided as sterile components (PZP and adjuvant) that were emulsified in alcohol-sterilized syringes prior to application. For hand injections, the emulsion was loaded into alcohol-sterilized syringes fitted with single-use sterile needles. For remote delivery, the emulsion was loaded into darts as they were removed from the manufacturer's packaging, and a small dab of petroleum jelly was placed on the dart tip to prevent leakage of the vaccine. Pellets were dipped in alcohol, coated with a thin film of petroleum jelly, and loaded into sterile needles at the place of manufacture. Each needle tip was also closed with a small dab of petroleum jelly to prevent the pellets from slipping out of the needle during handling. For all hand injections, hip hair was shaved and the area washed with alcohol prior to immunization (J. Turner, Jr., written commun., 2008).

Mares treated at gathers were held in corrals for 28–48 hours and observed for any reactions to injections, then released back to the range. Following remotely delivered treatments, we immediately recovered the dart (if possible) and recorded information on its condition and performance. We then attempted to observe the animal for 30 minutes, which was sometimes not possible for those that fled. We also attempted, with varying degrees of success, to observe each injection site once per week for the first 3–4 weeks or until any reaction disappeared. Additional observations were recorded opportunistically for up to 6 years. Observation distances ranged from 1 m to 500 m, with various optical devices (binoculars, spotting scopes) employed at longer distances. We tracked multiple injections to the same individual by carefully noting the location of each injection on the mare and specifically referencing each new injection site to any observed reactions from previous injections. We also took photographs of reactions opportunistically to aid in referencing specific injection locations.

We coded injection-site reactions in four categories: abscess (an open sore, usually with drainage), nodule (a well-defined circular lump of unknown histology), swelling (a raised area of tissue, but not sufficiently well defined to be considered a nodule), or stiffness (any abnormal range of movement in the limb where the injection was delivered). These categories were not mutually exclusive with respect to either a single observation or a single injection. Swelling and stiffness, for example, were sometimes recorded for the same observation, and multiple reactions were sometimes recorded for a single injection site (for example, swelling might develop into a nodule). We also looked for muscle tremors, behavioral depression, or other systemic reactions, none of which was ever observed.

Because of the opportunistic nature of many of our observations, we could not calculate frequency of occurrence of injection-site reactions directly from the raw data. For example, if an injection site was observed on days 0 and 180, and no reaction was seen, it would be inappropriate to conclude that no reaction occurred because a reaction could have developed and disappeared in the time between the two observations. As an alternative, we divided all of our observations into a series of intervals representing elapsed time after the injection and calculated the frequencies with which the four types of reactions were observed in each interval. Multiple observations of an injection site in a given mare in a period were counted as a single observation in determining sample size, and the reaction was coded as present if it was recorded for any observation during the period. For this analysis, as well as the analysis of covariates (see below), we excluded all injections that were given by hand because much of the concern about possible injection-site reactions in horses is related to darting.

The fact that abscesses occurred infrequently, coupled with the fact that four of the eight observed abscesses occurred in a single horse, precluded meaningful analysis of the relation of abscess occurrence to covariates. For the remaining types of reactions (nodules, swelling, and stiffness), we used logistic regression (PROC LOGISTIC in SAS/STAT®; SAS Institute, Cary, N.C.) to examine the relation between occurrence and four covariates: adjuvant (FCA, FMA, or FIA), delivery method, dart trauma, and age of the mare. For delivery method, we used two classes: rifle or blowgun. We pooled deliveries from the Dan-Inject® CO_2 rifle with those from the Pneu-Dart®

193 rifle because both were scoped delivery guns with longer range, even though the CO_2 rifle allowed user-defined power. In addition, the sample size for treatments delivered with the CO_2 rifle was small (n = 8). For dart trauma, we divided the injections into two broad classes: those where the result may have caused additional trauma at the injection site (bone plug or needle broke off, which we labeled as abnormal) and all others (normal). We did not include the distance from which the dart was fired in this analysis because (1) there were some cases in which distance was not recorded (which would reduce our sample size) and (2) distance tended to be highly correlated with method. Probabilities reported from these regressions are based on the Wald chi-square test statistic.

As noted above, there were many injection sites that were not observed early enough or often enough to be certain whether the various reactions occurred. Therefore, we had to establish criteria for including an injection in the analysis of possible covariates, and those criteria differed by reaction type. Swelling and stiffness, for example, tended to appear earlier and disappear more quickly than nodules. After careful examination of the data, we arrived at the following criteria: for nodules, at least one observation between days 7 and 90 postinjection, inclusive; and for swelling and stiffness, at least one observation between days 0 and 7 postinjection, inclusive. Note that, for these analyses, we are concerned only with whether or not a reaction occurred, not with how long it persisted. In all of these analyses, we pooled data from LBC and PRY in order to maximize sample size.

Results

Thirty-six mares treated at MCP received 72 injections by hand-held syringe, jabstick, or trocar. Because reactions from these hand injections were very rare (see section on Hand Injections, below), and because of the difficulty of observing injection sites at the distances involved, we made only limited followup observations at MCP after the horses were released back to the range. For LBC and PRY combined, 90 mares received a total of 314 injections in 2001–2007. Five mares representing eight injections were not observed postimmunization, leaving us with 714 individual observations of 133 injection sites on 29 mares at LBC and 726 observations of 173 injection sites on 56 mares at PRY (85 total mares, 306 total injections, 1,440 total observations). The majority of injections at LBC and PRY were remotely delivered by dart; 28 were delivered by hand.

Raw Counts of Reactions

For the three areas combined, eight injections resulted in abscesses (table 1). Four of the five abscesses at LBC occurred on a single mare. Six of the eight abscesses were first observed within 39 days of the injection, but we cannot be more definitive about when they formed. One abscess appeared at least 24 days after the injection. Six of the eight abscesses were resolved by the time our formal observations ended in the fall of 2007. One of the two unresolved abscesses at PRY was from a recent injection (July 7, 2007). This abscess had resolved by the time she was first observed in 2008. The other was an abscess that was first observed on day 329 postinjection (we do not know when it formed). The mare subsequently developed a large wound in the same location, which prevented further observation of the injection site. A veterinary examination in September 2007 concluded that the muscle tissue was not infected but was inconclusive in determining whether the wound resulted from the PZP injection, dart penetration, or some natural cause. When observed in April 2008, the large wound had resolved with scar tissue evident, but no further external sign of the abscess was present. The mean diameter for all abscesses (± SE) was 3.3 ± 0.37 cm (n = 9 observations of 8 abscesses, range = 1–5 cm). Figure 1 illustrates a typical abscess.

Nodules were observed more often than abscesses and more often remained unresolved at the end of our observations (table 1). Nodules formed as early as the day of the injection, and 51 were first observed within 90 days postinjection; the remaining 11 may have appeared in this period also, but we cannot confirm this from our observations. Seventeen nodules appeared at least 8 days postinjection, and one nodule appeared at least 48 days postinjection. While nodules often persisted for long periods (26 were observed at least 1 year postinjection), persistence did not preclude eventual disappearance (for example, one disappeared after at least 1,337 days and another after at least 1,114 days). Mean nodule size was 2.8 ± 0.10 cm (n = 194 observations of 62 nodules, range = 1–12 cm). Figure 2 illustrates two typical nodules.

Swelling was the second most common reaction (after nodules; table 1) and usually appeared soon after the injection; 28 of the instances that we observed were recorded on the day of the injection or the following day. At least 26 of the instances of swelling disappeared within 30 days postinjection, although one was still present at 62 days. The two instances of unresolved swelling represent sites that were last observed (in 2007) 28 and 33 days postinjection. Mean swelling diameter at LBC and PRY was 4.6 ± 0.35 cm (n = 64 observations of 49 cases of swelling, range = 1–12 cm). The two instances of swelling at MCP (from hand injections) were both 2 cm in diameter.

Stiffness resulted from 1 injection at LBC and 14 at PRY. Stiffness usually developed shortly after the injection; in 11 of the 15 cases it was observed in the first 3 days postinjection. In most cases, stiffness lasted a relatively short time; in 11 of 15 cases it disappeared within 24 days postinjection. This may also be the case for the remaining four injections, but our observations were not sufficiently frequent to narrow the time of disappearance.

Multiple reactions were recorded for only 10 of 1,440 (0.7 percent) individual observations. A combination of swelling and stiffness accounted for eight of these observations, with the other two involving stiffness and a nodule,

Table 1. Raw counts of injection-site reactions observed. Includes reactions from both hand and dart injections.

[— = not applicable]

	LBC		MCP	PRY	
	Hand injection	Dart injection	Hand injection	Hand injection	Dart injection
Abscesses observed	0	5	0	0	3
Abscesses resolved[1]	—	5	—	—	1
Nodules observed	1	17	0	0	44
Nodules resolved[1]	1	12	—	—	24
Swelling observed	0	8	2	0	41
Swelling resolved[1]	—	8	2	—	39
Stiffness observed	0	1	0	0	14
Stiffness resolved[1]	—	1	—	—	14

[1] Resolved indicates that the reaction had disappeared by the end of our observations in fall 2007.

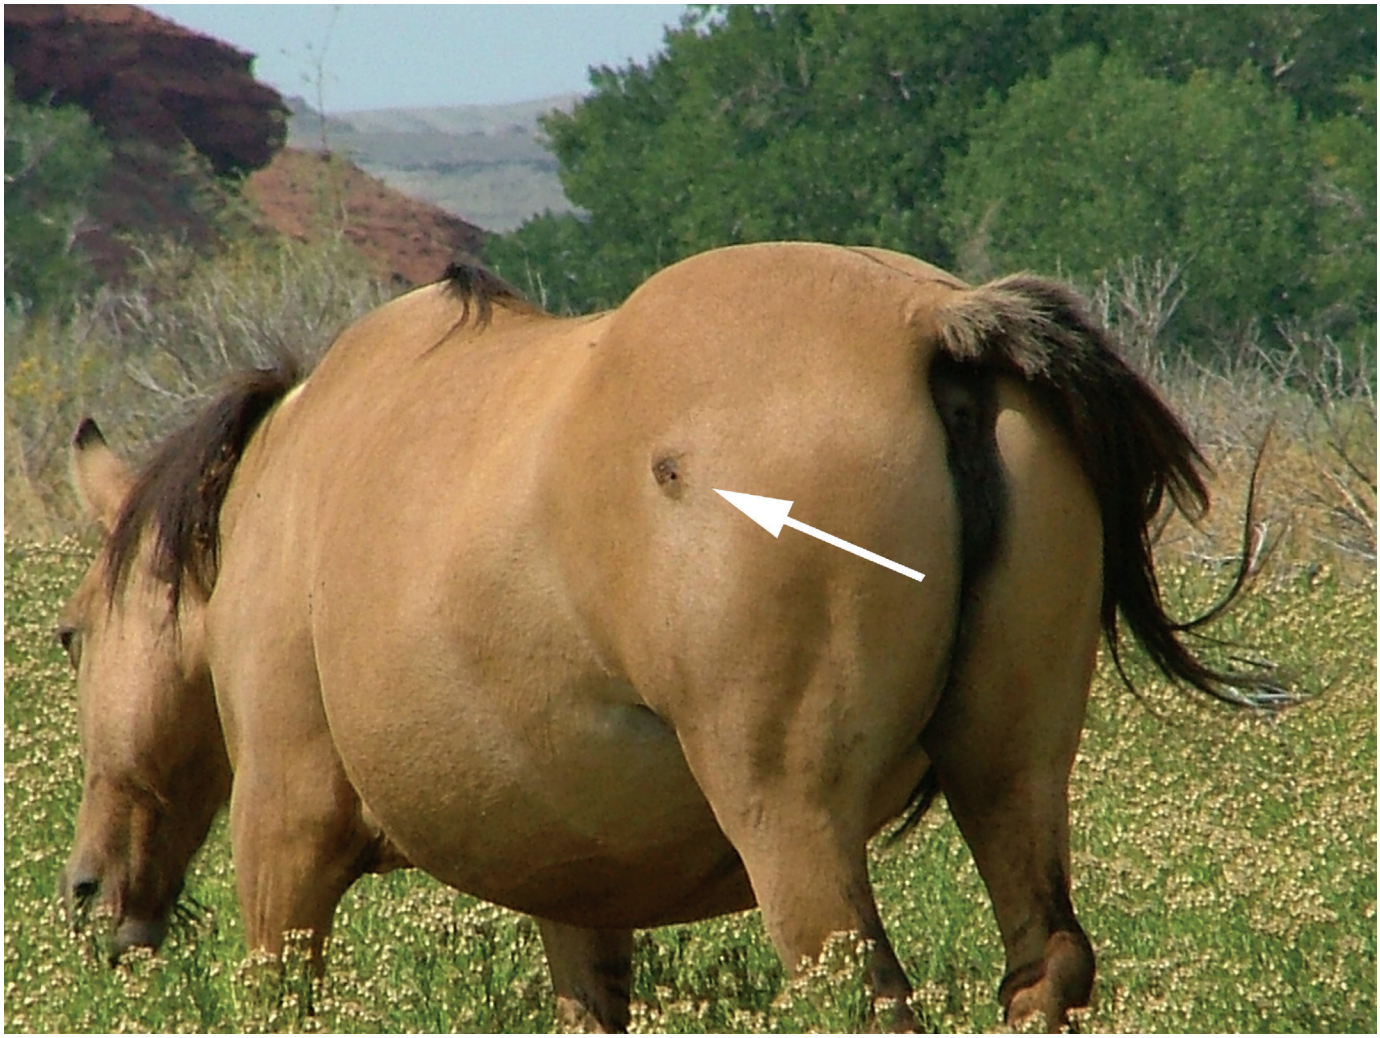

Figure 1. Abscess observed on Pryor Mountain horse #8901, 32 days after a booster injection delivered by CO_2 blowgun.

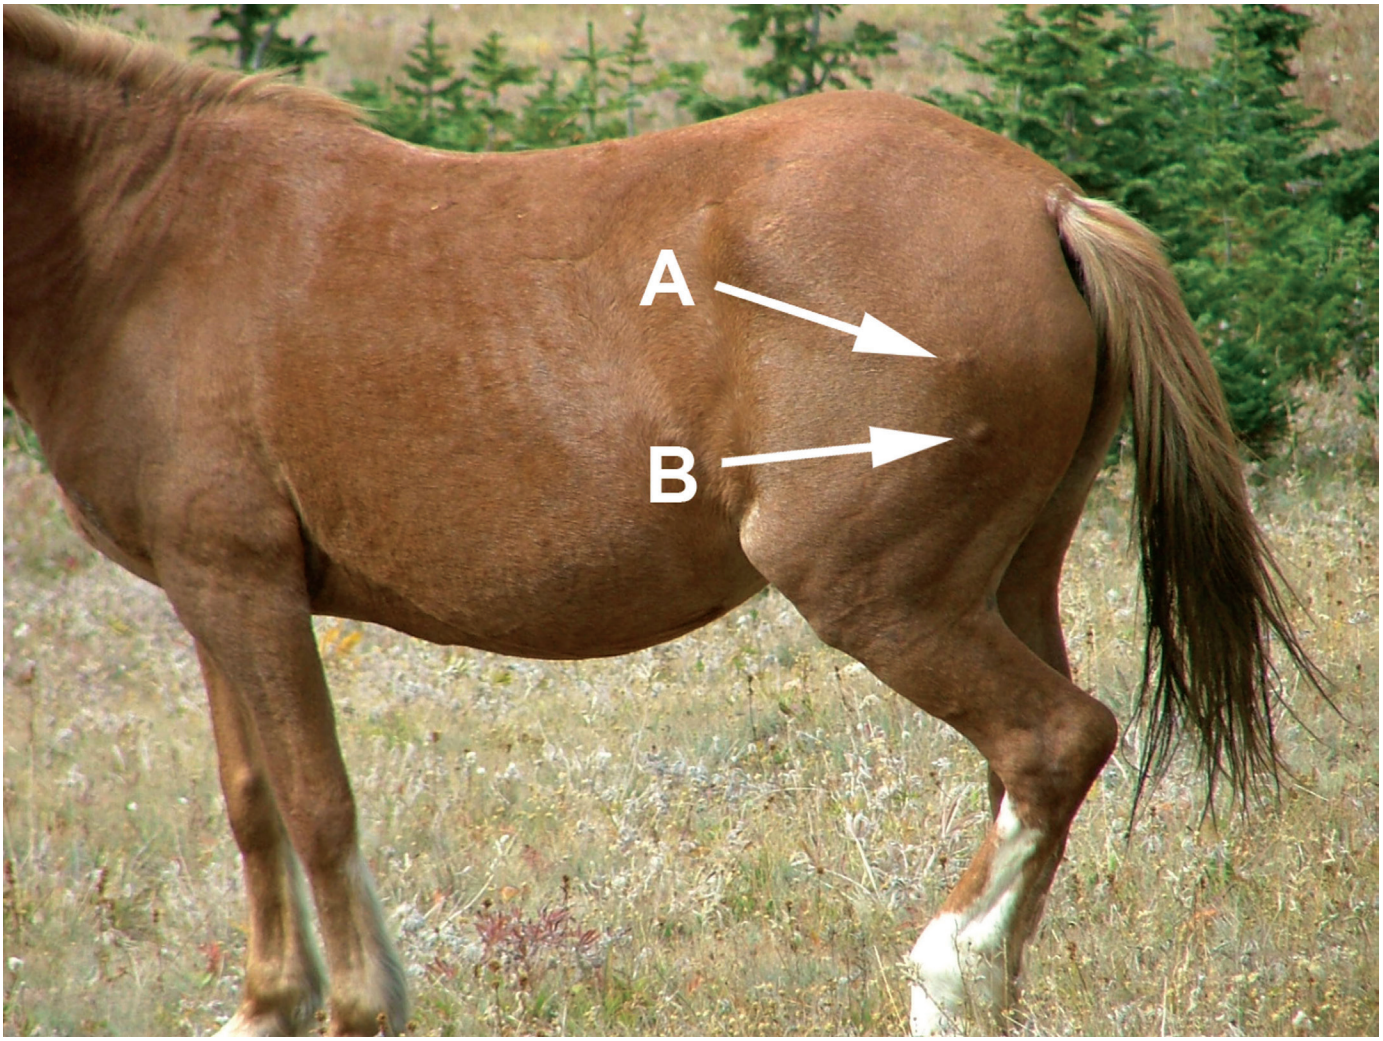

Figure 2. Two nodules observed on Pryor Mountain horse #9105, 2 years (*A*) and 56 days (*B*) after booster injections delivered by CO_2 blowgun.

and swelling and a nodule. In terms of injections, 35 (which includes the 10 mentioned above) of 306 (11.4 percent) resulted in multiple reactions, the most common combination being swelling and a nodule.

Hand Injections

The 72 injections by hand-held syringe, jabstick, or trocar at MCP resulted in two instances of swelling and no other reactions. In both cases, the swelling had disappeared by the time the animals were released back to the range. An additional 28 hand injections were given at LBC and PRY, resulting in only a single nodule, which formed on the day of the injection and persisted for about 150 days.

Dart Injections

Dart Performance

At LBC, 7 of 117 darts (6.0 percent) missed the animal completely and were not recovered. Four darts properly struck the target but were not recovered due to delayed ejection, rapid animal movement, thick vegetation, or some combination of these factors. Thus, 11 darts at LBC (9.4 percent of all darts fired) were not recovered. Similar data for PRY are incomplete and therefore are not reported here; however, due to the relatively short range of most shots at PRY, we believe that the unrecovered dart rate was likely lower than that at LBC.

The seven darts that missed the animal completely had no opportunity to discharge the drug properly and are thus not included in our assessment of dart performance (table 2). Based on the fact that the four other unrecovered darts struck the target properly, we assumed that they also functioned properly. Thus, for LBC and PRY combined, 278 injections were delivered remotely by dart from 2002 to 2007, and in 253 cases (91.0 percent) we judged that the injection was delivered properly (table 2). In 19 cases (6.8 percent), the dart either failed to discharge (the plunger was not depressed, two cases), partially discharged (the plunger was only partially depressed, three cases), split (the plastic portion split longitudinally, two cases; fig. 3), or came apart (the dart separated at the junction of the plastic and metal, 12 cases; fig. 3). In an additional six cases, the needle either broke off (three cases; fig. 3) or the dart hit bone (as evidenced by bone tissue in the recovered needle, three cases). When darts hit bone or came apart, the needles nevertheless fell free of the horse. In the few instances where the needle broke off, we do not know its fate. However, those three cases resulted in two nodules, both of which disappeared over time. The three injections where the dart hit bone cannot be considered a malfunction of the dart itself; excluding these three cases, 253 of 275 darts (92.0 percent) functioned properly.

Table 2. Performance of darts used in delivering the immunocontraceptive vaccine.

Dart performance	Number of darts		% of total
	LBC	PRY	
Bone plug	0	3	1.1
Came apart	5	7	4.3
Did not discharge	1	1	0.7
Functioned	102	151	91.0
Needle broke off	2	1	1.1
Partially discharged	0	3	1.1
Split	0	2	0.7
Total	110	168	100.0

Frequency of Reactions

Abscesses were relatively rare, resulting from at most 5–6 percent of the injections by dart (table 3). Most abscesses disappeared within 90 days of darting, though one persisted at PRY for more than 181 days. Nodules were both more frequent and more persistent than abscesses. Approximately 25 percent

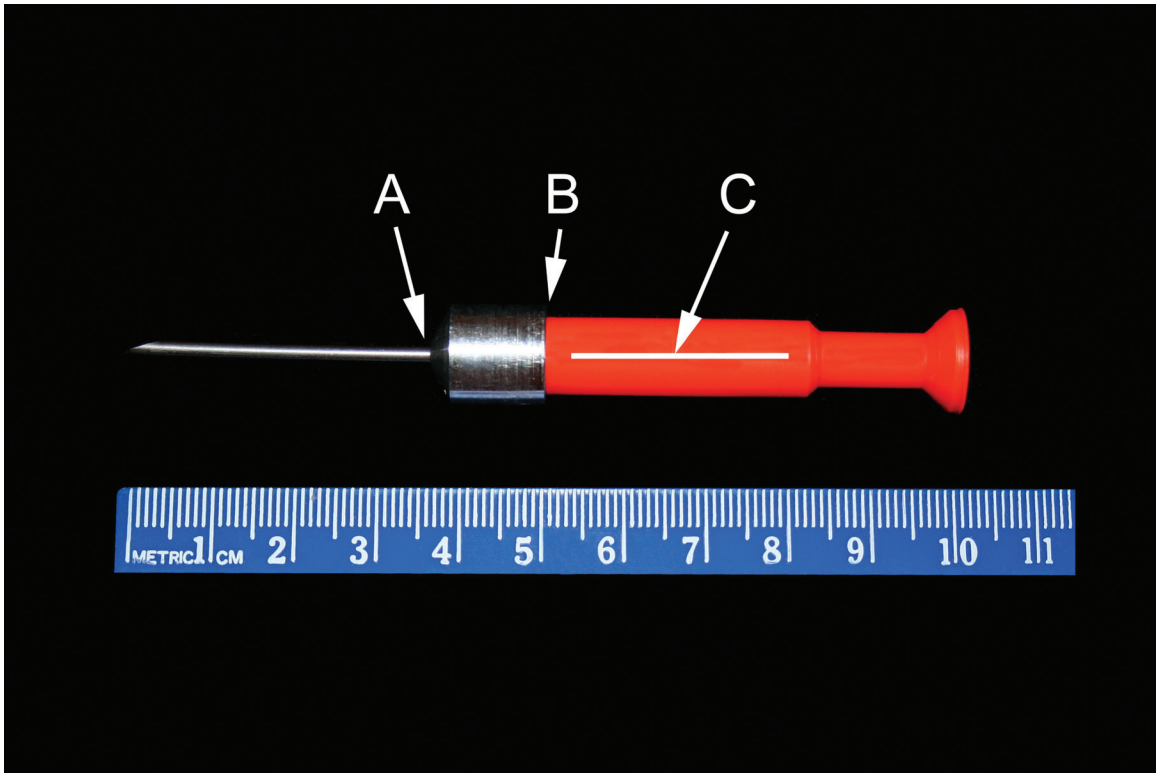

Figure 3. Example of a dart used for all injections. A is the point at which needles broke off, B is the point at which the metal separated from the plastic, and C illustrates the position of a typical longitudinal split in the cylinder.

of darts at both study areas resulted in nodules, and some nodules persisted into the fifth year. Most, however, eventually disappeared. Swelling resulted from about 11 percent of injections by dart at LBC and about 33 percent at PRY. At both study areas, swelling rarely persisted for more than 30 days and never for more than 90 days. Stiffness was recorded for 1.4 percent of the observations at LBC and 11.7 percent at PRY. In all cases, stiffness disappeared within the first 30 days.

Relation of Reactions to Covariates

For nodules, the criterion of at least one observation from day 7 through day 90 postinjection resulted in 185 of the 278 injections delivered by dart being selected for the analysis, including 50 (of the 61 known; see table 1) cases where a nodule occurred (27.0 percent) and 135 cases (73.0 percent) where none was observed (table 4). There perhaps was weak evidence that abnormal dart trauma (bone plug or broken needle) resulted in a higher occurrence rate for nodules, but the sample size for abnormal dart trauma was very small ($n = 4$). There was no evidence for a relation between nodule occurrence and either adjuvant formulation, delivery method, or age of mare.

The criterion of at least one observation from day 0 through day 7 posttreatment resulted in selection of 151 injections for analysis of swelling, including 43 (of the 49 possible) injections where swelling was known to have occurred (28.5 percent; see table 1), and an additional 108 (71.5 percent) injections for which swelling was not recorded (table 5). There was no evidence for a relation between swelling and either dart trauma, adjuvant, or age of mare, but strong evidence that swelling was more frequently observed when darts were delivered by blowgun than when they were delivered by rifle. Most (91.7 percent) of the 157 injections delivered by blowgun were at PRY.

Because the same criterion was used to select injections for analysis of both swelling and stiffness, the same 151 observations were chosen for both types of reactions. In the case of stiffness, this criterion resulted in the selection of 14 (of the 15 possible) injections known to have caused stiffness (9.3 percent; see table 1) and an additional 137 injections (90.7 percent) for which stiffness was not recorded (table 6). There was no apparent relation between stiffness and any of the covariates, though there were again few instances of abnormal dart trauma.

Table 3. Percentage of injection sites exhibiting abscesses, nodules, swelling, or stiffness as a function of time after injection. Only injections delivered by dart are included. Multiple observations of an injection site in a period were counted as a single observation in determining sample size (*n*). The reaction was coded as present if it was recorded for any observation during the time period.

Discussion

Darting

Excluding the three injections that resulted in bone plugs, the overall failure rate of darts was 8 percent, but failures were not distributed evenly through time. In 2002–2003, 20 of 112 darts (17.9 percent) failed to function properly. Following changes in manufacturing, the failure rate in 2004–2007 dropped to 2 of 163 (1.2 percent). This was an important improvement in the dart manufacturing process given the time and effort expended to find and dart individual horses. The small number of darts lost on the range presumably represent little biological hazard should they be found because impact with the ground or other natural objects probably triggered the release mechanism in the dart and discharged the contents. The very small amounts of PZP and adjuvant discharged also presumably do not pose an environmental contamination threat. The physical hazards of darts, as well as pieces of darts that were unrecoverable (broken needles or needle/cap separations), could pose minor danger if found by visitors simply due to the sharp nature and aging metal present. However, given the intensity of search effort by the darters at the time of operations, it is unlikely that an unrecovered dart would be discovered, even if another person passed by the exact location in these remote areas.

Abscesses

Our results for injections delivered by hand-held syringe or jabstick are consistent with the scant information on abscesses reported in the literature for equids. We observed no abscesses in 72 hand injections of 36 mares at MCP, and no abscesses (but a single nodule) in 28 hand injections at LBC and PRY combined. Turner and others (1997) hand-injected 60 mares in the gluteus muscle with PZP and FCA, and held them in corrals for 30 days awaiting a booster injection. No abscesses were observed in this 30-day period, and the authors further concluded that abscesses were unlikely to have occurred in an additional group of mares that were treated with a single injection of PZP and FCA and released within 72 hours posttreatment. In a similar experiment, Turner and others (2001) hand-injected 95 mares in the gluteus muscle with PZP and FCA and an additional 60 mares in the same location with PZP, FCA, and a carbomer adjuvant. These 155 mares were held in corrals for 13–17 days awaiting a booster treatment, and no abscesses were observed during this period. Further observations of some of these mares after release showed no injection-site marks, leading the authors to conclude that abscesses had not occurred. Lyda and others (2005) treated 7 mares with PZP plus FCA and 8 mares with PZP plus FMA; all 15 mares received a booster injection of PZP plus FIA 27 days later. All injections were delivered by hand in the hip or gluteal muscles. The 30 total injections in their study resulted in one abscess (3.3 percent of injections) following a booster with FIA in a mare initially treated with FMA.

Thus, it appears that abscesses are rare in horses for injections of PZP and any of the formulations of Freund's adjuvant where the injections are delivered by hand in the hip region. The location of the injection may be important, however. Lyda and others (2005) cited a personal communication from I.K. Liu indicating that abscesses can occur more frequently in horses receiving injections of PZP and FCA in the neck.

Information on abscesses resulting from injections delivered remotely to horses is similarly scarce. Kirkpatrick and others (1990) darted mares at Assateague Island National Seashore with PZP and FCA (n = 26 mares), followed by PZP and FIA boosters (n = 26, injection 2; n = 18, injection 3). Following the third injection (with FIA), they observed three abscesses, or a frequency of 4.3 percent (in 70 injections). Following several additional years of treatment at Assateague, the number of abscesses was reported as either two (Turner and Kirkpatrick, 2002) or three (Lyda and others, 2005) in a total of 381 injections (0.5 or 0.8 percent). Interestingly, both of these later publications attributed only one of the abscesses to an injection containing FIA. In any case, the frequency of occurrence of abscesses was low.

Our results for frequency of occurrence of abscesses in mares darted at PRY (0.8 percent; table 3) were very similar to those reported above, but somewhat higher (5.5 percent) at LBC. The higher rate at LBC is mostly a result of four abscesses occurring in a single mare that was clearly prone to reaction. In addition, however, our approach to calculating frequency of occurrence of reactions, necessitated by the fact that we were unable to observe injection sites on a regular schedule, is strictly valid only if the observations can be considered a random sample of all of the injection sites present in an interval. This is probably not the case, because field personnel were instructed to monitor injection sites where there was a known reaction as closely as possible until the reaction was resolved, and then record observations only opportunistically. In fact, the mean number of observations for injection sites that showed a reaction (5.10) was slightly higher than the mean number of observations for injection sites that did not show a reaction (4.53; generalized linear model with Poisson distribution, P = 0.03). Thus, it is likely that our results for frequency of occurrence of all reaction types are biased somewhat high.

Kirkpatrick and others (1990) also reported that the three abscesses they observed formed within about 48 hours of the injection and healed completely within 14 days. The single abscess observed in the study by Lyda and others (2005) appeared 1 month after a booster inoculation; time until healing was not reported. While our observations on the timing of appearance and disappearance of abscesses are not as precise, we do know that one abscess became visible at least 24 days posttreatment and that six of the eight abscesses observed were present on day 15. Additionally, one abscess was present at day 77 postinjection, and another at day 329. Thus, it appears that abscesses can form as much as a month posttreatment and can occasionally persist for much longer than has been reported previously.

Other Reactions

We are unaware of any published information on occurrence of other injection-site reactions in equids treated with PZP. This is curious, particularly for nodules, which in our study were fairly common and sometimes persisted for long periods. It is unclear whether reactions similar to what we termed nodules simply did not occur in other studies, or perhaps were considered too inconsequential to report. Similar reactions have occurred in other species, however. Turner and others (1992, p. 155), working on white-tailed deer (*Odocoileus virginianus*), reported that "a raised area of about 20 mm in diameter developed in the final injection site on 3 does." These reactions disappeared in 8–10 days in two cases and after 5 weeks in the third. Patton and others (2005, p. 160) also mention that the Freund's adjuvants often cause formation of a small (marble size) granuloma at the injection site, but they do not provide any examples.

Covariates

We were unable to detect a relation between any of the reactions we observed and the adjuvant used. Coupled with the fact that reactions are rare for injections delivered by hand, this suggests that most reactions are probably the result of trauma associated with dart delivery, or a combination of dart trauma and adjuvant. With that observation in mind, we were somewhat surprised to find a higher probability of swelling when darts were delivered by blowgun, which was used at closer ranges and allowed for variable power. The average distance from which darts were fired by blowgun was 11.8 ± 0.24 m, whereas for darts fired by rifle it was 31.8 ± 1.03 m, and the majority of the shots fired by blowgun (144 of 157, or 91.7 percent) were at PRY, where horses are generally more approachable than at LBC. Greater approachability at PRY probably led to both more frequent use of the blowgun and greater ability to detect swelling.

Conclusion

PZP is a promising management tool for limiting population growth in wild horses; however, as with any management tool, side effects, practicality of use, and physiological and biological implications must also be considered. PZP has been clinically tested for safety and some potential physiological side effects in both domestic and wild equids (Liu, 1989; Kirkpatrick and others, 1992, 1995, 1996; Kirkpatrick and Turner, 2002;), but there is less information available regarding safety in field applications. Currently, the most time-efficient method for applying PZP is by hand-delivered injection of 2-year pellets when horses are gathered. We observed only two instances of swelling from this formulation. Use of remotely delivered, 1-year PZP is generally limited to populations where individual animals can be accurately identified and repeatedly approached. This formulation produced injection-site reactions of varying intensity, though none of the observed reactions appeared debilitating to the animals. The longer term nodules observed did not appear to change any animal's range of movement or locomotor patterns and in most cases did not appear to differ in magnitude from naturally occurring injuries or scars. We were unable to perform histological examinations of these nodules, but they may be similar to granulomas reported by other investigators following administration of Freund's adjuvant. Further analyses should be considered to determine whether they pose any long-term physiological threat to the animal. Injection-site reactions represent only one of the potential effects of PZP on horses. Other factors, such as treatment efficacy, long-term ovarian function, individual and social behavior, and seasonality of parturition by post-treated mares are also important considerations for the assessment of PZP as a management tool.

Acknowledgments

This research was funded by the USGS Wildlife Program and conducted through a cooperative effort between the USGS Fort Collins Science Center, the BLM Wild Horse and Burro Program, the USDA's Animal and Plant Health Inspection Service (APHIS), the National Park Service (NPS), and Colorado State University. We give special thanks to the field technicians, contractors, and volunteers who spent countless hours searching for horses, often under difficult conditions: Hanem Abouelezz, Laura Caldwell, Melissa Esser, Marty Felix, Kayla Grams, Patty Grigsby, Susan Hahn, Billie Hutchings, Georgia Manus, Jane Nibler, Christina Petrandis, Phyllis Preator, Jennifer Severude, and Gerald Thygerson. We thank Jay Kirkpatrick, Kim Frank, and Robin Lyda of the Science and Conservation Center, ZooMontana, for supplying liquid PZP and for training our staff to safely handle and deliver it remotely in the field, and John Turner, Jr., at the University of Toledo College of Medicine for formulating and administering the PZP pellets. Logistical support was graciously provided by the BLM's Grand Junction, Cody, and Billings Field Offices as well as NPS's Bighorn Canyon National Recreation Area. In particular, we thank Linda Coates-Markle, Jim Dollerschell, and Tricia Hatle from the BLM, and Rick Lasko and Cassity Bromley from NPS for coordination, office space, equipment, and endless technical support. Thanks to Albert Kane at APHIS for his veterinary and statistical advice and to Dean Bolstad and Alan Shepherd for coordinating the BLM wild horse research efforts and providing management perspectives. Gregor Auble, Dean Bolstad, Brian Cade, Albert Kane, Alan Shepherd, John Turner, and Bea Wade provided many useful comments on earlier drafts of this report.

Demography of the Pryor Mountain Wild Horses, 1993–2007

By James E. Roelle,[1] Francis J. Singer,[1,2] Linda C. Zeigenfuss,[1] Jason I. Ransom,[1] Linda Coates-Markle,[3] and Kathryn A. Schoenecker[1]

Abstract

Wild horses (*Equus caballus*) at Pryor Mountain were studied by direct observation from 1993 through 2007. All horses present were individually identifiable on the basis of coat coloration, head and leg markings, gender, and band associations. Of the 609 horses either present prior to foaling in 1993 or born since, ages were precisely known for 491 (observed as a foal). Ages for 52 horses were estimated through tooth eruption and wear patterns, and for the remaining 66 horses through body size, morphology, and anecdotal evidence concerning when they were present on the range. At varying intensities, never less than 30 days per year, all horses were inventoried and their band associations noted. Foals were paired with dams based on observations of attachment during the early days and weeks of life. Year of death was determined by identification of the carcass where possible. In the absence of finding a carcass, an animal that was not observed for 2 years was considered to have died in the year that it went missing. Animals that were removed from the herd and mares that were part of a contraception study were excluded from calculations of survival and foaling rates, respectively, as appropriate.

The average prefoaling population over the 15 years of the study was 148.8 animals (range = 120–187), and the annual foal crop averaged 32.1 (range = 23–40). Large removals (19–60 animals) in four years helped maintain the herd at this level; apparent growth rate (calculated as though removals had not occurred) was 9.6 percent annually ($\lambda = 1.096$, range = 0.977–1.220). This annual growth rate is relatively low compared to that for many western horse herds, at least in part because of a decline in foal survival. Sex ratio of the foal crop varied widely among years, but pooled across years did not differ from 50:50. Sex ratio in the herd changed mostly as a result of removals. The average age of both males and females in the herd increased during the course of the study. Annual survival of males did not differ from that of females, nor did gender affect annual survival of foals. Pooled across years, ages, and sexes, the annual survival rate was 0.899. Annual foal survival rate was 0.697 and declined through time, with a tendency toward recovery in 2005–2007. Foal survival was higher in larger bands, but did not differ between foals born to primiparous and multiparous mares. A few 2-year-old mares produced foals; foaling rate (excluding contracepted mares and foals they produced) increased through age 10, remained high through age 15, and declined thereafter. Overall foaling rate for mares ≥3 years of age was 0.576 foals per mare, with no apparent trend during the period of our study. Foaling rate in years following gathers was somewhat lower than in other years. There was a positive relation between foaling rate and band size. Primiparous mares were somewhat less likely to foal in the following year than were multiparous mares. Most stallions that acquired a harem did so at age 5 or 6, and the average age of harem stallions increased during our study. Most harems had 1–3 mares ≥2 years of age, but harem size varied with age of the stallion, increasing through about age 11 and declining thereafter. About 6 percent of bands had a satellite stallion (≥5 years of age), but the mean number of mares did not differ between single- and multistallion bands. Most stallions left their natal band at age 2 or 3, but 17 percent remained with their natal band until age 4 or 5.

Foal survival rate was positively related to precipitation, suggesting a possible link to forage production and availability mediated through mare fitness. There also was evidence for density-dependent population regulation, as both population growth rate and survival rate were negatively correlated with population size from the previous year. These and other factors were not sufficient to stabilize the population during our period of study, however, as evidenced by the necessity for large removals in several years.

Introduction

The Pryor Mountain Wild Horse Range was created in 1968 by order of the Secretary, U.S. Department of the Interior, who directed that wild horses (*Equus caballus*) be managed in "a balanced program which considers all public values and without impairment of the productivity of the land" (Federal Register, Document 68-11056, Sept. 11, 1969;

[1] U.S. Geological Survey, Fort Collins, Colorado.

[2] Deceased.

[3] Bureau of Land Management, Wheat Ridge, Colorado.

Bureau of Land Management, 2006, p. 5). The Bureau of Land Management (BLM) was designated as the lead agency for management of wild horses, though the range also contains lands administered by the U.S. Forest Service (FS; Custer National Forest) and the National Park Service (NPS; Bighorn Canyon National Recreation Area). The Wild Free-Roaming Horses and Burros Act of 1971 (P.L. 92-195) further directed the FS and BLM to manage wild horses at Pryor Mountain and wild horses and burros (*Equus asinus*) wherever they occur "in a manner that is designed to achieve a thriving natural ecological balance on the public lands."

While laudable as general management goals, the conditions implied by phrases such as "a balanced program which considers all public values without impairment of the productivity of the land" and "a thriving natural ecological balance" have proven difficult to achieve for many wild horse herds. With the protection afforded by the Act and a dearth of natural predators, many wild horse herds can increase at annual rates of 15–25 percent (Eberhardt and others, 1982; Garrott and Taylor, 1990; Garrott and others, 1991b; Singer and others, 2000), thus threatening to exceed the carrying capacity of their ranges. BLM has addressed this problem largely through a gather and removal program in which excess horses are removed from the range and offered to the general public for adoption or sale to good homes. While hugely successful by some measures (BLM has adopted out more than 220,000 horses since 1971; *http://www.blm.gov/wo/st/en/prog/wild_horse_and_burro/wh_b_information_center/Fact_Sheet.html*), supply has exceeded demand, leaving nearly 32,000 horses in BLM corrals and long-term holding pastures. This approach is not embraced by all members of the public. Wild horse advocacy groups often favor a policy of minimum disturbance and intervention, arguing that there are too few, rather than too many, wild horses and that the gather and removal process is detrimental to horse health and well-being. On the other hand, ranchers and conservationists often see wild horses as competing with domestic cattle (*Bos taurus*) and native wildlife for forage, and would thus prefer that BLM reduce the size of many horse herds.

Given the contentious nature of the issues involved, BLM has a continuing need for the best scientific information available on the ecology and demography of wild horse herds. Since creation of the range in 1968, information on wild horses has been gathered nearly continuously by trained investigators and volunteers, making the Pryor Mountain horses perhaps the most studied herd in the Western United States. Furthermore, all of the horses at Pryor Mountain are individually identifiable (unique color markings), and many are of known (observed as a foal) or closely estimated (tooth eruption and wear patterns) age, making the resulting data dependable. The first study of horses at Pryor Mountain was initiated in 1970 by J.D. Feist, who focused largely on behavior (Feist, 1971), but also gathered some information on demography of the population (Feist and McCullough, 1975). Shortly thereafter, Hall (1972) performed an assessment of the herd and possible management alternatives. Perkins and others (1979) studied population dynamics, age distribution, and band composition in the Pryor Mountain herd from 1974 through 1978. Garrott and Taylor (1990), using information gathered by BLM personnel, reported on many aspects of herd demography from 1972 through 1986. F.J. Singer and several colleagues began studies at Pryor Mountain in the early 1990s, broadening their scope to include vegetation dynamics and conservation genetics as well as demography (Singer and Schoenecker, 2000). Prior to his untimely death in 2005, Singer also participated in work at Pryor Mountain on contraception and population estimation.

Here we report on the demographics of the Pryor Mountain wild horse herd from 1993 to 2007. The results contained herein represent a more detailed analysis of the data presented by Singer and others (2000) and an extension covering the next decade. While specific to the Pryor Mountain herd, and thus not necessarily representative of the other 180 Herd Management Areas (HMAs) overseen by BLM, we hope that our results will provide wild horse managers with useful insights as they continue to meet the challenges of managing wild horse herds in the Western United States.

Study Area

During the period of our study, horses actually used an area larger than the Pryor Mountain Wild Horse Range as originally designated. The northwestern and northern boundaries of our study area are not well defined, as there are no natural or manmade barriers to horse movement in that direction. As shown in figure 1, however, the study area encompasses about 22,300 hectares (ha). The following description of the area largely follows Singer and others (2000) and Ricketts (2004).

The study area lies along the Montana-Wyoming border at approximately latitude 45°4'N and longitude 108°19'W, 76 kilometers (km) south of Billings, Mont., and 14 km north of Lovell, Wyo. (fig. 1). The area is topographically diverse, dominated by narrow canyons and steep cliff faces. Elevations range approximately from 1,175 to 2,670 meters (m), with corresponding variation in climate and vegetation. Temperatures range from 40 ºC in the summer to -34 ºC in the winter. Mean annual precipitation ranges from 15 centimeters (cm) at lower elevations to nearly 70 cm at higher elevations, with much of the annual total falling in April–June. Midelevation ridges and plateaus often remain snow free or accumulate <10 cm of snow as a result of winds and southern and western exposures. Higher elevations often have winter snow accumulations of 1 m or more. In water years 1993–1998 (water year 1993, for example, runs from October 1992 through September 1993), mean annual precipitation at Lovell, Wyo. (*http://www.wrcc.dri.edu/summary/climsmwy.html*), was 17.2 cm, essentially identical to the 30-year average (Bureau of Land Management and others, 2008). From 1999 to 2004, however, severe drought conditions prevailed (mean annual precipitation = 12.3 cm). Prolonged drought can decrease plant health

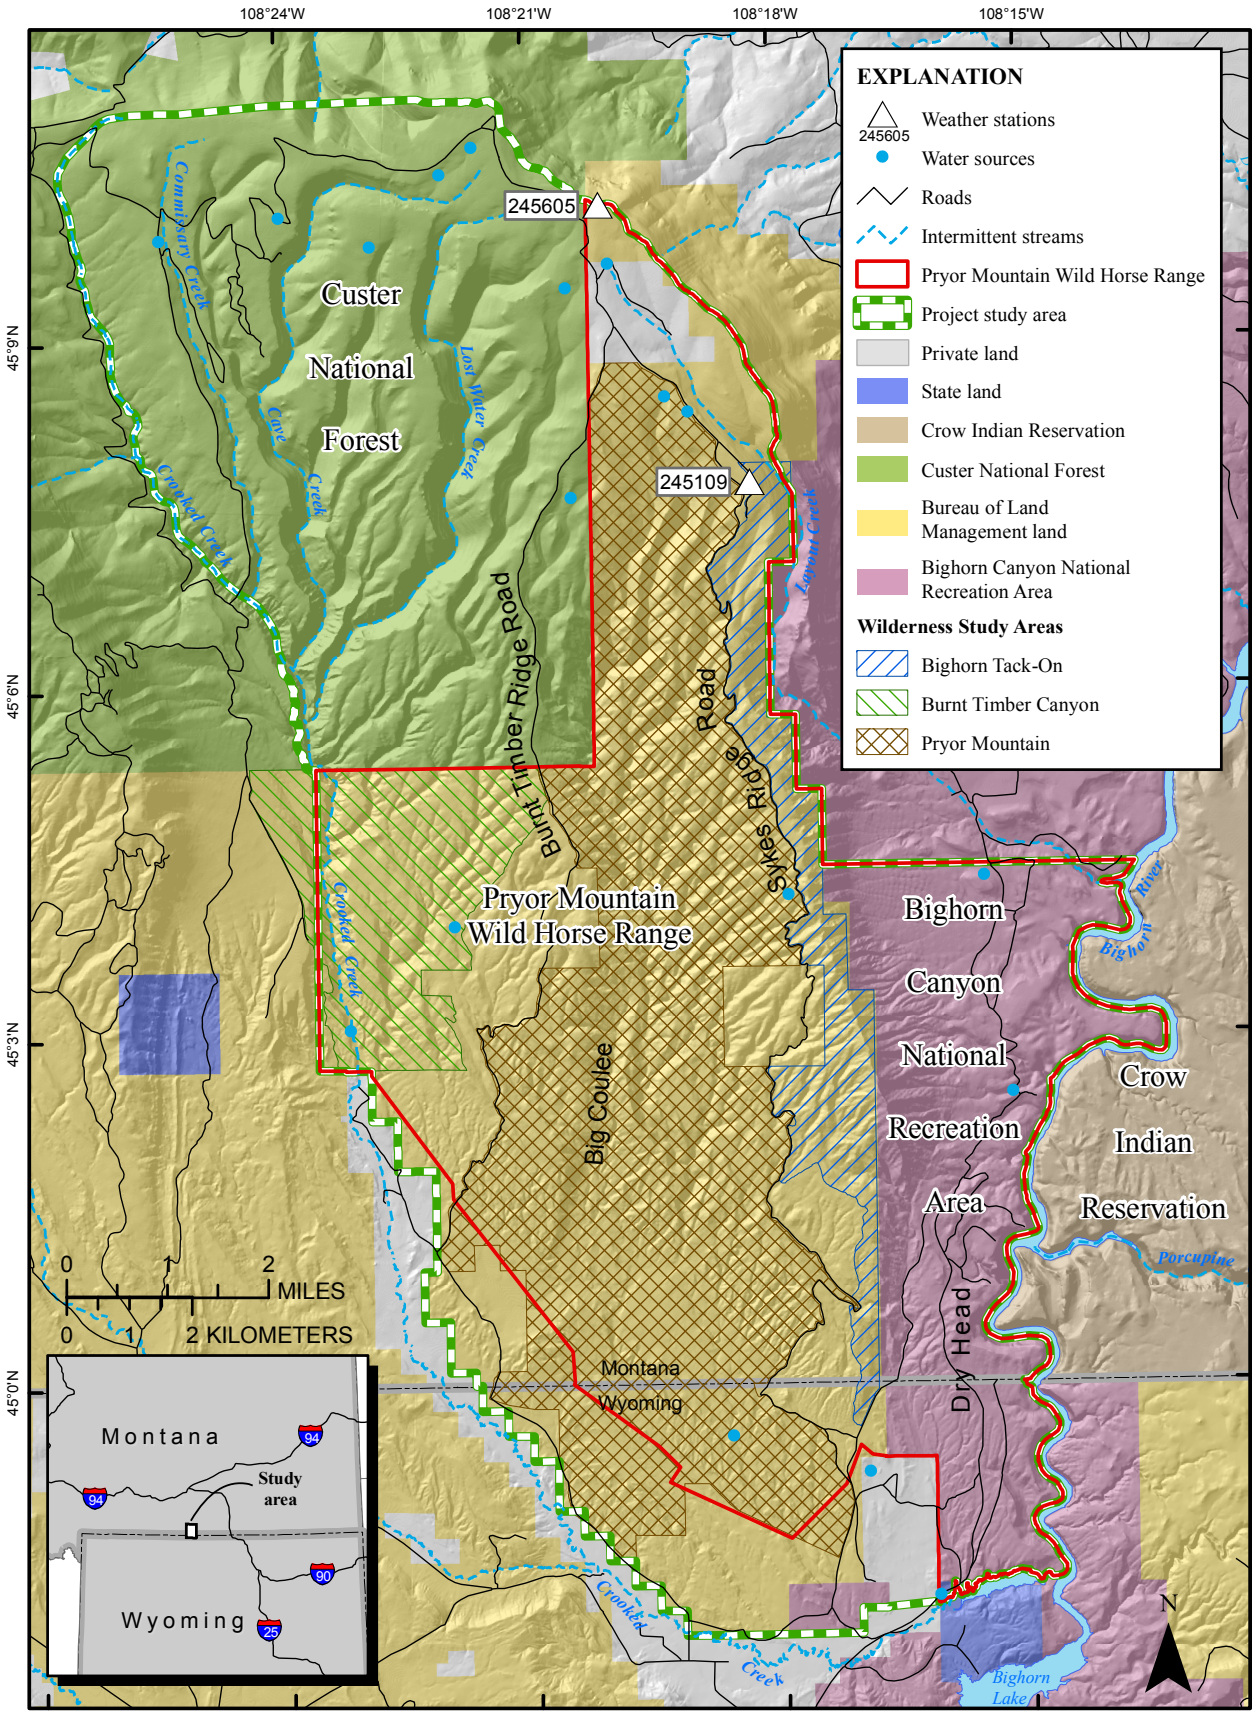

Figure 1. Location of the Pryor Mountain Wild Horse Range and study area.

and vigor and forage production. Temporary relief from the drought occurred in 2005 (annual precipitation = 21.2 cm) and 2007 (annual precipitation = 14.3 cm for 11 months, data missing for June) At least in 2005, greater precipitation probably resulted in improved forage production (Bureau of Land Management, 2006).

Vegetation in the study area changes dramatically with elevation. At the highest elevations, subalpine meadows (Idaho fescue, *Festuca idahoensis*; alpine timothy, *Phleum alpinum*; alpine bluegrass, *Poa alpina*; Ross sedge, *Carex rossii*; silky lupine, *Lupinus sericeus*) are interspersed with stands of subalpine fir (*Abies lasiocarpa*) and Engelmann spruce (*Picea engelmannii*). At somewhat lower elevations, Douglas fir (*Pseudotsuga menziesii*) occurs with an understory of snowberry (*Symphoricarpos* spp.). Still lower is a shrub community dominated by big sagebrush (*Artemisia tridentata*), rubber rabbitbrush (*Ericameria nauseosus*), shrubby cinquefoil (*Dasiphora fruticosa*), Utah juniper (*Juniperus osteosperma*), and curl-leaf mountain mahogany (*Cercocarpus ledifolius*) and a variety of grasses and forbs such as bluebunch wheatgrass (*Pseudoroegnaria spicata*), threeawn (*Aristida purpurea*), needle-and-thread (*Hesperostipa comata*), and blue grama (*Bouteloua gracilis*). For a more complete description of vegetation communities on the Pryor Mountain Wild Horse Range, see Ricketts (2004).

Herd Behavior and Management

The social structure of the Pryor Mountain wild horse population consists of bands that include a harem stallion, occasionally along with a satellite stallion, plus adult mares and yearlings and foals of both sexes. In general, we use the term band to refer to all members of the group and harem to refer to mares ≥2 years of age. Males older than yearlings that have not acquired a band usually are found in bachelor groups. Distribution and movements of the bands largely are restricted by topography to the west (Crooked Creek drainage) and east (Bighorn Canyon), and fences of varying integrity to the north and south (fig. 1). The wild horses occur in three more or less discrete subpopulations (Burnt Timber Ridge, Sykes Ridge, and Dryhead). These areas are separated by Big Coulee (a deep canyon) and a long, nearly vertical cliff face. However, the horses are able to move between these areas at high elevations and below Big Coulee, as well as occasionally by way of trails on the cliff face. Varying numbers of horses also use U.S. Forest Service land to the north and west of the original horse range boundary. Interchange of horses between subpopulations occurs regularly, but not with high frequency. The horses move with the seasons, spending winters at low and middle elevations where snow is less deep and summering at higher elevations. Distribution is restricted by available water in summer, when the horses tend to congregate near water sources. Water has less effect on distribution in winter, when the horses use snow to meet their water needs.

In the past, the herd has been managed consistent with national selective removal policy for the BLM Wild Horse and Burro Program, removing mostly young animals and conserving the core breeding component of the population. In general, BLM defines Appropriate Management Level (AML) as the number of adult wild horses (6 months and older) determined through the agency planning process to be consistent with the objective of achieving and maintaining a thriving natural ecological balance and multiple-use relation (Bureau of Land Management, 2006). Initially, the AML for the Pryor Mountain herd was set at 115–127, but was revised to 85–105 horses in 1992. However, based on genetic research (Cothran and Singer, 2000; Gross, 2000a,b), from 1996 to 2006 BLM attempted to manage the herd at an average of 140 adult horses to help conserve genetic diversity (Bureau of Land Management, 2006). More recently, BLM has determined that management at an AML of 90–120 adult horses is necessary to protect and improve rangeland health (Bureau of Land Management, 2009).

The BLM has managed the size of the Pryor Mountain herd primarily through a gather, removal, and adoption program. In 1994, wranglers on horseback attempted to capture the entire herd by moving horses into corral traps. In 1997 and 2001, a helicopter was used to move most of the family bands (individual bachelors typically were not gathered) into corral traps; approximately 125 animals were gathered in each of these years. Smaller gathers aimed at removing excess bachelor stallions and yearling females were conducted in 2003 and 2006. The 2003 gather involved a helicopter to move groups containing target horses into a corral trap. The 2006 gather was conducted using bait trapping to lure the horses into a trap, after which they were transported by vehicle to a holding corral.

Since 2001, some mares in the Pryor Mountain herd have received fertility control treatments using the contraceptive porcine zona pellucida [PZP; see Kirkpatrick and Frank (2005) for a recent review of contraception in equids and other free-ranging animals] as part of a cooperative research project between BLM, the U.S. Geological Survey (USGS), and the U.S. Department of Agriculture, Animal and Plant Health Inspection Service (APHIS). In 2001, six mares (age 1–2) that had not yet reached breeding status were treated with PZP by hand injection during the gather. A booster inoculation was administered to three of these females in August 2002; the remainder had either died or could not be located to deliver the booster. Fertility control was subsequently applied to younger mares (age 1–2, 2002–2004) and older mares (>14 years, 2002–2004; >10 years after 2004) that had already contributed to the genetics of the population. After 2001, all inoculations (both primers and boosters) were delivered remotely by darting. Because of the timing of booster inoculations relative to the breeding season, the first contraceptive effects were expected in 2004. From 2004 through 2007, 20.0, 29.0, 10.8, and 30.8 percent of the mares (≥3 years old) in the herd were presumptively contracepted.

BLM also has attempted to manage the herd to adjust the sex ratio in favor of males (Bureau of Land Management, 2006) and occasionally has introduced a limited number of horses (both mares and stallions) from outside herds in order to supplement the herd genetically. Introduction of outside horses was discontinued in 1994.

Methods

Field Data Collection

All data reported in this study were gathered through direct observations of the herd by trained BLM and USGS employees and volunteers. From 1995 to 1997, efforts were focused on the peak foaling season, May 1 to June 30. From 1998 to 2007, daily observations were made during the peak foaling and breeding period, May 1 to August 30. This effort totaled approximately 100 hours of observation per week during 1995–1997 and 100–150 hours per week during 1998–2007. Semi-weekly to weekly observations were made March–April and September–November. Fewer observations were made during midwinter, and they were limited to accessible areas of the range, which varied from year to year. Observations were made from the ground during systematic surveys along roads and trails that traverse the study area. Ground observations were augmented with two helicopter flights each fall or winter, 1995–2001, and one flight in late 2006, as well as 20–25 days of horseback surveys throughout each year, 1995–2005.

Greater than 90 percent of the bands were located at least twice per week during the May–July period, and all bands usually were located at least once per week from April to mid-May and August to mid-October. Reduced effort in the remainder of the year resulted in less than one observation per week per band. Observers collaborated during the peak observation season to develop a weekly list of band composition and foal presence.

Wild horses were approached within 100–250 m and could be observed for periods of 2–6 hours with no apparent effect on their behaviors. All horses were identified individually based on color, markings, gender, and band associations since 1993. All stallions, mares, yearlings, and foals observed in bands, bachelor groups, or alone were recorded. Lead harem stallions were identified based on behavior as described in Feist and McCullough (1975), Oom and Santos-Reis (1986), and Berger (1986). Interchanges between bands by mares and stallions were recorded, as were returns to the original band.

Each horse in the population was assigned a unique number during data compilation. Of the 609 animals in the population from 1993 to 2007, horses whose birth year was known from foal records included 480 of the 481 foals born during 1993–2007 and 11 horses born prior to 1993. Ages of an additional 52 animals were estimated by a veterinarian based on tooth eruption and wear patterns (American Association of Equine Practitioners, 2002). Ages of the remaining 66 animals were based on body size and morphology and anecdotal evidence of years the animals were on the range. Death year was determined by identification of the carcass of the deceased individual or, if an individual was not observed for two consecutive years, the animal was considered to have died in the year it went missing. Number of foals produced was determined by observation as described above. It is possible that some foals were born and died without being seen; however, given the intensity of the observations, we believe that this was rare. Identification of an individual's dam was based on observations of attachment of foal to mare during the early days and weeks of the foal's life.

Analysis

We conducted all of our analyses on the basis of biological years, which we defined as just prior to foaling in one year to the same time the next year. Thus, the biological year 1993 encompasses the period from spring 1993 to spring 1994. Because we defined the biological year in this way, because we made no attempt to pinpoint when during a year a horse was born or died, and because we have the benefit of hindsight (other reported data were often projections), our data will in some cases not match exactly those presented elsewhere (for example, various Environmental Assessments prepared by BLM).

We calculated annual population growth using the expression $\lambda_t = N_t / (N_{t-1} - R_{t-1})$, where λ_t is the growth multiplier from year $t-1$ to year t, N is the population size, and R_{t-1} is the number of animals removed in the period $t-1$ to t. In this formulation, λ represents the apparent growth rate of the population had horses not been removed (Garrott and Taylor, 1990).

Survival rates were calculated as the number of animals present at the end of a year divided by the number present at the beginning of that year. Animals that were removed from the herd were excluded from survival calculations in the year they were removed. Foaling rates were calculated as the number of foals born (regardless of how long they lived) divided by the number of mares present. Mares that were presumptively contracepted and foals that they produced were excluded from calculations of foaling rate.

Band composition has been recorded on "horse lists" regularly (usually weekly) since 1996. These are lists of all the harem stallions present and all the members of their bands, plus lists of bachelor males and animals in transit between bands. To derive information on harem stallions and band composition, we used two of these lists for each year from 1996 through 2007, one from the breeding season (usually early June) and one from fall (September–November, usually the last list available for the calendar year). For each harem stallion present, we calculated the number of mares ≥2 years of age in the band for each of the two time periods and then

took the maximum of those two values as the number of mares held in the harem in that year. We calculated total band size in an analogous manner, and we used these same lists to derive information on bachelors and satellite stallions, which we defined as ≥5 years of age. We defined a satellite stallion in this way in an effort to distinguish true multistallion bands from cases in which a male simply remained with his natal band longer than usual.

We looked for evidence of density dependence in foaling rate, herd survival, foal survival, and population growth rate in the Pryor Mountain wild horse population using stepwise multiple regression with the current year's postfoaling population and the previous year's postfoaling population as independent variables. For these analyses, we used data from Garrott and Taylor (1990) for 1976–1986 (foaling rate, herd survival, and population growth rate), as well as data from our study for 1993–2007. We excluded data from the winter of 1977–1978, during which 51 percent of the population died as a result of heavy snow and ice accumulations (Garrott and Taylor, 1990), from the analyses of density dependence in herd survival and growth rate. We also excluded data from 2004, when 96 percent of the foal crop was lost, from the analysis of foal survival. Foal losses in 2004 are suspected to have been the result of predation by mountain lions (*Puma concolor*). We believe that these exclusions are justified because the biological processes operating in these years were clearly different from those operating in other years.

It would be desirable to have consistent, long-term data on annual forage production for comparison with demographic parameters, but we are unaware of such data for the study area. As a possible surrogate, we examined weather records from a number of stations in the area, reasoning that forage production in this semiarid environment likely is related to precipitation, even though large elevation differences across the study area make it unlikely that any single station will be representative of the entire area. In terms of location, the best available data are from a Remote Automated Weather Station (RAWS; Wild Horse Montana, NWS ID #245605, elevation 2,675 m), which was operated in the study area from October 1991 to July 1997 (*http://raws.dri.edu/wraws/emtF.html*) (fig. 1). Unfortunately, overlap between this period of record and the period of our study is minimal. A National Climatic Data Center Station (NCDC #484770, elevation 1,170 m) at Lovell, Wyo., has a much longer period of record (1948–present; *http://www.wrcc.dri.edu/summary/climsmwy.html*), but its lower elevation caused us to question its relevance to higher elevations in the study area. For the 7 years of data in common, however, there was a strong correlation between the two stations for both total annual precipitation ($R^2 = 0.921$, $P = 0.0006$) and the minimum of the monthly average minimum temperatures ($R^2 = 0.763$, $P = 0.01$). We therefore used data from the Lovell station and stepwise multiple linear regression to analyze relations between weather and herd survival rate, foal survival rate, and foaling rate (mares ≥3 years of age). Data on annual herd survival and foaling rate were available from both our study and the work of Garrott and Taylor (1990), but data on annual foal survival were available only from our study. For the reasons cited above, we again excluded 2004 from the analysis of foal survival.

Other investigators (Heitschmidt and others, 2005; Smart, 2005) showed that spring precipitation (April–June) is related to annual forage production in the Great Plains. We therefore divided precipitation data into spring (April–June), summer (July–September), and winter (October–March). For each year, we also calculated the mean of the monthly average minimum temperatures (December–February) and the mean of the monthly average maximum temperatures (April–September) as indices of winter cold and summer heat.

For herd survival, we used the covariates winter precipitation in the previous year, spring precipitation in the current year, and summer precipitation in the current year (hypothesizing that all might have a positive relation with forage production in the current year), winter precipitation in the current year (potential negative effect of snow accumulation on forage availability in the current year), and average monthly minimum temperature in the current year (potential negative effect on ability to meet energy demands). For foal survival, we used the same set of covariates and added average monthly maximum temperature (possible effect of heat stress on more susceptible foals). For foaling rate, we used the covariates summer precipitation in the previous year (potential positive relation with forage production during early pregnancy), winter precipitation in the previous year (potential negative effect of snow accumulation on forage availability), average monthly minimum temperature (potential negative effect on ability to meet energy demands), and spring precipitation in the current year (possible positive relation with forage production during late pregnancy).

All data were entered into Microsoft Excel® spreadsheets (Microsoft Corporation, Redmond, Wash.). Analyses were conducted in SAS® v. 9.1 (SAS Institute, Cary, N.C.) using standard statistical techniques as noted in the Results section.

Results

Population Size and Growth

Prior to foaling in spring 1993, there were 128 horses ≥1 year of age in the study area. From 1993 to 2007, 481 horses were born; thus, our study encompasses 609 individual animals. During the period of study, the prefoaling population averaged 148.8 animals (range = 120–187), the foal crop (number born) averaged 32.1 (range = 23–40), and the postfoaling population averaged 180.9 animals (range = 149–227) (table 1). As we calculated it, the postfoaling population represents the maximum number of animals that could have been present at any time during the year, as it assumes no mortality of foals or adults during the foaling period. The number of deaths per year apparently increased during 1999–2006, while the foal crop remained relatively constant throughout

Table 1. Size and growth rate of the Pryor Mountain wild horse (*Equus caballus*) herd, 1993–2007.

[Growth rate (λ) is calculated based on the postfoaling population. —, not applicable; SE, standard error of the mean.]

the period of study. The mean annual apparent growth rate, calculated as though removals had not occurred, was 9.6 percent (λ = 1.096, range = 0.977–1.220), or 10.5 percent if the year (2004) of heavy foal loss is excluded. Although the growth rate rebounded somewhat in 2006 and 2007, there was a significant (R^2 = 0.514, P = 0.004) overall decline during the period of study as determined by linear least squares regression (fig. 2).

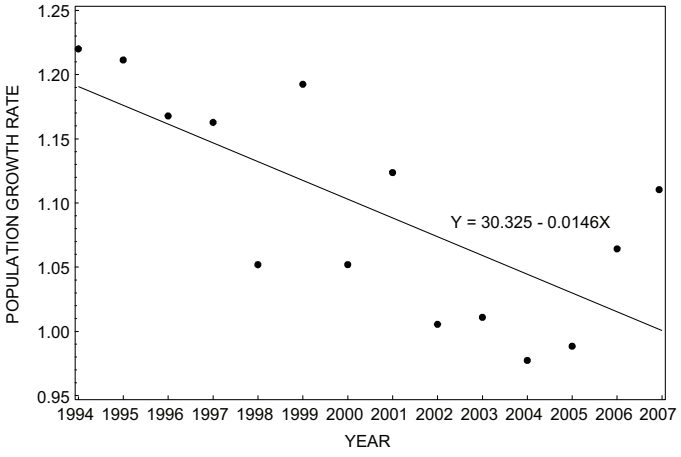

Figure 2. Trend in growth rate of the Pryor Mountain wild horse (*Equus caballus*) population, 1993–2007.

Removals

Major removals of wild horses occurred in 1994, 1997, 2001, and 2006, with smaller numbers of horses removed in four other years (table 2). For the entire period, adults (≥2 years of age) were removed most often (62.6 percent; n = 182), followed by yearlings (28.6 percent) and foals (8.8 percent). Across all age classes, slightly more males (56.6 percent; n = 182) were removed than females.

Sex and Age Structure

During the period 1993–2007, 477 foals of known sex were born; four foals disappeared before sex could be ascertained. Slightly more males (243) were born than females (234), but this difference was not statistically significant (χ^2 = 0.170, P = 0.68). On an annual basis, however, the proportion of males in the foal crop varied widely (range = 34.8–71.9 percent) (fig. 3). The proportion of males produced also varied by age of mare, declining from age 3 through about age 10, and then increasing in older mares (fig. 4).

The sex ratio of animals ≥1 year of age varied only moderately during the period of study, ranging from a high of 55.2 percent males in 1997 to a low of 44.2 percent males in 2000 and 2007 (fig. 5). The largest interannual changes in sex ratio occurred as a result of removals in 1994 (27 males, 33 females

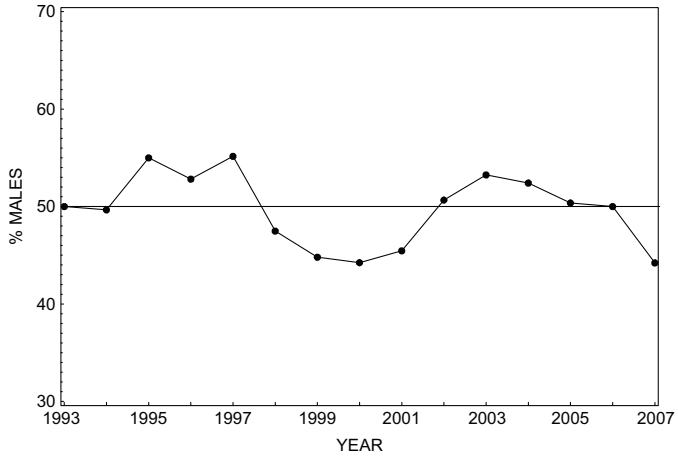

Figure 5. Annual sex ratio of adult (≥1 year old) wild horses (*Equus caballus*) in the Pryor Mountain herd, 1993–2007.

removed), 1997 (33 males, 13 females), 2001 (18 males, 28 females), and 2006 (14 males, 5 females).

The age structure of the Pryor Mountain wild horse herd, on the other hand, changed markedly between 1993 and 2007 (fig. 6*A*,*B*). In 1993, males in the herd averaged 4.4 years of age and females averaged 4.2 years. In 2007, the comparable values were 8.1 and 6.8 years, respectively. Both of these trends are statistically significant as judged by linear least squares regression (males, $P < 0.0001$, $R^2 = 0.911$; females, $P < 0.0001$, $R^2 = 0.832$).

Survival

Pooled across years, ages, and sexes ($n = 2{,}531$), the annual survival rate of horses on the study area was 0.899. Excluding four foals that disappeared before sex could be ascertained, survival of males (0.896, $n = 1{,}246$) did not differ from that of females (0.905, $n = 1{,}281$) ($\chi^2 = 0.486$,

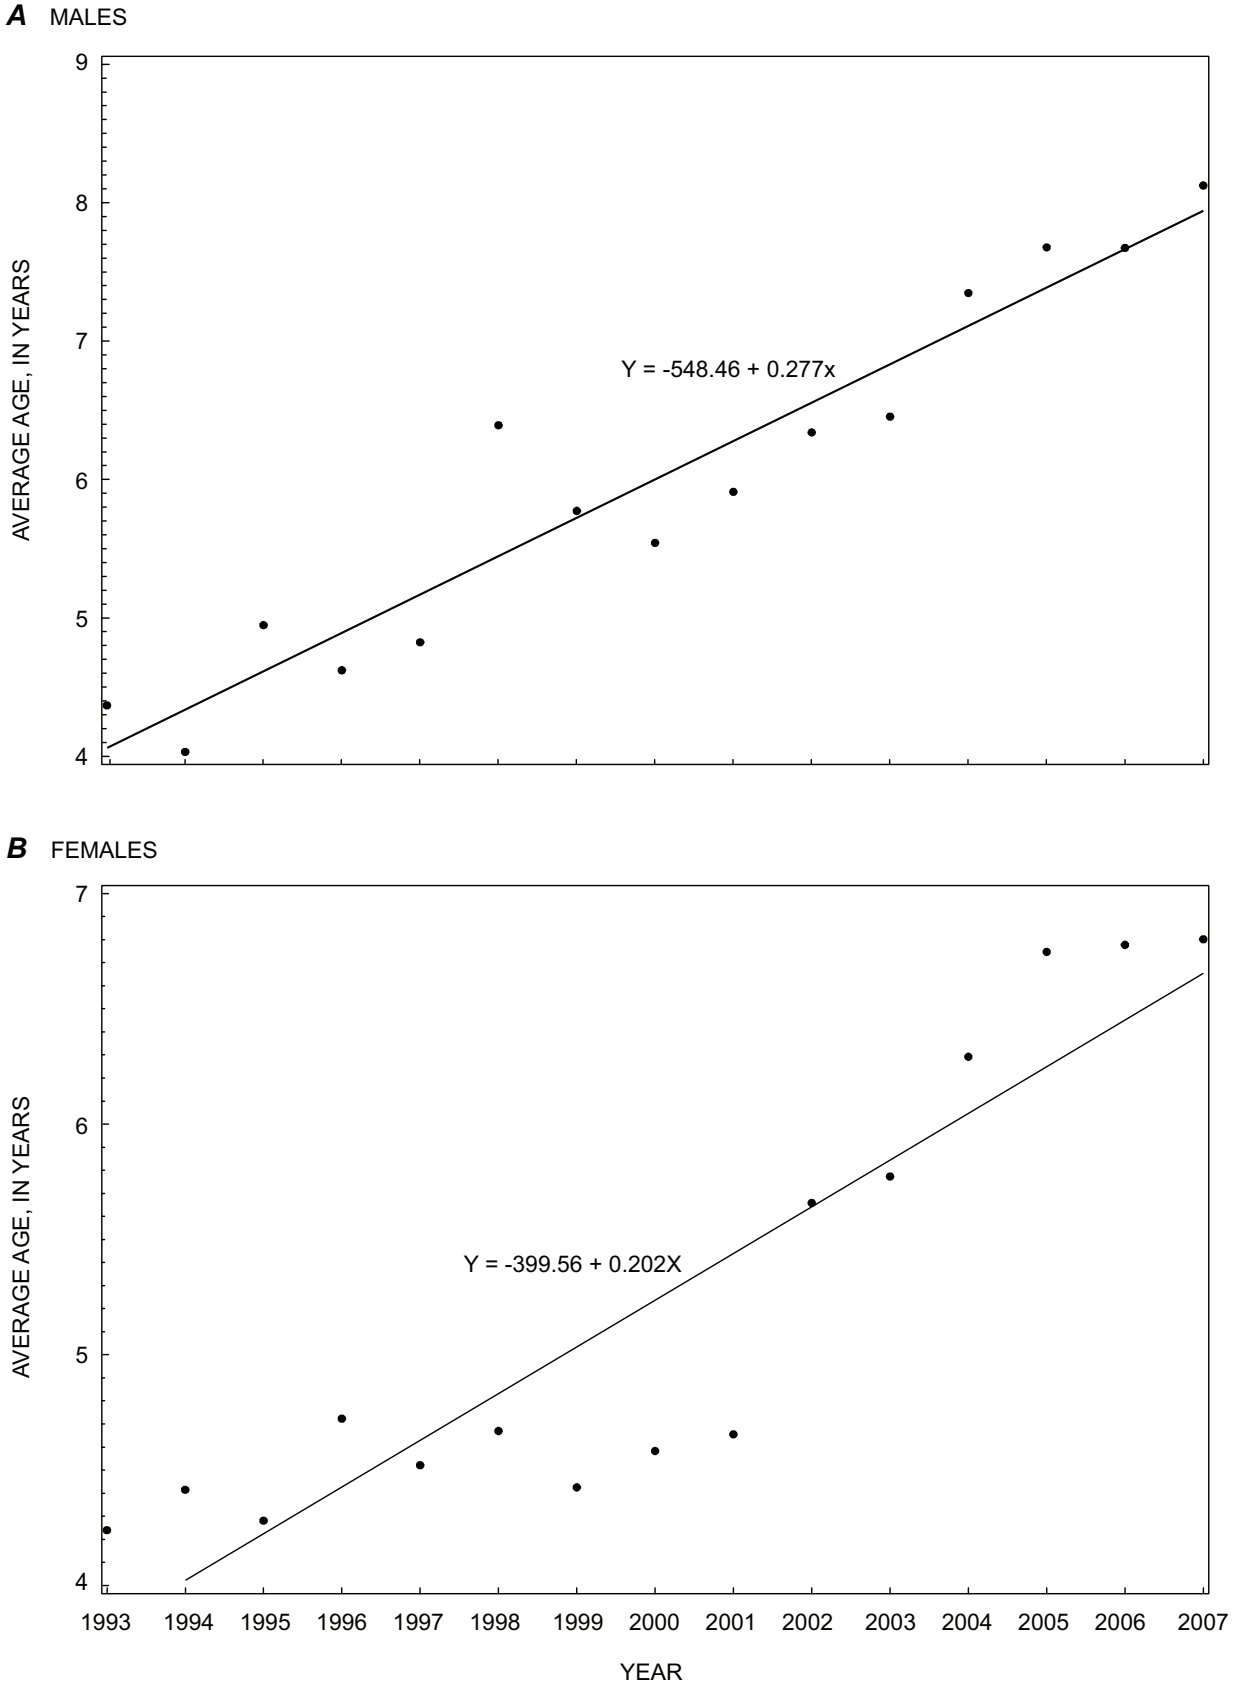

Figure 6. Average age of (*A*) male and (*B*) female wild horses (*Equus caballus*) in the Pryor Mountain herd, 1993–2007.

$P = 0.486$), nor was the difference between the sexes significant for foals ($\chi^2 = 2.500$, $P = 0.114$, $n = 461$). Data from both sexes were therefore pooled for calculations of survival by year.

Survival by year varied from a high of 0.993 in 1993 to a low of 0.780 in 2004 (table 3), when 27 of 28 foals were lost, with predation by mountain lions suspected as the cause (Bureau of Land Management, 2006). For the period of our study, there was a trend toward decreasing foal survival (fig. 7; $P = 0.020$, $R^2 = 0.353$), but there was no trend in survival of animals ≥1 year old ($P = 0.282$, $R^2 = 0.088$). Foal survival increased in the most recent three years of our study, however.

More than one half of the horses that died from 1993 to 2007 were foals, and annual foal survival pooled across years was 0.697 (table 4). Survival increased gradually from age 0 to age 3, remained high through age 15, and then declined gradually. Horses ≥18 years of age were pooled for this analysis because of small sample sizes in these age classes. The oldest animal recorded during the period of study was a male that died at age 26 in 2005. Nine horses lived to be 20 years of age or older, seven of which were males. Four horses (3 males, 1 female) age 20 and 21 were present on the range at the end of our study.

As judged by logistic regression, there was a positive relation between the probability of a foal surviving and the mean (average of summer and fall in a given year) number of members in the band ($n = 393$ foals in 1996–2007; Wald $\chi^2 = 14.964$, odds ratio = 1.244 with 95 percent CI = 1.114–1.390, $P = 0.0001$). Thus, for example, the regression yields a predicted foal survival rate of 0.457 (95 percent CI = 0.351–0.567) for a band size of two, and a predicted survival rate of 0.757 (95 percent CI = 0.688–0.815) for a band size of eight.

We also examined survival of foals in relation to parity of their dams—primiparous (those giving birth to their first foal) compared to multiparous (those that had given birth one or more times). For this analysis, we excluded all mares born before 1993 (since parity could not be determined with certainty) and any foals they produced. We also excluded mares that were presumptively contracepted or were present postcontraception (hereafter referred to as treated and posttreated) and foals that they produced. For the remaining subset of foals, there was no difference in survival based on parity of the dam ($n = 189$, $\chi^2 = 0.957$, $P = 0.328$).

Foaling Rates

For ease of comparison with other studies, we calculated foaling rates of mares ≥2 years of age, ≥3 years of age, and ≥4 years of age. Treated and posttreated mares were excluded from these calculations, as were foals born to unknown dams. Pooled across years, productivity was 0.501 foals/mare (range = 0.254–0.705) for mares ≥2 years of age, 0.576 foals/mare (range = 0.300–0.795) for mares ≥3 years of age, and 0.597 foals/mare (range = 0.311–0.795) for mares ≥4 years of age (table 5). Regression analysis showed a slight increase in foaling rate of mares over time (for mares ≥3 years of age, $P = 0.088$), but variability was high ($R^2 = 0.208$).

From 1993 to 2007, 464 of the 481 foals produced in the study area were born to 118 known or highly probable dams (table 6), an average of 3.93 foals per mare. Many of the dams represented in table 6 are still producing foals; thus, the data represent only a single point in time. Twenty-seven dams that each produced seven or more foals accounted for a total of 237 foals, or 51.1 percent of the production by known dams. Of the 54 dams that have been monitored since birth (that is, those born in 1993 or later) and have not been contracepted, 6 (11.1 percent) first produced a foal at age 2, 29 (53.7 percent) at age 3, 14 (25.9 percent) at age 4, 3 (5.6 percent) at age 5, and 2 (3.7 percent) at age 7. The average age at first foaling for these dams was 3.4 years. Age-specific fecundity was 0.048 foals per mare for 2-year-old mares, increased nearly monotonically through age 10, remained high through age 15, and dropped rapidly thereafter (table 7). The maximum age at which any mare gave birth during the study period was 17 years, although that mare was presumptively contracepted and thus is not represented in table 7. A single set of twin foals (both females) was born during the period of our study, to a 6-year-old mare in 1994.

We used logistic regression to examine the probability of foaling in years following a gather as compared to other years for three age groups of mares: 2 years old, 3 years old, and ≥4 years old. Foal production (yes or no) was the dependent variable and year was the independent variable, and we used a specific hypothesis test (or contrast) to compare the mean probabilities of foaling. For this analysis we considered

only the gathers conducted in 1994, 1997, and 2001 in which most of the family bands were gathered; in 2003, only groups containing animals targeted for removal were gathered, and in 2006 a subset of the herd was captured by bait trapping. For mares 2 or 3 years old, the data were too sparse to allow calculation of the maximum likelihood estimate in the logistic regression (for example, in some years no mares in these age groups produced foals). For mares ≥4 years old the probability of foaling was lower in years following a gather than in other years ($P = 0.03$). The absolute value of this difference was small, however. The mean predicted foaling rate in years following a gather was 0.522 ($n = 3$ years, 134 mares) as opposed to 0.622 ($n = 12$ years, 531 mares) in other years.

We also used logistic regression to examine the probability of a mare foaling as a function of number of members in the band in summer and found a positive relation ($n = 577$ mare-years, Wald $\chi^2 = 24.122$, odds ratio = 1.254 with 95 percent CI = 1.146–1.372, $P < 0.0001$). As an example, the regression yields a predicted probability of foaling of 0.427 (95 percent CI = 0.347–0.511) with a band size of two, as compared to a probability of foaling of 0.743 (95 percent CI = 0.682–0.797) with a band size of eight.

In addition, we compared the probability of foaling in the next year for primiparous and multiparous mares. Primiparous females were less likely to foal ($\chi^2 = 27.29$, $P < 0.0001$) in the year following their first foal (proportion foaling = 0.26, n = 43) than were multiparous females (proportion foaling = 0.72, n = 110). On the other hand, multiparous females were somewhat more likely to foal ($\chi^2 = 2.60$, $P = 0.107$) if they foaled in the previous year (proportion foaling = 0.72, n = 110) than if they did not foal in the previous year (proportion foaling = 0.61, n = 76).

Harem Stallions and Band Composition

During the 12 years (1996–2007) for which information was available, the number of bands varied from 29 to 38 (table 8), with an increasing trend through time (least squares regression, $P = 0.012$, $R^2 = 0.48$). There was no relation, however, between number of bands and band size (least squares regression, $P = 0.88$); that is, band size did not decline significantly as the number of bands increased. Bands were held by 64 different stallions during this period, the youngest being age 3 and the oldest being age 23 (fig. 8). The vast majority of bands, however, were held by stallions aged 5–17 (fig. 8; n = 399). A single stallion gained his first harem at age 3, but 18 of the 29 harem stallions (62.1 percent) for which we have records since birth (born in 1993 or later) acquired their first harem at age 5 or 6 (fig. 9). As might be expected from the increasing age of all males in the herd (fig. 6A), the average age of harem stallions also increased through time (table 8) (least squares regression, $P < 0.0001$, $R^2 = 0.82$).

Harems with as many as six breeding-age females (≥2 years old) were recorded occasionally, but more than 86 percent of the harems contained 1–3 breeding-age females (fig. 10; n = 399). Harem size varied by age of stallion, increasing from age 3 to about age 11 and declining thereafter (fig. 11; n = 399). There were four somewhat anomalous cases in which a male was listed as a harem stallion but the harem size was zero (fig. 10). In two of these cases there were no harem members at all when the observations were recorded. These represent harems in flux, with one or more mares sometimes with the stallion and sometimes not. In the other two cases the only band members were the harem stallion and a yearling female, and we counted only females ≥2 years old in our calculations of harem size.

Of 399 band-year combinations for which we have observations, only 25 (6.3 percent) involved satellite stallions, which we defined as a male ≥5 years old that was associated with a harem stallion. Three pairs of stallions that lived in the same band for 6, 6, and 5 years accounted for 17 of these 25 associations. The remaining eight associations lasted only 1 or 2 years. In only one case were three stallions involved, and that association was maintained for a year or less. Two of the long-term associations (≥5 years) involved stallions that were the same age (7 through 12 years of age) or 1 year apart (harem stallion 5 through 9 years of age; satellite stallion 6 through 10 years of age). The third long-term association included a harem stallion 17 through 22 years of age and a satellite stallion 7 through 12 years of age. The mean number of mares (≥2 years old) did not differ between single- and multistallion bands (2.2 mares in both cases), although 5 of the 25 multistallion bands had 4–6 mares.

Of the 180 male foals born from 1993 through 2003 (those born after 2003 would have been only 3 years old or younger at the end of our study), 124 died or were removed before reaching age 4 and thus had virtually no chance of becoming a harem stallion. An additional 17 died or were removed at age 4 or 5 and thus had a much reduced chance of becoming a harem stallion. Three died at age 6, and two were removed at age 7 without having held a harem. Of the original 180 male foals born, 29 became harem stallions. Of the remaining five animals, two were still bachelors at the end of our study (ages 4 and 6 in 2007), two briefly held harems (at ages 4 and 8) but reverted to bachelor status, and one was a satellite stallion in his natal band (at age 5).

Table 8. Number of wild horse (*Equus caballus*) bands, mean age of harem stallions, mean harem size (mares ≥2 years old), and mean band size (all members) in the Pryor Mountain herd, 1996–2007.

Bachelors

The number of bachelor males in a wild horse herd changes through the course of a year, as young males are expelled from or leave bands, middle-aged males (formerly bachelors) gain bands, and older males gain and lose bands. In the Pryor Mountain herd, the number of bachelor males in summer (early to mid-June) varied between 16 and 36 during the period of study (fig. 12). The largest interannual change occurred between 1997 and 1998, in part because of the removal of 18 bachelors in fall 1997. In total, 40 bachelors were removed from the herd from 1996 through 2007. Pooled across years, 188 of 328 bachelors (57.3 percent) were 2 through 5 years of age (fig. 13).

To examine the question of when young stallions leave their natal bands and become bachelors, we used a subset of our data that included all males born in 1996 or later (thus ensuring that we had complete information on their band associations since birth). Of the 59 males that were born in 1996 or later and reached bachelor status (many died or were removed before becoming bachelors, others were born too late in the study period to have an opportunity to become bachelors), 4 (6.8 percent) became bachelors at age 1 (though one subsequently returned to his natal band), 32 (54.2 percent) at age 2, 13 (22.0 percent) at age 3, 7 (11.9 percent) at age 4, and 3 (5.1 percent) at age 5.

Population Regulation

Density Dependence

Regression analyses showed no relation between the foaling rate of mares ≥3 years of age and population size in either the current year or the previous year ($P \geq 0.143$). Foaling rate of 2-year-old mares may have declined somewhat with larger population in the previous year ($n = 13$ years, $P = 0.090$), but variability was high ($R^2 = 0.239$). Other young age classes (3–5 years) did not show similar relations, nor did combinations of these age classes.

Overall herd survival was related negatively to the previous year's postfoaling population (fig. 14A) ($n = 23$ years, $P = 0.006$), but there was a great deal of variability ($R^2 = 0.305$). Foal survival, however, was unrelated to population size ($n = 13$ years, $P > 0.15$). There also was a relation between population growth rate and the previous year's postfoaling population (fig. 14B) ($n = 23$ years, $P = 0.002$, $R^2 = 0.382$). This is perhaps not surprising, because survival rate is an important component of population growth rate.

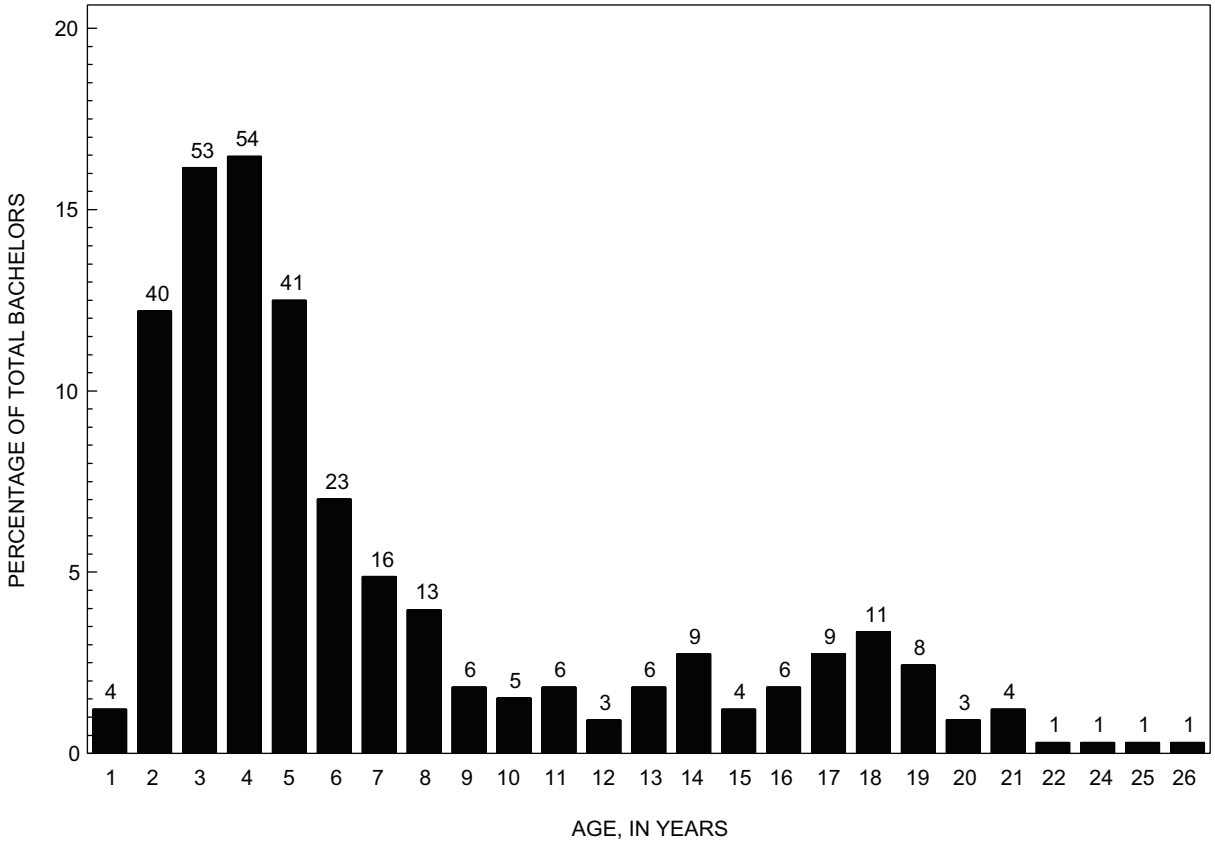

Figure 13. Age distribution of bachelor wild horses (*Equus caballus*) in the Pryor Mountain herd, 1996–2007. Values above the bars are number of bachelors.

Weather

None of the covariates that we used entered the stepwise multiple regression model for herd survival ($P > 0.15$; table 9). For foal survival, both summer and winter precipitation in the current year met the criterion for entry in the model ($P < 0.15$), and both were related positively to foal survival. In the case of winter precipitation in the current year, the positive relation was contradictory to our hypothesis. In combination, these parameters accounted for about 81 percent of the variability in foal survival. In terms of mare foaling rate, only the mean of the monthly average minimum temperature in the previous winter entered the model, and the relation accounted for only about 15 percent of the variability.

Discussion

Population Size and Growth

From 1993 to 2007, the prefoaling (adult) population averaged about 149 animals, only slightly more than the target population of ≈140 adults established on the basis of genetic considerations (Bureau of Land Management, 2006). Removals and a declining survival rate for foals appear to have been the primary factors keeping the population at this level. Contraception also may have played a role if it prevented the birth of any foals. However, it seems likely that the effect of the contraceptive program on population growth was small, given that relatively few mares were treated and that those mares were not in the most productive age classes.

The subject of population growth in wild horse populations has been controversial since early reports (for example, Cook, 1975) of rates as high as 30 percent annually. Other investigators challenged the accuracy of such estimates, and several used simulation modeling in combination with the scant data then available for wild horses and extrapolation of data from other ungulates to show that growth rates of 20–30 percent seemed highly unlikely given apparently reasonable assumptions about model parameters (Conley, 1979; Wolfe, 1980). Frei and others (1979) suggested that the apparently inflated growth rates might be an artifact of improved aerial census techniques and greater experience of observers.

As additional data were accumulated, however, it became apparent that initial assumptions regarding population parameters, particularly survival rates and age of mares at first reproduction, were probably conservative for many wild horse herds (Wolfe, 1986). Eberhardt and others (1982) calculated rates of increase of 20 and 22 percent for two herds

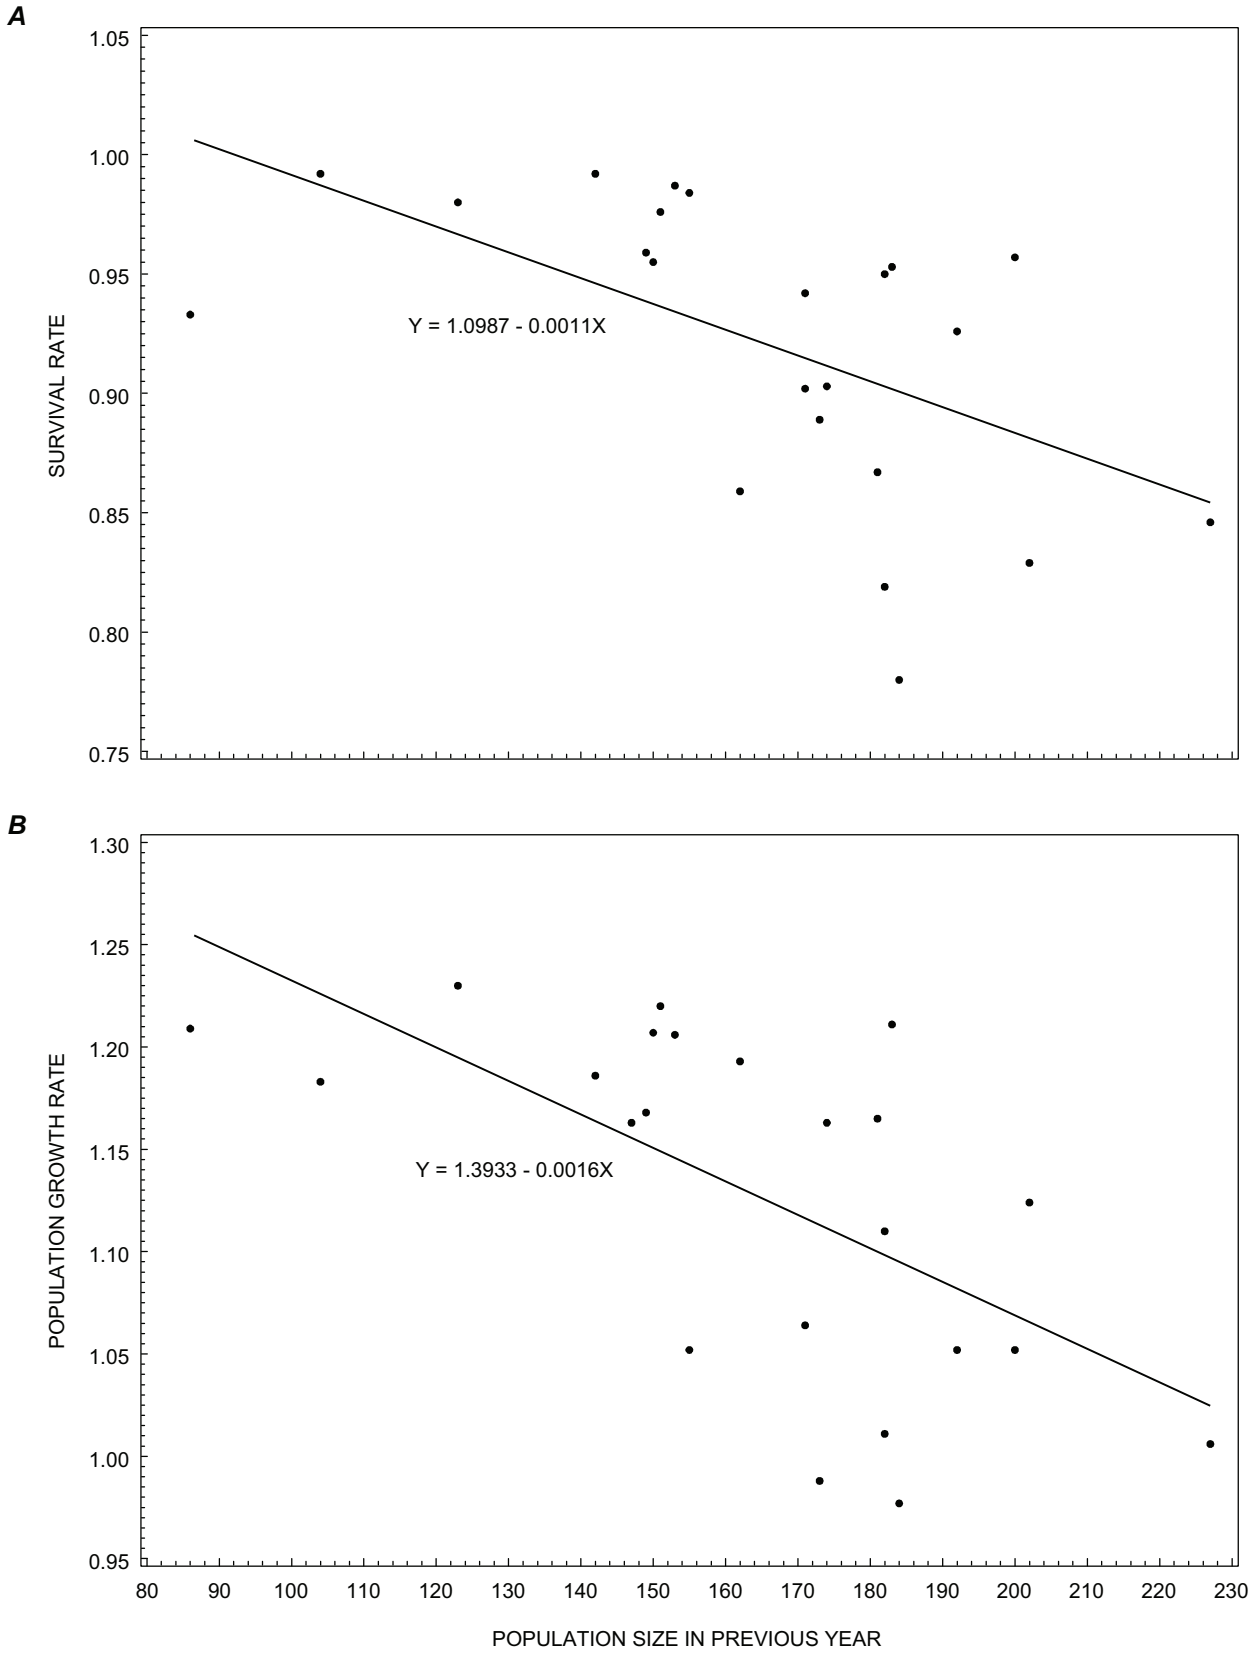

Figure 14. Relation of (*A*) survival and (*B*) population growth rate to the previous year's population for wild horses (*Equus caballus*) in the Pryor Mountain herd. Includes data from this study and from Garrott and Taylor (1990), excepting the abnormally severe winter of 1977–1978.

in Oregon and, by comparing pre- and postremoval populations with known removals, showed that the aerial counts used to derive the growth rates must have been reasonably accurate. Berger (1986, p. 76), based on a 5-year study of horses in the Granite Range of Nevada, reported an average annual growth rate of 31 percent. [Note, however, that Berger (1986, p. 77) also reported an exponential growth rate of 0.188, which is equivalent to a finite growth rate of only 20.7 percent annually.] Wolfe (1986), using data from an unspecified number of BLM herds (>40,000 animals), calculated an annual growth rate of 14 percent for the period 1981–1983 and 15 percent for 1983–1985. Garrott and others (1991b) reported an unweighted mean growth rate of 21 percent (range = 15–27 percent) for 12 western herds. High rates of population growth are not limited to western horse populations. Franke Stevens (1990), for example, reported that the horse population at Rachel Carson National Estuary, made up of four small islands off the coast of North Carolina, increased from 44 animals in 1984 to 68 animals in 1986, from which we calculated an annual growth rate of 24.3 percent.

Reported growth rates of wild horse herds have not been universally high, however. Keiper and Houpt (1984), for example, stated that the horse population on Assateague Island National Seashore grew from 42 to 80 animals during the period 1975 to 1982, which represents an average annual growth rate of 9.6 percent. Goodloe and others (2000) found an average annual growth rate of 4.3 percent (range = 3.0–6.8 percent) for horses on Cumberland Island, Georgia, from 1986 to 1990 and suggested that the low rates likely were the result of density-dependent response to limited forage. Greger and Romney (1999), studying a horse population at the Nevada Test Site (now the Nevada Wild Horse Range), found an average growth rate of -7.0 percent, which they attributed to very low foal survival as a result of predation by mountain lions.

The first multiyear study of horses at Pryor Mountain was that of Perkins and others (1979). While they did not calculate population growth rates, they presented information sufficient to do so for two years. Based on information in their table 1, we calculated growth rates of 7.5 and 16.0 percent for 1976 and 1977, respectively, for the postfoaling population. Garrott and Taylor (1990) reported growth rates at Pryor Mountain for 1977–1986 with a mean of 11.9 percent, but 17.8 percent if a year with heavy winter mortality (51 percent of the population died) was excluded. Singer and others (2000) found a mean growth rate of 17.6 percent at Pryor Mountain from 1992–1997.

Our mean annual growth rate (9.6 percent; 10.5 percent if the year of heavy foal loss is excluded) for the period 1993–2007 is thus toward the lower end of the range reported for the Pryor Mountain and other herds. The declining trend in growth rate through time appears to be a result of decreasing survival of foals, though both foal survival (2005–2007) and growth rate (2006–2007) increased in recent years. Contraception also may have played a small role in reducing the average growth rate, though it is difficult to separate the effects of multiple factors.

Sex and Age Ratios

Studies at Pryor Mountain and elsewhere have found foal sex ratios favoring both males and females, with the pattern sometimes switching for the same herd in different time periods. At Pryor Mountain, for example, Feist and McCullough (1975) reported that 54.3 percent of 35 foals were males, Singer and others (2000) found that 58.3 percent of "surviving" foals were males (sample size not given), but Perkins and others (1979) found 48.5 percent males among 103 foals. Similarly, Keiper (1979) reported 52.6 percent males among 190 foals on Assateague Island, but Keiper and Houpt (1984) found 46.6 percent males in 103 foals born at the same location. In many of these studies with relatively small sample sizes, of course, the results did not differ significantly from parity, which also is true of most studies with larger samples, including ours. Speelman and others (1944), for example, found 49.4 percent males in 568 foals born to domestic mares raised under range conditions in Montana. Garrott (1991), who

studied the sex ratio of more than 10,000 foals removed from 74 BLM herds, found no significant difference from parity in 65 of those herds; the foal sex ratio favored females in seven herds and males in two herds. Interestingly, one exception to this pattern is found in the study by Garrott and Taylor (1990) at Pryor Mountain, who reported a sex ratio of 39.7 percent males ($P < 0.001$) in a sample of 330 foals from 1972 to 1986. Garrott and Taylor offered no explanation for this result, but they did comment that other data from their study might suggest low forage availability. Other investigators have hypothesized that females in poor condition (as through low forage availability) should produce fewer male offspring (Trivers and Willard, 1973).

The foal sex ratio did not differ from parity during the course of our study, and there was no overall difference in survival between the sexes. Thus, apart from minor variations resulting from each foal crop entering the population, consistent departures from a 50:50 sex ratio are the result of removals. This is evidenced by the fact that the largest interannual changes in sex ratio occurred following the larger removals. The drop in the proportion of males in the herd in 2007 was because of the removal of 14 males and 5 females in 2006, but also because natural mortality in 2006 consisted of 13 males and only 3 females. The increasing age of the herd also is mostly explained by removals; for all animals removed during the period of study, the average age was 3.2 years for females and 2.7 years for males. This is in keeping with BLM's management strategy of retaining harem stallions and core breeding-age mares (6–10 years) on the range (Bureau of Land Management, 2006). Low survival of foals in 2003 (36.7 percent) and 2004 (3.6 percent) also reduced the proportion of young animals in the herd and thus increased the average age. To the extent that it prevented any mares from foaling, the contraceptive program also would have contributed to increasing age of the herd, but the magnitude of any such effect is unknown.

Survival

The most striking feature of the survival data from our study is the general decline in foal survival in 1993–2004, followed by an apparent increase in the next 3 years. It would be tempting to attribute at least the declining part of this pattern to increased observational effort and hence increased detection of neonatal loss. We do not believe this to be the case, however, because there was no trend in the number of foals produced through time (linear least squares regression, $R^2 = 0.06$, $P = 0.38$), and because all animals present in the herd in 1993 and all foals born since then have been accounted for. Predation by mountain lions is suspected as the cause of low foal survival in 2004 and perhaps in 2003, though only four foals were confirmed to have been taken by mountain lions (Bureau of Land Management, 2006). Three mountain lions were removed from the area by hunters in winter 2004–2005 (Bureau of Land Management, 2006), which might in part explain the increase in foal survival observed in 2005–2007. It also seems possible that predation began on a smaller scale much earlier than 2003, but we know of no evidence to support this hypothesis. Predation by mountain lions has been shown to be an important factor in foal mortality in at least one herd (Turner and Morrison, 2001) and has been implicated in others (Salter, 1979; Greger and Romney, 1999). Wolves (*Canis lupus*), when present, are also suspected of preying on wild horses (Salter, 1979; Oom and Santos-Reis, 1986). Another possible contributor to the observed pattern in foal survival is drought. The drought began in 1999, the same year as the first real drop in foal survival, and was somewhat ameliorated in 2005 and 2007, at which time foal survival increased. The results of our regression analyses between precipitation and foal survival would seem to support this explanation. On the other hand, the initial response to reduced forage availability would likely be a decline in body condition of mares and foals, and such a decline was not observed during the early years of the drought (LC-M).

Overall, survival rates from our study for 1993–2007 are similar to those reported by Perkins and others (1979), but lower than those reported by Garrott and Taylor (1990) and Singer and others (2000) for the same study area (table 10). The foal survival rate reported by Garrott and Taylor, however, probably is an overestimate because it covers the period from midsummer to midsummer; neonatal mortality, which often constitutes the majority of foal mortality (Boyd, 1979; Keiper, 1979; Berger, 1986; Monard and others, 1997; Goodloe and others, 2000), likely was missed. Age of the herd also may account for some of the difference between our survival rate and that calculated by Garrott and Taylor (1990). At the end of their study in 1986, about 22 percent of the herd was ≥11 years of age, whereas the comparable number for 2007 was 39 percent. Perkins and others (1979) and Singer and others (2000) did not provide sufficiently detailed age data to make similar comparisons. Survival rates from our study were also moderate compared to those reported previously for other horse herds in North America (table 10).

Relations between foal survival and band size have not often been reported in the literature on wild horses, and the few available results are equivocal. We found that foals from larger bands tended to survive better than those from smaller bands. Working on Camargue horses in France, Feh (1999) found that there was less foal mortality in bands with an alliance of two stallions (3.2 percent), than in single-stallion bands (22.0 percent). Multiple stallions often are associated with larger bands. Cameron and others (2003), on the other hand, found that among Kaimanawa horses in New Zealand more foals died in multistallion bands (survival = 80 percent, $n = 30$) than in single-stallion bands (survival = 94 percent, $n = 50$), but the difference was not quite significant ($P = 0.056$). Similarly, evidence for a relation between mare age or parity and foal survival is equivocal. We found no relation between foal survival and parity of the mare. Keiper and Houpt (1984) reached the same conclusion, but only 10 foals died in the course of their study. In contrast, Cameron and

Table 10. Survival rates reported for North American wild horse (*Equus caballus*) herds.

Source and location	Survival rate (*n*)				Comments
	Foals	Yearlings	Adults	Herd	
Greger and Romney (1999), NV	0.12	NA	NA	NA	Foal survival is a mean for 8 years and is a maximum estimate because some neonatal mortality probably went undetected.
Turner and Morrison (2001), CA and NV	0.32	0.88	0.92	NA	All data represent means for 10 years.
Goodloe and others (2000), GA	0.600 (105)	NA	0.923 (263)	NA	Adult rate is for mares only, probably ≥3 years old.
This study, (PMWHR)	0.697 (465)	0.917 (252)	0.949 (1,814)	0.899 (2,531)	
Perkins and others (1979), PMWHR	0.75	NA	NA	0.903 (579)	Foal survival is a mean for 4 years. Herd survival is a weighted mean calculated from Table 1, Perkins and others (1979).
Boyd (1979), WY	0.824 (51)	NA	NA	NA	Data for 1978 only.
Singer and others (2000), PMWHR	0.87	NA	NA	Males, 0.965 Females, 0.975	Not clear that data reported for the herd actually includes all animals.
Siniff and others (1986), Pine Nut, NV	0.875 (40)	NA	0.972 (72)	NA	Adult rate is a weighted mean for 2 years representing only mares, probably ≥2 years old
Siniff and others (1986), Pah Rah, NV	0.877 (73)	NA	0.975 (81)	NA	Adult rate is a weighted mean for 2 years representing only mares, probably ≥2 years old
Keiper and Houpt (1984), MD and VA	0.883 (86)	NA	NA	NA	Foal rate is a weighted mean for 8 years.
Pellegrini (1971), NV	0.905 (21)	NA	NA	NA	Data are for 1969. However, in 1968 no foals were observed, and in 1970 only one foal was observed.
Berger (1986), NV	0.917 (120)	0.969 (64)	0.951 (329)	0.945 (513)	Herd rate calculated from data on the three age groups.
Garrott and Taylor (1990), PMWHR	0.968 (249)	0.977 (173)	0.962 (865)	0.965 (1,287)	Excludes data from a severe winter. Adult and herd rates calculated from Table 2, Garrott and Taylor (1990). Foal rate measured from midsummer to midsummer and may be an overestimate.

others (2000) found significant differences in mortality of foals born to mares 3–5 years old (18 percent mortality), 6–8 years old (3 percent), and ≥9 years old (9 percent).

Foaling Rates

Foaling rates of mares at Pryor Mountain most often have been low to moderate when compared to those reported for other North American herds (table 11). In fact, the rate of 0.432 foals/mare for mares ≥4 years of age calculated from Feist and McCullough (1975) is among the lowest for any herd, although their study was primarily behavioral and lasted only 1 year. In addition, they attempted to classify mares aged 1, 2–3, and ≥4 years without the benefit of examining tooth eruption and wear, and they admit that some classification errors probably occurred. If there was a tendency to misclassify 3-year-old mares as being ≥4 years old, the resulting foaling rate would be biased low. Garrott and Taylor (1990), however, reported similarly low rates, and mares in their study were aged by dental characteristics. As noted above, Garrott and Taylor (1990) reported on foals present in midsummer; some neonatal loss likely was missed, which would tend to bias foaling rates low. Perkins and others (1979) did not report age-specific foaling rates of mares, but for the three years of their study for which data are complete (1975–1977), the foal crop was 15.1 percent of the prefoaling population (weighted average, $n = 411$ animals ≥1 year of age). The comparable value during our study was 21.6 percent (table 1, $n = 2{,}232$ animals). These values, of course, are affected by the sex and age structure of the herd. Similarly, Singer and others (2000) did not report age-specific foaling rates in sufficient detail to be included in table 11. They did, however, show rates of 0.107 foals/mare for mares of age 2, 0.54 for age 3, 0.67 for ages 4–11, and 0.46 for ages ≥12 in the period 1992–1997. Comparable values from our study (1993–2007) were 0.048, 0.414, 0.588, and 0.636, respectively. Thus, it appears that foaling rates at Pryor Mountain have varied considerably through time, with those from our study being intermediate.

Several investigators have suggested that forage availability can affect the condition of feral mares and thus foaling rates (Green and Green, 1977: Nelson, 1978; Berger, 1986; Siniff and others, 1986; Garrott and Taylor, 1990). Hall (1972) described range conditions at Pryor Mountain as being poor to extremely poor through much of the area. Feist and McCullough (1975) reported a low foaling rate in 1971, as did Garrott and Taylor (1990) in the first 3 years (1976–1978) of their study. Furthermore, Garrott and Taylor (1990) suggested that low foaling rates likely were a result of poor forage, also noting that the foaling rate increased markedly in 1979 following loss of 51 percent of the herd in the severe winter of 1977–1978. Singer and others (2000) reported somewhat higher foaling rates than were observed in the earlier studies and also noted that former managers who visited Pryor Mountain in 1997 remarked about the overall improvement in "plant condition." Again, our values for foaling rate appear to be intermediate. It also may be relevant that mean annual precipitation in the biological years covered by the study of Singer and others (17.55 cm; 1992–1997, all years included regardless of missing data) was greater than that for the remainder of our study (13.79 cm; 1998–2007).

In addition to its effects on foaling rates of adult animals, forage availability may affect age of first reproduction by mares. Feist and McCullough (1975), Perkins and others (1979), and Garrott and Taylor (1990) all worked at times when forage production may have been poor at Pryor Mountain and all found that mares first foaled at age 3. Singer and others (2000), on the other hand, at a time when forage production may have been somewhat better, found that 10.7 percent of 2-year-old mares produced foals; the comparable value from our study was 4.8 percent. First foaling at age 2 (Salter and Hudson, 1982; Berger, 1986; Lucas and others, 1991) and age 3 (Boyd, 1979; Keiper and Houpt, 1984; Goodloe and others, 2000) has been reported for other herds, with the rate for 2-year-olds varying both among herds and within herds in different years (Garrott and others, 1991a). In at least two studies, low foaling rates in young mares have been attributed to high rates of fetal and neonatal loss (Lucas and others, 1991; Linklater and others, 2004).

Other factors that have been shown or hypothesized to affect foaling rate include gathers, band stability, and parturition history of the mare. In the case of gathers, we found a small but statistically significant effect, with foaling rate being lower in years following gathers. It must be remembered, however, that we did not design an experiment specifically to test a hypothesis about the effect of gathers. In particular, we had to assume that the majority of mares were affected by the gather (either actually moved into a trap or significantly disturbed by helicopter activity) in each of the three years that we considered to be gather years. Given the nature of the gathers in those three years, we believe that such an assumption is reasonable. Other evidence for an effect of gathers on foaling rate is equivocal. Hansen and Mosley (2000) studied two herds, one in Idaho and one in Wyoming, and found no difference in foaling rate between mares ungathered, gathered and released, or gathered and adopted. The ungathered samples were small, however, consisting of only 14 mares in each herd. Ashley and Holcombe (2001), on the other hand, found that in one of the two years of their study, ungathered mares foaled at a higher rate than did those that were gathered and released or gathered and removed. They found no evidence for an effect of a gather in the other year.

Evidence for an effect of band stability on mare foaling rate is more consistent. Berger (1983) found that mares in bands with resident stallions produced foals at a higher rate than those in bands taken over by a new stallion. Kaseda and others (1995), working on Misaki horses in Japan, reported that mares in "stable consort relationships" had higher reproductive success than those that changed stallions. Similarly, Goodloe and others (2000) found that mares that changed bands had a lower probability of foaling than those that did

Table 11. Foaling rates reported for North American wild horse (*Equus caballus*) herds.

not. Data on mare interchanges are available from the Pryor Mountain herd, but have not yet been analyzed.

The question of whether parturition history of the mare affects foaling rate has been of interest since early investigators reported what they perceived to be a tendency to foal in alternate years (Green and Green, 1977; Nelson, 1978). This question has been addressed in a number of ways and results have varied. Seal and Plotka (1983) found that 68.4 percent (n = 76) of pregnant mares also had a foal at their side or were lactating, and Wolfe and others (1989) found no difference in pregnancy rates for lactating and nonlactating mares in six different populations. Neither of these studies, however, addressed the question of whether lactating and nonlactating mares are equally successful in bringing their pregnancies to term. On Assateague Island, 10.2 percent of 49 mares followed for 4 years foaled in alternate years, whereas 55.1 percent foaled in either 3 or 4 years (Keiper, 1979). Similarly, Keiper and Houpt (1984) could not see any tendency to foal in alternate years among 14 mares followed for 8 years. At Pryor Mountain, in both our study and that of Garrott and Taylor (1990), primiparous mares were less likely to foal in the next year than were multiparous mares. Cameron and Linklater (2000), on the other hand, found that the probability of foaling in a given year was reduced significantly if the mare had a foal in the previous year. Thus, while not universal, it appears that foaling in one year can sometimes reduce the probability of foaling in the subsequent year, particularly in primiparous mares.

Harem Stallions and Band Composition

Comparisons among band or harem sizes reported by various investigators are hampered by inconsistencies in defining what constitutes a harem member, or failure to do so at all. We defined harem members as mares ≥2 years of age, and found that the mean harem size was 2.2 mares with a range of 1.9 to 2.7 over 12 years; the number of bands ranged from 29 to 38. In other studies at Pryor Mountain, Feist and McCullough (1975) reported only average band size (5.0 including all members, not just mares), but they found 44 bands and 106 females ≥2 years of age, so the average harem size was likely somewhere near 2.4 mares. Note that the total population during the single summer of their study was about 225 animals, which probably explains the somewhat larger number of bands. Perkins and others (1979), working on a population that ranged from 95 to 168 animals (1974–1978), found 19–27 bands with a mean size of 4.9 (total animals), but did not report harem size in terms of number of mares. During a period (1992–1997) when the mean population was 161 animals, Singer and others (2000) reported an increase in the number of bands (18 to 31) and a decline in the number of mares (age unspecified) per harem from four to two. They attributed these trends to an increasing proportion of males in the population, death or waning vigor of a number of older males, and removal of members from the bands of several stallions aged 10–15 years. Investigators working on other herds have found similar or perhaps slightly larger average harem sizes. Mean harem size on Cumberland Island was 1.8 mares (Goodloe and others, 2000); the authors did not specify the age of mares included, but only mares ≥3 years old produced foals. Greger and Romney (1999) reported an average harem size of 2.4, which included all females ≥1 year of age, excluding daughters. Berger (1986, p. 130) found an average harem size of 3.1 mares with a range of 2.73–3.67 across years; age of mares was not specified but, because 2-year-old females reproduced, mares ≥2 years old may have been included. In Misaki horses (Japan), the annual average harem size ranged from 1.8 to 5.3 mares ≥2 years old; one stallion in one year had a harem of nine mares, and 55.0 percent of 60 harems (14 harem stallions) observed from 1979 to 1994 had four or more mares (Kaseda and Khalil, 1996).

In our study, 62.1 percent of harem stallions first acquired a harem at age 5 or 6. Other investigators have found comparable results: Berger (1986, p. 142), age 5–6; Kaseda and Khalil (1996), age 4–6; Asa (1999), age 5; Singer and others (2000), mean age = 6 years. In the last two years of our study, the mean age of harem stallions was 13 and 12 years, which is remarkably similar to the mean of 12.8 years reported at Pryor Mountain by Perkins and others (1979). Hall (1972), however, reported a mean age of 7.8 years, which is more similar to the data from the early years of our study. Age structure of removals is undoubtedly an important determinant of such results.

During our study, 6.3 percent of bands had multiple stallions. Feist and McCullough (1975) did not mention whether any of the 44 bands present during their study had multiple stallions. Perkins and others (1979) found only two multistallion bands in the 19–27 bands present during the 4 years of their study; if the mean number of bands present was, say, 23 per year, multistallion bands would have made up about 2.2 percent of the total. These percentages are lower than those reported for other herds: Goodloe and others (2000), 10.7 percent, n = 177; Nelson (1978), 11.8 percent, n = 17; Berger (1986, p. 129), 12 percent, sample size not given; Salter and Hudson (1982), 17.4 percent, n = 23; Asa (1999), 28 percent and 33 percent in 2 years, n = 18 and 9; Miller (1979), 23–45 percent for 3 years, n = 12–18; Bowling and Touchberry (1990), 39.1 percent, n = 69; Franke Stevens (1990), 50 percent, n = 12; Green and Green (1977), 45 percent and 54 percent in 2 years, n = 53 and 67, respectively. Kirkpatrick and Turner (1986) suggested that differences in proportions of bands with multiple stallions may be related to population density and sex ratio, with a greater ratio of males to females tending to lead to multistallion bands, and noted that some of the reported proportions may be high as a result of inaccurate aging of the animals based on body size [for example, Green and Green (1977)].

Bachelors

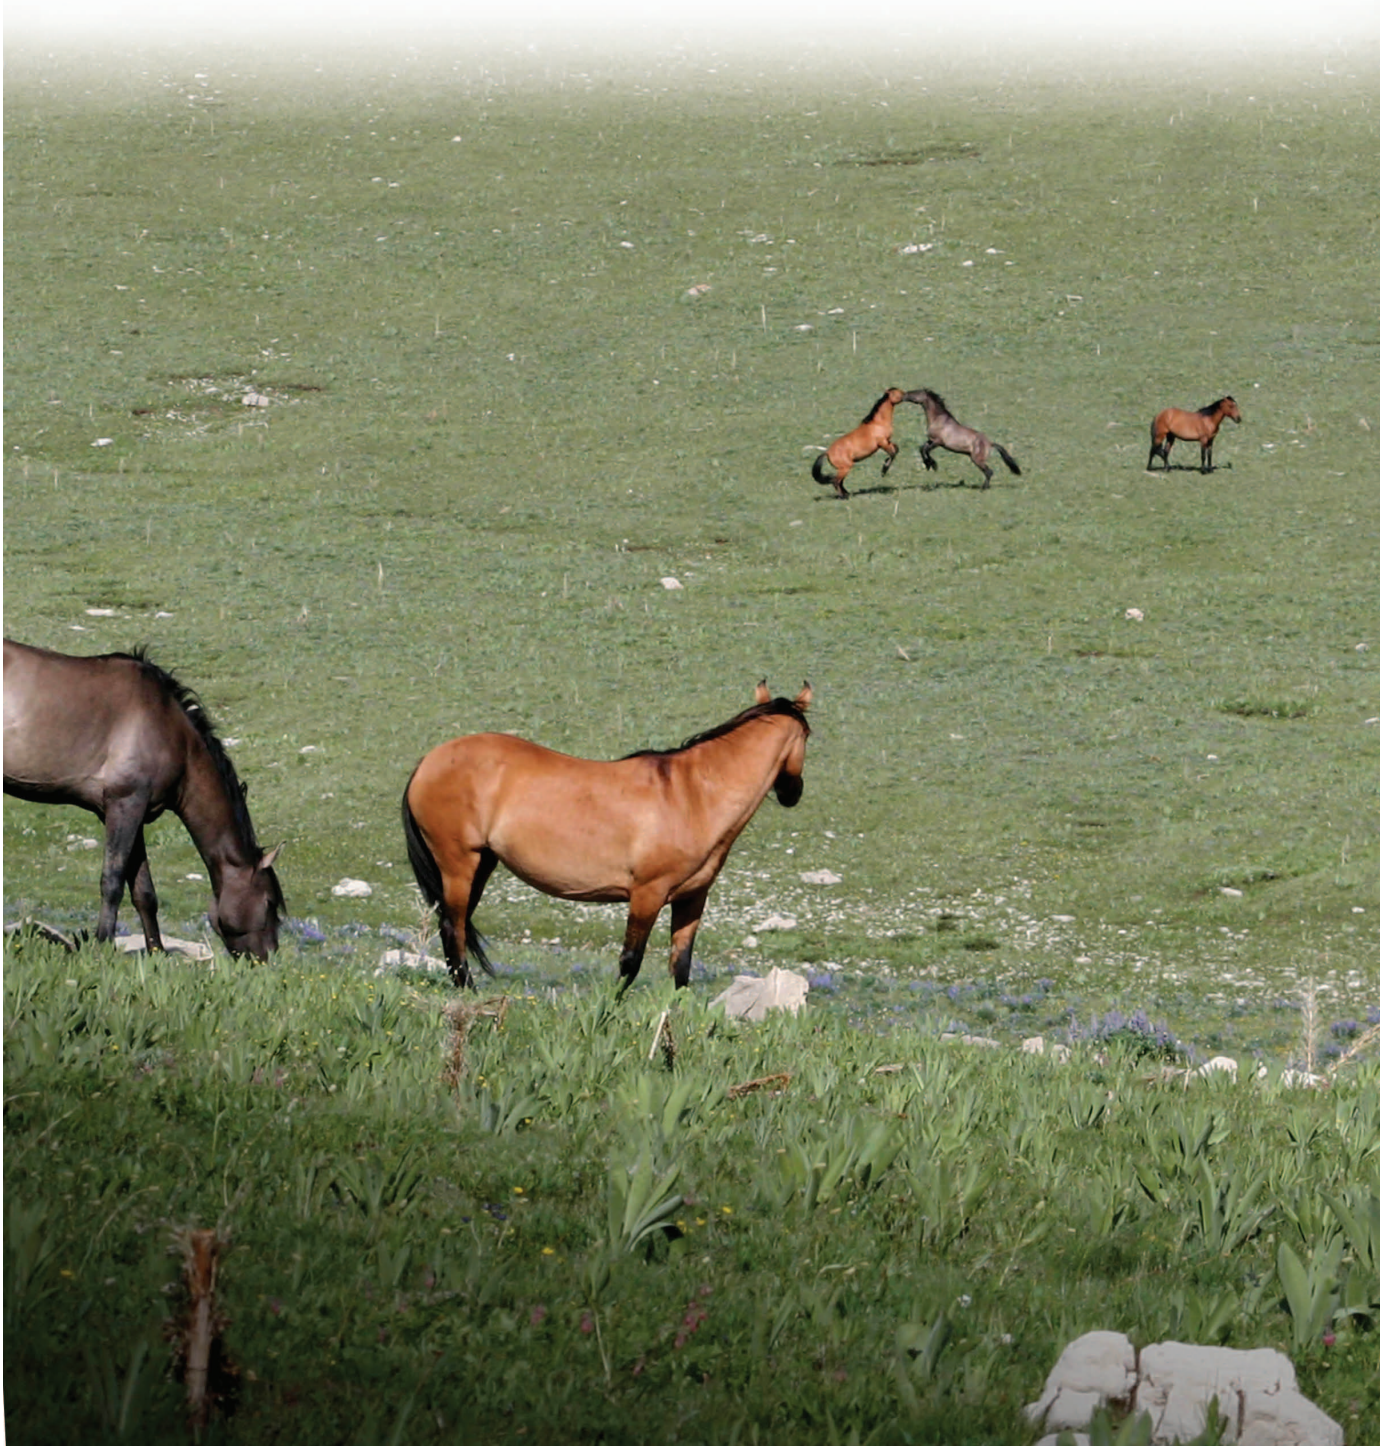
We have information on the total number of bachelors, but not on individual groups, which makes comparisons with other studies at Pryor Mountain difficult. Hall (1972) reported that the average size of bachelor groups was three, with individuals ranging in age from 1 to 5 years, and that older stallions usually lived alone after losing their harems. Feist and McCullough (1975) found 23 bachelor groups with a mean of 1.8 animals per group. Perkins and others (1979) found six bachelor groups, all with 2–3 individuals ranging in age from 3 to 8 years, as well as six older stallions that lived alone. With allowances for varying population size, our results do not appear to be greatly different from those found at other times at Pryor Mountain.

Most evidence suggests that males leave or are expelled from their natal band when they reach sexual maturity, which usually occurs at age 3 and occasionally at age 2 (Angle and others, 1979; Kirkpatrick and Turner, 1986). Our data show a somewhat different pattern. A few males left their natal band at age 1, most (54.2 percent) left at age 2, but 17 percent remained with their natal band until age 4 or 5. Of the three individuals that remained in their natal bands until age 5, two subsequently acquired harems and one was still a bachelor (6 years old) at the end of our study. Interestingly, one of these stallions took over his natal band, at which point his dam left the band for another. It seems possible that instances of stallions remaining with their natal band until age 4 or 5 account for some of the reports in other studies of a high proportion of multistallion bands.

Population Regulation

Several investigators have suggested a relation between forage availability and foaling rate, but few studies have been long enough and had sufficient variation in population size to allow detection of density-dependent effects. Berger (1986, p. 97) found little evidence for density dependence in his data from the Granite Range and suggested that the confounding effects of weather were responsible. He did, however, find some evidence for a decline in foaling rate with increasing population size in data from Keiper and Houpt (1984). Singer and others (2000) found that population growth rate at Pryor Mountain declined with increasing population size, but this result was clearly dominated by data from a single year [Singer and others (2000), fig. 5]. They did not find evidence for a density-dependent effect on either foaling rate or survival rate. Jenkins (2000) examined data from the Granite Range and Pryor Mountain herds, both having individually identified animals, as well as five additional herds where population size was estimated using aerial surveys. In all seven cases, he found that population growth rate decreased with increasing population size, but only one was statistically significant ($P \leq 0.05$). However, his meta-analysis of the entire data set indicated that the probability of the same result through chance alone was only 0.001.

Our results are similar to those of both Singer and others (2000) and Jenkins (2000) in that we also found that population growth rate declined with increasing population size, albeit population size from the preceding year, which suggests that lag effects may be important. Furthermore, we found similar evidence for a negative relation between overall herd survival and population size, and perhaps some weaker evidence that the foaling rate of 2-year-old mares is affected by population size. We did not, however, find evidence for a density-dependent effect on foal survival, perhaps in part because Garrott and Taylor (1990), whose study encompassed a range of population sizes, did not provide annual foal survival rates.



We used population size as a surrogate for population density in these analyses, as did all of the authors cited in this section. In doing so, we made the implicit assumption that the area used by horses did not change significantly through the course of the study. In the case of the Pryor Mountain herd, however, horses probably made increasing seasonal use of Forest Service lands north and west of the original wild horse range. It seems likely that any density-dependent effects would have been more pronounced had this increase in use of Forest Service land not occurred.

In all cases where we found evidence for density dependence, variability was high, suggesting that other factors also may be important in regulating the Pryor Mountain wild horse herd. Assuming that the cause of mortality was correctly identified, mountain lion predation may have had a dramatic effect on foal survival in at least one year. In the latter years of our study, contraception also may have had some effect on foaling rate, though it seems likely that this effect was small given that relatively few mares were treated and that they were not in the most productive age classes. One of the most important regulatory mechanisms appears to be precipitation, which we found to be strongly related to foal survival. Both density dependence and precipitation effects are consistent with an interpretation of forage availability per individual as an important parameter. All of these factors combined, however, were not sufficient to stabilize the population during our period of study, as evidenced by the necessity for large removals in several years.

Acknowledgments

Thanks to the Bureau of Land Management's Billings Field Office for logistical support and making historical data available, and to the National Park Service, Bighorn Canyon National Recreation Area, for providing access and logistical support for field work on NPS lands. The integrity of

long-term data for the Pryor Mountain herd can be partially attributed to the commitment and dedication of the late Reverend Floyd Schwieger, who graciously shared his work and answered many questions before his passing. Special thanks to the BLM and USGS field technicians who spent their summers following horses and accurately collecting the data: Hanem Abouelezz, Genie Amelung, Erin Anderson, Laura Caldwell, Steve Cordts, Kira Donnelly, Darla Dunaway, Jason Dungan, Melissa Esser, Jill Fanning-Rodgers, Don Galvin, Kayla Grams, Patti Grigsby, Susan Hahn, Christine Hardy, Heather Jensen, Martina Keil, Dan Kraemer, Megan Lallier, Samantha Lukas, Ian McCluskey, Sean Mead, Jessica Meredith, Jill Nannenga, Jane Nibler, Christopher Papouchis, Christina Petrandis, Justin Rodgers, Lisa Selner, Jennifer Severude, Aaron Swallow, Nani Teves, and Jamie Wages. Thanks also to Dan Baker, Jared Bybee, Bob Garrott, Al Kane, and Alan Shepherd for providing critical reviews of the manuscript, to Tammy Fancher for preparing the map of the study area, and to Jennifer Shoemaker for assistance with graphics.

ABSTRACT We tested the efficacy of 2 formulations of the immunocontraceptive SpayVac®, which packages the immunogen porcine zona pellucida (PZP) and an adjuvant in multilamellar liposomes, as a contraceptive in captive feral horses (*Equus caballus*) for 3 consecutive breeding seasons (Pauls Valley, OK, USA; 2012–2014) following a single inoculation. Annual fertility rates in control adult female horses ($n = 30$ each yr) were 100%, 96.7%, and 100%. In the nonaqueous treatment group, fertility was 16.7% in the first year ($n = 30$) and 75.9% in the second year ($n = 29$), at which point we dropped the group from the study. Fertility rates in the aqueous group were 13.3%, 46.7%, and 43.3% ($n = 30$ each yr). Fifteen of the females in the aqueous group were infertile in all 3 years. Across 11 sampling dates postvaccination, mean PZP antibody titers in serum were 33.7–91.9% greater in nonpregnant females than pregnant females for the aqueous treatment group and 7.8–82.8% greater for the nonaqueous group. However, the 15 consistently infertile females did not necessarily have the greatest antibody titers. Reactions at the injection site occurred in 29.8% of the 84 females that received an injection other than saline solution, but there was no evidence that the reactions were painful or affected mobility. The nonaqueous formulation produced more local reactions than did the aqueous, but presence of PZP did not increase the frequency of reactions above that seen with liposomes + adjuvant. Uterine edema was not found at frequencies greater than would be expected in untreated females. Additional research to explore relationships between vaccine dose, adjuvant, and efficacy is warranted. Published 2017. This article is a U.S. Government work and is in the public domain in the USA.

KEY WORDS *Equus caballus*, feral horse, fertility control, immunocontraception, porcine zona pellucida, SpayVac®, wildlife contraception.

Feral horse (*Equus caballus*) populations managed by the Bureau of Land Management (BLM) in the western United States often grow rapidly and, in the absence of intervention by BLM, would frequently exceed the carrying capacity of their ranges (Eberhardt et al. 1982, Garrott et al. 1991*b*, Roelle et al. 2010). The BLM has most often controlled herd size through a gather (round up) and removal process, offering excess horses to the public for adoption. Over time, the supply of horses has exceeded adoption demand, and BLM has moved thousands of animals to long-term holding pastures where they are cared for as long as they live at considerable expense to American taxpayers. In 2007, for example, the cost of holding animals off the range was approximately US$21 million, or about 67% of the budget for BLM's Wild Horse and Burro Program (U.S. Government Accountability Office 2008:9).

The BLM has long been interested in fertility control as a means of regulating feral horse reproduction and partial solution to the problem of escalating off-range holding costs. The most promising fertility control agents to date are based on porcine zona pellucida (PZP) glycoproteins extracted from pig (*Sus scrofa*) ovaries. When injected into mammalian species such as the horse, these proteins induce production of antibodies that bind to the surface of the ovum and block sperm penetration and fertilization (Liu et al. 1989). Possible effects on ovarian function have been noted as well (Kirkpatrick et al. 1992, Bechert et al. 2013). The most widely used form of PZP available at the present time is an emulsion registered as ZonaStat-H by the U.S. Environmental Protection Agency for use in horses and burros (*E. asinus*). Unfortunately, ZonaStat-H has 2 important drawbacks relative to use in BLM herds. First, a booster inoculation is required, ideally 3–4 weeks after the primer is administered (Liu et al. 1989). Because darting is rarely feasible on western rangelands, most BLM herds must be gathered in order to provide access to the horses for inoculation. Female horses would need to be held in captivity long enough to administer a booster 3–4 weeks later. Second, ZonaStat-H has a reported duration of efficacy of only 7–10 months, after which annual booster inoculations are required to maintain infertility (Liu et al. 1989, Kirkpatrick et al. 1990, Lyda et al. 2005). Some progress in overcoming

these drawbacks has been made by substituting time-release pellets, delivered at the same time as the primer injection, for the booster at 3–4 weeks and first annual booster. This formulation, sometimes referred to as PZP-22, has a reported efficacy of 22 months (Turner et al. 2007), but this is still less than ideal from the BLM's perspective.

A third formulation of PZP known as SpayVac®, produced by ImmunoVaccine Technologies Inc. (IVT; Halifax, NS, Canada) using a proprietary liposome technology, has been reported as having long-term, single-dose efficacy in several species, including grey seals (*Halichoerus grypus*; Brown et al. 1997*a*), fallow deer (*Dama dama*; Fraker et al. 2002), and most recently feral horses (Killian et al. 2008, Fraker and Brown 2011). Killian et al. (2008), for example, reported contraceptive efficacy of 100%, 83%, 83%, and 83% in 4 years following inoculation of 12 feral horses in Nevada, USA, with SpayVac. This result sparked renewed interest within the BLM to conduct further investigations on the efficacy of SpayVac in feral horses.

The 3 main objectives of our study were to 1) quantify the efficacy of SpayVac in preventing pregnancy and foaling over a maximum of 5 breeding seasons postinjection when females are exposed to breeding males in a pasture setting; 2) determine the relationship between PZP serum antibody titers and fertility; and 3) assess the frequency and severity of injection-related and general side effects, if any, following intramuscular injection by hand. In addition, for the 4 years of their study, Killian et al. (2008) reported that 70–100% of females treated with SpayVac showed some degree of uterine edema. Although we do not view uterine edema as a serious contraindication, others have indicated concern, so a fourth objective was to estimate the frequency and degree of uterine edema in females treated with SpayVac. Finally, Bechert et al. (2013) reported that 93% of females that they treated with SpayVac ceased estrous cycling within 3–4 months after vaccination. Our fifth objective was therefore to determine what proportion of our SpayVac-treated females stopped cycling.

STUDY AREA

We conducted our captive breeding trial at BLM's wild horse and burro adoption facility near Pauls Valley, Oklahoma, USA. Adult female horses resided year-round in 3 pastures of approximately 12 ha each, and were accompanied by breeding males from approximately the first week in June (2011) or the first week in May (2012 and 2013) to the first week in October (all years). During the remainder of the year, space limitations forced us to house the males in a separate facility in Nebraska, USA. We transported males to and from their winter quarters by trailer, moving them back to Oklahoma in the spring 2–3 weeks before beginning the breeding trial for that year. We immunized the females and drew blood samples in a processing facility consisting of a series of alleys and pens and a padded hydraulic squeeze chute located 100–300 m from the pastures.

Horses fed on pasture bermudagrass (*Cynodon* sp.) *ad libitum* and alfalfa hay provided at a rate of approximately 6.4 kg/animal/day. FlaxLic® protein/fat supplement (New Generation Feeds, Belle Fourche, SD, USA) and Ranch House trace mineralized salt blocks (United Salt Corporation, Houston, TX, USA) were also provided *ad libitum*. Bureau of Land Management personnel annually immunized horses against eastern and western equine encephalomyelitis, equine influenza type A_2, the EHV-1 and EHV-4 strains of equine herpes virus, and tetanus (Fluvac Innovator® 5; Zoetis, Florham Park, NJ, USA); West Nile virus (Vetera® WNV; Boehringer Ingelheim Vetmedica, St. Joseph, MO, USA); *Streptococcus equi* (Strepvax® II; Boehringer Ingelheim Vetmedica); and rabies (Imrab® 3; Merial Limited, Duluth, GA, USA). Additionally, BLM personnel dewormed horses at least annually (more frequently for specific susceptible individuals) using Ivermax™ Equine Oral Liquid (RXV Products, Westlake, TX, USA).

METHODS

Vaccine Preparation

We conducted all work on this study under the auspices of a protocol (#2011-06) approved by the Animal Care and Use Committee at the Fort Collins Science Center, U.S. Geological Survey, Fort Collins, Colorado, USA. We chose 2 formulations of SpayVac (an aqueous emulsion and a nonaqueous form) for testing based on a recommendation from a companion study on safety and mechanism of action conducted at Oregon State University, Corvallis, Oregon, USA (Bechert et al. 2013). Personnel at IVT prepared the vaccines as described by Brown et al. (1997*b*). Briefly, they obtained frozen pig ovaries from SiouxPreme Packing Co. (Sioux Center, IA, USA) and isolated PZP by grinding thawed ovaries and passing the resulting mixture through a series of nylon mesh screens with successively decreasing pore sizes to recover oocytes. They then homogenized the oocytes to release PZP, mixed the PZP at a rate of 200 μg/dose with phosphate buffered saline (pH = 7.4), and added 0.2 g lecithin and 0.02 g cholesterol (Lipoid, Newark, NJ, USA) per dose to form multilamellar liposomes. One half of the PZP-liposome mixture was added to Modified Freund's Adjuvant (MFA; Calbiochem, San Diego, CA, USA; 1:1 v/v) to form a water-in-oil emulsion (the aqueous vaccine; 1 mL/dose). The second half of the PZP-liposome mixture was lyophilized and then reconstituted with MFA to form the nonaqueous vaccine (0.5 mL/dose). Vehicle controls were produced in the same manner but without the PZP antigen. Saline controls consisted of 1 mL of phosphate-buffered saline. Technicians at IVT loaded all vaccines and control doses into individual syringes and delivered them to us frozen on dry ice.

Treatments and Blood Sampling

We randomly selected 90 females—ages 4 ($n = 68$), 5 ($n = 18$), 6 ($n = 2$), or 7 ($n = 2$)—from 120 females that were present at the Pauls Valley facility when we initiated our study. All females were thus at or near prime breeding age (Garrott et al. 1991*a*, Roelle et al. 2010), and all were open (nonpregnant) at the time of enrollment by virtue of separation from males during the previous breeding season. Age was either known precisely (i.e., removed from the range as a foal or born in captivity) or estimated by tooth eruption

and wear (American Association of Equine Practitioners 2002). Bureau of Land Management personnel uniquely marked each female on the left hip with a 4-digit freeze mark in numerals 7.6 cm high. We assigned each female to 1 of 3 experimental groups (aqueous vaccine, nonaqueous vaccine, and control) in a stratified-random fashion such that each group was equally represented in each of the 3 pastures. We further subdivided the 30 females in the control group into aqueous (4 F/pasture), nonaqueous (4 F/pasture), and saline (2 F/pasture) groups. After allowing all materials to thaw for approximately 30 min at room temperature, we delivered vaccines and sham doses on 30 March 2011 by hand injection in the left rump while each female was restrained in a padded hydraulic squeeze chute.

At the time of vaccination and on 7 additional occasions in 2011 (3 May, 7 Jun, 6 Jul, 2 Aug, 7 Sep, 5 Oct, and 14 Dec), we drew 10 mL of blood from each female in serum separator vacutainers by jugular venipuncture for PZP titer assays. We also drew blood samples on 7 March 2012, 9–10 January 2013, 6 March 2013, and 13–14 November 2013. Following collection, we allowed the blood samples to clot for approximately 2 hr at room temperature. We then centrifuged the samples at 1,300 G for approximately 12 min and removed 2 aliquots of approximately 2 mL of serum by pipette. We placed each aliquot in a 10-mL polypropylene transport vial labeled with the date and horse identification number, froze the samples overnight in a household freezer, and shipped them on dry ice to Fort Collins, Colorado, where they were stored at −80° C until being shipped on dry ice by overnight courier for titer assays.

To corroborate our foaling observations (see below), we drew an additional 10 mL of blood from each female in a plain red-top vacutainer on 12 December 2011, 9–10 January 2013, and 13–14 November 2013. We separated serum from these samples as described above and shipped the frozen samples to the Endocrinology Lab, Animal Health Diagnostic Center, Cornell University, Ithaca, New York, USA, for pregnancy testing. Personnel at the lab assayed the samples for pregnant mare serum gonadotropin and estrone sulfate and characterized each female as open, pregnant, or inconclusive.

Female Horse Health and Condition

During each blood draw through 7 March 2012, we observed females carefully for general health and palpated each injection site to ascertain whether a reaction had occurred. We characterized each site as follows: none = no reaction apparent; swelling = a diffuse raised area, perhaps irregular in shape, may be firm, but does not appear or feel hard; lump = a distinct, roughly circular nodule that appears or feels hard; abscess = a draining sore or pocket of fluid or pus. We characterized the severity of each reaction on a scale from 0 to 3, using the same scoring system both in palpation of the injection sites and pasture observations (see below): 0 = no reaction observable or palpable; 1 = reaction (swelling, lump, or abscess) present, but no pain or lameness noticeable; 2 = reaction present, mild to moderate lameness or response to palpation; 3 = reaction present, severe lameness or strong response to palpation. On 30 March 2011 and 7 March 2012, we also estimated body condition of our females using the system of Henneke et al. (1983). We assigned each female a score from 1 to 9 following observation in the chute and palpation of fat and soft tissue of the neck, back, ribs, and rump.

Serum Assays

Technicians at IVT used an enzyme-linked immunosorbent assay to determine PZP antibody titers in horse serum. They coated 96-well polystyrene microtiter plates (Bio-Rad, Hercules, CA, USA) with PZP antigen (prepared in-house, 1 μg/mL) and incubated them overnight at 4° C. They then washed the plates with a Tris wash buffer (Tris-buffered saline/Tween-20) and blocked them with 3% gelatin (Bio-Rad) for 30 min at 37° C. Following another wash, they added a standard horse serum sample and unknown horse sera samples to the wells and incubated the plates at 4° C overnight. They diluted unknown serum samples and a positive reference serum sample to 1/25,000 and added each sample to the plates in triplicate. They then washed the plates, added a secondary antibody, Protein G (Calbiochem) conjugated to alkaline phosphatase enzyme, to each well at a dilution of 1/1,000, and incubated the plates for 1 hr at 37° C. Following another wash, they incubated the plates for 1 hr at 37° C with a substrate solution containing 4-nitrophenyl phosphate disodium salt hexahydrate (Sigma–Aldrich Chemie GmbH, Buchs, Switzerland) at a concentration of 1 mg/mL. They then used a microtiter plate reader (ASYS Hitech GmbH, Eugendorf, Austria) to measure the optical density or absorbance of each well at a wavelength of 405 nanometers. They calculated titers of the unknown serum samples as the average absorbance of the triplicate unknown samples expressed as a percentage of the average absorbance of the triplicate positive reference sample. The positive reference sample was from a female previously vaccinated (in a separate study) with SpayVac and determined to have a strong, PZP-specific antibody response. The positive reference sample was considered to have a titer of 100%.

Male Horses

We randomly selected 12 adult males, 6–9 years of age at the start of the study, from a group gathered at the Adobe Town/Salt Wells Creek herd management complex in Wyoming, USA, in October 2010. We gelded and dropped 1 of these males from the study because of his aggression. We allowed 2 months following inoculation for anti-PZP antibody titers to build and introduced 3 randomly selected males into each pasture with the females on 7 June 2011. We anticipated that the pastures would be large enough for each male to acquire a stable harem from the 30 females present and coexist with minimal aggression, but this turned out not to be the case. Fighting was not uncommon, and in 2 of the pastures breeding activity was dominated by a single male. On 6 July 2011, we randomly assigned a single male to each pasture and developed a random rotation such that pastures received a new male approximately every 2 weeks, and all males had a rest period of ≥2 weeks following each session in a pasture. Following the first rotation, we eliminated another male because he was never observed breeding a female. In 2012

and 2013, we used a new randomly assigned order each year and each pasture session lasted approximately 3 weeks. Two males died of causes unrelated to the study, one due to impaction and rupture of the large colon and the other due to a spinal injury, during the winter of 2012–2013, leaving only 8 in the rotation in 2013.

Pasture Observations

A technician who was blind to the treatment status of individual females observed each pasture $\geq$2 hr/day and $\geq$3 days/week to record information on injection-related (2011 only) or other health issues, estrous and breeding behavior, and foaling. We tried several vantage points or modes of transportation (e.g., from the fence surrounding the pasture, from a truck in the pasture, mounted on a domestic horse) for making these observations, ultimately settling on a golf car as the best platform; using the car, we were able to move within a few meters of the females while evoking little reaction other than curiosity. We recorded the nature and severity of reactions to the injections using the system described above. We characterized estrous and breeding behavior on a scale from 0 to 5 as follows: 0 = no evidence of estrous or breeding behavior observed; 1 = warm = squatting, winking, or urination observed, but female is not completely receptive to the male; 2 = hot = squatting, winking, or urination observed and female is receptive to the male; 3 = mounting observed; 4 = penetration observed; and 5 = ejaculation (flagging of the male's tail) observed. The main purpose of these observations was simply to ensure that females were being bred. We associated foals with individual dams based on nursing by the foal that was readily accepted by the female and protective behavior by the female, especially during the first few days and weeks of the foal's life. Female–foal pairings were observed $\geq$3 times/week from birth through the end of the breeding season.

Uterine Edema

On 9–10 January 2013 and 13–14 November 2013, we examined each female in the study per rectum using a Universal Medical Systems 900 (Bedford Hills, NY, USA) portable ultrasound and a 5-MHz linear transducer. Uterine edema was characterized as none, slight, moderate, or extensive. During these examinations, we also recorded information on follicular development, stage of estrous cycle, and pregnancy. All examinations were performed while females were restrained in a squeeze chute; none required sedation.

Cyclicity

On 3 June, 10 June, 17 June, 23 June, and 1 July 2014, we drew 10-mL samples of blood in a plain red-top vacutainer from each female treated with the aqueous formulation of SpayVac. We extracted serum as previously described and shipped it to the Endocrinology Lab, Animal Health Diagnostic Center, Cornell University for progesterone analyses. Females with $<$0.5 ng/mL progesterone in all 5 samples were considered to be not cycling.

Analyses

We had the following information available for assessing drug efficacy: foal observations (2012 and 2013), palpation and ultrasound (2013 and 2014), and hormonal pregnancy tests (all 3 yr). In the hormonal pregnancy tests, there were 20 cases where the results were inconclusive; in 18 of those 20 cases, no foal was observed. It thus seemed important to include those cases in our analyses, by using the other 2 criteria, to obtain the best estimate of drug efficacy. We therefore performed all of our analyses on a composite outcome measure in which a female was judged to be fertile if any of the 3 criteria (ultrasound, hormone test, foal observation) was positive. Use of this composite measure allowed us to include females whose hormone assays were inconclusive, but likely had only a small effect on our overall results, because results from the various measures of fertility were in complete agreement in 220 (92.1%) of 239 cases. We also performed duplicate analyses (data not shown) using only the results of hormonal pregnancy testing (because data were available for all 3 yr); in no case did the results differ substantively from those presented here for the composite measure of fertility.

We compared the binomial composite measure of fertility across the 2 treatment groups (aqueous and nonaqueous) with logistic regression when we were interested in estimating treatment group differences after adjusting for effects of years since treatment, body condition, and pasture assignment. We did not include female age in our models, but rather controlled for the effects of age through randomization and restricting enrollment to females 4–7 years of age. We used Akaike's Information Criterion (AIC; Burnham and Anderson 2002) to select those models better supported by the data. Because control females were fertile in 89 of 90 possible instances, the logistic model estimates were limited to comparisons of aqueous and nonaqueous groups. We also compared fertility in the control group with each of the treated groups without any additional covariates using Fisher's exact tests for the homogeneity of proportions fertile in each year. Comparisons of 2 treatment groups with Fisher's exact test provided a corresponding 95% confidence interval on the odds ratio. In addition, we compared injection-site reactions across the control and treatment groups, and by formulation (aqueous vs. nonaqueous, treated and control females combined) and ingredient (liposomes plus adjuvant with PZP or without PZP, treated and control females combined) with logistic regression and Fisher's exact test for homogeneity of proportions.

RESULTS

There was the potential for females in the control group to be fertile in 90 cases (30 F $\times$ 3 yr) during the course of our study. Using the composite measure, fertility occurred in 89 cases, indicating that males were able to cover females adequately with the rotation schedules that we used. Thus, differences in pregnancy rate or composite fertility rate between control and treatment groups can likely be attributed to the treatment, rather than to a failure of the males to breed.

The aqueous formulation of SpayVac was effective in 2012 as evidenced by a fertility rate of only 0.133 foals/female as compared with 1.00 foals/female in the control group (odds ratio 95% CI = [29.8, ∞], $P < 0.001$; Table 1). Fertility in

[a] Aqueous and nonaqueous refer to 2 formulations of SpayVac.
[b] Fertility rate is expressed as proportion of females. Fertility was determined through hormone assay (pregnant mare serum gonadotropin and estrone sulfate), rectal palpation and ultrasound, and direct observation of foals. A female was considered fertile if any of the 3 measures was positive.
[c] *P*-value is the probability that the fertility rate is the same in the treatment and control groups as determined by Fisher's exact test.

the aqueous group increased in 2013, but remained different from rates in the control group (odds ratio 95% CI = [4.1, 1,424.5], $P < 0.001$), which also occurred in 2014 (odds ratio 95% CI = [7.7, ∞], $P < 0.001$). Fertility rate in the nonaqueous group differed statistically from that of the control group in 2012 (odds ratio 95% CI = [24.5, ∞], $P < 0.001$) and 2013 (odds ratio 95% CI = [1.0, 428.9], $P = 0.03$). In 2013, however, the difference was quite small biologically (nonaqueous group = 0.76 foals/F, control = 0.97 foals/F), and we judged that the BLM would not find the small reduction in foaling due to contraception to be of interest. Having no reason to suspect that drug performance would improve in subsequent years and not wanting to contribute foals unnecessarily to the off-range population of BLM horses, we removed the nonaqueous group from the experiment at the end of the second foaling season. The fact that few treated animals were fertile in the first year indicates that the time we allowed between vaccination and introduction of the males (~2 months) was sufficient for contraceptive efficacy to develop.

We used logistic regression to model probability of foaling in the aqueous and nonaqueous treatment groups in 2012 and 2013. Our initial model contained the potential explanatory variables treatment, year, and a treatment by year interaction. Of these, only year was significant ($z = 2.675$, $P = 0.007$), consistent with the fact that the fertility rate increased in both groups in 2013. Addition of body condition at the time of treatment did not improve the model ($\Delta AIC = 0.96$).

Mean recorded PZP antibody titers reached a maximum more quickly for the nonaqueous formulation, but also declined more quickly and were consistently lower than means for the aqueous formulation after 6 July 2011 (Fig. 1). A similar pattern was apparent in the number of females that exhibited their maximum recorded titer on each sampling date (Table 2). Greater than half of the 30 females treated with the nonaqueous formulation exhibited their maximum recorded titer on 3 May 2011, and 29 of the 30 did so by 6 July 2011. In contrast, individual females treated with the aqueous formulation exhibited their maximum titers over a longer period of time. Across 11 sampling dates postvaccination, mean PZP titers were 33.7–91.9% greater in nonpregnant females than in pregnant females in the aqueous treatment group (Fig. 2A) and 7.8–82.8% greater in the nonaqueous group (Fig. 2B). The relationship between antibody titer and fertility in individual females was less clear (Table 3). Female number 609, for example, had a maximum titer of 60.11%, was not one of the females that ceased cycling postvaccination, and did not become pregnant in any of the 3 years of our study, whereas several females with greater maximum titers did become pregnant.

None of the 6 females that received saline control inoculations exhibited any reaction at the injection site (Table 4). Of the 84 animals that received either SpayVac or the liposome+adjuvant control doses, 25 (29.8%) exhibited a reaction of some kind (swelling, lump, or abscess). Abscesses were present in 5 (6.0%) of the 84 during the year in which we monitored the injection sites; all 5 occurred in animals that received either the nonaqueous vaccine or the nonaqueous control injection. Abscesses appeared as early as 2 months postinoculation and as late as 5 months; some healed only to reappear at a later date. On female 3425, for example, an abscess was first recorded on 7 September 2011, was recorded again on 5 October, had disappeared by 14 December, and reappeared by 7 March 2012. In no case,

however, did we record a severity score >1 (reaction present, but no pain or lameness noticeable).

Neither Fisher's exact test ($P = 0.28$) nor logistic regression analysis (deviance = 2.648, df = 2, $P = 0.27$) revealed an effect of treatment (control, aqueous vaccine, or nonaqueous vaccine) on the probability of a female exhibiting a reaction at the injection site. However, combining control and treated animals by formulation (aqueous or nonaqueous) in a logistic regression model revealed a greater ($z = 2.183$, $P = 0.03$) incidence of injection-site reactions in animals receiving the nonaqueous formulation (41.5%) than in those receiving the aqueous formulation (19.0%). Interestingly, adding a variable for presence or absence of PZP did not improve the model ($\Delta AIC = -1.52$); that is, reactions were as likely to occur in animals receiving liposomes+adjuvant as in animals that received the vaccine with antigen. Addition of body condition also failed to improve the model ($\Delta AIC = -1.91$).

On 9 and 10 January 2013, we rectally palpated 59 treated females (1 F in the nonaqueous treatment group died of torsion of the small intestine unrelated to the study in Feb 2012). Of those, 25 were open and only 1, treated with the aqueous vaccine, exhibited slight uterine edema. On 13 and 14 November 2013, we rectally palpated 30 animals treated with the aqueous vaccine. Of the 17 females that were open, 2, 2, and 1 showed slight, moderate, and extensive uterine edema, respectively.

Of the 30 females treated with aqueous SpayVac, 5 (numbers 461, 3763, 3904, 4305, and 4330) had progesterone levels consistently <0.5 ng/mL and were thus judged to be not cycling. None of the 5 was fertile in any of the first 3 years of the study, but they were not the females with the highest maximum antibody titers (Table 3).

DISCUSSION

A single-injection contraceptive having multiyear efficacy in horses would be of great utility to the BLM and other agencies that manage feral horses. In the only other trial of SpayVac in horses where pregnancy or foaling was an endpoint, Killian et al. (2008) reported pregnancy rates in 12 treated adult females of 0% in the first year after vaccination and 17% in the next 3 years, as compared with pregnancy rates of 75%, 75%, 88%, and 100% in 8 control females. In addition, although breeding was not a part of their study, Bechert et al. (2013) found that 93% of 14 adult females treated with SpayVac ceased estrous cycling within 3–4 months of vaccination. Thus, both of these earlier studies offered hope that SpayVac might provide the single-injection, multiyear efficacy desired by the BLM for management of wild horses. Although we received all vaccines frozen, the nonaqueous vaccine was of particular interest because the lyophilized material could be stored unfrozen and easily reconstituted with adjuvant in the field, rather than having to create an emulsion as with the aqueous version.

We were unable to attain contraceptive efficacy as great as that reported by Killian et al. (2008). Individual variation in response to the vaccine may account for some of the difference between our results and those of Killian et al.

Table 3. Number of pregnancies and maximum recorded porcine zona pellucida (PZP) antibody titer, expressed as percent of a positive reference, in adult female feral horses treated with the aqueous formulation of the immunocontraceptive SpayVac in a captive breeding trial at Pauls Valley, Oklahoma, USA, 2012–2014. Females are listed in order of increasing maximum PZP antibody titer.

Female ID number	Max. PZP titer[a]	No. of pregnancies[b]	Female ID number	Max. PZP titer[a]	No. of pregnancies[b]
7802	31.19	3	4305	85.00	0
3908	37.94	2	3904	85.40	0
1688	39.66	3	8816	86.38	2
500	41.90	2	4257	92.69	0
4320	44.31	2	504	96.88	0

8667	78.12	2	4319	297.25	0

[a] PZP antibody titer is expressed as a percentage of a positive reference, represented by a female vaccinated in a previous study and judged to have a strong, PZP-specific antibody response. The positive reference sample was considered to have a titer of 100%.
[b] Pregnancy was determined through hormone assay (pregnant mare serum gonadotropin and estrone sulfate), rectal palpation, and direct observation of foals. A female was considered pregnant if any of the 3 measures was positive.

(2008); other factors that may be important include dose, adjuvant, and injection site. Henderson et al. (1988) showed that dose (amount of PZP administered) can affect both estrous cyclicity and duration of infertility. In the study by Killian et al. (2008), each dose contained 400 μg of PZP, whereas our vaccines and those used by Bechert et al. (2013) contained only 200 μg of PZP/dose. This change was first instituted by the manufacturer in the vaccine provided to Bechert et al. (2013) based on the fact that a primer dose of 65 μg of PZP emulsified with Freund's Complete Adjuvant (FCA) followed by a booster dose of 65 μg of PZP emulsified with Freund's Incomplete Adjuvant was sufficient to contracept horses on Assateague Island, Virginia, USA (Kirkpatrick et al. 1990, 1995). The manufacturer thus expected that 200 μg of PZP in the liposome formulation used in SpayVac would be more than sufficient for contraception. The fact that 93% of females treated by Bechert et al. (2013) stopped cycling seemed to support that expectation.

Our choice of adjuvant was influenced by several factors. First, we were uncertain that AdjuVac™, which was used by Killian et al. (2008), would be readily available in the future. The various versions of Freund's adjuvants, on the other hand, are available from several suppliers. Second, MFA is thought to be less likely to cause injection-site reactions than FCA. Lyda et al. (2005) showed that antibody titers in adult females treated with MFA+PZP were greater than those in females treated with FCA+PZP, although this finding was not statistically significant. Finally, Bechert et al. (2013) achieved what appeared to be positive results with SpayVac formulated with MFA. All of these factors influenced our choice of MFA as the adjuvant.

Table 4. Percent of treated and control adult female feral horses exhibiting an injection-site reaction in a captive breeding trial of the immunocontraceptive SpayVac at Pauls Valley, Oklahoma, USA, 2012–2014.

		Females exhibiting a reaction	
Treatment	*n*	No.	%
Saline control	6	0	0
Aqueous control	12	1	8.3
Nonaqueous control	12	5	41.7
Aqueous SpayVac	30	7	23.3
Nonaqueous SpayVac	30	12	40.0

In both previous studies of SpayVac in horses, injections were given in the neck (Killian et al. 2008, Bechert et al. 2013). Although no data were presented, several authors suggested that reactions to injections given in the rump were less common and perhaps less severe than to injections given in the neck, which influenced our decision on injection site (Lyda et al. 2005, Kirkpatrick et al. 2011, Bechert et al. 2013). Additional work to clarify the relationship between injection location and reactions may be warranted.

Antibody titers in response to vaccination with PZP have been shown to vary considerably within a species even when dose and adjuvant are the same (Kirkpatrick et al. 2011). Differences in response may to some extent depend on an animal's physiological state, but we saw no effect of body condition on probability of foaling. This is perhaps not surprising in that body condition ranged only from 4.0 to 6.0 ($\bar{x} = 4.9$ for all 90 females) when vaccinations were given in March of 2011, and improved substantially by March of 2012 ($\bar{x} = 6.6$, range = 5.0–8.0).

Comparisons between antibody titers measured in our study and those reported by Killian et al. (2008) and Bechert et al. (2013) are difficult because of differences in measurement scale and units in which titers were quantified. In general, however, it appears that, for unknown reasons, high titers were sustained longer in those 2 previous studies than in ours. Other studies have shown a correlation between antibody titers and contraception in females, with antibody

titers 50–60% of a positive reference serum being sufficient to render 90–95% of adult females infertile (Liu et al. 1989, 2005; Turner et al. 1997). However, none of these studies were >1 year in duration. Our data suggest that a similar threshold may exist for multiple-year efficacy in horses treated with SpayVac. Only a single foal was produced (female 4253) in 3 years following inoculation in females having a maximum titer greater than approximately 90% of the positive reference; we believe that datum may be an error in foal assignment to a dam, because the female tested inconclusive for pregnancy by hormone analysis and negative for pregnancy by palpation in that year. Despite our careful efforts to associate foals with dams, an occasional error is possible because many of our females, particularly those with bay coloration, were very similar in appearance. Titers reported as a percentage of a positive reference compare serum taken from a successfully contracepted female (the positive reference) with sera from other treated and control females. The lower values reported here, for example in the control females, were probably below the limit of detection for the assay and likely reflect background issues, which are not uncommon when testing for polyclonal antibodies. As such, most values below approximately 30% of the reference serum likely do not represent true immune responses, which may explain the fluctuations in control values through time.

Our study and that of Bechert et al. (2013) clearly showed that reactions at the injection site were fairly common even with MFA as adjuvant and, contrary to a previous report (Roelle and Ransom 2009), even when injections are delivered by hand rather than by dart. Both studies reported that reactions can resolve only to reappear at a later time, and both studies provided some evidence that reactions at the injection site are attributable to the adjuvant rather than the immunogen. Increased rates of injection-site reactions in these 2 studies are most likely the result of more frequent and closer examination, both visually and by palpation. Interestingly, however, even such close scrutiny does not detect all reactions. In our study, necropsy of female 740, which died of torsion of the small intestine, revealed a sterile abscess that had gone undetected in 7 examinations (visual and by palpation) over a period of 7 months. It thus seems highly likely that studies based on field observation alone under report injection-site reactions. Bechert et al. (2013) found injection-site reactions to be more frequent for the aqueous formulation of SpayVac (5/7 = 71.4%) than for the nonaqueous formulation (3/7 = 42.9%), whereas the reverse was true in our study. Reasons for this difference are unclear, but the small sample sizes ($n = 7$ F/group) in the study by Bechert et al. (2013) may be a contributing factor. Despite the fact that injection-site reactions were fairly common in our study, perhaps the most striking and important observation was that none of the reactions appeared to be painful or caused any noticeable change in mobility or gait.

Unlike Killian et al. (2008), we found uterine edema in only a small proportion of open females in January of 2013, likely because most of the females were in anestrus. In November of 2013, however, we found uterine edema in a proportion of females similar to the expected normal frequency (~25–30%) suggested by Killian et al. (2008) assuming a 21-day estrous cycle and 5–7 days of the cycle actually in estrus. Our November examinations should be roughly comparable to those done by Killian et al. (2008) in mid to late October, so the reasons that they found much higher rates of uterine edema remain unclear. We reiterate, however, that we view the frequencies of uterine edema observed here as normal and not a contraindication to the use of SpayVac.

Bechert et al. (2013) found that 93% of females treated with SpayVac ceased cycling 3–4 months after vaccination. Unfortunately, they were unable to follow the females to see whether normal ovarian function was restored over time. We found that 5 of 30 females treated with the aqueous formulation of SpayVac were not cycling >3 years after vaccination, which may suggest that loss of ovarian function is permanent when it occurs. As would be expected, none of these 5 females was fertile in the first 3 years of our study. However, an additional 10 females that appeared to be cycling were also infertile in the first 3 years of our study, which suggests that some mechanism other than disruption of ovarian function is responsible for infertility. One possibility is that antibody titers, even though they declined significantly following vaccination, were still high enough to prevent sperm binding to ova in these 10 females.

MANAGEMENT IMPLICATIONS

We did not find SpayVac to be as efficacious as other investigators have. However, both modeling (Ballou et al. 2008) and field studies (Kirkpatrick and Turner 2008) have shown that significant reductions in fertility can be achieved with <100% contraceptive efficacy. If even the modest results that we observed could be duplicated on a large scale, which would require registration of SpayVac by the U.S. Environmental Protection Agency, the BLM and other agencies charged with managing feral horses would have a more effective fertility control tool than has heretofore been available, especially given the fact that no booster inoculation is required with SpayVac. Concerns about reactions at the injection site and uterine edema appear to be minimal and should not deter BLM or others from using SpayVac.

ACKNOWLEDGMENTS

It is with extreme gratitude that we acknowledge the many contributions of our technician, C. English, in collecting the field data for this project. We thank the many Bureau of Land Management employees who made this study possible, particularly D. Bolstad for his consistent support, and P. Hofmann, G. Hughes, and J. Stratton for day-to-day care and management of the horses. We gratefully acknowledge Dr. T. Gilmore, Garvin County Veterinary Hospital, Elmore City, Oklahoma, for his assistance in obtaining blood samples and monitoring the general health of the animals. We are also grateful to Dr. M. Mansour, L. MacDonald, and V. Morgan, ImmunoVaccine Technologies Inc., who provided the vaccine and useful advice on its application. L. MacDonald also conducted porcine zona pellucida titer assays, along with V. Kaliaperumal. M. Fraker, Terramar Environmental Research, provided advice on study

design, and Drs. I. Liu and U. Bechert and 3 journal referees provided helpful reviews of earlier drafts of this manuscript. We are especially grateful to Dr. Liu for performing ultrasound exams of female horses used in the study. Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Behavioural ecology of island feral horses

D. I. RUBENSTEIN
The Research Centre, King's College, Cambridge CB2 1ST

Summary

In a horse population on Shackleford Banks, an island off the American east coast, major changes in social organisation have occurred. Instead of typically living in harems occupying overlapping home ranges, it was found that some harems defended territories and some horses did not even live in fixed membership groups. The existence of these social variations appeared to be correlated with the unique habitat and geographical features of the island. Territories, whose boundaries ran the width of the island, only occurred where the island was narrow, the visibility unrestricted and the essential vegetation zones ran along the island's long axis. Only here were the difficulties in defending reduced and feeding and male mate-guarding opportunities increased. Where the sand dunes were high and forest dense temporary assemblages occurred and non-territorial harems occupied the patchy semi-open area with the batchelor males.

Once territories were defended many aspects of individual social relationships became altered. Territorial stallions were less likely to influence the daily activity patterns of their groups and more likely to groom their dominant females and round-up their subordinate females than were their non-territorial counterparts. In addition, interpersonal distances were likely to be greater among horses living in territorial, as opposed to non-territorial, harems.

Introduction

ISLAND biotas differ in many ways from their mainland counterparts. Perhaps the most salient features of islands are that they possess fewer species than nearby mainland areas and that, in general, large near-shore islands have more species than smaller more distant islands. But the differences in behaviour and ecology of insular populations are just as striking. These populations often show more dimorphism (Schoener 1967; Wallace 1978), forage in more foliage levels (Karr 1971) and display reduced stereotype in seed selection (Pulliam 1973) than their mainland counterparts. Even changes in social organisation have been observed. For example, the yellow faced grassquit *(Tiaris olivacea),* which is gregarious in Costa Rica, is territorial on Jamaica (Pulliam *et al* 1972). Typically, these effects are attributed to insular isolation, small size and topographic simplicity (Preston 1962; MacArthur and Wilson 1967; Lack 1976). But the way in which these factors actually alter island fauna appear to be complex and are, as yet, incompletely understood.

The work reported here was undertaken to examine whether islands affect the social behaviour of feral horses and, if so, what attributes of islands are responsible for these changes. This entailed comparing the social behaviour and patterns of social organisations of feral horses inhabiting a number of different mainland and island habitats. Apart from the data gathered during the last 5 years on the ponies of Shackleford Island, the other data were derived from the published studies of Welsh (1973) on Sable Island, Berger (1977) in the Grand Canyon and Feist in the Pryor Mountains (Feist and McCullough 1976).

Dr Rubenstein's present address is: Biology Department, Princeton University, Princeton, New Jersey 08544, USA

Social organisation of wild equids

A brief look at the social organisation of the living equids — the zebras, asses and horses — suggests that phylogenetic constraints will only minimally influence feral horse social organisation. Wild equids show a remarkable diversity of social organisation (Table 1). Basically, 2 categories of social organisation exist; that involving permanent groups and that involving temporary assemblages. Typically the asiatic wild horse *(Equus prezwalski)* (Mohr 1971; Groves 1974) and the plains *(E burchelli)* and mountain *(E zebra)* zebras (Klingel 1974) live in small permanent groups that are composed of females, their offspring, juveniles and a dominant stallion. Adult males not possessing harems live either alone or in permanent bachelor groups. Both kinds of groups inhabit large overlapping home ranges. For plains zebra in the Serengeti, home ranges vary in size from 600 km^2 in the dry season to 300 km^2 in the wet season (Klingel 1974). Some zebra populations undertake seasonal migrations in search of suitable food and water. The Serengeti populations, for example, migrate up to 150 km to their dry season foraging ranges. The few anecdotal accounts of the ranging behaviour of the Asiatic wild horse suggest that harems have well-defined home ranges centred around water holes during the spring foaling period and summer dry season but that they wander more widely during the winter when snow and melt water are widely available (Mohr 1971).

In the case of wild asses and Grevy's zebra the pattern of social organisation is very different. According to Klingel (1977), in both the African *(E africanus)* and the Asiatic *(E hemionus)* wild asses, there are no permanent associations other than small mother-offspring groups. Nevertheless, temporary assemblages consisting of only males, only females or of both sexes do occur. During the day these small groups and solitary individuals may even coalesce into large feeding herds but by evening these herds break up. During the breeding season, however, a large proportion of the adult males establish territories. These territories are large, averaging 23 km^2, and are only defended against other males when a female in oestrus actually enters the territory.

Klingel's observations show that the social organisation of Grevy's zebra *(E grevyi)* is basically similar to that of the wild asses (Klingel 1974). Permanent associations among adults are rare and most of the adult males restrict their activity to territories that are only defended in the presence of females in oestrus. These territories appear to be smaller than those of the asses (6 km^2) and they appear to be maintained throughout the year except during the dryest years.

Why there should be 2 major types of equid social organisa-

TABLE 1: Social groups exhibited by different equid species

	Permanent groups			Temporary groups	Solitary territorial males
	Harems	Bachelor groups	Solitary males	All males; all females; mixed sexes	
Wild horses	5-6	?	?	No	No
Plains zebra	4-7	2-3	?	No	No
Mountain zebra	6-7	4-8	?	No	No
Grevy's zebra	No	No	—	2-8	Yes
Wild asses	No	No	—	2-6	Yes

Numbers reflect range of group sizes, otherwise presence or absence is indicated

tion is not obvious. What appears to be common to all equids is that in drier habitats and in areas where resources are distributed in a more patchy fashion, systems of temporary assemblages and solitary territorial males occur more frequently than systems involving harems. This relationship probably arises largely because low quality vegetation distributed in small widely scattered patches makes it uneconomical for females to form permanent fixed membership groups by intensifying intraspecific competition. Without female associations to defend, males instead defend large areas containing the resources females require. Only larger more evenly distributed patches of higher quality vegetation allow females to feed in permanent membership groups, thus fostering a harem social system.

Social organisation of mainland feral horse populations

In general, the social organisation of mainland feral horses is similar to that of the Asiatic wild horse and the plains and mountain zebras, with one exception; there appear to be no long distance seasonal migrations. However, as with the non-migrating plains zebra of Ngorongoro Crater, feral horse populations are constrained either by geological features, such as the Grand Canyon, or man-made barriers. Thus it is difficult to surmise whether feral horses would migrate if the opportunity were available.

Some details of the population characteristics and social organisation of 2 mainland populations are shown in Table 2. At the time of the surveys both populations were composed of a variety of permanent groups. Typically, most dominant stallions possessed small harems which consisted of females, their young and juveniles. The average size of these harems was about 5 horses although they ranged in size from 2 to 20. There were also bachelor groups consisting only of adult males and during the breeding season these tried to establish their own harems by stealing females from neighbouring harems. In the Pryor Mountains the average size of these bachelor groups was 1.8 horses. Occasionally solitary males were found which were thought to be older males that had lost their harems. The stability of the groups in these populations seemed pretty high; only 7.6 per cent of the Pryor Mountain adult females changed bands in a year while none changed groups during a 6-month period in the Grand Canyon. In these 2 mainland populations, groups possessed home ranges of about 20 to 25 km^2 but these often overlapped with those of neighbours.

Social organisation of island feral horses

The social organisation of feral horses on islands is more variable than that on mainlands. Sable Island, which lies about 100 miles east of Nova Scotia, is inhabited by a population of feral horses which probably originated in the early 1700s. The population, which fluctuated between 150 and 300 horses, was dispersed along the island in about 50 groups. Some were typical harems which contained a dominant stallion, females, offspring, juveniles and occasionally a subordinate male. Others were bachelor groups or even groups whose composition continuously changed. Although this type of group is characteristic of asses and Grevy's zebra, it is not generally described for horses. In addition, there were a few solitary males in the population. The sizes of these groups were slightly larger than those of the mainland populations (Table 2). Furthermore, on Sable Island, which is approximately 40 km long and 1.3 km wide, the population density was greater than that of the mainland populations, while the average size of the overlapping home range was less. The age structure, however, was not too different from that of the Pryor Mountain population.

Shackleford Banks, a barrier island off the coast of North Carolina, is inhabited by approximately 100 horses whose ancestors were probably shipwrecked on the outer banks in 1565 (Anon 1975). Certain facets of the social organisation of this

population were found to be very different from those of the other studies. As in other horse populations there were stallion dominated harems, bachelor groups, solitary males and even temporary assemblages containing adults of both sexes. But the population on Shackleford was unique in that two-thirds of the harems maintain well-defined, non-overlapping territories. Furthermore, these territories were permanent. During the course of this study the boundaries remained remarkably constant, shifting not more than 15 to 20 m. Even when harems were stampeded together and driven far from their territories, all the horses returned to their previous territories after human harassment had ceased.

Territorial boundaries ran the width of the island from the ocean to the back sound. Generally, these boundaries coincided with subtle geographic features such as a row of low dunes, a tidal inlet or a patch of fresh water marsh. Although large dung piles occasionally lay along the boundaries, equally large dung piles were situated throughout the territory. But even though these boundaries were not conspicuously marked, they were rarely crossed. Two reasons may account for this. First, stallions are very solicitous of females, especially during the breeding season, and when females approach the boundary stallions herd them towards the centre of the territory. Secondly, neighbouring stallions and bachelor males rarely cross these boundaries because the resident stallion defends his territory vigorously. Typically, encounters stop after a ritualised sequence of defaecations and dung sniffing. But often these encounters escalate into physical contests in which the horses kick and chase each other. During the period of this study resident stallions won all encounters. The costs of such vigorous territorial defence, however, were presumably quite high because resident stallions often received deep cuts around the mouth and jaw.

The feral horse populations on Sable and Shackleford Islands had similar age structures, population densities and ranging areas (Table 2). Shackleford had significantly larger harems and smaller ranges than some of the other populations but these characteristics might just as likely be the consequences of territoriality as its cause. Furthermore, band stability, as measured by the percentage of adult female movements, was not much lower than that found in the Pryor Mountain population.

Advantages of territoriality

Why then did the population on Shackleford Island exhibit such a different pattern of social organisation? There appears to be an absolute correspondence between particular habitats and the types of groups that inhabit them and it is therefore proposed that a number of features concerning the topography and habitat structure of Shackleford were responsible for the pattern of social organisation. Shackleford Banks is a long, narrow island approximately 17 km long and 1 km wide. The eastern half of the island is virtually flat and is composed of 3 major vegetation zones, each running parallel with the long axis of the island. Running inwards from the ocean (Fig 1) there is a sandy beach about 10 m wide followed by a narrow zone of low dunes that are predominantly covered with sea oats *(Uniola paniculata)*. The dunes are rarely higher than 5 m but they do provide the centre of the island with some protection from ocean waves and salt spray. There is an extremely wide flat swale that is dominated by salt-meadow cordgrass *(Spartina patens)*, the rush *(Juncus rosemerianus)* and other grasses and sedges. The distribution of species is often patchy and in places the ground cover is fairly sparse. In this zone there are both permanent and temporary pools of fresh and brackish water. Finally, there is a salt marsh bordering the sound in which saltwater cordgrass *(Spartina alterniflora)* and glasswort *(Salicornia virginica)* are dominant. It was only on this flat, eastern half of the island that territorial harems were found.

The western end of the island has a strikingly different profile. There are virtually no flat open areas (Fig 2). Along the beach there are tall dunes reaching 10 to 15 m in height. These dunes stretch across the width of the island and eventually slope into dense maritime forest. Occasionally, there are small flat areas among the dunes and these are covered by typical swale vegetation. Intruding into the forest from the rear are pockets of fresh marsh which support a rich and varied flora. In this topographically complex area horses were often found alone, in bachelor groups or in temporary assemblages. At this end of the island animals of both sexes mingled freely but when groups formed their composition continuously changed.

Between the eastern and western end of the island there is a small flat area which is punctuated by 2 small stands of

Fig 1. Cross-section of the eastern end of Shackleford Island

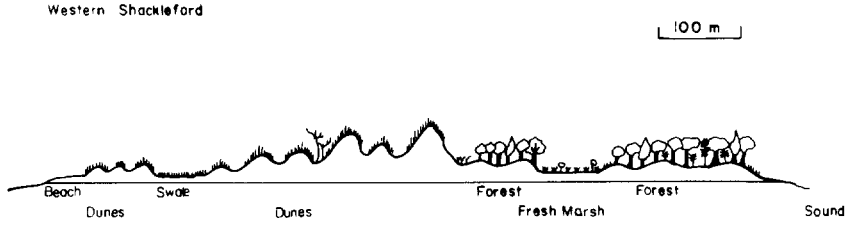

Fig 2. Cross-section of the western end of Shackleford Island

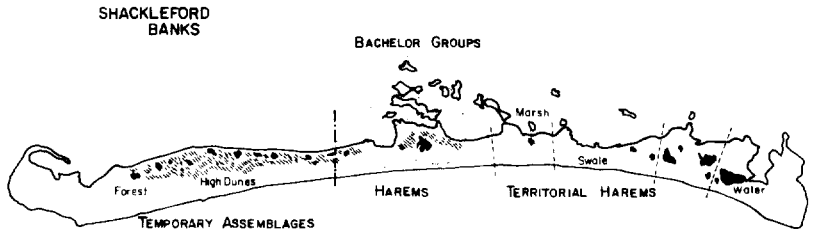

Fig 3. Map of Shackleford Island showing the location of the major environmental features and the location of the territorial harems, non-territorial harems which overlap with the bachelor groups, and the location of the temporary assemblages

maritime forest (Fig 3). In the centre of this area were situated several small groups of bachelor males and on the fringes of the forest were located 2 harem groups. The ranges of the harems were not exclusive and they did overlap almost completely with the ranges of the bachelor males. As a result they were not considered to be true territorial harems. The location of the various habitat areas and the arrangement of the types of groups inhabiting them is depicted in Fig 3. Note the fairly even distribution of fresh or brackish water along the back side of the island.

It is suggested that territoriality would exist in all horse populations if the costs associated with maintaining it were offset by large enough benefits. Only on the eastern end of Shackleford, however, did it appear that the benefits of exclusive access to a variety of seasonal food types and of increased control over females in oestrus exceeded the costs of excluding competitors. This favourable benefit/cost relationship might have arisen because:

(1) The island is narrow;
(2) the habitat is open and visibility is excellent;
(3) each of the 3 essential feeding zones runs lengthwise along the island;
(4) water is fairly evenly distributed along the length of the island.

Two facts suggested that foraging considerations were important and that having territories might provide horses with increased feeding advantages. First, the horses spent an average of 75 per cent of their time foraging. Fig 4 shows that there were daily and seasonal effects but time spent feeding made up a considerable part of a horse's daily time budget. Secondly, despite this large proportion of time spent feeding, the overall condition and health of the animals remained low (Fig 5). Ribs could be seen through the coat year round and most deaths occurred just before the foaling season when the nutrient and energy content of the sparse forage was lowest.

On Shackleford the abundance of forage types varies seasonally and the grazing behaviour of the horses reflected this changing availability. Typically, horses spent most of their time feeding on the saltmarsh and the swale during the summer but during the winter they switched their activity patterns and concentrated feeding on the swale and on the dunes. These seasonal feeding patterns are shown in Fig 6 for horses living in territorial harems but the pattern also applied to horses living in non-territorial harems and bachelor groups. Apparently horses needed to forage in all 3 vegetation zones in order to survive.

Since home ranges traversing the island from ocean to sound would secure access to each of the 3 major zones, why did some horses establish territories and maintain exclusive access to this forage? This was done possibly to derive 2 additional feeding benefits. First, home ranges had large areas of overlap (Fig 3) and this might have temporarily prevented individuals in a group from obtaining a particular resource at a particular time. Obviously establishing a territory, even if more costly in terms of time and energy expenditure, would alleviate this problem. Secondly, exclusive use of an area might have enabled individuals to use the forage more efficiently. By regularly rotating grazing patches in a particular zone, each horse could continuously harvest the highly nutritious new vegetative growth. Preliminary analyses showed that territorial harems seemed to alternate consistently among regenerating patches. Although there was much variation, the time from abandoning a patch to recommencing feeding in that patch was longer within territories (10 to 14 days) than in areas of overlapping home ranges (less than 7 days). As a result, the grass was longer in territorial as opposed to non-territorial areas. Even if difficult at

present to explain why individuals did not cheat and crop the forage prematurely, it would appear that individuals in groups that had exclusive access to resources were deriving increased feeding benefits.

Because stallions performed all the territorial defence, it was possible that they could increase the number of females in their harems and increase the likelihood that they actually fathered their offspring by maintaining a territory. Two observations suggested that the reproductive success of territorial males may indeed be higher than that of non-territorial males. First, it was found that male-male contacts were more likely to occur further away from the harem when a male had a territory than when he did not. Thus, the risk of a female being stolen by a neighbouring stallion was lower for territorial stallions than for non-territorial stallions. Secondly, territorial harems consisted of more adult females than non-territorial harems and, more importantly, territorial harems tended to increase in size, whereas non-territorial harems either did so more slowly or decreased in size.

Costs of territoriality

On Shackleford, guaranteed access to fresh water and to the 3 essential vegetation zones seemed to provide all horses, regardless of sex, with some additional feeding benefits. Also, males appeared to derive additional mating benefits. But what about the costs associated with this unique occurrence of equid territorial behaviour? During the study, it was not possible to estimate the costs associated with territoriality but normally the costs of excluding other individuals from an area were high (Gill and Wolf 1975; Carpenter and MacMillan 1976; Rubenstein 1981). On the eastern end of Shackleford Banks, however, these costs may in fact have been quite low because first, visibility was high and stallions could monitor their boundaries with a minimum of lost time and energy and secondly, half the perimeter, on average, of a territory running the width of such a narrow island was bounded by water and thus devoid of potential competitors. Therefore, even if the additional costs to ungulates of being territorial were usually high, the habitat structure on the eastern end of Shackleford kept them low, making "affordable" the small feeding and mating advantages associated with territorial behaviour.

Circumstantial evidence lends support to this hypothesis. In the mainland populations water was not evenly distributed about the habitats and as a result bands shared watering holes and had overlapping home ranges. The same situation seemed to exist on Sable Island (Welsh 1973). Even on Shackleford, where water was less uniformly distributed, the visibility poorer and the island wider, territoriality did not occur. In the transition zone where there was only one large centrally located pool, forests and accessible islands almost touching the sound side of the island, both harems and bachelor groups maintained overlapping ranges. Although in this area groups sometimes drank simultaneously from this pool, one group usually waited in the forest until the drinking group had left. Furthermore, Hoffman (1980, personal communication) noted that on an island less than 2 miles from Shackleford, with similar vegetation but with different spatial arrangements and with centrally located water holes, the horses lived in harems that did not possess territories. So it appeared that the dispersion of forage and water played an important role in determining whether harems will have overlapping home ranges or territories.

Consequences of territoriality

Once territories were formed subsequent changes in other aspects of social behaviour were possible. For example, the reduced likelihood of interference from neighbours probably enabled a stallion to control his harem and prevent raiding males from stealing his females, with less effort. Therefore, it was not surprising that during and immediately before the breeding season the individual distance among members of territorial harems was significantly larger than among members of harems that did not have exclusive home ranges (Fig 7).

Territorial stallions were also less likely than non-territorial stallions to direct or influence many daily activities such as choosing feeding areas, determining the duration of feeding episodes, leading local or short distance movements and intervening in intragroup conflicts. Only when initiating and directing long distance movements and when herding widely dispersed females did territorial and non-territorial stallions behave in a similar fashion.

Dominance relationships within a harem were also affected by the territorial nature of the group. Although harem stallions dominated all their females, females differed in their ability to dominate each other. By recording how often females threatened each other (eg, headshakes, ear lay backs, neck extensions, rump turns and kicks) it was possible to rank

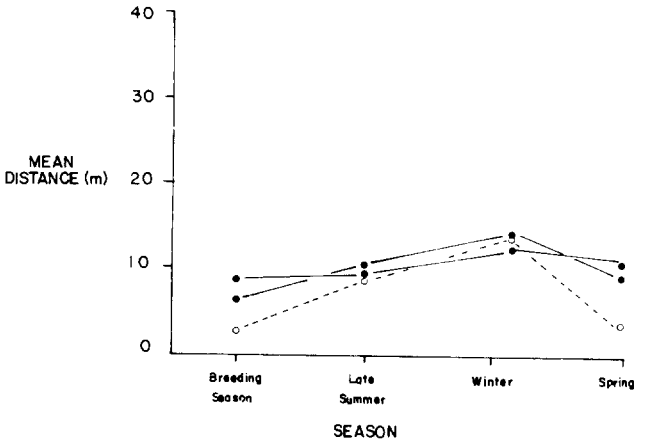

Fig 7. Seasonal changes in the mean distance among group members. ●——● territorial groups; o- - -o non-territorial groups. Differences significant during breeding season (t_{25} = 2.81; $P < 0.01$) and spring (t_{31} = 3.02; $P < 0.005$)

females. Both territorial and non-territorial harems exhibited nearly linear female dominance hierarchies. Typically, adult females ranked above yearlings and yearlings ranked above 2 year olds, regardless of harem type (Fig 8). But territorial and non-territorial stallions threatened their females differently, especially during round-ups. Territorial males tended to round-up lower ranking females disproportionately more than they did higher ranking females, whereas non-territorial males tended to round-up females more equally, regardless of rank (Table 3).

Territoriality also seemed to affect the grooming relationship between stallions and their females. Among horses living in territorial harems a correlation was found between the extent to

TABLE 3: Number of times territorial and non-territorial stallions rounded-up high and low ranking females in their harems

Statistical test: chi = 12.5; significance level P-squared <0.001.

which females were groomed by the stallion and their rank. The male groomed higher ranking females more than lower ranking females. Among horses living in non-territorial harems, however, the stallion appeared to groom all his adult females equally (Fig 8).

From these few examples it appeared that the relationship between a stallion and his females depended on whether he had established a territory. With respect to "bonding" behaviours, as measured in terms of interpersonal distance, and grooming and round-up behaviour, territorial males responded differently to females depending on their relative rank than did non-territorial males. It seemed likely that such differences were the consequences of the different risks of mating failure suffered by each type of stallion.

The linear arrangement of territories also had consequences for inbreeding and kin relations. Adult and, to a lesser extent, juvenile females moved only short distances when they left a band, whereas juvenile males usually moved longer distances to the western end of the island or to the bachelor groups in the

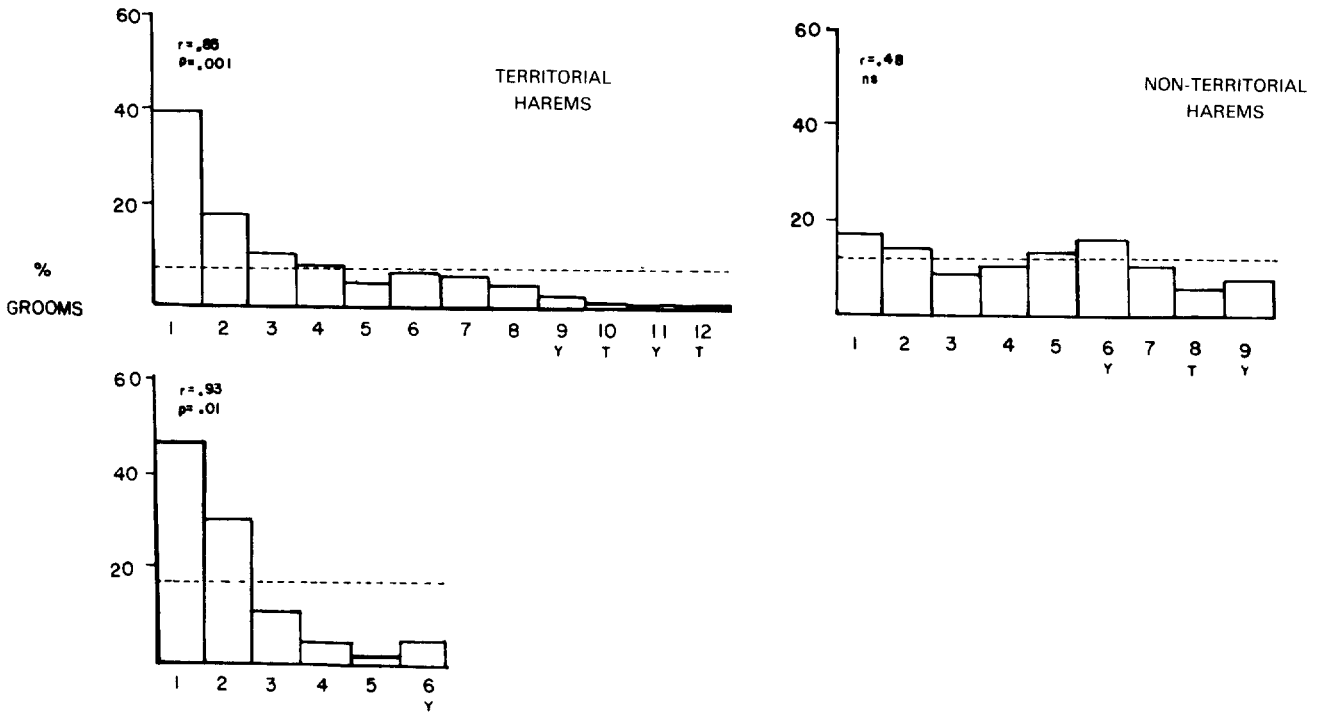

Fig 8. Relationship between a female's rank and the frequency of male grooming contacts. Dashed line shows the expected level if all females were groomed equally frequently by the male. transition areas. Some never seemed to leave their natal territory. However, larger samples are needed before the ramifications of these different sex-related dispersal patterns on group dynamics can be completely unravelled.

Conclusions

These comparisons reveal that horses have a typical pattern of social organisation but that variations can arise under unusual environmental conditions. On Shackleford Banks the types of groups that formed, relationships between groups and the social cohesion within groups were largely controlled by the habitat structure of the island, which in turn was influenced by the size and shape of the island. But does Shackleford Bank represent a topographically and vegetationally unique situation? Or are there other areas that might provide novel arrangements of habitats or unusual environmental pressures? It would not be surprising to find that most islands, because of their peculiar shapes, limited floral diversity, ruggedness, fluctuating fresh water levels and extreme climates, are areas that are most likely to provide habitats that must be adapted to in novel ways. The spectacular variety of endemic bird species on islands certainly suggests that forceful selection pressures are operating.

But even on mainlands, a species' range is comprised of a variety of environments. And as 2 recent and continuing studies of mainland horse populations demonstrated, some of these differences also influence equid sociality. In the New Forest where the adult sex ratio was highly skewed and females greatly outnumbered males, males appeared to possess harems and exclusive non-overlapping home ranges (Pollock 1980, personal communication). But unlike the Shackleford horses, a proportion of females appeared to live apart from harems. Some lived in harems only during the breeding season, leaving the group during the winter as the forage abundance and quality declined. Others never attached themselves to harems, wandering among harems regardless of season. In a Camargue horse population another social variant occurs. In a population consisting of 42 adult horses, 36 lived in a cohesive large group comprising many harems. Duncan and Vigne (1979) were able to demonstrate that individuals in larger groups were parasitised by fewer biting flies. They argued that the debilitating effects on condition associated with blood loss were a major factor in affecting this social arrangement.

These studies on feral horse populations demonstrate that a species such as the horse may exhibit a "typical" social system under "normal" conditions. However, the social system is likely to alter when changes occur in ecological factors, such as habitat structure, the distribution of forage and water and the diversity and quality of the vegetation, as well as demographic factors such as size, sex ratio and age structure. In addition, because islands differ quite markedly from the ideal or normal environment, populations living on them will most likely exhibit novel and exciting social variations.

Acknowledgements

I thank M. La Barbera, D. Baxter, L. Fairchild, R. Hoffman, N. Rubenstein and J. Travis for their assistance in the field, and R. Dunbar for his comments on an earlier draft of this manuscript. Special thanks go to Dr John Costlow, director of the Duke University Marine Laboratory, for kindly providing me with the boats to get to and from Shackleford Bank. Presently I am being supported by NATO postdoctoral and King's College fellowships, but during the period in which I monitored the population, I was a National Science Graduate Fellow at Duke University. An earlier version of this paper was presented at a 1978 Animal Behaviour Society Symposium entitled 'Social Behaviour on Islands'.

Résumé

Dans la population équine de l'île de Shacklesford Banks au large de la côte est est USA, des changements majeurs de l'organisation sociale sont apparus. Au lieu de vivre classiquement en harems occupant des territoires se "chevauchant", on s'est rendu compte que certains harems défendaient leur territoire et même que certains chevaux n'appartenaient même pas à des groupes fixes. L'existence de ces variations sociales semble être due à l'habitat et aux caractéristiques géographiques uniques de l'île. Les territoires, dont les limites couraient le long de l'île, n'existaient que là où celle-ci est étroite, la visibilité non obstruée et où les principales zones de végétation courent le long de l'axe principal de l'île. Ce n'est qu'à ces endroits que les difficultés de défense étaient réduites et les posibilités de se nourrir et d'assurer la garde pour les mâles étaient supérieures. Dans les zones de hautes dunes de sable et de forêt épaisse, des assemblages provisoires ont été observés et des harems sans territoire fixe occupaient les zones semi-ouvertes accidentées avec des mâles célibataires.

Une fois les territoires défendus, de nombreux aspects des relations sociales individuelles changent. Les étalons à territoire ont moins tendance à influencer les activités quotidiennes de leurs groupes et plus à s'occuper de leurs femelles dominantes et à regrouper leurs femelles subordonnées que les étalons sans territoire. De plus, les distances individuelles sont généralement plus grandes entre animaux vivant dans des harems territoriaux par opposition à des harems non territoriaux.

Zusammenfassung

Bei einer Pferdepopulation auf Shacklesford Banks, einer Insel vor der amerikanischen Ostküste, haben sich größere soziale Organisationsveränderungen ereignet. Anstatt in den typischen Harems in sich überschneidenden Heimatgebieten zu leben, wurde festgestellt, daß einige Harems ihre Territorien verteidigten und einige Pferde noch nicht einmal in festen Gruppen lebten. Das Bestehen dieser sozialen Variationen schien mit dem einzigartigen Lebensraum und den geographischen Besonderheiten der Insel in Zusammenhang zu stehen. Territorien, deren Grenzen über die ganze Breite der Insel verliefen, gab es nur an den Stellen, wo die Insel schmal und die Sicht unbegrenzt war und wo die Vegetationszonen entlang der Längsachse der Insel verliefen. Nur hier waren die Schwierigkeiten der Verteidigung reduziert und die Ernährung sowie die Möglichkeit der männlichen Partnerbewachung besser. Wo die Sanddünen hoch und die Wälder dicht waren, fanden zeitweise Zusammenschlüsse statt, und nicht-territoriale Harems bewohnten zusammen mit den weibchenlosen Männchen die uneinheitliche, halboffene Landschaft.
Mit dem Beginn der Territoriumsverteidigung veränderten sich auch zahlreiche Aspekte der individuellen sozialen Verhältnisse. Territoriale Hengste neigten weniger dazu, das tägliche Aktivitätsmuster ihrer Gruppe zu beeinflussen, und tendierten eher dazu, ihre dominanten Weibchen zu versorgen und zu pflegen und ihre untergeordneten Weibchen zusammenzutreiben als ihre nicht-territorialen Gegenstücke. Bei territorialen Harems wurden auch größere Abstände zwischen den einzelnen Tieren beobachtet als bei nicht-territorialen.

Mesodiverticular bands as a cause of small intestinal strangulation and volvulus in the horse

FEEEMAN, D. E., KOCH, D. B. and BOLES, C. L. (1979) *J. Am. vet. med. Ass.* **175**, 1089-1094.

MECKEL'S diverticulum and persistent vitello-umbilical bands are already documented as causes of intestinal obstruction in horses and cattle respectively. A third and distinct developmental anomaly, described as a mesodiverticular band, was responsible for bowel strangulation and secondary volvulus in the 3 cases reported in this paper. The band derives from a persistent vitelline artery and extends from one side of the mesentery to the antimesenteric surface of the bowel, usually along the jejunum as in these animals. The resultant double fold of mesentery thus forms a pouch into which intestines may migrate and become incarcerated. An interesting pathological feature in these cases was strangulation of the bowel, not within the pouch itself but through a tear in the jejunal mesentery close to the hernial opening, which is thought to develop as a result of increased tension caused by incarceration. The presence of ramifications of the vitelline artery may render the anomalous mesenteric band stronger than the normal jejunal mesentery. Fixation of bowel within the pouch also led to volvulus as an additional complication. Mesodiverticular bands may be present without causing pathological changes. A further case is reported in which 2 such bands were incidental findings at post mortem examination.

Treatment of bovine and equine ocular squamous cell carcinoma by radiofrequency hyperthermia

GRIER, R. L., BREWER, W. G., PAUL, S. R. and THEILEN, G. H. (1980) *J. Am. vet. med. Ass.* **177**, 55-61.

THE treatment of ocular squamous cell carcinomas in cattle and horses using radiofrequency (RF) hyperthermia is described. The efficacy of the treatment in destroying tumours is ascribed to the apparent greater sensitivity of malignant cells to non-coagulating temperatures of between 41°C and 45°C. The tissue hyperthermia was created by passing a RF (2MHz) electric current for approximately 30 secs between 2 electrodes placed on the tumour surface or within the tumour mass. Most of the animals were treated under topical anaesthesia and sedation, without resort to general anaesthesia. Total treatment time ranged from 30 secs to 15 mins depending on the size and number of tumours. Forty-five ocular squamous cell carcinomas in 17 cattle and 8 horses were treated. In cattle 88 per cent of tumours receiving a single treatment regressed completely while there was 67 per cent complete regression in those tumours which received 2 or more treatments. In horses there was 75 per cent complete regression in the 8 tumours treated. The conclusion is that hyperthermia is an effective and easily applied treatment for ocular squamous cell carcinoma in cattle and horses when the tumour mass is small, less than 5cm diameter, and there is no deep eyelid or conjunctival penetration.

Abstract

Context. At some sites, wild horse populations have been effectively and non-invasively regulated using remote darting with porcine zona pellucida (PZP) immunocontraceptive vaccines. However, this model has not been widely applied to wild horse herds in western USA, many of which are difficult to access because they roam large areas and are wary of people. Single-treatment, multi-year contraceptive vaccines would significantly broaden the scope for successful contraceptive management.

Aims. The aims of the present field studies were to (1) test the contraceptive effectiveness and longevity of primers incorporating PZP–adjuvant emulsions plus PZP and adjuvant in controlled-release pellets ('PZP-22'); and (2) compare the contraceptive effectiveness and duration of PZP–adjuvant emulsion-only boosters with those of PZP-22 boosters when administered by hand or remote darting to PZP-22-primed mares.

Methods. Wild horses in herd management areas in Colorado and Utah, USA, were rounded up in 2008 and in Utah again in 2012. Previously untreated females received a single hand-injection of PZP–emulsion plus controlled-release PZP pellets ('PZP-22' vaccine) and were then released. In Autumn 2010, 50 Colorado females treated in 2008 were booster-darted with either the PZP-22 vaccine or the PZP emulsion alone. In Utah, 57 previously treated females rounded up in 2012 received hand-injections of either the PZP emulsion–pellet vaccine or the PZP emulsion alone. Maternity was established through field observation of nursing and other close associations.

Key results. Effectiveness of initial controlled-release PZP treatments over 2 years was low relative to previous trials. However, boosters delivered by dart or by hand to PZP-22-primed mares yielded high levels of contraceptive effectiveness for 3 years, with no consistent difference between simple PZP-emulsion boosters and boosters incorporating controlled-release pellets.

Conclusions. Priming mares with PZP-22 extends the efficacy of a subsequent PZP booster to at least 3 consecutive years.

Implications. Regulation of wild horse populations may be achieved with existing contraceptive agents by developing models and management plans that account for the increased longevity of repeated contraceptive treatments.

Additional keywords: feral horse, immunocontraception, porcine zona pellucida, remote delivery.

Introduction

The 1971 *Wild Free Roaming Horse and Burro Act* (P.L. 92-195) assigned primary responsibility for managing wild horses and burros occupying public lands to the US Bureau of Land Management (BLM), with secondary responsibilities to the US Forest Service (USFS) for managing the species on USFS lands. In 1978, prompted by growth of the herds subsequent to passage of the *Act*, Congress authorised the BLM and USFS to gather, remove and make available for adoption by the public wild horses and burros deemed excess relative to appropriate management levels set by public land use planning processes (*Public Lands Improvement Act*, P.L. 95-514).

Through the fiscal year (FY) 2015, the BLM had adopted out more than 239 000 wild horses and burros to the public (BLM 2016*a*). However, the rate at which horses have been adopted has failed to keep up with the number of horses removed from the range, especially since FY2001, resulting in increases in wild horse numbers in captive-holding facilities and on the range. As of March 2015, more than 45 000 formerly free-roaming wild horses were being maintained in short- and long-term holding facilities at a budgeted cost of US$62 million for FY 2016 (BLM 2016*b*). In addition, the 67 027 wild horses and burros estimated to be living on the range as of 1 March 2016 significantly exceeds BLM estimates of a system-wide

Journal compilation © CSIRO 2017

appropriate management level (AML, the number of horses and burros defined by the BLM as the number that can thrive in balance with other public-land resources and uses) of 26 715 (BLM 2016*b*). While BLM estimates of AML can be challenged, it is clear that the system is unsustainable as currently being operated.

Both BLM documents and outside reviews have repeatedly identified on-the-range fertility control as a plausible option for reducing the rate of growth of wild-horse herds, thereby reducing pressure on the system of removal and adoption as well as the range itself. In response, BLM has been funding research into practical, safe, and effective wild-horse contraception since the 1970s (Turner and Kirkpatrick 1982; Plotka *et al*. 1988, 1992; Turner *et al*. 1997, 2007; National Research Council 2013). Several potentially suitable immunocontraceptive agents have emerged from BLM-funded research, including porcine zona pellucida (PZP) and GnRH vaccines (Killian *et al*. 2008; National Research Council 2013). Porcine zona pellucida has the deepest research history, having been previously tested and applied for several years at Assateague Island National Seashore, MD, and elsewhere (Kirkpatrick *et al*. 1990; Kirkpatrick and Turner 2002, 2003, 2008; Ransom *et al*. 2011; National Research Council 2013).

In a minority of BLM herd management areas (HMAs), wild horses are approachable enough so that contraceptive vaccines can be delivered directly by dart (Ransom *et al*. 2011; Naugle and Grams 2013). However, in others, horses are too wary to approach closely enough for darting, and are thinly dispersed over wide areas (Naugle and Grams 2013). In these areas, either gathers or trapping must be used to make horses accessible for treatment. Where accessing horses for treatment is challenging, the availability of a multi-year, single-treatment contraceptive vaccine would be enormously helpful in effectively and substantially reducing foaling rates and, consequently, rates of population growth.

Evidence for multi-year effectiveness of contraceptive vaccines is mixed. Killian *et al*. (2008) showed that single doses of SpayVac® (Immunovaccine Technologies, Halifax, NS, Canada) and GonaCon™ (USDA/NWRC, Fort Collins, CO, USA) significantly reduced fertility in a small sample of captive horses for up to 4 years. Gray *et al*. (2010) showed that GonaCon-B™ and a formulation of PZP with Adjuvac™ (USDA/NWRC, Fort Collins, CO, USA) reduced fertility in free-roaming Nevada mares for 3 years, although efficacy was modest for both vaccines (reducing fertility from control levels by 25–59%). Turner *et al*. (2001) showed that a single dose of native PZP plus PZP prepared in controlled-release microspheres produced a 1-year reduction in fertility comparable to that of two doses of native PZP administered 3 weeks apart. However, the microspheres tended to clump in the syringe and proved difficult to handle under field conditions (Turner *et al*. 2002). In a subsequent field trial at Clan Alpine HMA, NV, a single injection of 65 µg PZP emulsified in Freund's complete adjuvant (FCA) plus 410 µg PZP and 875 µg QA-21 adjuvant in controlled-release pellets reduced fertility in treated mares by 91%, 73%, and 38% from control levels in Years 1–3 after treatment (Turner *et al*. 2007).

On the basis of the results of the Turner *et al*. (2007) trial and supporting data on captive and non-captive mares (Turner *et al*. 2002; Liu *et al*. 2005), BLM initiated wider use of the PZP emulsion plus PZP/QA-21 pellet vaccine (dubbed 'PZP-22,' based on antibody titer concentrations displayed in Liu *et al*. 2005; National Research Council 2013), treating between 500 and 1000 mares annually between 2007 and 2013. However, the Clan Alpine study was not replicated, and information on the efficacy of BLM administrations at both the individual and population levels was anecdotal. Also lacking are any studies of the effectiveness and longevity of PZP boosters administered to mares primed with PZP-22.

As a part of a larger study to further evaluate the individual- and population-level effectiveness of PZP-22, and to establish the effectiveness and longevity of PZP boosters administered to mares that had previously been primed with PZP-22, we conducted field studies in two BLM herd management areas.

Materials and methods

Study areas

Sand Wash Basin Herd Management Area, Colorado

The Sand Wash Basin (SWB) HMA comprises ~638 km^2 located ~72 km west of Craig, CO, USA. Elevation ranges from 1900 to 2660 m. SWB receives 18–30 cm of annual precipitation, and the climate is typical of the cold deserts of the Rocky Mountain Region, with warm summers and very cold winters. Vegetation types within the HMA include sagebrush (*Artemesia spp*), bunchgrasses, saltbush (*Atriplex* spp.), and pinyon–juniper woodlands. Horses, livestock and wildlife at SWB rely for water on a combination of developed wells, undeveloped springs and seeps and artificial reservoirs.

According to BLM aerial-survey estimates, there were ~463 wild horses on the SWB HMA and 50 wild horses off HMA. Our initial ground inventory after the BLM gather in October 2008 indicated the presence of 194 horses (K. Grams and A. Rutberg, unpubl. data). The appropriate management level at SWB is 163–362 (BLM 2017).

Cedar Mountains Herd Management Area

The Cedar Mountains (CM) HMA comprises 727 km^2 and is located ~80 km west of Salt Lake City, UT, USA. Approximately 425 km^2 within the HMA is part of a congressionally designated candidate wilderness area; vehicles and permanent structures are not permitted within the designated wilderness area. Elevations vary from 1400 to 2460 m. Annual rainfall in the lower elevations averages 20–25 cm, and 25–38 cm of rainfall is received in the upper elevations. Desert shrubs and bunchgrasses are common in the lowlands, with sagebrush and juniper woodlands dominating higher elevations. Water is seasonally scarce, and is concentrated in dry summer months at cattle troughs and a few natural springs.

Our ground-based population inventory indicated that there were at least 608 horses on CM when the study began in 2008, with additional horses on adjacent military lands that had not yet been documented. Initial estimates by BLM based on their aerial survey indicated that 191 remained after the December 2008 BLM gather, although subsequent ground-based population inventories indicated that there were at least 265 horses present post-gather. The appropriate management level for CM is set by the BLM at 190–390 (BLM 2017).

Horse identification

Beginning in 2008, information was documented in the field and then entered into a database. This working document included sex, colour, face and leg markings, unique descriptions, mane and tail description, year of birth and the subpopulation in which the horses lived. Each horse was assigned an ID number to establish individual identity. Horses, including bachelors, were grouped by band in the areas in which they were most recently found. The horse list was updated weekly to reflect any changes or additions and was used in the field to help identify horses. Horses were individually recorded in the Wild Horse Identification Management System (WHIMS, US Geological Survey, Fort Collins, CO, USA). Information from the horse list was placed into this database along with individual pictures of each horse. A photo catalogue allowed for viewing each horse, with the pertinent information to that horse.

Horses that were identified during the study but were not observed within the HMA were excluded from the analysis.

PZP treatments

Wild-horse mares were gathered by the BLM and restrained in squeeze chutes for PZP treatments at Sand Wash Basin on 23 October 2008, and at Cedar Mountains on 17 December 2008 and 25–28 February 2012. Porcine zona pellucida treatments were also administered remotely by dart at SWB from 11 September to 17 November 2010. Thus, boosters were administered at SWB 2 years after the initial treatment, and at CM 3.2 years after the initial treatment.

Hand-injections

In October 2008 and December 2008 respectively, 62 mares (2+ years old) at SWB and 70 mares (2+ years old) at CM were gathered and treated with hand-injections of PZP-22, consisting of one priming injection of 100 µg PZP in 0.5-mL phosphate buffer solution (PBS) emulsified in 0.5 mL of modified FCA (mFCA, Calbiochem, LaJolla, CA, USA) (following Kirkpatrick *et al*. 1990), and a second injection of three heat-extruded lactide–glycolide polymer pellets (polymers from Lactel/Durect, Pelham, AL, USA) containing a total of 450 µg of PZP and 900 µg of QA-21 (Antigenics, Lexington, MA, USA), a saponin adjuvant, engineered to release at 1, 3 and 12 months (Turner *et al*. 2008). The 1- and 3-month pellets each contained 100 µg of PZP and 200 µg QA-21, and the 12-month pellet contained 250 µg PZP and 500 µg of QA-21. Both injections were delivered intra-muscularly into the hip, the PZP–mFCA emulsion with a hand-held syringe fitted with an 18-gauge needle, and the pellets with a trocar fitted with a 14-gauge needle. In the squeeze chute, the horses were also freeze-branded on the hip with a marking that identified them as PZP-treated mares. In February 2012, 85 previously untreated mares at CM were similarly treated and released. Of these mares, 23 were 2 years old, and 62 were ≥3 years old.

Booster trials

To examine the relative effectiveness of the PZP-22 booster when hand-injected, 58 mares that had been treated at CM in 2008 and recaptured for treatment in February 2012 received a hand-injection of either PZP-22 (with Freund's incomplete adjuvant (FIA, Calbiochem, LaJolla, CA, USA) substituted for mFCA, 'PZP-22–FIA'; $n = 39$) or the PZP–FIA booster alone ($n = 19$).

A parallel test of the PZP-22 booster when delivered remotely, by dart, was conducted at SWB. From 11 September to 17 November 2010, 34 mares received PZP-22–FIA delivered in a Pneu-dart® (Williamsport, PA, USA) dart designed with a rod within the 1.5-inch needle, to simultaneously inject both the emulsion and the dart (see Walter *et al*. 2012 for a similar device). Another 16 mares received only the PZP–FIA emulsion by dart (Kirkpatrick *et al*. 1990). Two dart projectors were utilised for short and longer distances. The Dan-Inject CO2 pistol (Børkop. Denmark) projected darts at a distance of 10–18 m. The Pneu-Dart X-Caliber Gauged CO2 projector rifle projected darts at a distance of 17–45 m. Depending on the tractability of the animal, the Dan-Inject was primarily used for close range.

Observations

Observational data were collected beginning in 2008, focusing on the months from June to October in SWB and April through to December at CM. Observations were conducted from the ground, usually by one but sometimes by two observers. Depending on distance, observations were made through binoculars or 20–60 × 80 spotting scope.

For each band encountered, observers identified all known horses present, described any new horses in the band that had not previously been described, tabulated the age–sex composition of the group, and, using maps and field notes, noted the location of the band. Mares were matched with foals within 2 weeks of birth, as indicated by persistent proximity and nursing. Within limits of visibility and accessibility, the observer also estimated and recorded body condition scores on a 1–5 scale (after Rudman and Keiper 1991) and noted any apparent injuries, lameness, abscesses and other injection-site reactions, or other signs of ill health, for each band member, as well as any reproductive activity or mortalities that occurred.

Data analysis

Foaling data inferred from observations of foal–mare associations and behaviour were compiled by mare age (when age data were available) and PZP treatment status. The relationship between age and foaling rates was examined using the linear regression function of IBM SPSS®-22, using study site, age and age squared as independent variables (modified from Ransom *et al*. 2011). Foaling rates were compared among treatment groups and between treatment groups and untreated mares by year after treatment, using Pearson's chi-square tests or, if sample sizes were too small, by two-tailed Fisher's exact tests. Sham controls were not used, because Turner *et al*. (1997) had previously demonstrated that fertility rates among sham controls and untreated controls were virtually identical.

The proportions of untreated and pretreatment mares of known age that foaled in a given year were calculated for each site. Foaling data comprised 170 foals born to mares of known age (2–17 years old) in 311 mare-foaling opportunities at SWB between 2008 and 2014, and 193 foals born to mares of known age (2–24 years old) in 376 mare-foaling opportunities at CM

between 2008 and 2015. Because fewer records existed for older mares, ages were consolidated into groups of at least 10 mares in each age category, assigning the median age to each group. Sample size per age group ranged from 12 to 154.

Because of uniformly low foaling rates among untreated 2-year-old females (see below), all comparisons between treatment groups and untreated controls were performed using mares 3 years old and older at the time of foaling. The criterion for rejecting null hypotheses was set at $\alpha = 0.05$.

Results

Effects of age on likelihood of foaling

In both study sites, 2-year-old females were less likely to foal, then older females (Fig. 1). Site, as an independent variable, was not a significant predictor of foaling rate ($P = 0.824$), and was eliminated from the analysis. Because the form of the relationship between age and fertility appeared to differ at both sites, each site was analysed separately. At CM, the probability of foaling followed a fairly strong parabolic relationship with age ($R^2 = 0.817$, $F_{2,5} = 11.14$, $P = 0.014$; Fig. 1*a*). However, at SWB, the age–foaling relationship was flat for mares older than 2 years old relative to CM, and the parabolic relationship was not significant ($R^2 = 0.580$, $F_{2,5} = 3.46$, $P = 0.114$; Fig. 1*b*).

Initial treatments with PZP emulsion and controlled-release pellets

Sample sizes for observation of foaling in treatment groups showed only slight attrition during the study, whereas samples of untreated controls observed for foaling generally grew from year to year as new individuals in the population were identified or were recruited as foals born into the herd during the study aged into the 3+ years age group (Table 1).

In all three priming treatments (CM 2008 and 2012 and SWB in 2008), foaling rates were statistically indistinguishable between treated and untreated mares during the foaling period immediately after treatment, defined as Year 0 (reflecting pretreatment pregnancy rates; Fig. 2). Significantly lower foaling rates were found among mares ≥3 years old in treated mares in Year 1 at CM in the 2008 ($\chi_1^2 = 29.04$, $P < 0.0001$; Fig. 2*a*) and 2012 ($\chi_1^2 = 24.99$, $P < 0.0001$; Fig. 2*b*) treatments, but not in the 2008 SWB treatments ($\chi_1^2 = 3.4$, $P = 0.065$; Fig. 2*c*), relative to untreated controls. In Year 2, foaling rates in treated mares were significantly lower than those in untreated mares for both the 2008 and 2012 CM treatments ($\chi_1^2 = 5.94$, $P = 0.015$; $\chi_1^2 = 5.57$, $P = 0.018$) and the SWB treatments ($\chi_1^2 = 6.2$, $P = 0.013$). Summed over the two post-treatment years, foaling

(*a*) Cedar Mountains, UT, USA, 2008–15 ($Y = -0.005X^2 + 0.126X + 0.165$, $R^2 = 0.817$, $F = 11.14$, d.f. = 2,5, $P = 0.014$). (*b*) Sand Wash Basin, CO, USA, 2008–14 ($Y = -0.009X^2 + 0.157X + 0.144$, $R^2 = 0.580$, $F = 3.46$, d.f. = 2,5, $P = 0.114$).

Table 1. Number of mares 3+ years old for which foaling data were obtained in each treatment group at Cedar Mountains (CM) Herd Management Area, Utah, USA, and Sand Wash Basin (SWB) Herd Management Area, Colorado, USA

At CM, 39 mares received PZP-22–FIA boosters and 19 received PZP–FIA boosters. At SWB, 34 mares received PZP-22–FIA boosters, and 16 received PZP–FIA boosters

Year	Cedar Mountain HMA			Sand Wash Basin HMA		
	PZP-22 primer	PZP boosters (total)	Untreated control	PZP-22 primer	PZP booster (total)	Untreated control
2008	70 hand-treated	–	–	62 hand-treated	–	–
2009	69	–	61	62	–	15
2010	69	–	63	61	50 dart-treated	18
2011	68	–	73	61	50	22
2012	85[A] hand-treated	58 hand-treated	38	–	50	52
2013	83	57	44	–	49	68
2014	80	56	56	–	28[B]	107
2015	–	55	94	–	–	–

[A]Twenty-three (23) mares that were 2 years old at the time of treatment were not included in Year 0 (2012) foaling-rate calculations.

[B]Twenty-one (21) mares were lost to the study because they received additional PZP treatments in 2013. Of the 28 remaining in the study, 17 had received PZP-22 boosters and 11 had received PZP emulsion only.

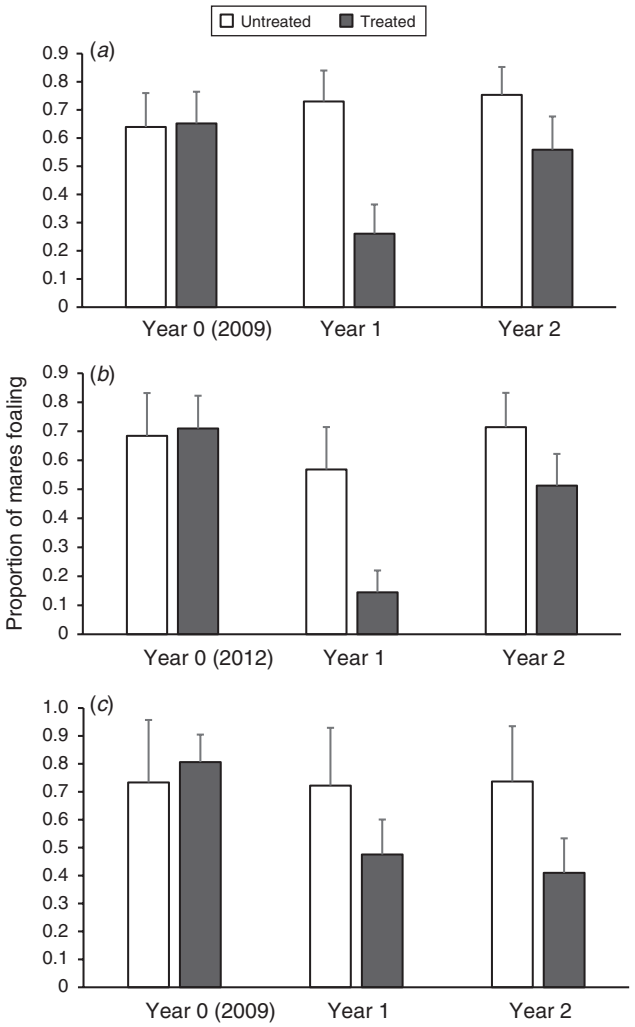

Fig. 2. Foaling rates in mares ≥3 years old. Error bars represent 95% CI. (*a*) Cedar Mountains herd-management area (HMA), UT, USA, following December 2008 administration of porcine zona pellucida (PZP)-22 primers by hand. Year 0 = 2009. (*b*) Cedar Mountains HMA, UT, USA, following February 2012 administration of PZP-22 primers by hand. Year 0 = 2012. Twenty-three PZP-22-treated females that were 2 years old in 2012 were excluded from the Year 0 analysis. (*c*) Sand Wash Basin HMA, CO, USA, following October 2008 administration of PZP-22 primers by hand. Year 0 = 2009.

rates among treated mares were reduced by 39% at SWB in 2008, by 45% at CM in 2008, and by 50% at CM in 2012.

No injection-site reactions were observed in mares after priming via hand-injection.

PZP booster treatments

At both SWB and CM, PZP boosters were associated with significant reductions in foaling rates among mares ≥3 years old every year for 3 years after treatment (Fig. 3).

At SWB, foaling rates in mares boosted with PZP by remote darting averaged 25.2% over 3 years (range 22.0–32.1%) versus 74.9% (65.4–79.4%) in untreated mares (Fig. 3*b*), i.e. foaling rates in booster-treated mares were reduced by 66% relative to those of untreated mares. In each year, foaling rates were significantly lower in treated mares than in untreated mares (Year 1, $\chi_1^2 = 19.46$, $P < 0.0001$; Year 2, $\chi_1^2 = 34.94$, $P < 0.0001$; Year 3, $\chi_1^2 = 20.00$, $P < 0.0001$). Mares darted with PZP-22–FIA showed lower foaling rates (averaging 17.8% across 3 years) than did mares darted with PZP–FIA emulsions alone (averaging 39.5% across 3 years), but there were no significant differences in foaling rates between the two treatment groups in any year.

Injection-site reactions were seen in 32 of 47 darted SWB horses (68.1%) observed in the weeks following darting. Of these reactions, 5–8 were draining abscesses (uncertainty owing to observation quality), of which at least five had resolved by the last time the horse was observed in the 2010 field season (15–52 days after darting). The remainder were swellings and granulomas averaging 2.75 cm (s.d. = 0.87 cm) in diameter. The two treatment types did not differ from one another in either the frequency of swellings and granulomas or in the frequency of draining abscesses.

At CM, hand-injected PZP boosters were also highly effective, with foaling rates of treated mares across 3 years averaging 14.9% (ranging from 7.0% to 20.0%) versus 67.5% (range 56.8–71.4%) for untreated females ≥3 years old, i.e. foaling rates in booster-treated mares were reduced by 78% relative to those of untreated mares (Fig. 3*a*). Treated mares had significantly lower foaling rates than did untreated controls in all years (Year 1, $\chi_1^2 = 30.09$, $P < 0.0001$; Year 2, $\chi_1^2 = 30.38$, $P < 0.0001$; Year 3, $\chi_1^2 = 35.03$, $P < 0.0001$). At CM, no consistent differences in efficacy emerged between the two treatment groups, and there was no significant difference in foaling rates between the PZP-22–FIA and the PZP–FIA-only group in any treatment year. No injection-site reactions were observed in hand-boosted mares.

Discussion

Mares hand-injected with PZP-22 primers generally demonstrated lower foaling rates than did untreated control mares. However, the effectiveness and longevity of PZP-22 were much lower at both CM and SWB than was reported in Turner *et al*. (2007) for wild horses in Clan Alpine. Several differences in manufacturing and protocol may account entirely or in part for the differences.

(1) *Treatment month of administration.* The 1-, 3- and 12-month pellet-release times were engineered to optimise effectiveness of vaccines delivered December to February. The highest 2-year efficacy of primers in the present study occurred when vaccinations were delivered in February (CM 2012), followed by vaccinations delivered in December (CM 2008), with those delivered in October (SWB 2008) being least effective. However, even with optimal administration timing, the efficacy levels observed in these trials following Year 1 did not match those observed at Clan Alpine, suggesting that timing alone is not a sufficient explanation for the differences.

(2) *Differences in timing of antigen release*. Subsequent *in vitro* testing of the heat-extruded controlled-release pellets of batches used in this trial was undertaken to ascertain whether changes in pellet-release characteristics originally described in Turner *et al*. (2007) and Turner *et al*. (2008)

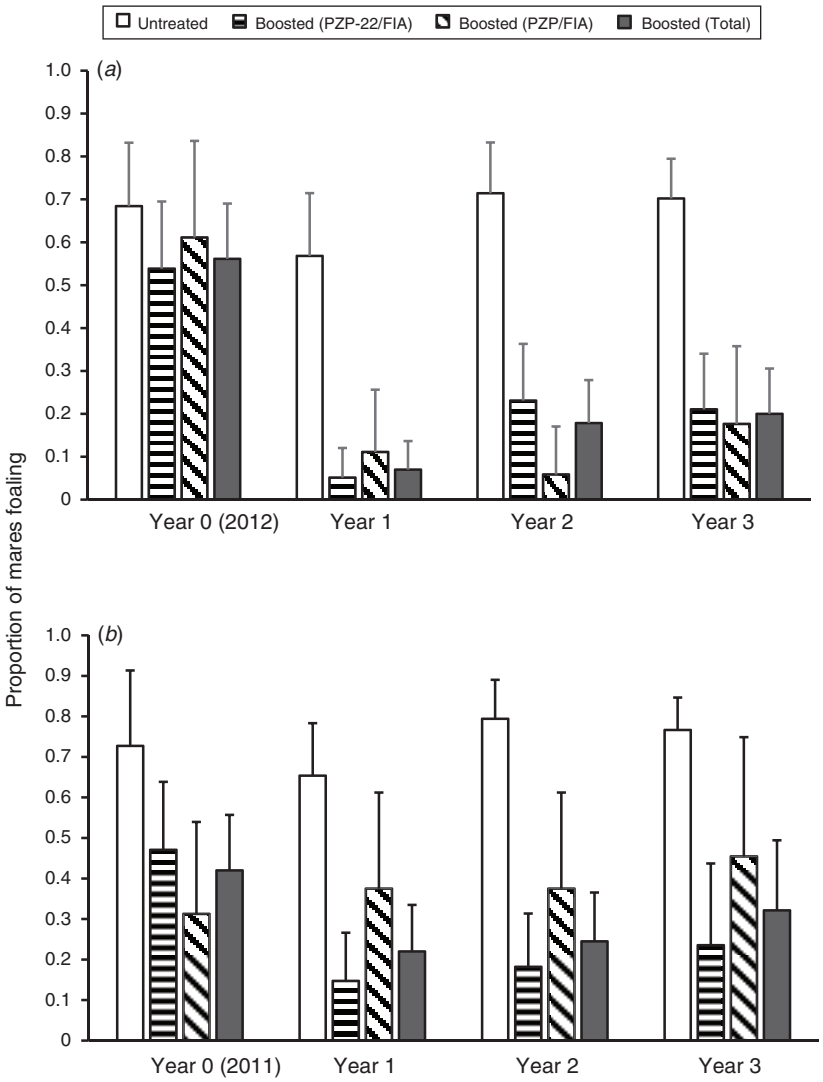

Fig. 3. Foaling rates in mares ≥3 years old. Error bars represent 95% CI. (*a*) Cedar Mountains herd-management area (HMA), UT, USA, following February 2012 administration of PZP-22–FIA or PZP–/FIA boosters by hand. Year 0 = 2012. (*b*) Sand Wash Basin HMA, CO, USA, following Autumn 2010 administration of PZP-22–FIA or PZP–FIA boosters by dart. Year 0 = 2011. Note that the Year 0 (2011) foaling rates for treated mares are the same as those for Year 2 in Fig. 2*c*.

contributed to suboptimal PZP-22 performance. Comparison of release characteristics of pellets produced before and after 2007 revealed that post-2007 pellets of the 12-month delay type released prematurely and more gradually than was expected (J. W. Turner, unpubl. data). Possible contribution of polymer-batch and pellet-manufacture variations to this circumstance are under investigation.

(3) *Method of injection.* PZP-22 at Clan Alpine was delivered by jab stick, and both the emulsion and pellet components were delivered together at the same injection site, whereas emulsion and pellets were delivered by two separate injections in all hand-injection protocols of PZP-22 followed in the present study. Although being an implausible explanation for the differences, this hypothesis also receives weak support from the improved PZP-22 efficacy relative to the PZP–FIA emulsion associated with dart delivery in booster trials (described below).

(4) *Difference in adjuvant.* PZP vaccine prepared before 2005 utilised FCA, and, thereafter, mFCA was used. Similar anti-PZP titer responses to primer-dose PZP treatment with these two adjuvants have been reported (Lyda *et al*. 2005). However, contraceptive efficacy was not determined, and it is possible that the antibody type and quality generated by these two adjuvants differed sufficiently to influence the immune memory generated by pellet-based boosters (M. Wooten, pers. comm.). In light of the limited future for FCA (related to tissue reactions and false-positive TB tests) and the promise of alternative multi-target adjuvants (e.g. Lu *et al*. 2015), comparison of mFCA with such novel adjuvants to address the above issue may be warranted.

Although the initial PZP-22 treatments tested in the present study showed disappointing effectiveness, a single PZP booster (either the PZP–FIA emulsion or PZP-22–FIA) effectively reduced fertility across three consecutive years. Whether delivered by dart, as at SWB in 2010, or by hand, as at CM in 2012, PZP boosters reduced foaling rates in treated mares by roughly 65–72% relative to untreated control mares over the 3 years. We do not know, because the studies had to be ended 3 years after boosting, whether some contraceptive effectiveness might persist into a 4th year.

Most previous research on PZP in western wild horses has presented data only on the effectiveness and longevity of the initial treatment (Turner *et al.* 1997, 2001, 2007). Working on wild horses at Little Book Cliffs Wild Horse Range, CO, USA, and the Pryor Mountain Wild Horse Range, MT, USA, Ransom *et al*. (2011) examined the relationship between the number of consecutive years of treatment (up to 4 years) with PZP emulsion boosters and the interval between the last booster and the first foaling. This interval ranged from 7 to 18 months, with some trend towards longer intervals as the number of consecutive years of treatment increased, although the sample size for 3 and 4 consecutive years of treatment was very small and the trend was not significant. In their study of reversibility of PZP treatments of wild horses at Assateague Island National Seashore, MD, USA, Kirkpatrick and Turner (2002) showed that most mares receiving two initial injections and up to one subsequent annual booster returned to fertility within 1 year, whereas mares receiving three or four consecutive years of treatment experienced delays of 3–4 years in return to foaling. Although our measures of the longevity of vaccine effectiveness differ from those used in other studies, namely annual foaling rates of treated mares relative to those of controls, rather than interval between last booster and first foaling, as used by Ransom *et al*. (2011) and Kirkpatrick and Turner (2002), our results appear to parallel those for Assateague mares receiving three or more consecutive years of treatment. Thus, even if the initial effectiveness of PZP-22 was low relative to previous studies, the combination of a PZP-22 primer and a single PZP booster appears to have yielded effectiveness comparable to three or more years of consecutive treatments (i.e. 4+ injections) of Assateague mares initially treated with the PZP–mFCA emulsion primer.

Our study failed to show that the addition of the controlled-release pellets to the PZP emulsion increased the efficacy and longevity of the booster. At CM, addition of pellets in hand-administration did not increase the efficacy or longevity of the PZP emulsion over the 3 years of the study. Dart delivery of the booster was associated with a doubling of efficacy across all 3 years at SWB, but because the sample is small, this test warrants replication.

Conclusions

Long-term management of wild horse populations with a non-invasive reversible contraceptive will require repeated treatments over the life of the wild mare. Thus, we believe that the research emphasis placed on the effectiveness and longevity of the primer vaccination may be misguided. The data presented here, as well as in Kirkpatrick and Turner (2008), suggest that population models should be constructed that allow for increased longevity of vaccine effectiveness with successive boosters. In practice, the initial application of contraceptives to a wild horse herd may produce only a modest reduction in population foaling rates, but sustained contraceptive applications over time could result in a much greater reduction in population foaling rates, even with current technology.

At Assateague, the initial management step was to treat every mare with a single primer of PZP–FCA emulsion (Kirkpatrick and Turner 2008). Although the primer alone was only somewhat effective as a contraceptive, subsequent boosting yielded increased effectiveness, and, ultimately, a reduction in herd numbers. This lesson needs to be applied in Western herds.

Also encouraging is the demonstration of management flexibility in PZP-22 application. First, the data suggest that the interval between initial and booster treatments, i.e. 2 years at SWB, and 3.2 years at CM, does not obviously influence effectiveness or longevity of the booster over the range of times tested. Second, the SWB data indicate that PZP-22–FIA can be effectively delivered remotely, at least matching the effectiveness of the PZP–FIA emulsion. However, until technical improvements and additional tests show that the controlled-release pellets significantly increase booster efficacy, managers can employ the much less costly PZP–FIA emulsion as a booster following administration of the PZP-22 primer.

Continuing to improve vaccine longevity is essential. The more individual mares are darted, the more difficult they become to re-treat (Kirkpatrick and Turner 2008; Naugle and Grams 2013). As the controlled-released pellets are refined, re-darting can be performed less frequently, making contraceptive control more cost effective.

Acknowledgements

The authors thank Amanda Conner, Kira Donnelly, Katie Guntly and Josh Irving for their work with darting and data collection at Sand Wash Basin; Aleta Wagner and Great Escape Mustang Sanctuary for corroborating foaling and identification data at SWB in 2014; and Ron Osborn of Wildwise Solutions for assistance applying WHIMS. Rick Naugle of HSUS and Pneudart® developed and tested the dart used to deliver the emulsion/pellet vaccine. The Science and Conservation Center, Billings, Montana, and Dr I. K. M. Liu supplied PZP for the study; preparation of the controlled-release pellets was conducted under the supervision of Dr D. R. Flanagan, University of Iowa, Iowa City, Iowa. We especially thank Gus Warr, Kathy McKinstry, Jerome Fox and the BLM Salt Lake and Little Snake field offices, and the Resource Management Division of the USA Army's Dugway Proving Ground. This study was conducted under the auspices of Tufts University IACUC protocols G949-08 and G2011-65, and was principally funded by a generous gift from the Annenberg Foundation to The Humane Society of the United States.

PASSAGE OF ZONA ANTIBODIES VIA PLACENTA AND MILK FOLLOWING ACTIVE IMMUNIZATION OF FEMALE MICE WITH PORCINE ZONAE PELLUCIDAE

A.G. SACCO, M.G. SUBRAMANIAN and E.C. YUREWICZ

Wayne State University School of Medicine, Department of Gynecology and Obstetrics, C.S. Mott Center for Human Growth and Development, 275 East Hancock Avenue, Detroit, MI 48201, U.S.A.

(Received 3 June 1981; accepted 24 August 1981)

Female mice heteroimmunized with heat-solubilized porcine zonae produced a significant antibody response to this immunogen as measured by radioimmunoassay (RIA) but their fertility was unaffected and normal litters were delivered. Monitoring for anti-zonae pellucidae activity in the sera of offspring from such immunized mothers by RIA indicated that the zonae antibodies were transferred from mother to young via the placenta and milk. Such transferred antibodies cross-reacted with and bound to the zonae of female offspring as demonstrated by immunofluorescent techniques. These data are significant to the future consideration of use of specific zona antigens for development of a contraceptive vaccine.

INTRODUCTION

Immunocontraception is described as the prevention of fertility by immunologic methods. The high level of specificity exemplified in the antigen–antibody binding reaction as well as the neutralizing potential of antibody molecules make the immunologic inhibition of fertility an attractive approach to contraception. Recently, the zona pellucida has gained much attention as a potential immunocontraceptive target antigen (Sacco, 1981). The zona contains one or more tissue specific antigens, antibodies directed against such antigens totally inhibit fertility and, the pig and human share a similar zona specific antigen(s) (Sacco, 1981; Takai et al., 1981; Shivers and Dunbar, 1977; Sacco, 1977). This latter observation has identified the pig as a potential source of zona antigen material in attempts to develop a contraceptive vaccine with possible human application.

The consideration of an immunocontraceptive approach, as applicable to the human female and which utilizes porcine zonae, would likely ultimately involve active immunization using a purified porcine zona macromolecule as immunogen. Experiments describing the inhibition of fertility following active immunization of females with zonae pellucidae, although few in number to date, have been encouraging (Shivers et al., 1981; Gwatkin and Williams, 1978; Gwatkin et al., 1977). Also, the inhibition of in vitro fertilization of human eggs by antibodies to pig zona pellucida has been recently reported (Trounson et al., 1980). However, other studies (Sacco et al., 1981a,b) have also vividly demonstrated that the degree of immunologic similarity between zonae used as immunogen and zonae of the female immunized is of critical importance for the resulting cross-reacting zona antiserum to exert its contraceptive effect in the injected female. For

0165-0378/81/0000–0000/$02.50 © 1981 Elsevier/North-Holland Biomedical Press

example, although heteroantibodies produced against either mouse or pig zonae do cross-react with the other species' zona and are contraceptive in their respective homologous system (Sacco, 1981; Sacco et al., 1981a, b; Jones, 1980), mouse antibodies to pig zonae do not inhibit mouse fertility in vivo (Sacco et al., 1981a). Likely, although components present in mouse and pig zonae do possess some antigenic similarities as evidenced by the cross-reaction of their respective anti-zonae sera, mouse and pig zonae are not sufficiently similar for zona antibodies to exert a contraceptive effect in respect to heterologous zonae (Sacco et al., 1981a, b). In the present study we have taken advantage of the observation that while mice heteroimmunized with porcine zonae produce a potent immune response to this antigen, mouse fertility is unaffected by such antibodies and viable litters are produced. We demonstrate here, for the first time to our knowledge, the transfer of zona antibodies from an immunized mother to her offspring. While antibody transfer from mother to young is not unique (Collins et al., 1980; Castro, 1971; Cramet et al., 1974; Barnes and Holliday, 1970; Desay and Creger, 1963), with the recent detection of zona pellucida antigen(s) in primordial follicles of the human (Bousquet et al., 1981), this observation regarding zona antibodies is of considerable importance in respect to the possible use of the zona in an immunocontraceptive approach to fertility regulation.

MATERIALS AND METHODS

Immunogen preparation

Porcine solubilized isolated zonae pellucidae (SIZP) were prepared as detailed elsewhere (Sacco et al., 1981a). Briefly, the procedure consisted of homogenizing pig ovaries in Tris buffer (0.05 M Tris/0.15 M NaCl/0.02% NaN_3/0.004 M Na_2EDTA, pH 8.0) using a commercial meat grinder and isolating oocytes by sieving the homogenate on nylon screens (Tetko, Inc.) of decreasing pore size (500–100 μm). The washed oocytes were resuspended in a measured volume of buffer (approx. 100 ml), a measured aliquot of this suspension withdrawn, and its oocyte content counted using a stereomicroscope. The total number of oocytes present in the suspension was then calculated. Following the determination of oocyte concentration, zonae were then solubilized by heating the oocyte suspension in a 73°C water bath for 20 min. Intact oocytes were removed by centrifugation at 27 000 $\times g$ for 15 min and the solubilized zonae material (SIZP) contained in the supernatant concentrated by the stepwise addition of ammonium sulfate to a final 70% saturation. The resulting zonae precipitate was dissolved in and dialyzed against 0.1 M phosphate-buffered saline (pH 7.3). The volume of the dialyzate was measured and the number of SIZP per unit of volume calculated. Aliquots of this preparation were used as SIZP immunogen as indicated below. Antisera raised against such heat-solubilized zonae material has been previously shown to be specific for zonae pellucidae (Gwatkin et al., 1980; Gwatkin and Williams, 1978).

Immunizations and antisera collections

Groups of Sch:ARS(CF1)f female mice (10 mice/group) were each heteroimmunized, using the methodology of Vaitukaitis et al. (1971) of multiple intradermal injections, with quantities equivalent to 1000, 2000, 4000 or 50 000 porcine SIZP per mouse, respectively, as detailed elsewhere (Sacco et al., 1981a). Blood samples for antisera

(approx. 150 μl/bleeding) were collected from adult mice via the orbital sinus using 75 mm capillary tubes. For newborn and young (approx. 22 days old) mice, blood was obtained by decapitation immediately followed by collection into a capillary tube. Following centrifugation, the antiserum was stored frozen at −20°C. Immunization and bleeding schedules are indicated in Figs. 1, 2, 4 and 5. Female mice immunized with adjuvants only or unimmunized mice served as controls.

Antibody detection

(a) Radioimmunoassay (RIA). The double antibody RIA method used to detect and monitor mouse antibodies to porcine SIZP has been previously described (Sacco et al., 1981c). SIZP radiolabeled with $Na^{125}I$ by the chloramine-T procedure was used as the labeled antigen ([^{125}I]SIZP). For use in the RIA, activity in the tube immediately following the peak tube was adjusted by dilution with PBS containing 0.5% BSA to 25 000 dpm/100 μl (equal to approx. 0.1 zona). Sera for antibody evaluation were diluted serially in PBS containing 1% normal mouse serum. The precipitating second antibody was a rabbit anti-mouse gamma-globulin (1:30 dilution). Triplicate tubes devoid of anti-zona activity were included in each assay to estimate nonspecifically bound (NSB) radioactivity. For the assay itself, 200 μl of various dilutions of mouse anti-zona serum were incubated with 100 μl [^{125}I]SIZP and 500 μl PBS–BSA for 4 h at 37°C, following which 200 μl of second antibody was added. After an overnight incubation at 4°C, 3 ml of cold PBS were added to each of the tubes, the tubes centrifuged (1100 × *g*, 35 min), the supernatants discarded and the precipitates drained and counted in a Searle Model 1185 gamma counter. The NSB tubes and the radioactivity precipitated in the antibody-containing tubes were calculated as the percentage of total counts added to the assay system.

(b) Indirect immunofluorescence. The indirect immunofluorescent antibody technique was used to detect the presence of mouse anti-porcine SIZP serum on the zonae of superovulated mouse eggs. Eggs were obtained from the female offspring (age = 49–59 days) of mothers actively immunized with porcine SIZP by flushing the reproductive tracts of hormonally primed animals. Established procedures for inducing superovulation and removal of cumulus cells with hyaluronidase (300 μl/ml PBS, Sigma Type 1) were used. Rabbit anti-mouse IgG serum labeled with fluorescein isothiocyanate (Cappel Laboratories) was employed as the second antibody. Methodology used was patterned after previously reported procedures (Sacco and Shivers, 1978). Eggs obtained from offspring of adjuvant only injected mothers served as controls and were processed and viewed simultaneously with the experimental eggs.

Matings

Immunized and control mice were allowed to undergo spontaneous matings with males of proven fertility and the presence of a copulatory plug was considered as evidence of a successful mating. Mice injected with adjuvants alone and/or unimmunized mice served as the controls. For experiments involving the transfer of litters between an immunized mother and a control mother, matings were initiated so pregnant immunized and control females would deliver at approximately the same time. Litters were switched immediately after delivery using a gloved hand and out of view of the mothers. In studies which

involved monitoring antibody levels over a period of days in such transferred offspring only those mothers having large litters (10–12 offspring) were selected since a portion of the litter had to be killed at intervals over this experimental period for serum collection.

For studies involving nonsuckled newborn mice, pregnant females, just prior to delivery, were placed in cages having a wire screen floor. During delivery, the newborn mice dropped through the screen and thus had no contact with the mother. All mice were weaned at approximately 21 days.

RESULTS

Immune response to porcine SIZP

The individual immune responses for four mice injected with 1000, 2000, or 4000 porcine SIZP and as monitored by RIA using a 1×10^{-4} antiserum dilution are presented in Fig. 1. Complete mouse immune profiles produced in response to this antigen for mice in all the immunized groups have been presented in detail and discussed elsewhere (Sacco et al., 1981a). For this study, these particular females were selected because they were representative of mothers whose litters had been monitored for anti-SIZP activity. Although demonstrating considerable individual biologic variation, Fig. 1 indicates that each of the four mice, regardless of SIZP dosage injected, produced a significant immune response to this antigen. The percentages of [^{125}I]SIZP bound by a 1×10^{-4} antibody dilution ranged from approximately 26–42% during their respective periods of pregnancy (Fig. 1).

Transfer of SIZP antibodies to offspring

Fig. 2 presents the antiserum titration profiles of a single bleeding from each of these mothers (first bleeding following delivery and designated by arrow in Fig. 1) and three consecutive bleedings from a representative female offspring from each. All offspring (including males) possessed significant antibody activity directed against porcine SIZP when initially tested at 26–36 days of age and which gradually decreased to barely detectable levels at 106–116 days of age. No antibody activity was detected in control immunized animals or their offspring. This anti-SIZP activity present in the female offspring from immunized mothers cross-reacted and bound to native intact mouse zonae as indicated in Fig. 3. Superovulated mouse eggs obtained from such female offspring at 49–59 days of age demonstrated moderate fluorescence associated with their zonae when tested by the indirect immunofluorescent assay. Furthermore, anti-SIZP activity could also be demonstrated by immunofluorescence procedures when these sera were reacted against zonae obtained from either control immunized mice or their offspring.

Antibodies to porcine SIZP were present in offspring immediately following birth as indicated in Fig. 4A. Sera, from newborn mice from a mother immunized with 50 000

Fig. 2. Antibody titration profiles of a single bleeding from mothers (M, ▪) and three consecutive bleedings of a single representative female offspring (●) of each as assayed over a period of days (d). A, mother immunized with 1000 SIZP; B, 2000 SIZP; C, 4000 SIZP; D, 4000 SIZP. The bleeding titered in this figure for each mother is designated by arrow in Fig. 1.

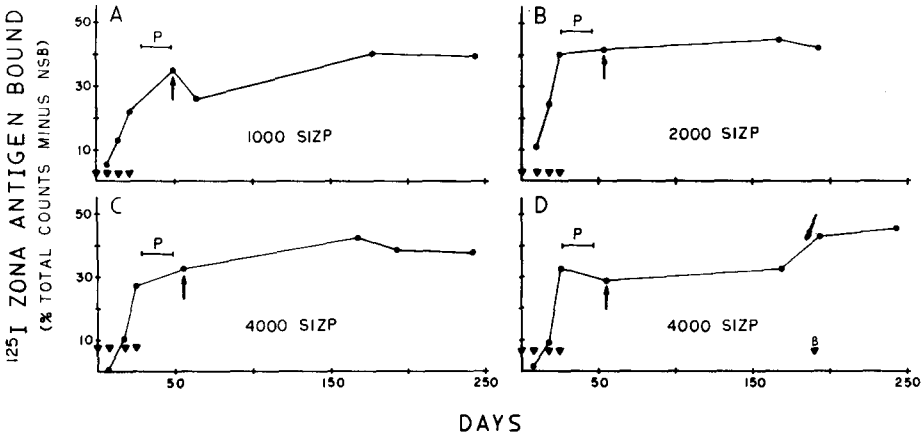

Fig. 1. Female mouse immune response to injection with various dosages of heat-solubilized isolated porcine zonae pellucidae (SIZP) as monitored by radioimmunoassay (RIA) using a 1×10^{-4} serum dilution. Female immunized with: A, 1000 SIZP; B, 2000 SIZP; C, 4000 SIZP; D, 4000 SIZP. ▼, injections in initial series of immunizations. $\overset{B}{\blacktriangledown}$, booster immunization following initial injection series. P, time period that mouse was pregnant. Arrow represents first bleeding assayed following delivery of litter.

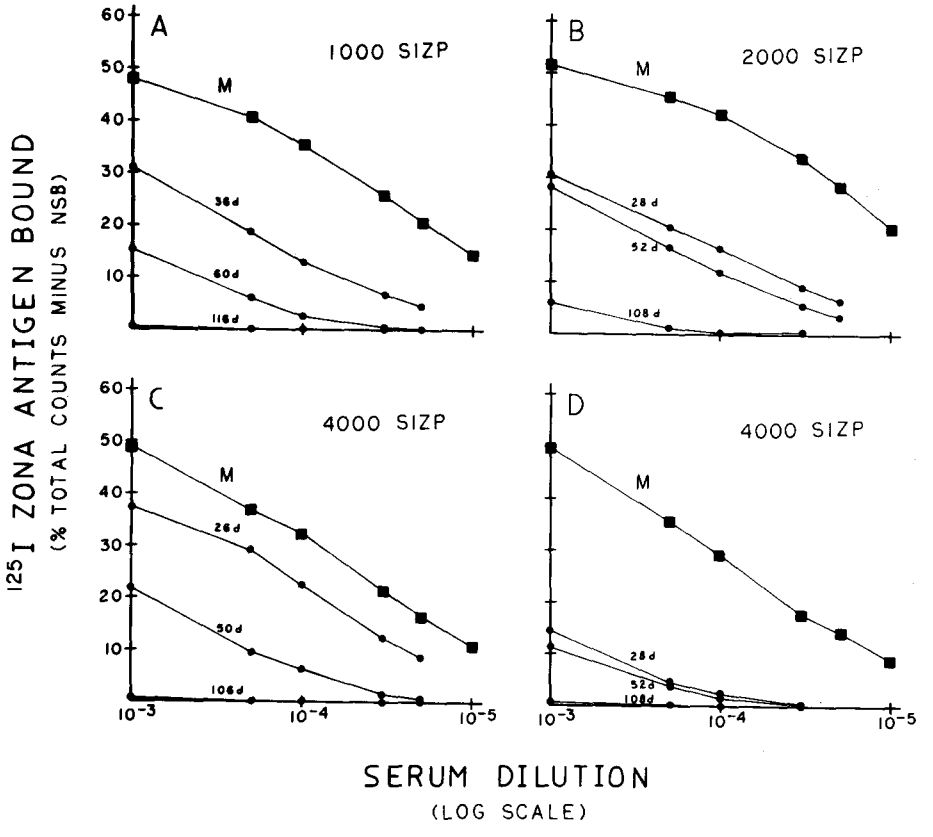

Fig. 2. See opposite page for legend.

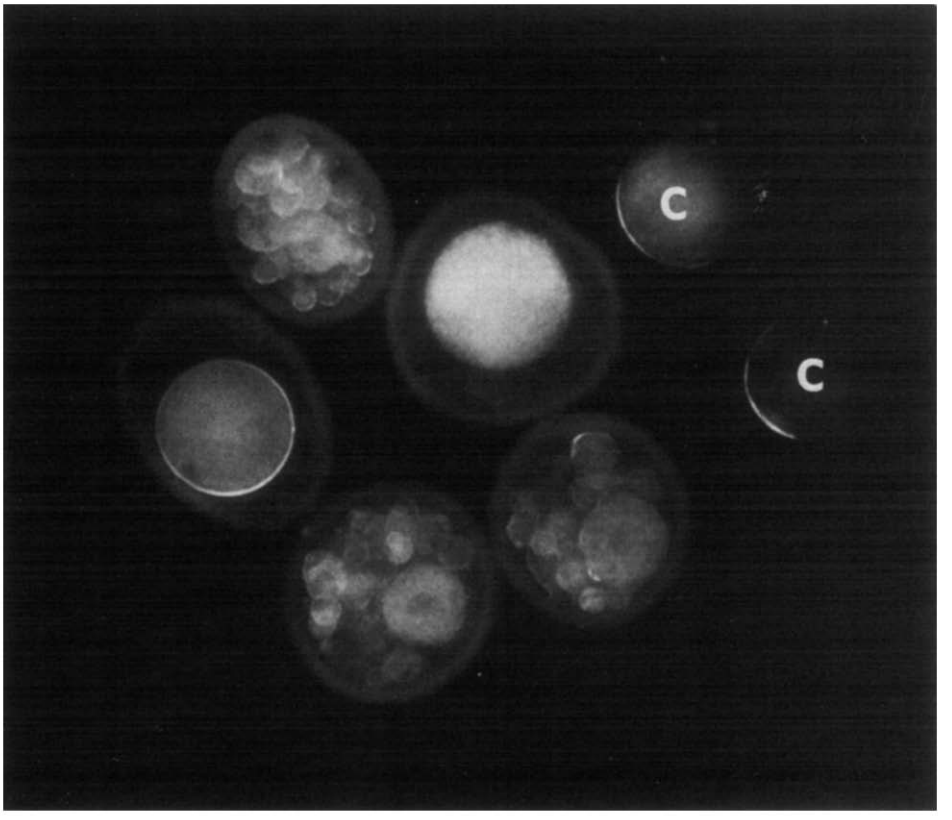

Fig. 3. Superovulated zona-encased mouse eggs obtained from a representative female offspring and tested for antibodies bound to zonae pellucidae by the indirect immunofluorescent assay. The mother of this particular female offspring was immunized with 4000 solubilized porcine zonae. Eggs were obtained and tested when the age of this female offspring was 49 days. Note moderate fluorescence associated with zonae pellucidae indicating the in vivo cross-reaction of antibodies to porcine zonae with mouse zonae in female offspring. No fluorescence is associated with zonae (C) of offspring obtained from control immunized mother. Fluorescence by vitellus is attributed to nonspecific autofluorescence.

SIZP and which were killed immediately after delivery and prior to nursing, precipitated 30.25 ± 1.23% ($\bar{x}$ ± SD) [^{125}I]SIZP at a 1×10^{-3} dilution. The mother's serum at time of delivery precipitated 35% [^{125}I]SIZP at a comparable serum dilution. However, nursing also contributed to antibody presence in offspring as suggested in Fig. 4B. Another mother immunized with 50 000 SIZP produced a litter of 12 offspring at 46 days following her initial immunization. During the period of time that included this pregnancy (which extended from 27–46 days following the initial immunization) the percentage of [^{125}I]SIZP bound by a 1×10^{-3} dilution of the mother's serum was increasing from 43% (at 21 days) to 58% (at 54 days). The percentage of [^{125}I]SIZP precipitated by a 1×10^{-3} serum dilution from offspring ($n = 6$) killed immediately after delivery and prior

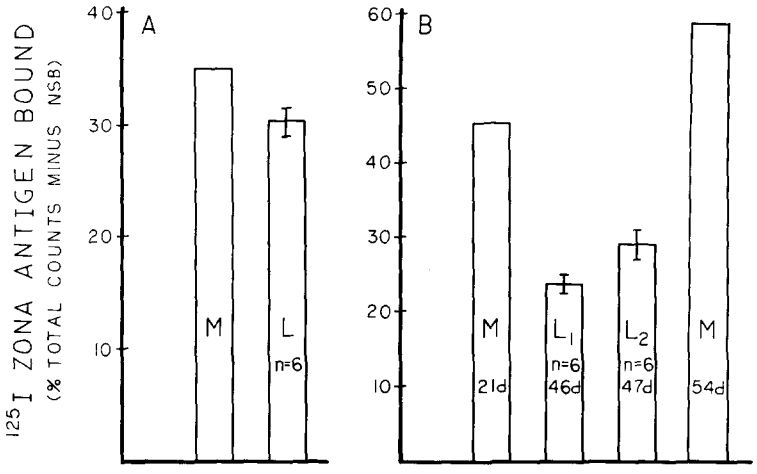

Fig. 4. Percentage of ^{125}I-labeled zona antigen bound by sera (1×10^{-3} dilution) from immunized mothers (M, 50 000 SIZP/female) and their litters (L). A. Comparison of percentages of zona antigen bound by serum from a mother and her newborn offspring ($n = 6$) which were tested immediately after their birth and prior to nursing. B. Comparisons of percentages of zona antigen bound by sera from a mother obtained at 21 and 54 days (d) following immunization and her litter ($n = 12$) which was delivered at 46 days following mother's initial immunization. L_1, offspring ($n = 6$) killed immediately following birth and prior to nursing. L_2, offspring ($n = 6$) allowed to nurse during 16 h exposure to mother. Vertical lines represent ± 1 S.D.

to nursing was 23.84 ± 1.35 ($\bar{x}$ ± SD) and was significantly lower (Student's t-test, $P < 0.001$) than the percentage of [^{125}I]SIZP bound by sera from the remaining offspring ($n = 6$) killed approximately 16 h following delivery and which were allowed to nurse (29.01 ± 1.89 [^{125}I]SIZP bound).

The passage of antibodies directed against porcine SIZP to offspring via mothers' colostrum and milk was confirmed by litter transfer experiments. Litters were switched between immunized mothers (50 000 SIZP) and control mothers immediately after delivery and prior to nursing as illustrated in Fig. 5. The percentage of [^{125}I]SIZP bound by a 1×10^{-3} serum dilution from offspring of the control mother and killed immediately after delivery was insignificant (Fig. 5A, day 1). However, when the remaining offspring, immediately following their birth, were switched to and allowed to nurse from the immunized mother and their sera tested 15 days later, significant anti-SIZP activity was present (56.62% [^{125}I]SIZP bound at a 1×10^{-3} dilution) in their sera. These titers slowly decreased over a period of time (15–65 days) as indicated in Fig. 5A. The anti-SIZP activity in sera of offspring from the immunized mother was initially high immediately following their birth and prior to nursing (40.4% binding on day 1; Fig. 5B). Following the transfer of the remaining litter mates immediately after their birth and prior to nursing to the control mother, the anti-SIZP activity in their sera gradually decreased over the period ranging from 1 to 65 days (Fig. 5B). During this particular experiment the titer of the immunized mother was increasing from a percent binding level

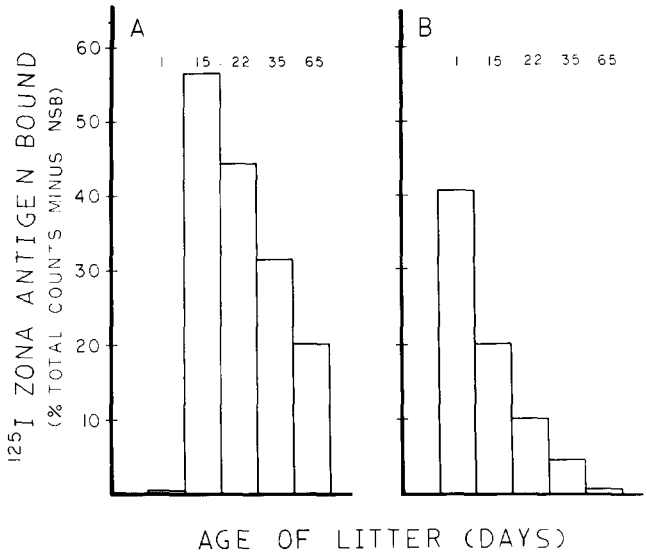

Fig. 5. Percentages of ^{125}I-labeled zona antigen bound by sera (1×10^{-3} dilution) of offspring from a control mother and offspring from immunized mother. Immediately after delivery, the offspring from the control mother were transferred to immunized mother and the offspring from immunized mother were transferred to control mother. A. Data from litter born from the control mother and switched to the SIZP-immunized mother immediately after birth. B. Data from litter born from the SIZP immunized mother and switched to the control mother immediately after birth. $n = 3$ for day 1 values; $n = 2$ for all other days. See text for details.

of 49% on day 1, the day of the delivery, to 58% at 65 days following delivery. No anti-SIZP activity was detected in serum from the control mother.

DISCUSSION

Zonae pellucidae represent a potent heteroimmunogen as demonstrated both in the present investigation by the high anti-SIZP titers achieved using RIA (Fig. 1) and by others using the more conventional biologic zona antibody detection assays (Shivers et al., 1981; Tsunoda et al., 1981; Tsunoda and Sugie, 1979; Mahi and Yanagimachi, 1979; Sacco and Shivers, 1978; Gwatkin et al., 1977). Zona antibodies exert their contraceptive effect by inhibiting sperm attachment to and passage through the zona (Shivers et al., 1972). Recently, it has been suggested that this inhibition is achieved by a generalized zona antibody lattice formation occurring on the zona surface rather than a specific antigen–antibody reaction directed against sperm receptors (Ahuja and Tzargos, 1981; Aitken and Richardson, 1981). The present study has demonstrated that antibodies to SIZP produced by the mother are passively transferred via the placenta and milk to her offspring (Figs. 2–5). Furthermore, such antibodies retain their biologic activity within the offspring, as indicated not only by their ability to precipitate [^{125}I]SIZP in the RIA but, more importantly, by their binding in vivo to the zonae of female offspring (Fig. 3). Similar in vivo antibody binding to the zonae of actively immunized mothers has been

previously shown (Shivers et al., 1981; Gwatkin et al., 1977).

In investigations where active immunization of females with zona material produces a contraceptive effect during periods of high anti-zona levels, fertility of the immunized female gradually returns once zona antibody titers decline to low levels (Shivers et al., 1981; Gwatkin and Williams, 1978; Gwatkin et al., 1977). Our current findings strongly indicate that even in those situations where pregnancy is prevented due to high zona antibody levels, once titers decrease and a pregnancy ensues, any residual zona antibodies from the immunized pregnant mother will be transferred to the offspring with their subsequent binding to zonae in the females. All present data indicate that zona antibodies produce no physiologic effect other than the inhibition of fertility, a fact substantiated both by the demonstrated tissue specificity of zonae antibodies (Subramanian et al., 1981; Gerrity et al., 1981; Palm et al., 1979) and by the return of normal fertility and the production of normal pregnancies and offspring in zonae immunized females (Shivers et al., 1981; Gwatkin and Williams, 1978; Gwatkin et al., 1977). Nonetheless, to evaluate fully the immunocontraceptive approach to fertility regulation, based upon a zona pellucida target antigen, detailed evaluation of possible effects such zonae antibodies may have in fetal, newborn and prepuberal females must now also be considered.

BREEDING AND GENETICS

Direct and Correlated Response to Divergent Selection for Serum Immunoglobulin M and G Levels in Chickens

NITISH SARKER, MASAOKI TSUDZUKI, MASAHIDE NISHIBORI, and YOSHIO YAMAMOTO[1]

Laboratory of Animal Breeding and Genetics, Faculty of Applied Biological Science. Hiroshima University, kagamiyama, Higashi-Hiroshima 739-8528, Japan

ABSTRACT Two pairs of chicken lines were divergently selected for serum immunoglobulin M and G levels at 10 wk of age to examine the effect of selection on direct and correlated traits. After three generations of selection, the lines were tested for their ability of antibody production against SRBC, a T cell dependent antigen. At 14 and 17 wk of age, the lines were immunized intravenously with 1 mL of 5% SRBC solution. Blood samples were collected at 7 and 14 d of post primary immunization (PPI) and post secondary immunization (PSI). Selection was effective ($P < 0.01$) in changing the serum immunoglobulin M levels. The G levels were changed in a downward direction initially in the high line. The differences between the high immunoglobulin M (HIM) and low immunoglobulin M (LIM) lines as well as high immunoglobulin G (HIG) and low immunoglobulin G (LIG) lines became larger during the course of selection. Selection differentials varied considerably during the selection, but the selection response was almost constant. Realized heritability was relatively high, ranging from 0.58 to 0.66 and from 0.40 to 0.60 for the IgM and IgG selected lines, respectively. Total antibody titers to SRBC differed significantly ($P < 0.01$) between the HIM and LIM lines at 7 and 14 d PPI, and 7 d PSI. The HIM line also produced significantly higher mercaptoethanol resistant antibody titers to SRBC than the LIM line at 7 and 14 d PPI and PSI. The LIG line had significantly higher total antibody titers to SRBC than the HIG line at both 7 and 14 d of PPI and PSI. From these results, it is suggested that selection of chickens on the basis of serum immunoglobulin isotypes may change antibody producing cells as well as other immunocompetent cells that modulate the immune response of the selected lines.

(*Key words*: chicken, selection, immunoglobulin M, immunoglobulin G, immune response)

1999 Poultry Science 78:1–7

INTRODUCTION

The production of poultry continues to be plagued with disease problems, although vaccination programs have dramatically reduced the incidence of diseases. Vaccination programs alone cannot cope adequately with infectious diseases. A combination of vaccination and genetic resistance is essential to maximize the protection from diseases. Genetic resistance of chickens can be improved through selection for immunocompetence (Gavora and Spencer, 1983; van der Zijpp, 1983a; Warner *et al*., 1987). Consequently, several lines of chickens have been developed for humoral or cell mediated immune responses. Developing lines against specific antigens is the most popular and frequent approach of selection to improve the immune response and to increase disease resistance. In mice, Biozzi *et al.* (1979, 1984) reported that differences in antibody production within lines selected for high (H) or Low (L) antibody production to SRBC were associated with antigen handling and antigen presentation of macrophages and the multiplication rate of B lymphocytes. Antibody production against SRBC has also been used in selection experiments in chickens (Siegel and Gross, 1980; van der Zijpp, 1983b; Martin *et al*., 1990; Pinard *et al*., 1992). Siegel and Gross (1980) found that the high antibody production line was more resistant to parasites and viruses than the low antibody production line. Selection for antibody response to glutamic acid-alaline-tyrosine (GAT) and also for antibodies against *Salmonella pullorum* has also been reported (Pevzner *et al*., 1981a,b). Pitcovski *et al.* (1987) selected for high and low early antibody response to Newcastle disease virus vaccine and *Escherichia coli*, and after four generations of

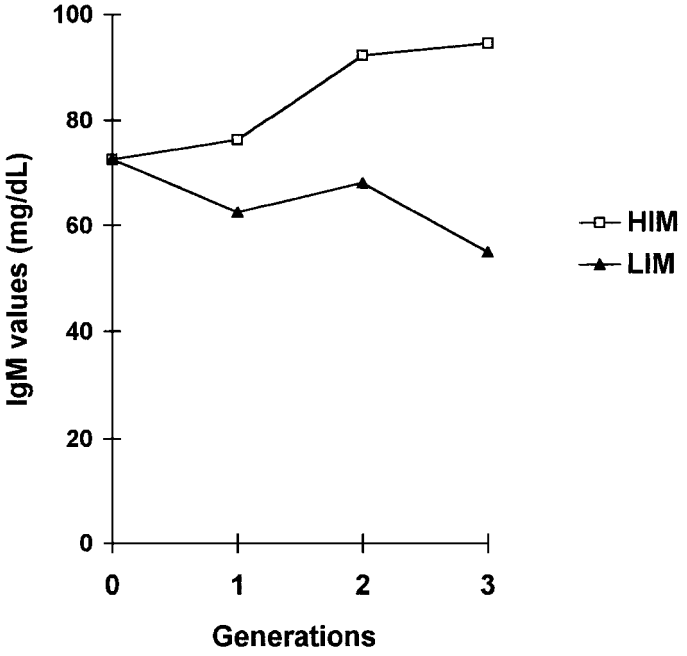

FIGURE 1. Effect of divergent selection for a serum IgM level over three successive generations in chickens. The serum IgM level changed considerably over the course of selection. A significant difference ($P < 0.01$) was found between the high (HIM) and low (LIM) lgm lines during the course of selection.

selection they found that the average antibody production of the high responder line exceeded that of the low responder line. Selection on the basis of multitrait immunocompetence, as well as high and low donor competence of splenomegaly was also conducted (Okada and Mikami, 1974; Cheng *et al*., 1991; Kean *et al*., 1994).

On the contrary, improved disease resistance may also be achieved without challenging animals with disease agents. Selection of chickens on the basis of serum immunoglobulin isotypes, which represent the response to a wide variety of unknown antigens, may be a useful tool in this regard. However, considerably less attention has been paid towards this technology thus far. Tamaki (1981) determined that chicken lines selected for a high serum IgG level were more susceptible to Marek's disease than their low IgG counterparts. In another experiment, Okada and Yamamoto (1987) demonstrated that the high IgG line was associated with higher incidence and mortality to Marek's disease, high antibody responses to SRBC, and lipopolysaccharides (LPS). However, Krieg *et al.* (1978) reported that low IgG levels were associated with mortality to myeloblastosis virus. Therefore, the purpose of the present selection program was to develop divergent chicken lines for serum IgM and IgG levels and to determine the effects of selection on direct and correlated traits.

MATERIALS AND METHODS

Chickens

The base population for this divergent selection experiment consisted of crosses of six lines. The lines were HA, LA, HG, LG, C, and GSP. Lines HA, LA, HG, and LG were established from the N strain of Hokkaido University, Sapporo, Japan, by four generations of selection for high and low competences of splenomegaly in graft-vs-host reaction (GVHR). The details about these lines have previously described (Okada and Yamamoto, 1987). Briefly, lines HA, LA, HG, and LG were developed from the N strain of Hokkaido University, Sapporo, by selection for high and low competences of splenomegaly index in GVHR in 1969. Line C was a randombred control line and established from crossbreds of White Leghorns and White Rocks maintained at the authors' laboratory for 35 yr. The GSP line (Somes, 1988) was established by pedigree breeding from the Fayoumi breed at the Nippon Institute for Biological Science, Kobuchizawa, Yamanashi, Japan in 1971. To construct the base population, firstly the lines were crossed to produce GHA (GSP♂ × HA♀), GHG (GSP♂ × HG♀), CLA (C♂ × LA♀), and CLG (C♂ × LG♀) populations. Then these GHA and CLG, and GHG and CLA were crossed reciprocally to established the base population.

From this combined gene pool, progeny with highest IgM and those with highest IgG, from 10 sires and 20 dams, became the parents of HIM and HIG lines.

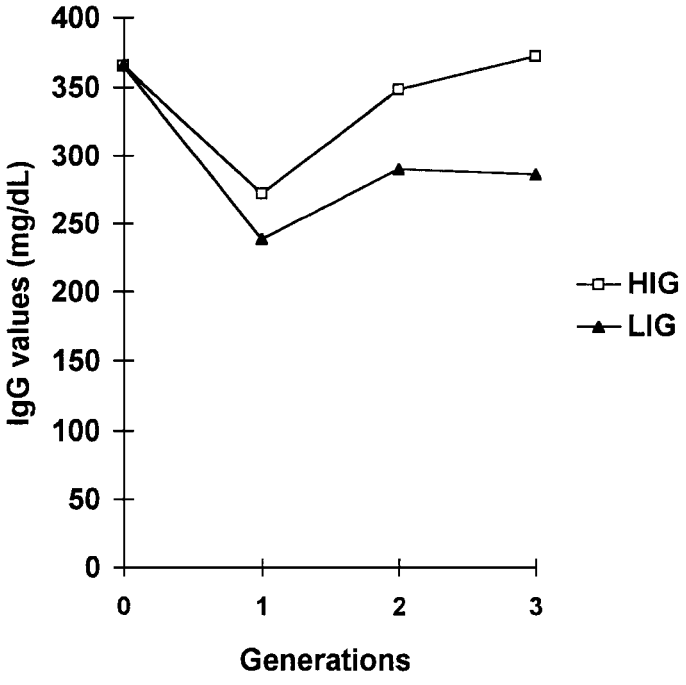

FIGURE 2. Effect of divergent selection for a serum IgG level over three successive generations in chickens. The serum IgG level changed gradually over the course of selection. A significant difference ($P < 0.01$) was found between the high (HIG) and low (LIG) lgG lines as the selection progress.

**Sex means within the lines differ significantly ($P < 0.01$).

Similarly, progeny with lowest IgM and IgG, respectively, from the same 10 sires and 20 dams, became the parents of LIM and LIG lines. Thereafter, individual phenotypic selection was carried out within each closed line for serum IgM and IgG levels at 10 wk of age. In each generation, chickens with highest serum IgM and IgG as well as chickens with lowest IgM and IgG were chosen as breeders for the next generation. Chicks from all the lines were hatched in a single hatch and reared together under the same environmental condition. Simultaneously, at hatching, all the chicks were wing-banded and vaccinated for Marek's disease. Also, fowl pox and Newcastle disease vaccines were administered per schedule. Birds of all the lines were provided *ad libitum* access to water and a commercial diet. After three generations of selection, birds of all lines were tested for their ability to produce antibody against SRBC antigen.

Quantification of IgM and IgG

The IgM and IgG were quantified by a single radial immunodiffusion (SRID) technique (Mancini *et al*., 1965). At 10 wk of age, blood samples were collected from the ulnar vein and separated by centrifugation at $1,700 \times g$ for 10 min. Four percent special noble agar[2] was dissolved in PBS (8 g sodium chloride, 0.2 g potassium chloride, 1.15 g disodium phosphate, 0.2 g monopotassium phosphate in 1 L of distilled water, pH 7.5) containing 0.02% sodium azide (NaN_3) at 62 C to prepare the agar solution. Goat anti-chicken IgM (μ chain specific[3]) or goat anti-chicken IgG (heavy and light chain specific[3]) was incorporated in the amount of 0.01 mL in 1.90 mL of PBS at 62 C. Finally, 3.5 mL of well mixed agar antiserum solution was used to make the gel for one agar diffusion plate. The serum sample, 0.003 mL, was applied in duplicate consecutively into the wells (1 mm of diameter) of the agar plate. The same amount of chicken immunoglobulin reference serum[3] was also applied to the same plates. The plates were incubated at 37 C for 24 and 8 h for IgM and IgG, respectively. After completion of the incubation period, the diameter of precipitation circle was measured by a slide caliper and the average concentration (milligrams per deciliter) of IgM and IgG was determined by comparison of the average diameter of the ring of precipitation in the test sample with diameters obtained using varying concentrations of purified IgM and IgG.

Administration of Antigen

At 14 and 17 wk of age, 30 chickens from the respective lines were injected intravenously with 1 mL of SRBC antigen. Sheep red blood cell, a T cell dependent antigen, was collected in Alsever's solution (2.05% dextrose, 0.42% sodium chloride, 0.8% sodium citrate). Cells were washed three times and were diluted to 5% in PBS. Blood samples were collected from the ulnar vein at 7 and 14 d post primary immunization (PPI) and post secondary immunization (PSI), respectively.

Agglutination Assay

Total and mercaptoethanol-resistant (MER) antibody titers were measured by agglutination test as described by van der Zijpp and Leenstra, (1980). The agglutination titer was expressed as the $\log_2$ of the reciprocal of the highest dilution where agglutination occurred.

Selection Differentials, Selection Response, and Realized Heritability

Selection differentials (*S*D) was measured by subtracting the means of tested population from the selected population of the high and low lines. Selection response (*S*R) was the difference of the tested populations of two consecutive generations. Realized heritability was calculated dividing the selection response by selection differentials. Therefore, realized heritability $h^2 = SR/SD$.

Statistical Analysis

Data were analyzed using the General Linear Models (GLM) procedure of SAS® software (SAS Institute, 1985). Treatment means were separated by Duncan's multiple range test.

RESULTS

Serum IgM and IgG levels at 10 wk of age changed considerably over the course of selection. Figures 1 and 2 demonstrate the changes in serum immunoglobulin M and G levels for HIM and LIM lines and HIG and LIG lines, respectively, after three generations of selection. The divergence of the selected lines became gradually larger with each successive generation of selection. Tables 1 and 2 shows the means of IgM and IgG values in sexes and lines over generations. A significant difference ($P < 0.01$) was observed between the sexes of HIM line in the first and second generations of selection. In the LIM line, the sex difference was observed only in the first generation. Even after a single generation of selection, a significant ($P < 0.01$) line difference was observed and followed in the subsequent generations. By contrast, in the IgG selected lines, the sex difference was significant ($P < 0.01$) only in the HIG line at the first generation of selection. The HIG line had significantly ($P < 0.01$) higher IgG levels over the course of selection than the LIG line.

Selection differentials, SR, and h^2 in the respective generations are presented in Tables 3 and 4. In the present study, no control population was used; therefore, the SR was measured by the difference between the high and low lines. Although the SD varied substantially over the course of selection, the SR was almost constant. Realized heritabilities were relatively high, with a mean value of 0.61 and 0.52, respectively, for M and G selected lines.

TABLE 3. Selection differential, selection response, and realized heritability on the basis of difference between the HIM and LIM lines[1]

Generation	Selection differential	Selection response	Realized heritability
1	23.47	13.75	0.58
2	17.70	10.52	0.59
3	15.55	10.40	0.66

[1]HIM = high IgM; LIM = low IgM.

Least squares means for total and MER antibody titers to SRBC in the HIM and LIM lines and HIG and LIG lines are presented in Tables 5 and 6, respectively. In the IgM selection, the females of the HIM line had significantly ($P < 0.01$) higher total antibody titers to SRBC than the males at 14 d of PPI and PSI than the males. Similarly, the females of the LIM showed significantly higher total and MER antibody titers to SRBC than the males at 14 d PSI, and at 7 and 14 d of PSI, respectively. The HIM line had significantly ($P < 0.05$) higher total antibody titers to SRBC than the LIM line except at 14 d PSI. The MER antibody titers to SRBC were also observed to be significantly higher in the HIM line than the LIM line on both the PPI and PSI. In the IgG selection, the females of the HIG line had significantly ($P < 0.01$) higher total and MER antibody titers than the males at 7 d PPI, and 14 d PPI, and at 7 and 14 d PSI, respectively. In the LIG line, total and MER antibody titers were significantly higher in the female than in the male at 7 d PPI, 7 and 14 d PSI, and 7 d PSI, respectively.

Total antibody titers to SRBC were significantly ($P < 0.01$) higher in the LIG line than in the HIG line at both 7 and 14 d of PPI and PSI; whereas, MER antibody titers were not significant between the two lines.

DISCUSSION

In this study, divergent selection for serum immunoglobulin M and G levels resulted in significant line differences during the course of selection. Successful selection for serum IgG levels as well as selection of chickens for antibody titers to SRBC has been demonstrated (Tamaki, 1981; Martin *et al.*, 1990; Dunnington *et al.*, 1996). The average h^2 for M and G selected lines were 0.61 and 0.52, respectively. Although comparable data were not available in the literature regarding selection of chickens for a serum IgM level, relatively high h^2 as found in this study indicates the usefulness of this kind of selection. Eide *et al.* (1991) reported h^2 of 0.19 for antibody response to diphtheria toxoid in goats.

TABLE 4. Selection differential, selection response, and realized heritability on the basis of difference between the HIG and LIG lines[1]

Generation	Selection differential	Selection response	Realized heritability
1	74.50	29.75	0.40
2	49.84	29.74	0.60
3	48.70	27.06	0.56

[1]HIG = high IgG; LIG = low IgG.

In chickens, h^2 for antibody response to *Escherichia coli* were 0.23 and 0.32 for high and low response lines, respectively (Leitner *et al*., 1992). Realized heritabilities for antibody response to SRBC varied from 0.17 to 0.52 (Siegel and Gross, 1980; van der Zijpp *et al*., 1983a; Martin *et al*., 1990). However, the upper value is in concordance with our study. The estimate of h^2, especially for IgG selected lines, varied over the course of selection. This divergence could have been due to the absence of a control population in this study.

In the present experiment, the female chickens generally had higher serum IgM and IgG levels as well as antibody titers than the males. This result was in agreement with the result of Leitner *et al*. (1992). Similar results were also reported in humans and mice (Ahmed *et al*., 1985; Astorquiza *et al*., 1987; Nelson and Steinberg, 1987; Grossman, 1989). From this result, it is suggested that hormones of the females may have modulated the immune response.

van der Zijpp (1983b) studied the total and MER antibody titers to SRBC of three lines of chickens with different genetic origins, and found that there were significant differences among them. In the other bidirectional experiments carried out on antibody response to SRBC and *Salmonella pullorum* (SP), the difference between the high and low responder lines was significant after three to five generations of selection (Siegel and Gross ,1980; Pevzner *et al*., 1981b). Genetic control of antibody response to SRBC, SP, and GAT has also been reported (Haddad *et al*., 1994). In our study, significant line differences were found for total and MER antibody titers to SRBC, which further demonstrates that genetic differences are major factors that influence the antibody production to the SRBC antigen. Okada and Yamamoto (1987) reported that a high IgG line had higher antibody response to SRBC. However, in the present experiment, the LIG line produced significantly higher antibody titers to SRBC than the HIG line (Table 6). This discrepancy may be due to the differences in the genetic background of the lines. Another possibility is that the LIG line may have more T lymphoproliferative cells than the HIG line, which react efficiently with SRBC, a T cell dependent antigen. The LIG line was also associated with higher degree of splenomegaly indices and lower level of antibody production to *Brucella abortus*, a T cell independent antigen, than the HIG line (Sarker *et al*., 1997, 1998). On the other hand, the HIM line had higher total and MER antibody titers than the LIM line at all points of PPI and PSI. The HIM line may have more B cells for multiplication and differentiation as well as T cells which react specifically to SRBC for antibody production. The HIM line was also associated with higher antibody production to *B. abortus* (Sarker *et al*., 1998), which also led to the possibility of better antigen processing and presentation of macrophages in this line as demonstrated by Biozzi *et al*. (1979, 1984) in mice.

From the results, it is postulated that selection of chickens for serum immunoglobulin isotypes may change other immunocompetent cells as well as antibody producing cells. However, further investigation of the T cell subsets and T cell receptor along with B cell number would be helpful to better understand the immune mechanism of this line. An effect of selection on IgM and IgG levels as well as correlated response to SRBC as found in this study may be helpful in understanding the immune mechanism and disease resistance in chickens.

SAFETY DATA SHEET

ZONASTAT-H (PORCINE ZONA PELLUCIDA IMMUNOCONTRACEPTIVE VACCINE)

SECTION 1 – IDENTIFICATION

PRODUCT IDENTIFIER: Zonastat-H

OTHER MEANS OF IDENTIFICATION: Porcine Zona Pellucida Vaccine, Porcine Zona Pellucida Immunocontraceptive Vaccine, Native PZP

MANUFACTURER: Science and Conservation Center

RESPONSIBLE PARTY:

MAILING ADDRESS: 2100 South Shiloh Road, Billings, MT 59106

PHONE: 406-652-9718

HOURS: 8:00 AM TO 4:00 PM, MST Mon-Fri.

PRODUCT USE: Used to inhibit fertility in elephants, all members of Family Ursidae, all ungulates, including the Perissodactyla, Artiodactyla, excluding the Family Suidae, and pinnipeds.

RESTRICTIONS ON USE: None

SECTION 2 – HAZARD INFORMATION

PRIORITY IDENTIFIERS: ANIMAL REMEDY
KEEP OUT OF REACH OF CHILDREN
FOR ANIMAL TREATMENT ONLY

EMERGENCY OVERVIEW: Non-toxic; possible abscess after im injection; temporary reproductive inhibitor if injected intramuscular.

Adverse Effects: Adverse effects in target animals may include injection-site abscess, or minor swelling. Material cannot pass through the food chain, thus ingestion is not dangerous.

SECTION 3 – COMPOSITION INFORMATION ON INGREDIENTS

CHEMICAL NAME: Native Porcine Zonae Pellucidae

COMMON NAME AND SYNONYMS: Porcine Zona Pellucida Vaccine, Porcine Zona Pellucida Vaccine, Porcine Zona Pellucida Immunocontraceptive Vaccine, Zonastat-H, Native PZP

Table 1. Chemical Components of Porcine Zonae Pellucidae*

Component	ng/zona
Protein	35.5 ±1.8
Hexose	2.5±0.1
Sialic Acid	0.02±0.00
Uronic acide	0.34±0.03
Amino Sugars	3.01±0.13

Active Ingredients:

The 4 ZP glycoprotein family protein separation via two dimensional polyacrylamide gel electrophoresis (2D- PAGE) and 2D-PAGE immunoelectrophoresis revealed approximately 7% contamination with non-ZP materials. Heat solubilization of ZP yields a product that does not contain organ cross-reactive antigens.

The major PZP component is ZP3, which is a 55 kD glycoprotein comprising 71% of the purified PZP. This glycoprotein serves as the primary immunogenic antigen in the PZP vaccine. The species-specific antigen that generates fertilization-blocking antibodies is an 11 kD fragment of the 55 kD ZP3 protein.

Nominal Concentration in Weight Percent: 500 μg PZP/1.03 g vaccine = 0.052%. 100-550 μg PZP (equivalent of 5-20 × 103 zonae) per immunization (intramuscular).

Purpose of Ingredient: The ingredient serves as an antigen to generate anti-PZP antibodies, which bind to ovulated eggs and block sperm attachment to the egg, preventing fertilization.

Impurities of Toxicological Significance Associated with Active Ingredient No detectable toxicological impurities are present in the immunization-ready PZP preparation.

SECTION 4 – FIRST AID MEASURES

Inhalation: No known effects of inhalation

Eye: May cause irritation. Flush with water

Skin: This material cannot be absorbed through the skin, but flushing with water is recommended

Ingestion: Because of its protein nature this vaccine cannot be absorbed in the gastrointestinal tract.

Poisoning Symptoms: No information regarding the symptoms of poisoning is available for this product.

Workplace Facilities: Other than a reliable freezer, no special facilities are required for storage. In the field some form of storage with cold or freezer capabilities must be available.

Hygiene Practices: Avoid ingestion, inhalation and contact with skin and eyes. Do not eat, drink or smoke while using this product. Wash hands and exposed skin before eating, drinking or smoking and after work.

SECTION 5 – FIREFIGHTING MEASURES

Vaccine is not flammable.

SECTION 6 - ACCIDENTAL RELEASE MEASURES

Spill Response: Spilled or released vaccine, on the ground or in water, will quickly degrade upon exposure to the elements, because of its protein nature. Because vaccine is packaged in 0.5 cc volumes, no more than 0.5 cc of the vaccine can be released at any one time.

Procedure for Disposal: Dilute with water and flush to sewer. Empty containers can be decontaminated with water. Syringes and needles and used darts must be disposed of in accordance with state regulations for medical waste.

SECTION 7 – HANDLING AND STORAGE

Storage: Vaccine is stored frozen and kept frozen or cold in the field. It may be refrozen after thawing as long as it has been kept cold. Expiration is two years from date of acquiring the vaccine.

Handling: No special technical protective measures required. No special handling advice required beyond that given in ***required*** training.

Handling Practices: Avoid ingestion, inhalation and contact with skin and eyes. Do not eat, drink or smoke while using this product. Wash hands and exposed skin before eating or smoking and after work.

Approved Handlers: Acquisition of the vaccine and application to equine requires a three-day training program, conducted at the Science and Conservation Center.

SECTION 8 – EXPOSURE CONTROL/PERSONAL PROTECTION

Application in the workplace: Vaccine may be loaded into darts in the workplace or most commonly in the field.

Exposure Standards Outside the Workplace: There are no established exposure limits.

Personal Protection: The following procedures are meant for people coming into frequent and lengthy contact with this product. For occasional use, take precautions suitable for conditions under which the product is used.

Respiratory: It is safe to avoid using dust masks or respirator protection because of the nature of the product and handling procedures.

Eyes: Protective eyewear is not necessary when using this product. However, it is always prudent to use protective eyewear because of other conditions encountered in the field.

Skin: Because the product cannot be absorbed through the skin, no special precautions need be taken.

Hands: Rubber, latex or PVC gloves are not necessary, but are desirable if prolonged use of the product is occurring.

SECTION 9 – PHYSICAL AND CHEMICAL PROPERTIES

Appearance: Aqueous solution

Odor: None

Specific Gravity:

Melting Point: 0° C

Boiling Point:

pH: 7.0 -7.1

Flashpoint: Not Applicable

Solubility in Water: Soluble

Oxidizing Properties: Not applicable: this product is not an oxidizer

Corrosive Properties: Not applicable; this product is not corrosive

Vapor Pressure:

SECTION 10 – STABILITY & REACTIVITY

Reactivity: None

Chemical Stability of Substance: The product is stable for up to two years if stored frozen and kept cold in the field and for up to 48 hours in darts, if kept refrigerated

Conditions to Avoid: Store frozen, keep at 2-8o C in the field.

Incompatible Materials to Avoid: None known

Hazardous Decomposition Products: No products of decomposition, either in or out of fire exist.

Hazardous Polymerization: The product cannot polymerize

SECTION 11 – TOXICOLOGICAL INFORMATION

TOXICOLOGY – ACUTE

Exposure: Principal routes of exposure are by skin contact and accidental needle stick. As with any chemical product, contact with skin or ingestion in any form should be avoided by observing good work/medical practices. This material is not regarded as pathogenic in humans.

TOXICOLOGY – CHRONIC/LONG TERM EFFECTS

Fate of Product after Injection: Following injection, both components of the

vaccine follow the common immunological and metabolic path of vaccines detected by the humoral immune system. Briefly, both the PZP and the bacterial peptidoglycans are hydrolyzed in cells of the immune system. The breakdown products of this hydrolysis bear no resemblance to PZP or bacterial peptidoglycans, and are indistinguishable from other products of lysosomal hydrolyis. After hydrolysis, these metabolic products are excreted and eliminated from the body in forms (such as CO2, water, lactic acid, and urea) that are indistinguishable from other metabolic products. Likewise, the antibodies produced in response to ZonaStat-H injection are broken down into their component amino acids, and recycled into other body proteins or metabolized and excreted as urea, CO2, and water. PZP and the adjuvant antigens are not stored in body tissues in a stable or physiologically active form, thereby eliminating the possibility of continued exposure of the target animal to the vaccine components, or of non-target animals and humans of exposure to vaccine components from excreted products. 30% of the hexadecane component of the adjuvant mineral oil remained at the injection site after 10 months. The mineral oil is readily incorporated into lipids and appears as triglycerides, sterol esters, and free sterols in the liver, at 3 months in liver phospholipids, and were absent from the liver by 10 months. Metabolic products also appeared as triglycerides in depot fat, a small amount of which still remained after 10 months and are lost slowly over time through metabolism and elimination via respiratory CO2, and there was no bioaccumulation of mineral oil. Mannide monooleate is dissipated more quickly from the injection site than mineral oil, with the oleate component largely being incorporated into lipids, with subsequent elimination through respiratory CO2, and the mannide largely eliminated from the body in urine in the form of non-esterified sugars – 25% in the first 24 hr after administration.

SECTION 12 – ECOTOXICITY INFORMATION

Ecotoxicity Effects: Delivery of this product to the target animal is highly specific, by either hand injection or dart delivery, thus toxicity to birds, fish, algae, aquatic invertebrates, soil dwelling organisms or bees does not occur.

Environmental Fate: Once thawed the vaccine degrades rapidly by bacterial degradation and pH changes.

SECTION 13 – DISPOSAL CONSIDERATIONS

Product Disposal: Preferably dispose of the product by use. Otherwise dispose of the product at an approved landfill, or other approved facility in accordance with local, regional and national regulations.

Container Disposal: dispose of vaccine vials, needles, syringes and used darts in accordance with state, regional or federal regulations for medical waste disposal. All needles, syringes and used darts should be kept in a sharps container until proper disposal.

SECTION 14 – TRANSPORT INFORMATION

Not classified as dangerous by rail, sea or air transport regulations. Keep frozen during transportation.

SECTION 15 – REGULATORY INFORMATION

Registered as a Pesticide by the Environmental Protection Agency (EPA Registration No. 86833-1). Also authorized for Equids under FDA INAD # 8857-G0002 and for Captive Animals and Deer under FDA INAD 8841-G0003-004.

SECTION 16 – OTHER CONSIDERATIONS

NOTE: This product is a veterinary medicine and must therefore be used in accordance with the container/label/insert directions and as indicated in required training. A comprehensive package of toxicological and environmental data for the active ingredient of the product has been provided and is on file with the Environmental Protection Agency and has been inspected by expert toxicologists and environmental scientists before approval in February 2012.

This material safety data sheet summarizes our best knowledge of the health and safety hazard information of the product and how safely to handle and use the product in the workplace and field. Each user should read the MSDS and consider information in the context if how the product will be handled and applied, including in conjunction with other products.

A polyanhydride-based implantable single dose vaccine platform for long-term immunity

Robert G. Schaut [a,1,3], Matthew T. Brewer [a,3], Kriscelle Mendoza [a,2], John Jackman [b], Balaji Narasimhan [c,d], Douglas E. Jones [a,d,*]

[a] Department of Veterinary Pathology, Iowa State University, Ames, IA 50011, United States
[b] Department of Industrial and Manufacturing Systems Engineering, Iowa State University, Ames, IA 50011, United States
[c] Department of Chemical and Biological Engineering, Iowa State University, Ames, IA 50011, United States
[d] Nanovaccine Institute, Iowa State University, Ames, IA 50011, United States

Traditionally, immune priming followed by an antigen-boost is utilized for vaccine-induced protective immunity and maintaining long-term immunity often requires repeated exposure to antigen. Here, a novel single dose vaccination platform designed with gonadotropin releasing hormone multiple antigenic peptide as a model antigen is shown. Initially a soluble component will prime the immune system followed by vaccine release from a biodegradable polyanhydride (PA) copolymer rod of 1,8-bis(*p*-carboxyphenoxy)-3,6-dioxaoctane (CPTEG) and 1,6-bis(*p*-carboxyphenoxy) hexane (CPH) for immune boosting (Appendix A) [1]. A second PA-based vaccine depot is enclosed within an implant of biocompatible high molecular weight polyethylene, which limits PA degradation and antigen release to a single surface, significantly extending the release kinetics (Supplemental Table). Collagen is used to generate an immunodiffusion barrier [2] over the PA wherein antigen-antibody complex formation can occur for an immune feedback design (Fig. 1). Therefore, antigen release is impeded, theoretically, by high antibody titers. The cap of the implant is a hydrophilic poly (vinylidene fluoride) membrane with 0.65-μm pores that allows flow of proteins into and out of the implant, while excluding leukocytes. Thus, this device enables vaccine priming, boost and long term maintenance with a single administration of antigen.

Summary

Reasons for performing study: Active immunisation against gonadotrophin-releasing hormone (GnRH) provides a reversible method for control of oestrous behaviour and fertility in mares. Previous reports failed to demonstrate the interval to resumption of cyclic ovarian activity after GnRH-vaccination.
Hypothesis: Administration of the GnRH-vaccine Improvac in a large group of mares of various ages will result in effective, reliably reversible suppression of ovarian activity within a 2 year period.
Methods: The mares, subdivided into 3 age categories, were vaccinated twice (with a 35 day interval) using 400 μg Improvac and monitored via blood samples until Day 720 after initial vaccination for serum progesterone concentration determination by radioimmune assay and anti-GnRH antibody titre by enzyme immunoassay. Samples were collected until individuals resumed cyclic ovarian activity.
Results: All mares showed suppression of cyclic ovarian activity by clinical examination and serum progesterone concentration (SPC) ≤1 nmol/l by Day 70 and 92.2% resumed cyclic activity by SPC at Day 720 with a mean interval = 417.8 days (s.d. ± 23.9; range 232–488 days, median 344 days). A significant age effect (P = 0.028) on the interval, but not on GnRH-antibody titre response, was observed between the youngest (≤4 years) and oldest (≥11 years) categories.
Conclusions: Immunising adult mares of all ages with Improvac resulted in a reversible suppression of cyclic ovarian activity in most mares. An age effect, with the youngest mares showing a longer interval to reversibility, was observed.

Keywords: horse; mare; GnRH-vaccination; anoestrus; reversibility; titres

Introduction

Suppressing reproductive function and associated oestrous behaviour in mares has been managed by several approaches. Pharmacological methods utilising progesterone or progestins and potentially reversible GnRH-agonist or -antagonist therapy and their associated shortcomings including costs, practicality and potential negative side effects are reported [1–3]. Surgical ovariectomy is generally considered to be undesirable, due to its associated risks and irreversible loss of breeding potential [4].

Various immunocontraceptive methods have been used to control fertility in mares. Although porcine zona pellucida (pZP) vaccine is effective, it neither prevents mares from cycling nor suppresses oestrus-related behaviours [5]. Gonadotrophin-releasing hormone (GnRH) vaccines utilise a modified form of GnRH hormone conjugated to a foreign protein administered to stimulate the production of anti-GnRH antibodies. These antibodies neutralise endogenous GnRH, preventing natural binding to receptors on the pituitary gonadotrophs, suppressing pituitary secretion of follicle stimulating hormone (FSH) and luteinising hormone (LH) [6–8]. Studies report successful but variable suppression of ovarian activity [6–13]. Age effects on response and of using serum progesterone concentration (SPC) to reliably monitor cyclic ovarian activity have been reported [8,12]. Short monitoring periods generally limit these reports. Reliable reversibility and the associated duration of anoestrus induced by vaccination have not been reported.

This study investigated the reversibility of anoestrus over a period of 2 years in a large group of mares of different ages after 2 treatments with the GnRH-vaccine Improvac[a].

Materials and methods

Experimental design

A previous controlled study reported on the efficacy, safety and interval to suppression of reproductive activity after vaccination of nonpregnant mares with Improvac[a] [12]. The current study was designed as a continuation to observe the reversibility of treatment. Mares (n = 51) aged between 3 and 17 years and either Thoroughbred or similar light-horse type, were subdivided into 3 age categories: Category 1 (≤4 years, n = 25), Category 2 (5–10 years, n = 16) and Category 3 (≥11 years, n = 10). The trial was approved by The University of Pretoria's Animal Use and Care Committee (V068/05).

GnRH immunisation

The mares were injected into the gluteal muscles with 2 ml Improvac[a] (400 μg GnRF-protein conjugate) approximately 3 months after the onset of the physiological breeding season in South Africa. All showed cyclic reproductive activity via transrectal palpation and ultrasound examination at the time of vaccination. One booster (2 ml) was administered 35 days after primary vaccination. By 70 days after primary vaccination, 100% of mares showed SPC reflecting anoestrus concentrations and ovarian activity was absent on clinical examination [12]. Resumption of ovarian activity was henceforth defined by a blood sample exceeding a baseline SPC prospectively set at ≤6 nmol/l, the reported upper threshold concentration for winter anoestrus [11].

Blood sampling

Blood samples were collected by jugular venipuncture from Day 232 after primary vaccination at 2-weekly intervals until resuming cyclic activity or failing that, until the end of the study on Day 720. The blood samples were collected in plain Vacutainer tubes[b] and left to clot. Serum was separated by centrifugation (4000 × ***g***, 10 min) on the same day before storage at -20°C until assayed for both SPC and anti-GnRH antibody titre.

Serum progesterone assay

Assays for SPC were conducted by means of radioimmune assay (RIA)[c]. Assay sensitivity was 0.06 nmol/l. The main cross-reactivity was with progesterone (100%), 5α-pregnane-3,20-dione (9.0%), 17α-hydroxyprogesterone (3.4%) and 5β-pregnane-3,20-dione (3.2%). The intra- and inter-assay coefficients of variation were 8.8, 3.6 and 2.7 and 9.7%, 3.9 and 3.9% for low, medium and high concentrations, respectively.

GnRH-antibody titre determination

The anti-GnRH titres were determined by enzyme immunoassay (EIA), using a modification of the method described by Elhay *et al*. [11]. Briefly, 96 wells MaxiSorp MTPs[d] were coated overnight (ON) at 4°C with 10 μg/ml GnRH peptide in sodium carbonate buffer at pH 9.6. The plates were washed with phosphate-buffered saline (PBS) containing 0.05% Tween 20 and then blocked ON at 4°C with 0.3% BSA in PBS. Plates were incubated with serial dilutions (dilution factors 200, 400, 800, 1600, 3200, 6400, 12,800) of test mare serum and standards for 1 h at 37°C. The plates were washed and bound antibody was detected by incubating plates with protein G-horseradish peroxidise (HRP)[e] for 1 h at 37°C. Subsequently, plates were washed and bound protein G-HRP was visualised with tetramethylbenzidine microwell peroxidase substrate[f]. Pooled samples of high titre (high standard) at Day 70 and low titre (low standard) at Day 35 after primary vaccination and samples of unvaccinated horses (negative control) served as reference points for the unknown samples on all plates analysed.

The plates were normalised by dividing all optical densities (ODs) by the maximal OD, thereby setting the high standard in 1:200 dilution to 1.0 for each plate. Subsequently, a negative titre threshold was defined as OD of the average of the negative controls plus 2 s.d. In this regard, titres were determined as the first OD exceeding the negative titre (negative control) threshold (starting from dilution 1:12,800 and decreasing). For method validation, titres of standards and positive controls were recorded for all 26 plates. The high and low standard titres were 3200 for all 26 plates and 800 for 18 plates and 400 for the remaining 8 plates, respectively. The negative control titres were 0 for all plates.

Data analysis

Data analysis was performed using Sigma Stat[g]. A Kruskal–Wallis one way analysis of variance (ANOVA) was performed on the ranked data to assess significance of age on the variables for general linear models. A Dunn's Multiple Comparison Test for means separation was also performed with Category 1 as control. Statistical significance was defined as $P<0.05$.

Results

Interval to resumption of cyclic activity

By Day 720, 47/51 (92.2%) mares had resumed cyclic activity with a mean interval of 417.8 days (s.d. ± 23.9; range 232–488 days, median 344 days). The remaining 4 mares (all Category 1) were still in anoestrus.

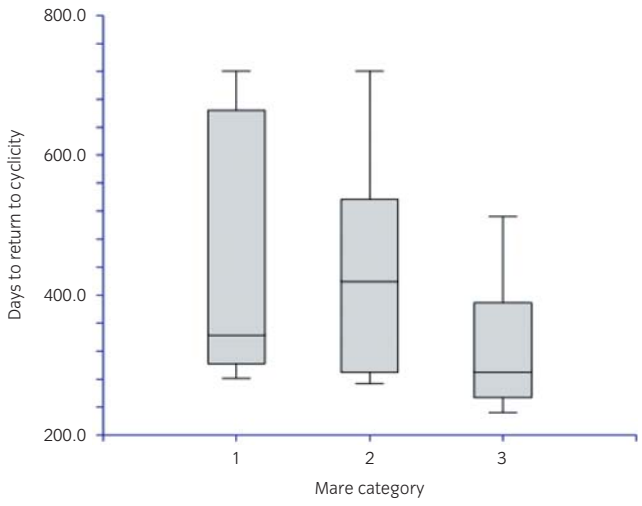

Fig 1: Box plot of days to return to cyclicity for different age categories of mares. Category 1 (≤4 years, n = 25), Category 2 (5–10 years, n = 16) and Category 3 (≥11 years, n = 10).

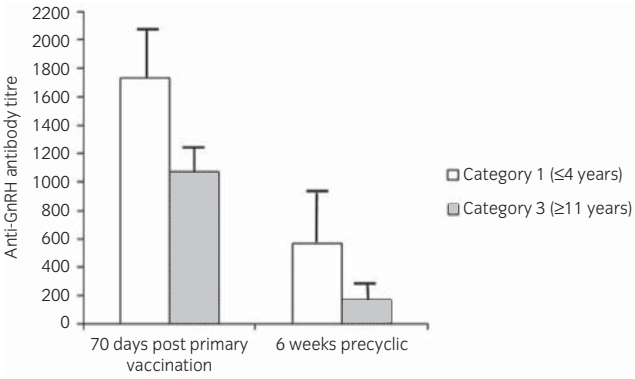

Fig 2: Mean (s.e.) gonadotrophin-releasing hormone (GnRH) antibody titres for selected mares in Categories 1 and 3 at 70 days post primary vaccination and 6 weeks prior to resumption of cyclic activity.

Effect of age on resumption of cyclic activity and GnRH-antibody titres

The median interval in Category 1 was significantly greater than in Category 3 mares ($P = 0.028$) (Fig 1). The mean anti-GnRH-antibody titres of 6 mares randomly selected from each of Categories 1 and 3 at 70 days post primary vaccination and at 6 weeks prior to resuming cyclic activity showed no significant difference (Fig 2) although mean titres were higher at both intervals for Category 1 mares.

Discussion

In previous GnRH-vaccine studies, animal numbers were either small or monitoring discontinued before most had reversed. Dalin *et al*. [8] treated 3 mares with GnRH-bovine serum albumin-conjugate vaccine, 2 responded with reversal at 13.5 and 15 months after primary vaccination, respectively. Imboden *et al*. [10], treating 9 mares with Improvac[a], reported down-regulation of ovarian activity in all mares, but no reversibility in 4 mares within a 2-year period. Elhay *et al*. [11] reported using Equity[h] in 24 mares. No treated mare exceeded anoestrus SPC threshold levels at 20 weeks and ovarian shutdown lasted 4–23 weeks in 10/16 mares. The other 6 mares remained inactive at the end of the 29–34 weeks observation period. Killian *et al*. [13] comparing contraceptive methods, treated 15/43 mares with a single-shot GnRH-vaccine (GonaCon). The rates of contraception in these mares decreased from 94–40% between years 1–4, but time to resumption of cycling was undetermined.

The resumption of cyclic ovarian activity was used to monitor the reversibility of anoestrus induced in all mares following Improvac[a] administration. By Day 720, all but 4 mares (all Category 1) had resumed ovarian activity with a median interval of 344 days. The effect of vaccination on subsequent reproductive performance in these mares was not observed. A significant effect of mare age on reversibility was found between the oldest and youngest categories. Stout and Colenbrander [2] similarly reported 2 treatments of GnRH-tandem-dimer vaccine suppressed testosterone secretion in young sexually-mature stallions whereas older stallions generally required further boosters. In this study, although anti-GnRH-antibody titres were not significantly different between youngest and oldest mares, the mean titres were higher for the youngest and may explain their later return to cyclic activity.

In conclusion, variable reversal of anoestrus was shown in 92.2% of mares within 2 years after vaccination with Improvac[a]. Older mares showed significantly earlier resumption of cyclic ovarian activity than the youngest mares.

Conflicts of interest

No conflicts of interest have been declared.

Source of funding

The Equine Research Centre of the University of Pretoria funded the study.

Acknowledgements

We express our gratitude to the South African Police Services for the provision of horses and to their personnel for valuable contributions during the course of this study.

EVJ BOOKSHOP

Equine Reproduction 2nd edition

Editors: A.O. McKinnon, E.L. Squires, W.E. Vaala and D.D. Varner

Publisher: Wiley, January 2011 • Hardback, 3288 pages

Now in a much-anticipated two-volume new edition, this gold-standard reference stands as the most comprehensive and authoritative text on equine reproduction. Serving theriogenologists, practitioners and breeders worldwide as a one-stop resource for the reproductive assessment and management of equine patients, Equine Reproduction, Second Edition provides detailed information on examination techniques, breeding procedures, pregnancy diagnosis and management, reproductive tract diseases and surgery, and foaling. For this new edition, the stallion, mare and foal sections have been thoroughly updated and revised to include the latest information on every subject.

EVJ price: £247.49 plus p&p
BEVA member price: £222.75 plus p&p

New topics include discussion of nutritional and behavioural factors in the broodmare and stallion, parentage testing, fetal sexing and the health and management of older foals, weanlings and yearlings. Additionally, this edition features a new section on assisted reproductive techniques, including detailed information on artificial insemination, *in vitro* fertilisation, embryo transfer and technology.

CONCURRENT SESSION #5 (UNGULATES/MONKEYS)

WHITE-TAILED DEER ACTIVITY, CONTRACEPTION, AND ESTROUS CYCLING

STEPHEN A. SHUMAKE, U.S. Department Animal Plant Health Inspection Service, Animal Damage Control, National Wildlife Research Center, 1716 Heath Parkway, Fort Collins, CO 80524-2719

GARY KILLIAN, Dairy Breeding Research Center, Pennsylvania State University, University Park, PA 16802

Abstract: Reliable activity measures in free-ranging white-tailed deer could be useful for the assessment of estrous cycling and general activity changes that can occur after immunocontraceptive vaccine treatments. Electronic data-logging (Countcard™) devices attached to 9 white-tailed doe deer on neck collars were used to monitor their movement activities during 2 rutting seasons in 2.5 acre fenced enclosures. Direct daily behavioral observations on buck responses toward individual does were used to detect estrus and to validate changes in 24-hour activity counts as another indication of estrous cycling. When individual activity counts for the estrus days on the does were compared to diestrus counts as estimated by mean values over days 10 through 15 post-estrus, a significant high product moment correlation of 0.946 was obtained indicating similar and proportional changes in activity under the 2 behaviorally-detected conditions. As predicted, mean activity counts for the estrus days were significantly higher ($P<0.0039$) than the mean counts for the diestrus days. This indicated some potential utility for the devices as sensors for estrus detection. Even though the individual deer showed different activity baseline levels and a high degree of daily variation, estrus days were frequently characterized by minor peaks in the daily activity counts followed within a day or a day and a half by a sharp activity decline, an indication that the does were at this point receptive to mounting by bucks.

Key Words: deer activity, contraception, data-logger, estrous cycle, *Odecoileus virginianus*

Control of localized white-tailed deer (*Odecoileus virginianus*) populations using immunocontraceptive treatments is a potentially attractive wildlife management technique in terms of social acceptance, humaneness, and feasibility (Kirkpatrick and Turner 1991; Turner, Liu and Kirkpatrick 1992; Turner, Kirkpatrick and Liu 1996; Mc Shea, Wemmer and Stuwe 1993). In some areas of the Northeastern and Midwestern U. S., hunting and other management methods have failed to stem deer overpopulation levels. As a result, damage to fruit trees, vegetable gardens and ornamental plantings; automobile and ground aircraft traffic hazards; and the spreading of Lyme disease from ticks have been identified as deer-related problems. In newly sub-divided rural areas adjacent to urbanized cities, individual land owners are often opposed to hunting as a deer management method, and prefer to apply repellents or to alter habitats. Because these

methods may achieve only temporary or partial reduction of the deer-related problems, immunocontraception is viewed as an attractive possibility for a more permanent solution.

Although Porcine Zona Pellucida (PZP) treatment has been demonstrated to be a highly effective immunocontraceptive for preventing pregnancies in white-tailed deer, treated does also show extended estrous cycling beyond the normal rut season (Turner et al. 1992; Shumake and Wilhelm 1995) and 3 or 4 extra cycles are not uncommon. Gonadotropic releasing hormone (GnRH), on the other hand, will generally reduce reproductive behaviors in both sexes with extended treatment leading to regression and atrophy of the gonads (Kirkpatrick and Turner 1991). The overall effects of the absence of estrus in does on buck behavior have not been fully documented.

Bucks are normally attracted to powerful chemosignals generated in does at the time of estrus (Murphy et al. 1994) and their behavior toward individual does can be used to detect receptive animals. It may be also possible to detect the time of estrus in individual does by either a slight change in doe body temperature or movement activity as is the case with dairy goats and cows (Doherty et al. 1987; Redden et al. 1993). The objectives of the 1995-1996 study were: (1) to evaluate the effects of PZP treatment on buck pursuit/mounting/copulation, and (2) to determine whether neck-collar-mounted Countcards™ could be used to detect behavioral estrus in PZP-treated does. Objectives of the 1996-1997 study were: (1) to compare the effects of PZP treatment in 4 previously dosed does with 4 control does treated with vehicle only, and (2) to evaluate the neck-collar-mounted count card sensors on both PZP-treated and control doe deer. Detection of estrus in the white-tailed doe deer was accomplished by observing the behavior of bucks housed in enclosures with small doe herds at the Deer Research Facility during 2 rut seasons. Statistical correlations and comparisons between the movement activity counts for individual does during detected estrus and the counts for diestrus days were performed. This allowed an assessment of the Countcard™ data logger devices as a potential means of estrus detection.

STUDY AREA

Both studies were conducted at the Pennsylvania State University Deer Research Facility, University Park, PA. The facility consists of a 22 acre enclosure with high fencing for the captive management and propagation of white-tailed deer. The area is further divided into 9 paddocks or sub-enclosures, each separated by 8 ft (2.44 m) diamond mesh wire fencing, and topped with 3 strands of barb wire. A centrally-located runway building is used for handling, weighing, blood sampling, injecting, and examining the animals. The first study extended over 107 days from November 8, 1995 through February 22, 1996. The second study lasted 86 days from November 8, 1996 through February 3, 1997.

METHODS

Observation Procedures

To detect behavioral signs of estrus in each of the does for the 1995-96 rut, observations were made by trained staff twice per day from 0800 to 0900 EST and from 1600 to 1700 EST. In addition, reproductive behaviors were observed at other hours during the day by Deer Research Center staff. Individual does were identified by their ear tag colors and by numbers. For does with similar tag colors, a small patch of hair was shaved on unique areas of their bodies. The complete list of tag numbers, colors, and shave marks was made available to all observers. Animals were identifiable from a minimum of 20 yards from all locations within the 2.5 acre paddock.

For the 1996-97 rut, observation procedures were identical to those described for the previous year's rut. All animals were observed 3 times per day over 1-h intervals (0800 to 0900, 1130 to 1230, and 1600 to 1700 EST) throughout the 86 days of observation. Individual doe interactions with the bucks were again recorded on data sheets in the pen enclosure and periodically on videotape recordings for later comparisons of activity and behavioral signs of estrus in the does as extrapolated by buck interest.

Data Logger Devices

Countcard™ devices are credit card sized data logger units that can be preprogrammed to automatically sense and record daily movements. The devices are normally used to monitor automobile and truck highway traffic and are imbedded into the road surface. Operational detection is achieved by disturbances in the earth's magnetic field forces as the vehicles pass over the device. The Countcard™ units will, however, also register movement counts when they are moved themselves. Data generated in this manner are based on discrete episodes or bouts of movement activity. In other words, rapid movement of the devices without interruption will not register high activity counts, but repetitive stop-and-start movements are registered. This use of the devices has some advantage in terms of filtering some forms of rapid activity (e.g. scratching), but also has a disadvantage of not registering extended movements (e.g. long distance running) unless interrupted by pauses. A method for mounting the devices inside of plastic project boxes (Radio Shack®, Tandy Corp., Fort Worth, Tex.) and then onto neoprene deer collars (Advanced Telemetry Systems, Isanti, Minn.) was developed for attachment to individual does.

Determining Behavioral Estrus

For the 1995-96 rut, does were equipped with model NC-30X Countcard™ devices (Nu-Metrics, Uniontown, Penn.) and were previously treated with PZP vaccine in 1992, 1993, and 1994. They were not re-boosted with vaccine injections prior to the Fall 1995-96 rut. This initial deer herd size was 17, including 9 PZP-treated and 8 GnRH-treated does. Because no does in the GnRH group were instrumented with Countcard™ devices, their observed behaviors are not reported here. Of the PZP-treated does, 5 animals were monitored with devices (#0033, #0040, #0049, #228, and #327).

For each observation period, student observers entered the paddock, located the buck(s), and verified individual ear tags using binoculars. For the remainder of the observation period, the behaviors of 1 to 3 bucks and the responses of individual does were observed from the maximal distance that allowed animal identification. For each encounter in which the buck(s) showed an interest in a doe, rut behaviors were classified and recorded as one of eight categories as further described in Table 1.

Table 1. Eight categories of rutting behavior in white-tailed deer used to detect estrus in does.

Behavioral Category (Level)	Brief Description
No Interest 0	No male displays any interest in activities of a given doe. The doe is assumed to be in diestrus.
Following/Standing/Lying 1 within 8 yards	The buck visually orients in the direction of the doe and may exhibit urine sniffing and the Flehmen response. The buck and doe are observed together, either walking or bedding down, for a period of at least 15 minutes.
Short Pursuit 2	The buck follows the doe wherever she moves in the paddock, for a period of less than 2 minutes. While exhibiting this activity, the couple is frequently observed standing within 8 yards of one another.
Extended Pursuit 3	This is the same description as listed above for short pursuit, but the activity is continued over at least a 5 minute interval.
Aggressive Guarding/Pursuit 4	Highly aggressive behavior is shown by the buck toward any other male that approaches a doe in estrus. If the doe attempts to escape from this buck, the alpha male, he continually pursues her.
Female Stands for Male 5	This activity involves the buck licking the urogenital area of a receptive, estrous doe, with a mounting attempt. This is often accompanied with the buck resting his chin on the back of the doe. At this time, the alpha male aggressively defends the doe from pursuits of other bucks.
Mounting and Copulation 6	The doe allows mounting and copulation. Often, the doe will step out from under the buck on his first few mounting attempts. Actual mating lasts only 8-15 seconds and is therefore rarely observed.
Post Copulatory Posture 7	These postures exhibited by does typically follow a successful copulation, where ejaculation has occurred. The posture of the doe consists of a urination stance (legs spread, tail raised, and a hunched back). The buck may also urinate at this time.

All data were recorded manually and were documented on videotape. The recorded data sets were later analyzed to extrapolate the time periods in which each doe came into estrus. Repeated estrous cycling was a strong indication that the doe was not pregnant even though matings may have been repeatedly observed.

For the 1996-97 rut, student observers were employed again to make the 3, 1-h observations each day of the test. Inclement weather conditions as well as disturbances due to humans, dogs, and construction activities were noted each day in an attempt to account for potential aberrations in the doe activity. The same 8-category scale of buck interest toward individual does (Table 1) was used for detection of behavioral estrus in each instrumented animal. Countcard™ collars were installed on 8 deer. Five of the animals (i.e., #0001, #0040, #0049, #139, and #228) had been previously treated with the PZP vaccine but had not received booster vaccinations since 1994, and 3 of the animals (i.e., #661, #793, and #8108) had never received the PZP vaccine treatment. Animals were included as a part of a herd of 18 does penned together in a single enclosure with 1 to 3 bucks.

Data Analyses

Descriptive analysis involved tabulation of the number of estrous cycles observed in each doe treatment group. For the 1995-96 rut, final fawn birth data were tabulated by July 19, 1996, for comparisons of contraceptive efficacy among treatments. To evaluate the degree of proportional changes in movement activity counts for behaviorally-detected estrus versus diestrus days, correlation analyses were performed. Differences in the daily movement activity count means for the estrus versus diestrus conditions were compared with Student paired t-tests and Wilcoxon signed rank tests to assess the potential of using doe movement counts to serve as a supplemental method of estrus detection.

RESULTS AND DISCUSSION

1995-96

Data for the 1995-1996 rut were obtained from only 3 of the 5 Countcard™ devices on the collared does (#0033, #0049 and #228) when down-loaded manually or via computer through the serial port. Reasons for failure to obtain movement activity count data on does #0040 and #327 remain obscure. Reasons were probably not related to battery failure, but were most likely due to programming errors since the obtained outputs were in the form of counts per hour rather than counts for the previous 24-h period. Neither of these 2 does showed signs of estrus as detected by observation of buck behavior after November 23, 1995. Table 2 is a summary of the number of estrus cycles as detected by buck behavior directed toward the 3 does that yielded movement activity count data over the 107-day observation interval. Countcard™ movement activity data for selected observation days when estrus was detected by buck behavior are included along with the mean movement count values for days 10 through 15 post-estrus (diestrus). Daily changes in the movement counts, particularly for does #049 and #0033, indicated that a sharp increase or peak in activity did not necessarily correspond with an estrus day as detected by observers. With deer #228, there was an indication of a brief increase in movement activity counts followed by a sharp decrease. This would be a predicted pattern since the bucks normally show extended pursuit toward does in early estrus followed by a reduced movement of the does when they stand for the buck as he attempts to mount and copulate. In other words, when deer #228 was most receptive and allowed mounting, she also became relatively less active. The remaining 4 non-instrumented does showed up to 2 extra cycles with the last sign of estrus observed on February 11, 1996.

Of these 9 PZP-treated deer, 3 became pregnant and all had produced fawns by June 3, 1996. Deer #0033 produced a male and a female fawn on May 21, 1996 even though only the short pursuit category (level 2) of buck interest was observed and mounting attempts were never observed. Deer #327, also instrumented with a Countcard™, produced 3 female fawns but, unfortunately, no movement activity count data were obtained for this animal. The remaining doe, #16B, produced a single female fawn.

1996-97

During the 1996-1997 rut, count data were obtained for 3 control does (#0062, #661, #8108). There was again an indication of an increased movement activity count on the day that estrus signs were recorded by student observers as indicated in Table 2. Based on the 5-day means for the putative diestrus interval, there was an approximate 20 to 25 percent decrease in movement activity 10 days post-estrus.

Movement activity counts for does #661 and # 8108 reflected a high degree of variance within and between the untreated does. For example, whereas #661 showed extreme lapses of activity down to <1000 counts/day (i.e., days 2, 6, 7, 8, 11, 12, 14, 20

etc.), #8108 was more stable and never produced <4750 counts/day throughout the observation interval. At the time of this writing, the pregnancy rate for these animals as indicated by fawn births was unknown for this season, but no estrus signs for the 3 control does were recorded after the date of November 24, 1996 (i.e., Day 16).

PZP-treated animals that had not received booster immunocontraceptive vaccine for the past 3 years still continued to show repeated estrous cycling. There were 4 cycles detected for #0040, and all animals (i.e., #0001, #0040, #0049, #139, #228) showed estrus signs (as indicated by buck behavior) through the month of January, 1997 (i.e., Day 67). As with the previous year's rut, buck pursuit generally produced an increase in daily movement activity counts of does when estrus signs were first detected. The advanced categories of buck interest (e.g., mounting, aggressive guarding, copulation) were again sometimes correlated with generally below average daily activity counts. This pattern in doe activity at estrus was fairly consistent and repeatable within and between animals. For several animals (#0001, #0040, #139, and #228) pursuit responses by bucks produced higher daily counts followed within a day by lower counts when the does allowed buck mounting and copulation. The daily activity counts for deer #228 (Figure 1) exemplify the pattern of peaks followed by sharp declines that correspond with signs of estrus as recorded by the student observers.

Comparison of Movement Activity Counts and Estrus Detection

Assuming a nominal value of 25 days between estrus cycles for white-tailed deer, a 12-day post-estrus interval is a logical period of elapsed days for taking a 1-day sample of activity during diestrus. The prediction can be made that there should be consistently less movement activity (i.e., fewer proportional counts) on day 12 post-estrus when compared to the counts on the estrus-detected day. However, this was not confirmed by our data sets when a Pierson product moment correlation coefficient was calculated for the 9 collared animals. The r value was 0.3787 (not significant). However, both a Student paired t-test (T = 3.02, df = 8, P<0.0165) and a Wilcoxon signed rank test (P<0.004) on the data sets detected reliable differences between the 2-sample counts for each animal. Whereas the mean for diestrus days was 4718.0 Å 3304.3 and the mean for estrus days was 8224.5 Å 2665.7, the individual animal variation lowered the correlation value. With a low n of only 9 does, 1 or 2 animals with extremely low counts during diestrus can degrade the correlation coefficient value.

On the other hand, when a 5-day mean of the daily movement counts for days 10 through 15 post-estrus was used (instead of the 1-day count for 12 days post-estrus), a significant correlation was achieved ® = 0.946; T = 7.722, df = 7, P<0.00011). A paired t-test on the data set for estrus counts compared to the 5-day means for diestrus counts was significant (T = 6.187, df = 8, P<0.00026) as was a Wilcoxon signed rank test (P<0.0039). This 5-day-mean-count procedure tended to dampen the extremes for 2 does that showed disproportionately low counts during some days during the diestrus stage and thus improved the consistency of proportional activity changes. Both procedures were also influenced by 1 doe that had extremely low counts during both estrus and diestrus. Figure 2 shows a scatter plot of the correlated count measures using the mean-count procedure. Influences of other more subtle effects such as rain, snow, temperature, and human disturbance were also, at times, evident in the data set with some animals more sensitive than others to these disturbances. Despite these uncontrolled extraneous factors, a moderately consistent pattern of movement activity changes was detected in the data sets.

The consistent proportional decrease in movement activity counts for estrus days versus corresponding 5-day mean diestrus days ® = 0.946) implied that 89% of the count variation was accounted for by estrous cycling. If baselines for individual doe activity levels could be also factored into a detection equation algorithm, the activity data could become a useful additional means of detecting estrus in deer. A moderately high degree of predictive power for detection of estrus has been previously reported using body temperature and pedometer measurements in dairy cows (Redden et al. 1993). With captive white-tailed deer in small herd situations, a peak in activity followed by a sudden and sharp drop within 1 or 2 days of the peak may be a likely candidate for comparison with a 5-day mean estimate value for a potential diestrus interval. Variability between does and within the same animal was, however, a limiting factor in the predictive power and more experimental data will be needed to fully assess the potential of the devices. Studies will be continued in the Deer Research Facility pens and may be extended to field testing if results appear encouraging. Whether the Countcard™ devices could be useful for estrus detection in free-ranging field situations is unknown. However, the deer-movement effects of other management tools such as buffer-fencing, hunting to thin herds, or habitat modification probably could be monitored using these kinds of data logging devices. Devices are in fact available that would allow for deer movement activity monitoring with radio telemetry and remote down-loading of the data. These systems are, however, currently quite expensive (i.e., $2000 per doe vs. $250 per doe for Countcards™). This would either limit the number of does that could be monitored when working within a reasonable research budget or could easily become cost prohibitive when aircraft radio-tracking and other expenses are included.

Abstract

Changes in rabbit ovarian hormonal responses and cellular differentiation of ovarian follicles after immunization with porcine zona pellucida (ZP) have been examined. Steroid and peptide hormone levels were monitored after immunization to evaluate ovulation and pseudopregnancy cycles in immunized and control animals. All immunized rabbits developed serum antibodies to specific ZP antigens and failed to form functional corpora lutea in response to hCG administration, as evidenced by the absence of elevated serum progesterone concentrations. This is in contrast to control rabbits, which had elevated progesterone levels 8–9 days after hCG administration. Furthermore, all immunized animals showed greatly increased serum levels of FSH and LH compared to those of control animals. These effects on ovarian function were apparent within 20 weeks of the primary immunization. Follicular development was analyzed by light and electron microscopies.

The numbers of primary, secondary, and tertiary follicles in ovaries of immunized animals were markedly reduced within 7 weeks compared with control values. By 23 weeks, few if any growing follicles were present. Although numerous distinct clusters of cells with ultrastructural properties that resemble those of normal follicular cells were present in immunized animals, they contained no oocytes. These studies suggest that antibodies to ZP glycoprotein alter ovarian function by interfering with cells during the stage of follicle differentiation at which the ZP proteins are being synthesized and secreted. This system should provide an excellent model with which to study the early events associated with ovarian follicular cell differentiation and subsequent hormonal responsiveness.

Preface

During the last century, the number of African elephant (Loxodonta africana) declined dramatically as a result of over-hunting, poaching for ivory and, more recently, the loss of habitat area due to encroachment of the human population. In some areas, however, the trend to declining numbers was reversed after the elephant was placed on Appendix 1 of the Convention for International Trade in Endangered Species (CITES) and a worldwide ban was imposed on the sale of ivory. Unfortunately, the resulting recovery in elephant numbers within both National and privately owned game parks poses a threat to the survival of many other species. Indeed, when elephant numbers exceed the carrying capacity of a game park, the gradual destruction of vegetation and habitat is catastrophic and, if left unchecked, is only arrested when the elephants themselves begin to die of starvation. Over the last 30 years, it became generally accepted that the best way to prevent this boom-and-bust scenario and, in addition keep epidemic diseases under control, was to maintain elephant numbers below the carrying capacity by culling. During the 1990s, however, popular opinion turned against culling as a means of controlling elephant populations and the focus shifted instead to translocating animals from areas of high to areas of low population density. Self-evidently, while relocation may be a useful way to control elephant numbers in relatively small parks, it is unrealistic to expect to relocate thousands of animals per year to keep the population under control in the large parks, for example, in northern Botswana.

Of course, the best method for controlling population growth depends critically on the size and rate of growth of that population and, in this respect, it has been proposed that contraception may offer an alternative to relocation or culling in relatively small parks with a limited number of elephants. However, while the first experiments to examine the efficacy of immune contraception in female elephants have offered promising results, and preliminary experiments to modulate the behaviour or fertility of bulls have also begun, there are as yet no agents proven to be reliable, effective in field conditions and without significant side effects. The aim of this workshop is to discuss the current policies for controlling elephant numbers and to assess the suitability of newer strategies being developed to address this problem. Given the increasing interest in pharmacological means of controlling population size, it is hoped that experiences with various compounds in other species may help to indicate the approaches most likely to be applicable to the African elephant. It is also hoped that this workshop will stimulate collaborative research projects to identify the best approach to population control in a given situation, and to develop the means to implement that plan safely and effectively. This information may come to provide a valuable source of support when the management decisions required to ensure the health and viability of a game park and its elephant population are complicated by politics.

It goes without saying that a workshop of this nature would have been extremely difficult to organise without financial support from The Prince Bernhard Nature Fund. I would also like to offer my sincere thanks to Mr. Paul Fentener van Vlissingen for his foresight in proposing this initiative and his interest in nature conservation in Africa.

Induced abortion to control population increases in African elephants

WR Allen[1] and SS Stout[2]

[1]University of Cambridge, Department of Clinical Veterinary Medicine, Equine Fertility Unit, Mertoun Paddocks, Woodditton Road, Newmarket, Suffolk, CB8 9BH, UK;
[2]Faculty of Veterinary Medicine, Utrecht University, Yalelaan 1, 3584 CL Utrecht, The Netherlands

Morphological, histological and histochemical examinations, and hormone precursor incubations, of biopsies of placenta, gonad and fetal liver recovered post mortem from 59 pregnant elephants carrying conceptuses estimated, on the basis of fetal weight, to be between 20 days and 21 months of age, showed:

1. A zonary placenta encircles the equatorial region of the ovoid unicornuate conceptus. It is endotheliomonocytochorial in structure and consists of intensely folded or pleated lamellae. They contain maternal capillaries that are closely invested by a mononuclear trophoblast layer which is itself closely invested by fetal capillaries. The placental zone is attached to the endometrium only by a remarkably narrow fibrous pedicle through which all the maternal blood vessels pass to vascularise the maternal side of the fetomaternal interface. A haemophagous region forms at the lateral edges of the placental zone in which phenotypically specialised trophoblast cells phagocytose leaked maternal red blood cells.

2. Between 2 and 5 large, plum-like corpora lutea persist in one (usually) or both (occasionally) ovaries throughout pregnancy. These are present from the earliest stages of gestation and are appreciably bigger (3-5 cm diameter) than the biggest (1.5 cm diameter) follicle observed at any stage of the oestrous cycle or pregnancy. However, no form of chorionic gonadotrophin (CG) is detectable in elephant placenta.

3. Incubation of placenta and fetal gonad, alone and in combination, with radioactively labelled steroid hormone precursors showed that whereas the enlarged fetal gonads are capable of synthesising progesterone and other progestagens from cholesterol or pregnenelone, the placenta itself is unable to synthesise any progestagens and it does not possess any aromatising capacity to synthesise oestrogens.

This endocrinological inertia of the elephant placenta suggests the likelihood that the maintenance of pregnancy in this species is entirely dependent upon luteal sources

of progestagens. Hence, it would be reasonable to expect that, as in some large domestic animal species, uncomplicated abortion induced by luteolysis would follow the administration of a prostaglandin F analogue at any stage of pregnancy. If so, a single intramuscular injection of PGF analogue delivered by dart gun could perhaps constitute an efficacious method for controlling unwanted increases in maintained elephant populations. However, intramuscular administration of cloprostenol (Estrumate; Schering-Plough, Middlesex, U.K.) on each of 3 consecutive days to a young Indian elephant at 6 months of gestation caused a rapid but temporary decline in urinary pregnanediol concentrations and the pregnancy continued unscathed. Hence, further research is necessary before induced abortion could be considered as a means of preventing unwanted births in elephants.

Contraception of African elephant cows in two pivate conservancies using porcine zona pellucida vaccine, and the control of aggressive behaviour in elephant bulls with a GnRH vaccine

Contraception of elephant cows with pZP vaccine

Previously, Fayrer-Hosken et al. (1999) demonstrated that the pig and African elephant share zona pellucida epitopes, and suggested that it should be possible to use porcine zona pellucida (pZP) proteins as the basis of a contraceptive vaccine for elephants. Two subsequent field trials performed in the Kruger National Park proved that pZP vaccine is an efficacious contraceptive treatment for female elephants (Fayrer-Hosken et al. 2001); further studies are continuing in two smaller populations of elephants in private game reserves.

Makalali Game Reserve

When the first pZP vaccination programme commenced in May 2000, the total elephant population in Makalali Game Reserve stood at 66, including 16 adult and seven 9-12 year-old cows. The vaccine was manufactured at The Science and Conservation Centre of ZooMontana, USA. The primary vaccination (600 µg) was administered in Freund's modified, and boosters (400 µg) in Freund's incomplete, adjuvant. Initially, 18 cows were immunised using a primary course of three injections administered at 3-week intervals via dropout darts shot from the ground. The darts were retrieved to confirm discharge of the vaccine, and behavioural patterns returned to pre-darting patterns within two days. During 2001, all of the immunized cows were 'boosted' with a single injection, while a further two cows were treated with a 3 injection primary course and added to the trial group. The following year, 3 new cows were given a single primary vaccination, and the rest were boosted. In 2003, all of the immunised cows were boosted; 17 were darted from a helicopter and the rest from the ground.

The effects of the contraception programme to date are shown in Table 1. In summary, no calves have been born to matings dating from after the commencement of vaccination. Bearing in mind that the average inter-calving period in the Lowveld is ± 4 years, contraception has therefore definitely been achieved in 5 cows (their calves are now 5-6 years old). In addition, four cows were immobilised and examined

for pregnancy using ultrasound in July 2003; none were pregnant, and blood progesterone concentrations suggested very little or no luteal activity. The next two years will provide a lot more information with respect to the efficacy of contraception. The safety of pZP vaccination during pregnancy was confirmed by the fact that 14 cows immunised during months 2-21 of gestation subsequently gave birth to normal healthy calves at term. One of the criticisms levelled at the use of pZP-immunocontraception, is that it may lead to an increased number of matings and presence of bulls. This has not been the case in Makalali. During 2002, only five cows were observed to be in heat, and two were mated. Their calves were 14 and 18 months and 3½ years (x 3) old at the time.

Mabula Game Reserve

Mabula Game Reserve has a herd of 9 elephants, including one sub-adult and 3 adult cows. The details of vaccination are provided in Table 2. As the project is only

18 months old, it is too early to assess the contraceptive effects of the vaccine.

Controlling aggressive behaviour in elephant bulls using a GnRH vaccine
Both captive and free-ranging elephant bulls can present serious management problems if they display aggressive behaviour, either in or out of musth. They can so endanger the lives of other animals and people, that trained elephants usually have to be removed from work programmes and restrained to an extent that may become a welfare issue. As there is currently no proven practical way of controlling musth, culling often constitutes the only solution to free-ranging problem bulls. However, both musth and aggressive behaviour appear to be related to high concentrations of testosterone, and a project is currently underway to test the effects of a GnRH vaccine on testosterone secretion and behaviour, with a view to developing the vaccine as a means to control musth and aggressive behaviour in elephant bulls.

The vaccine (GnRH-tandem-dimer conjugated to ovalbumin, Pepscan Systems, The Netherlands) will be administered with either the Montanide ISA 51 or Covaccine adjuvants (Oonk et al. 1998). Five elephant bulls will be injected with 2 mg GnRH plus adjuvant by darting, 3 times at 3-week intervals. In addition, two control bulls will be darted with adjuvant only. From a few weeks prior to the first vaccination until 4 months after the last injection, faecal samples will be collected weekly, and testosterone secretion monitored via an EIA for faecal epiandrosterone. Over the same period, sexual and aggressive behaviour will be monitored.

In fact, the first elephant bull has already vaccinated at Johannesburg Zoo. This bull has been exhibiting aggressive behaviour and temporal gland secretion for a considerable time. Four vaccinations using the ISA 51 adjuvant have been administered, and the faecal epiandrosterone profile following the first two vaccinations is shown in Figure 1. Although, during this period, no change in the faecal epiandrosterone profile was apparent, the elephant has displayed calmer episodes after each vaccination and has shown a reduction in temporal gland secretion. This effect was more marked after the 4th vaccination, while no side effects have been noted. Subsequently, a further one and three bulls have been vaccinated three times and once, respectively.

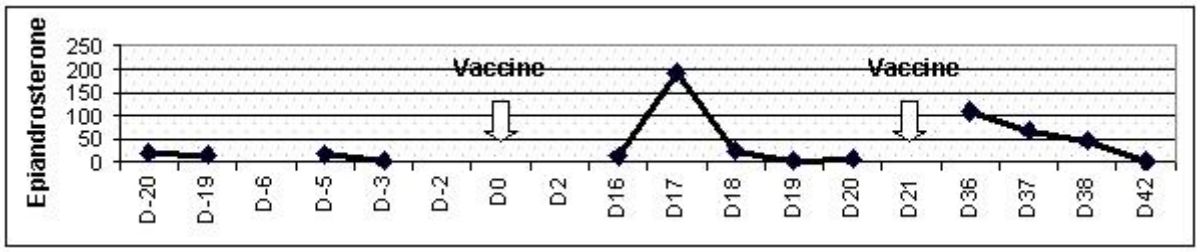

Fig 1: Faecal epiandrosterone concentrations (ng/g dry faeces) in a bull elephant before and after the first two vaccinations against GnRH

Epididymal approaches to contraception

TG Cooper and C-H Yeung

Institute of Reproductive Medicine, Domagkstrasse 11, University of Münster, D-48129 Münster, Germany

The epididymis performs a variety of functions, notably transport, maturation, storage and protection of spermatozoa (Cooper 1999). It is the cause of some cases of infertility and provides an attractive target for male contraception. However, to know if epididymal contraception is relevant for elephants it must first be ascertained whether these animals do indeed have an epididymis. Short et al. (1967) stated that “The elephant does not have an anatomically distinct epididymis”, and some years later Jones et al. (1974) agreed that there was no regional demarcation of the paired genital duct of the male African elephant comparable to its differentiation in scrotal mammals. Subsequently, Jones (1980) showed that many aspects of sperm maturation do indeed occur in the elephant’s organ, thereby concurring with the earlier work of Glover (1973) that “signs of sperm maturation occur in the epididymis of testicond mammals” and that the cauda epididymidal sperm store is near the exterior.

Assuming that the elephant’s epididymal physiology is similar to that of scrotal mammals; namely, that the maturing spermatozoa are influenced by the nature of secretions in the luminal fluid bathing them, three basic approaches to the design of a contraceptive to act on this organ become apparent (Cooper 2002): (i) alteration of the time of contact of spermatozoa with secretions, via peritubular contractions and alteration of transit times; (ii) interference with the composition of luminal fluid by inhibiting synthesis, transport, function or availability of secretions and (iii) attack upon sperm-specific/sensitive pathways.

Studies in rats have examined the effects of local or systemic cholinergic, adrenergic and purinergic agonists and antagonists, and peptides that either increase or decrease sperm transport through the epididymis. Where examined, fertility was not always affected, but in no case was an entire population of treated rats infertile. Those animals that were, displayed only subfertility.

Theoretically, elimination of an epididymal secretion involved in the (epididymal) acquisition of the spermatozoon’s fertilising capacity should have a contraceptive effect. However, the number of secretions with a known function is limited, although such a role could be proposed if inhibitors were to cause infertility. Few such experiments have been conducted, but it has been shown that neither drastic reduction of the epididymal content of carnitine nor abolition of glucosidase activity in

the rat epididymis cause infertility. Surprisingly, despite the paracellular blood-epididymis barrier, immunisation against epididymal secretions (CRISP, P26h) have led to reduced fertility or complete infertility in rats, mice and hamsters, possibly by entry of immunoglobulins into the efferent ducts or by a transcellular vesicular route.

Initially, the most promising approach to functional sterility was employment of chlorinated antifertility compounds to inhibit sperm glycolysis, which depended on two facts; 1) that spermatozoa preparing for fertilisation are more dependent upon glycolysis than respiration for the production of energy, and ii) that glycolytic enzymes in spermatozoa differ in structure from those in somatic cells. For example, sperm glyceraldehyde 3-phosphate dehydrogenase (GAPDH) has an additional domain involved in anchoring the enzyme to the axoneme, by which ATP would be produced directly at its site of utilisation. Chlorinated antifertility compounds such as α-chlorohydrin and ornidazole produce chlorinated structural analogues of the substrate of GAPDH which inhibit the enzyme. Although, when fed at antifertility doses, α-chlorohydrin and ornidazole had no toxic effects on rats over a period of 1 – 2 years (Jones and Cooper 1999), at the higher doses required for toxicological evaluation, central nervous effects were induced. To circumvent this problem, novel chlorinated compounds were synthesised that should generate, by the process of glycolysis itself, the same chlorinated inhibitor of GAPDH produced from α-chlorohydrin and ornidazole. Such “suicide” compounds were shown to be effective in vitro at inhibiting glycolysis and modulating motility of spermatozoa from rats, mice and men but they failed to induce infertility in rats as a result of dechlorination and urinary excretion. Compounds are being synthesised that should be rapidly accumulated within the epididymal lumen, thus avoiding excretory loss and dechlorination and limiting toxic side effects.

The difference in osmotic pressure between the male (high) and female (low) gamete tracts has long been known, but its significance has only recently been appreciated. Observations on certain infertile transgenic male mice have highlighted the importance of volume regulation in fertility, because spermatozoa that fail to regulate their volume cannot pass the uterotubal junction. The abnormal volume regulation exhibited by spermatozoa from infertile male mice reflects a failure in volume regulation, considered to result from insufficient intracellular osmolytes that are normally lost, together with intracellular water, to counter swelling that occurs as the spermatozoa enter the hypotonic fluids of the female. The epididymis has been hypothesised to provide osmolytes to spermatozoa during epididymal transit (Cooper and Yeung 2003), so that the reduced intrasperm osmolytes in the infertile males would reflect reduced provision of osmolytes by the epididymis which, in the infertile males, is abnormal due to the lack of the initial segment. Specifically, a glutamate transporter expressed in the initial segment is down-regulated in the knockout male and, as a consequence, less glutamate is present in epididymal spermatozoa. Other epithelial transporters are up- or down-regulated in this animal model and the

osmolyte and their channels are currently being sought in spermatozoa.

The infertility of some domestic animals that exhibit spermatozoa with a similar phenotype to that of the c-ros knockout male (e.g. Dag defect; Cooper 1992), suggests that poor sperm volume regulation could underlie unexplained infertility. Furthermore, as swollen human sperm display altered motility patterns and reduced entry into artificial mucus, it is likely that targeting either epididymal transporters so as to modify luminal fluid, or sperm channels to block osmolyte influx or efflux, could be a new, post-testicular, contraceptive approach for man as well as the elephant.

To date the studies on post-testicular contraceptives have involved daily oral administration so that rapid onset of action and reversal after withdrawal can be appreciated. While this regimen may be convenient for man, there is no reason why, like hormonal contraceptives, the post-testicular variety could not be formulated so as to be delivered continuously from a slow-release depot.

Introduced brushtail possums (Trichosurus vulpecula) are major pests in New Zealand because of their impacts on conservation values, biodiversity and agriculture. Annually, about NZ$80 million is spent on spreading 2.5 tonnes of 1080 poison and increasing quantities of anticoagulants and other poisons. Currently, > 9 million hectares are under sustained possum control. Issues like ongoing costs, environmental contamination, non-target risks and changing public attitudes have driven research into alternative approaches, such as fertility control.

Fertility control research for possums is guided by a national strategy that is aimed at effecting long-lasting infertility and/or sterility in treated animals. Research on immunological blocks to fertility is focused principally on targeting proteins of the zona pellucida (ZP; Landcare Research), ovarian vesicle-associated proteins (AgResearch) and embryonic shell coat proteins (Melbourne University). An alternative approach is aimed at developing gonadotrophin-releasing hormone (GnRH)–toxin complexes that will target appropriate pituitary cells (AgResearch). Parallel research is underway on delivery, including mucosal immunology and uptake of materials from the possum gut. Genetically modified plants and bacterial ghosts are being assessed as potential oral vaccines. The potential for a combined vaccine based on BCG, that would immunise possums against infection with bovine tuberculosis and induce infertility simultaneously, is also being researched. Disseminating delivery systems are being investigated, with current focus on identifying and characterising possum viruses, and genetically modifying a possum-specific nematode parasite to express infertility-inducing proteins and/or epitopes.

Our research has concentrated on immunocontraception by targeting egg proteins of the zona pellucida (ZP). Trials of an injectable vaccine containing whole recombinant ZP3 and ZP2 proteins demonstrated 70-75% reduction in fertility of captive animals bred naturally or by artificial insemination. Immunisation with a ZP3 epitope that spanned the putative sperm-binding region resulted in a reduction of about 66% in the proportion of female possums that produced at least one embryo. Recent epitope mapping identified a ZP2 epitope which, on testing by injection, also reduced fertility significantly.

Two approaches are being taken to examine oral delivery of immunocontraceptives, by seeking expression of contraceptive antigens in transgenic plants, or bacterial ghosts. To date, immune responses, including antibodies detected in blood, reproductive tract secretions and in follicular fluid, have been demonstrated against a model antigen expressed in transgenic potato and Lucerne plants. Recombinant bacterial ghost vaccines expressing possum ZP3 stimulated humoral immune responses in serum, ovarian follicle fluid, and reproductive tract secretions in female possums when applied to mucosal surfaces of the eye and nose, or were administered orally. Cellular immune responses and effects on ovarian function and fertility following mucosal immunisation are now being assessed.

Finally, computer modelling based on field-derived parameter estimates of possum population dynamics has been used both to define minimum vaccine efficacy and to identify strategies for integration of fertility control baits and poison baits that are likely to produce benefits of reduced costs and reduced toxin use.

Immunomodulating GnRH to alter sexual and aggressive behaviour in the male: a bovine model

WJ Enright

Intervet International BV, PO Box 31, 5830 AA Boxmeer, The Netherlands

The rationale for several decades of research into immunocontraception and immunocastration of farm, domestic and feral animals has been discussed extensively (see text box: Bonneau and Enright, 1995; Enright, 1995; Enright et al. 1995; Meloen, 1995; Becker et al. 1999; Delsink et al. 2002). If developed properly, active immunisation regimens can be cheap, practical and effective ways of generating effective antibody titres against a target molecule; however, the immune response can vary considerably between animals and a lag period is inevitable before the biological response is observed.

Possible uses of immunomodulation in animals

- Suppression of oestrous behaviour in heifers, racing fillies, cats, dogs
- Reduction of aggressive behaviour in bulls, stags, racing or show-jumping stallions, wild elephants, tomcats, dogs
- Prevention of boar taint
- Reduction of fertility in feral horses, wild elephants, pest species (rodents, rabbits in Australia), disease carrying species (possums in New Zealand, badgers), cats, dogs
- Increased litter size in farm species
- Improved efficiency and leanness in farm animals

There are many factors other than inter-animal variation that determine the success of an active immunisation approach, including species, age, structure of the hormone/peptide, type of carrier molecule and adjuvant used, conjugation procedure, dose of antigen and adjuvant, molar ratio of hormone to carrier, and frequency and relative timing of immunisation (see Crowe et al. 1995).

(Dis)Advantages of bull beef production

Aggressive behaviour and libido can be a serious problem during the husbandry of male cattle. Post-pubertal bulls are difficult to handle, cannot be grazed near heifers, cause pasture damage and are a threat to human safety. These problems create management difficulties in all commercial beef systems, including grass-based extensive and intensive housing/feedlot systems. In addition, because of their high activity level, bulls have a greater tendency to yield bruised and dark-cutting meat at slaughter. To overcome these problems, in many countries male cattle are castrated using either the burdizzo or conventional surgical methods. However, while castration renders male cattle docile, it also decreases growth and feed conversion efficiency by 15%, and increases the fat content of the meat. The challenge is to therefore to

reduce aggressive behaviour while maintaining the performance advantages of bulls. Immunisation against GnRH has proven a promising approach.

Immunisation of pre-pubertal bulls

In an initial study, Finnerty et al. (1994, 1996) immunised 47 three-month (mo) old Friesian bull calves against GnRH using various GnRH conjugate doses, adjuvants and booster intervals (1 or 2 mo post primary injection). Immunisation decreased LH and testosterone (T) secretion for 2 to 4 mo after the booster; thereafter, LH and T returned to levels approaching those of control bulls. Immunisation also decreased the incidence of aggressive and sexual behaviour at pasture, but had no effect on growth. In a follow-up study, Finnerty et al. (1997a, b) confirmed that GnRH immunisation prior to puberty (injections at 3 and 5, 3 and 7, 3 and 9, 3 and 11 or 3, 5, 7, 9 and 11 mo of age) transiently reduced T in all 50 animals (e.g. Figure 1) and reduced aggressive behaviour until slaughter at 21 mo of age (although not quite to the level of control steers). When a primary and a single booster were used (e.g. 5 and 7 mo group), growth was similar to that of control bulls and much superior to that of steers. Repeated immunisation (3, 5, 7, 9, 11 mo group) resulted in aggressive behaviour similar to that of steers for the duration of the study, including the last week (see Figure 2), while growth rate was similar to control bulls and considerably better than steers. Immunised bulls showed reduced homosexual behaviour at pasture at 9-12 mo of age, although there was no consistent effect at later ages.

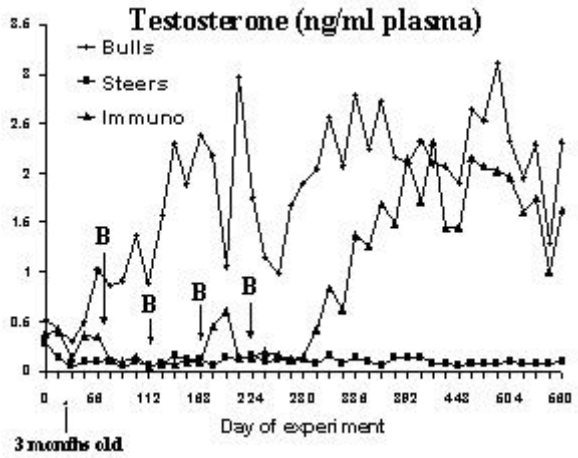

Fig. 1

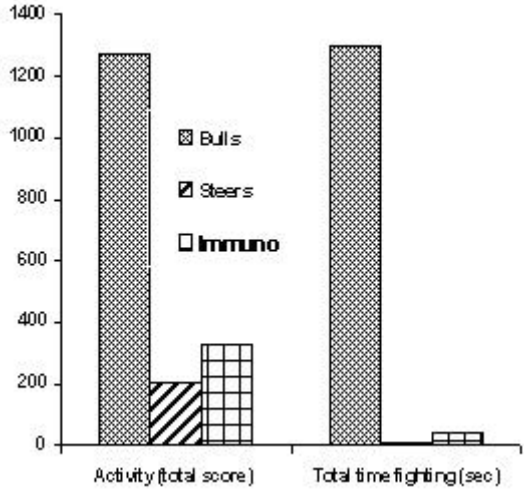

Fig. 2

In a similar study in New Zealand, Jago et al. (1997) looked at the effect of the timing of primary immunisation (as early as 2 mo of age, as late as 7.5 mo of age) and the number of booster immunisations. In all cases, immunisation delayed the prepubertal increase in T, and there was no difference in behaviour between the immunocastrate groups. From 10-17 mo of age, sexual behaviour of immunocastrates was intermediate between that of steers and bulls. Throughout the study aggressive behaviour was highest in bulls, while steers and immunocastrates were equal until 16 mo of age. Immediately prior to slaughter, at 18 mo of age, close monitoring during a 16 hr period of lairage revealed that steers now displayed much less sexual and aggressive behaviour, and that immunocastrates were only marginally less aggressive than bulls.

Immunisation of peri- and post-pubertal bulls

When 12-mo-old bulls were immunised against GnRH (Finnerty et al. 1995), T concentrations fell to at or near surgical castrate levels for the last 14 wk of a 20-wk study. During this time, sexual behaviour of the immunocastrates was also similar to that of surgical castrates while, compared to intact bulls, aggressive interactions were slightly reduced in duration but not frequency. Immunisation retarded growth to the same extent (≈25%) as surgical castration. In studies performed in California (Huxsoll et al. 1998; Price et al. 2003), bulls received a primary immunisation at 1, 4 or 6 mo of age and a booster at 12 mo. When observed at 16 mo of age, immunocastrates had aggressive behaviour similar to that of steers.

Conclusion

On the basis of the above studies, it is apparent that an optimised GnRH immunisation protocol for pre-pubertal bulls would be a viable option for obtaining the docile behaviour of steers but (close to) the growth rate of bulls. However, if GnRH immunisation is delayed until after puberty, growth rate is more likely to be adversely affected while the effects on behaviour may be inadequate. Furthermore, immunomodulation of endogenous hormone activity is an attractive alternative to

other methods of increasing the efficiency of animal production because vaccine residues are not perceived by consumers to be a problem, and because the approach is conducive to good animal welfare.

Immunocontraception of African elephants using porcine zona pellucida vaccine

HJ Bertschinger[1], JF Kirkpatrick[2], RA Fayrer-Hosken[3], D Grobler[4], JJ van Altena[4]

Zona pellucida proteins isolated from the ovaries of pigs (pZP) have proven an effective basis for an immunocontraceptive vaccine in horses (Kirkpartrick et al. 1985, Kirkpatrick and Turner 2002; Turner et al. 2002) and a range of wild and captive non-domestic herbivores (Kirkpatrick et al. 1996a; Kirkpatrick et al. 1996b; Naugle et al. 2002; Shideler et al. 2002). In these species, the pZP vaccine was shown to be both safe and, where tested, reversible. The potential to use a pZP vaccine as a contraceptive in free-ranging African elephant populations has been recognised for some time, and the current paper documents a project carried out in three phases to investigate whether pZP vaccine represents a viable contraceptive for elephants in the Kruger National Park (KNP).

Phase 1

The aim of phase 1 was to establish whether there was a reasonable degree of homology between the zona pellucida proteins in pigs and African elephants. In 1995 during the last elephant cull performed in KNP, ovaries were collected from several elephant cows. After fixation, ovarian blocks were embedded in paraffin, and thin sections were cut and processed for immunocytochemistry. Immunostaining was then performed using a rabbit-anti-pZP primary antibody followed by a secondary antibody labelled with colloidal gold. Finally, the staining was enhanced with silver. Histological examination of the sections revealed distinct immunogold staining of the zona pellucida of oocytes in primary, secondary and tertiary follicles. This staining pattern was confirmed in samples examined by transmission electron microscopy. It was, therefore, established that the ZP proteins of pig and African elephant share significant epitopes, and this in turn suggested that antibodies to pZP should cross-react with elephant zona pellucida proteins (Fayrer-Hosken et al., 2000).

Phase 2

Phase 2 was designed to establish an effective pZP vaccination regime for African elephants. To this end, two elephant cows (both at zoos in the USA) were injected with 400 µg of pZP in 5mg of a synthetic trehalose dicorynnomycolate adjuvant.

Booster vaccinations (400 or 600 µg) were administered 4 weeks and 10 months later. The anti-pZP antibody concentrations achieved in both cows after the second booster were comparable to those recorded in horses that had been successfully contracepted with pZP vaccine (Fayrer-Hosken *et al*., 2000).

Phase 3

The objective of Phase 3 was to test the contraceptive efficacy of the pZP vaccine in a sample of free-ranging elephant cows in the KNP. In 1996, 41 cows (21 treatment and 20 controls) were selected for the first trial. Criteria for selection included a small calf (< 1 m high) at foot and a negative transrectal ultrasound pregnancy result. Cows in the Treatment Group were vaccinated with 600 µg of pZP combined with the adjuvant described above; controls were injected with placebo. All injected cows were radio-collared and, 6 weeks later, they were located and injected with a booster vaccination using drop-out darts fired from a helicopter. A second booster was administered similarly 6 months after the primary vaccination.

Twelve months after the primary vaccination, 19 treated and 18 control elephants were located, immobilised and examined ultrasonographically for pregnancy. One cow in the Treatment Group had to be excluded because the results demonstrated that she was already pregnant at the time of the primary vaccination. Of the remaining vaccinated cows, 8 (44 %) were pregnant compared to 16 (89 %) of the controls. Although this difference in pregnancy rate was statistically significant, the results were disappointing compared to those achieved in free-ranging horses. Therefore, a second trial was planned that included 10 vaccinated cows. This time the intervals between the primary vaccination and first and second boosters were seat at 2 and 6 weeks, respectively. In this trial, significantly fewer vaccinated cows became pregnant (2; 20 %). The trials also proved that the vaccine is safe to use in pregnant elephants, that contraception can be maintained by administration of an annual booster and, that if a booster is not administered, that cows recover fertility. These are important qualities when selecting a contraceptive for wildlife species

In conclusion, the results of these studies demonstrate that pZP vaccine is a safe and effective contraceptive for free-ranging African elephant cows. However, because the current vaccine requires three administrations during the first year, it is probably only suitable for use in small populations (< 100 cows).

The elephant population problem in Zimbabwe: Can there be any alternative to culling?

C M Foggin

Wildlife Veterinary Unit, P/Bag BW 6238, Borrowdale, Zimbabwe

Aerial counting of elephant populations has been carried out in Zimbabwe since 1967. The latest census in 2001 revealed a total of approximately 88100 elephant in 4 separate populations (Table 1)

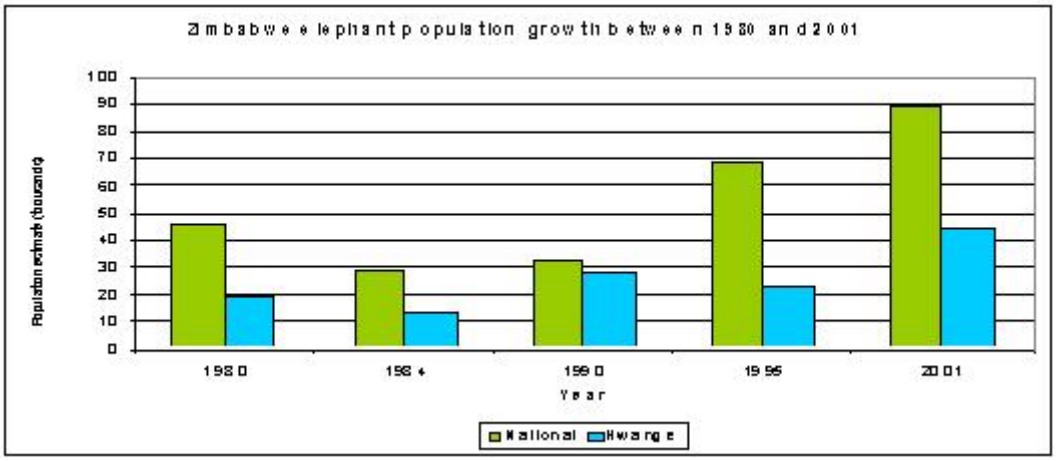

Table 1: Aerial Census of Zimbabwe's Elephant in 2001

Population sampled	Area (km^2)	Percent sampled	95% confidence limits	Population
North-west Matabeleland (includes Hwange NP)	25100	7.8	12.3	49300
Sebungwe	15600	13.8	15.2	14000
Zambezi Valley	17100	15.5	13.1	19300
South-east lowveld	8800	14.1-22.5	32.8 – 60.2	5500
TOTAL	66600		8.0	**88100**

The total population has increased from an estimated 47,000 animals in 1980, with the greatest percentage increase occurring in Hwange National Park (HNP) which, on its formation in 1928, was believed to contain between 1000 and 2500 elephant. Overall, Zimbabwe's elephant population has been increasing at approximately 5% per annum, and is therefore likely to be as high as 97,000 animals at the present time (Figure 1).

Figure 1: Elephant population increases in Zimbabwe, nationally and in Hwange

National Park

In Hwange National Park (HNP), the provision of some 70 artificial, perennial water points has increased the dry season foraging range of elephants from 35% to 75% of the Park's total area. Elsewhere, compression of the elephants' range by the increase in the human population from 0.5 million in 1900 to 12.5 million in 2001 and the recent "land crisis" has raised elephant densities to as high as 6 per km2. The major effects of this increase in elephant density have been erosion, vegetation damage and the loss of biodiversity. Erosion has occurred as a result of the loss of tree cover and has led to the siltation of water points. Vegetation damage has included a severe loss of trees which, combined with uncontrolled fires, has caused a loss of palatable species of shrubs and grasses. The effect of the elephant over-population on biodiversity has been less easy to monitor. It has been estimated that at densities of < 0.5 elephant per km2, forage and biodiversity may actually be enhanced, while higher densities lead to a loss of biodiversity. Of particular concern has been the effect on rhino in HNP. They are now unable to utilize areas under heavy elephant pressure and may even be prevented from access to some water points.

In addition, there has been more human-elephant conflict because of increased damage to crops and water facilities. These elephant attacks are likely to increase since 15% of Zimbabwe's elephant live outside the protected areas. The recommended elephant population for Zimbabwe is around 35000 - 40000 animals (0.6 per km2).

Efforts to control the elephant population

Cropping elephants by shooting was instituted in 1960, and by 1988 some 44000 elephants had been shot, mostly by eliminating whole breeding herds. Between 1989 and 1995, when elephant culling was stopped, approximately 2500 more animals were shot in problem animal control operations. In the 1980s, it was proposed that the number of elephant in HNP be reduced and held at 13000 (< 1 per km2). Although this target was reached in 1985, the policy was not continued and the

population has been allowed to increase unchecked, to the point where a “die-off” is likely to occur in the Park in the near future.

No plans exist to re-institute cropping of elephant in the protected areas. This has resulted from international pressure against elephant culling and a lack to resources within the Parks and Wildlife Management Authority of Zimbabwe to undertake such large-scale operations.

Options for the future

Options for future control of elephant in Zimbabwe include a laissez-faire approach, culling, translocation and contraception. Inactivity will lead to massive die-offs in some areas of the country such as HNP, Chizarira and Mana Pools National Parks. It would also result in an unacceptable loss of vegetation and bio-diversity. For culling to be reinstated, the necessary resources would have to be found in a country that already faces a severe economic crisis. Even if it could happen the task will be difficult. At the peak of culling in the 1980s, a maximum of 5340 elephant were shot in one year. If that total could now to be increased to, say, 10000 per annum, the recommended total population of 40000 would only be attained after 10 years of sustained effort.

However, an attraction of culling would be the sizeable economic return if the skin, ivory and meat could be recovered and successfully marketed. It has been estimated that a 5% off-take of excess elephant by a combination of safari hunting, culling and problem animal control could return as much as US$ 320 per km2. This compares favourably with the calculation of US$ 200 per km2 to manage an intensively protected wildlife area, particularly when only US$ 10 per km2 is presently available in Zimbabwe. However, culling is not generally acceptable to the international conservation community, and Zimbabwe would probably receive widespread condemnation if large numbers of elephant were shot.

Translocation of elephant breeding herds was undertaken in Zimbabwe in 1992/3, when around 1000 elephant were successfully moved from Gona-re-zhou National Park following a severe drought. Most were moved to the nearby Save Valley Conservancy, and 200 were taken to South Africa. Therefore, mass translocations are certainly feasible, but they are very expensive at > US$ 1500 per animal and there are few areas to which the elephant can now be moved, all of which are outside Zimbabwe. Translocation cannot therefore be considered seriously as an option for significant population reduction.

Contraception or sterilization of males and females is an attractive alternative for elephant population control. However, it has been shown by modelling that at least 75% of breeding females would have to rendered infertile for a period of >10 years to produce a significant drop in the population and that it might be more efficient to sterilize pre-breeding females. However, this is unlikely to be achievable with the drugs and technology presently available. An ideal contraceptive would be

deliverable as a single dose in a dart fired from a helicopter. Treated animals or their breeding groups would have to be identifiable, the cost per animal would be moderately high (at around US$ 150) and there would be no economic return for the effort. Problems with social and behavioural changes in treated individuals may occur, as well as the major disturbance during the treatment programme.

Ultimately, it appears likely that a combination of culling and contraception, with the latter having more application after elephant numbers have been reduced significantly, would find greatest acceptability. Those opposed to culling might be less vocal if contraception was being used simultaneously, while critics of population reduction without an economic return would be satisfied that the cropping option was not being ignored.

Conclusions

The following conclusions are pertinent to Zimbabwe's elephant overpopulation problem:

· The elephant population in Zimbabwe has now reached crisis proportions and large-scale die-offs are probably imminent and unavoidable.

· Severe impacts on the environment and bio-diversity will continue for some time, even if population-reduction measures could be initiated rapidly. However, the resources needed to implement effective control and subsequent monitoring are lacking.

· A combination of culling and some contraception or sterilization would probably be the best solution. Local opinion would favour culling alone but the arguments for this course are not generally supported internationally.

Contraception by ZP immunisation: Organon's involvement

A Grootenhuis and M van Duin

N.V. Organon, Research & Development Laboratories, P.O. Box 20, 5340 BH Oss, The Netherlands

Immunological disruption of gamete interaction by vaccinating against sperm and/or oocyte antigens is considered a promising alternative approach to human birth control. In this respect, considerable recent progress has been made in characterising the proteins that make up the mammalian zona pellucida (ZP), the extracellular matrix that surrounds the oocyte. And although the exact molecular composition of the ZP does vary between species, in most cases the ZP consists primarily of three to four major sulphated glycoproteins (Epifano and Dean 1994). Among these glycoproteins, ZP3 is generally believed to be responsible for the species-specificity of sperm-binding to the oocyte and for the induction of the acrosome reaction in bound sperm (Rosiere and Wassarman 1992). Not surprisingly, the oocyte-specific expression of their genes during oogenesis led to the suggestion that ZP proteins could be used as targets for vaccines to regulate both human and animal fertility. Indeed, numerous studies to assess this concept in animal models have resulted in the desired infertility. However, optimism about the feasibility of this approach for birth control in man has been tempered by numerous studies in a variety of mammalian species in which active immunisation against purified porcine ZP resulted in significant ovarian pathology. For example, immunization of the common marmoset (Callitrix jacchus) with purified pig ZP3 (pZP3) and deglycosylated pZP3b (32 kDa) induced ovarian degeneration characterized by a depletion of primordial follicles, appearance of follicular clusters lacking oocytes and depletion of the pool of recruited follicles (Paterson et al. 1992). By contrast, active immunization of rabbits with deglycosylated pZP3b did not result in any visible signs of ovarian pathology (Keenan et al. 1991). The reason for the immunopathology observed in some species is unknown, but it has been postulated to reside in contamination of supposedly purified ovarian-derived ZP3 preparations. To this end, recombinant human ZP3 (rec hZP3) was produced in Chinese hamster ovary (CHO) cells (Van Duin et al. 1994) but, in marmosets, even active immunization with this “pure” hZP3 disrupted ovarian function to the extent of complete cessation of ovarian cyclicity and the loss of primordial follicles (Paterson et al. 1996). This latter loss was completely unexpected, given that it was previously believed that ZP3 was absent from primordial follicles. Although the immunological mechanism underlying ZP3-triggered depletion of the primordial follicle pool was still unexplained, it was proposed that vaccinating with very specific immunocontraceptive ZP3b cell epitopes might circumvent the immunopathology. To verify this hypothesis, highly specific

mouse monoclonal antibodies were generated against different epitopes (linear and conformational peptides) of hZP3. These novel tools were then used to perform more in-depth immunohistological studies to map the temporal and spatial expression of ZP3 in rabbit, marmoset monkey and human ovaries. Immunoreactive staining of primordial follicles indicated the presence of ZP3 in early primordial follicles, thereby explaining why vaccination against ZP3 often disrupted all stages of folliculogenesis. Unfortunately, this finding simultaneously suggested that ZP3 is not a sufficiently stage-specific target for the development of a reversible form of immunocontraception (Grootenhuis et al. 1996).

Modelling the effect of fertility control on elephant population dynamics

H Heesterbeek[1] and A Dobson[2]

[1]Department of Farm Animal Health, Faculty of Veterinary Medicine, Utrecht University, Yalelaan 7, 3584 CL Utrecht, The Netherlands; [2]Department of Ecology and Evolutionary Biology, Princeton University, Princeton, NJ 08544, USA

Mathematical models have a long and rich tradition in epidemiology, population biology and ecology and are valuable tools for predicting the long-term, and to a lesser degree short-term, effects of various interventions on population dynamics. Models are particularly useful for studying the consequences at a population level of changes and mechanisms operating at an individual level. We propose that a model for elephant population dynamics could be designed to gauge the long-term effects and consequences of population management by immunocontraception. This model could then be used to determine whether immunocontraception is a viable alternative to culling or translocation for controlling population size and structure in a sustainable way.

We propose to use a matrix population model, a flexible and well-developed class of model that collates information on life-history characteristics across age classes and generates short, medium and long-term predictions of population growth and demography (see Caswell 2001). The long-term population dynamics are predicted by calculating the asymptotic growth rate of a population and the stable age distribution that is associated with that growth rate. Matrix models are simple in so far as the number of variables and parameters are small, however their major advantage is their mechanistic nature and the clarity of the assumptions that underlie them. Both density dependent (e.g. population self-regulation by changes in the age at first reproduction) and stochastic effects (both demographic and environmental) can be taken into account. In addition, it is possible to perform factor sensitivity analysis to determine which parameters most influence population growth rate. This helps to identify not only the key parameters of growth within a population, but highlights how different parameters may influence the steady-state age distribution.

To date relatively little elephant population modelling has been documented. Armbruster and Lande (1993) modelled elephant demographics using a Leslie model (a special class of matrix population model) to investigate the minimum reserve area required to sustain an elephant population. Their model included aspects of environmental stochasticity, such as occasional long periods of drought.

Dobson and Poole (1993) also used a Leslie matrix approach to model elephant

population dynamics, although they included density dependent rather than stochastic effects, and also took the social structure into account. The resulting model was used to analyse the impact of ivory poaching on East African elephant populations, and to estimate the time needed for a population to recover from heavy poaching pressure after it became fully protected. All of the parameters of their model were based on empirical data obtained from field studies, and one of their primary conclusions was that “social structure and reproductive physiology are crucial to understanding the demography of elephants”.

Dobson (1993) used the model designed by Dobson and Poole (1993) to predict the effects of immunocontraception or inducing abortion on elephant population dynamics. Importantly, the model included 2 parameters known to play a critical role in elephant population regulation, namely density dependent variation in the age at first reproduction and in the inter-calf interval. Based on data from the Amboseli population, it was predicted that an elephant population could be maintained at a stable level by any form of birth control that extended by two years both the age at first calving and the inter-calving interval.

More recently, a model similar to that of Dobson and Poole’s was used to investigate the effect of culling on the elephant population in the Kruger National Park (KNP: Van Aarde et al. 1999; Whyte et al. 1998). The authors discussed various contraceptive options but concluded that none were practical in a population as large as that in KNP (see Pimm and Van Aarde, 2001). Their model suggested that a large proportion (75%) of the female population would need to be contracepted successfully if zero population growth was to be achieved, and that population stagnation would be reached only after a considerable length of time. They, therefore, concluded that culling remains the best option available for controlling elephant numbers in the KNP.

Since the publication of Dobson’s population model ten years ago, there have been major advances in our knowledge of fertility control in elephants. Clearly, however, there remains considerable uncertainty about the likely knock-on effects of contraception or abortion on individual elephants (see Whyte et al. 1998; Pimm and Van Aarde 2001; Fayrer-Hosken et al. 2001); these effects need to be clarified. Nevertheless, our understanding of elephant population biology, demography, behaviour and social organisation has increased significantly during the last decade. Importantly, several detailed long-term studies have charted elephant population structure and behaviour, and these studies should play a major role in both building and validating a new model. Significantly, the data sets are drawn from different populations with very different age distributions (e.g. an aged population in Amboseli National Park and a younger population in Tarangire), and this should help clarify the impact of population structure on growth rate. We believe that it is now possible to extend the matrix model to study more thoroughly the impact of social, reproductive and behavioural changes resulting from procedures like immunocontraception. Our

aim is thus to collate information from the relevant experts to establish the effects of fertility control on individual elephants, and thereafter to design a model for predicting population dynamics in the face of various methods of population control.

Aspects of male reproductive physiology and the phenomenon of temporary infertility in adult bulls

T.B. Hildebrandt

Institute for Zoo Biology and Wildlife Research, Alfred-Kowalke-Str. 17, 10315 Berlin, Germany

Abstract
Worldwide, the success rate of breeding programmes for captive elephants is poor. In this respect, alongside undiagnosed reproductive disorders in females and fatal diseases like the newly discovered elephant herpes virus infection (EEHV: Richman et al., 1999), male infertility has been identified as a major factor contributing to the failure of captive populations to become self-sustaining (Hildebrandt et al., 2000). To investigate the possible causes of male reproductive inadequacy, approximately 400 ultrasonographic examinations of the internal genitalia combined with semen collection were performed in captive (n=15) and wild (n=13) African (Loxodonta africana) and captive (n=91) Asian (Elephas maximus) bull elephants, ranging in age from 4 to 50 years. Approximately half of the reproductive assessments were performed in protected contact situations with elephants handled in a restraint device, while the other half involved assessments of unrestrained trained Asian bulls, or examinations under general anesthesia. In the latter category, 14 examinations were performed in the field on wild adult African bull elephants immobilized during either translocation projects or GPS home-range studies.

Transrectal ultrasonography was used to characterise the morphology and functionality of the entire urogenital tract, including the size and developmental status of testes and accessory sex glands (Hildebrandt et al., 1997a; Hildebrandt et al., 1998, Hildebrandt et al., 2000a). In fact, transrectal ultrasonography enabled the identification of pre-pubertal and pubertal individuals, who were then excluded from further analysis (Hildebrandt et al., 1999). In addition, bulls were categorised on the basis of breeding status (breeders versus non-breeders) and, where possible, social rank (i.e. type of interaction with male and female conspecifics and keepers). Most of the bulls were adult non-breeders, and the rate of apparent infertility of non-organic origin (i.e. not due to specific anatomical abnormalities) in otherwise healthy animals was surprisingly high.

In general, breeding bulls had a fully developed genital tract, moderate blood testosterone concentrations (10 - 40 ng/ml) and delivered a fertile ejaculate of adequate volume (>200 ml) after manual stimulation (Hildebrandt et al., 1997b; Schmitt and Hildebrandt, 1998) or electro-ejaculation (Hildebrandt et al., 2000b). In

these breeding bulls, the seminal vesicles contained large volumes of fluid prior to ejaculation. With regard to social environment, captive breeding bulls were usually housed singularly with a group of female elephants or with other significantly younger bulls. In the wild, bulls identified as breeding animals by dint of their semen quality and the sonomorphologic appearance of their internal genital organs were never found associated with other adult bulls. By contrast, wild non-breeding bulls generally lived in bachelor groups of two or more individuals and were characterized reproductively by low ejaculate volumes, underdeveloped accessory sex glands and low circulating testosterone concentrations (<10 ng/ml). Captive non-breeding bulls were, in most cases, housed together with other adult males of a similar age or within a group where they were dominated by older cows. On occasions, captive bulls identified as non-breeders were apparently dominated only by zoo staff. This correlation between social rank and genital and spermatological findings was only overturned when a bull entered into musth. In musth bulls, blood testosterone concentrations were always high (up to 160 ng/ml) and the seminal vesicles were very large. However, semen collection from musth bulls was difficult and never resulted in a high quality ejaculate because of urine contamination.

On the basis of the correlations between semen quality, genital development and social status/situation, it is proposed that, in the wild, breeding bulls capable of impregnating cows are almost exclusively represented by dominant solitary animals. By contrast, adult males in bachelor groups are usually sexually inactive, presumably so that they can avoid social conflicts within their group until they have built up sufficient bodily resources (and experience) to enter an annual musth cycle and fight for a breeding-bull position. Preliminary results indicate a ratio, in the wild, of approximately 1 breeding bull to every 50-100 non-breeding bulls. The phenomenon of temporary or permanent social rank-induced sexual inactivity in bull elephants should be studied more intensively for possible future application to population management strategies for wild African elephants.

Viral-vectored immunocontraception for the wild house mouse, mus domesticus, in Australia

LA Hinds

Pest Animal Control Cooperative Research Centre, GPO Box 284, Canberra, 2601, ACT, Australia

Introduction
Populations of the introduced house mouse erupt irregularly in the grain growing regions of South-eastern Australia, reaching densities greater than 1000 mice per hectare. These mouse plagues have major economic impacts as well as causing social stress within rural communities. Current control strategies usually involve the use of rodenticides that are not highly target specific, are costly to apply, can lead to environmental damage and are not humane.

As an alternative to current lethal agents, we are developing fertility control approaches whereby viruses are being assessed as delivery vectors. Non-toxic baits are also being considered. The research combines molecular biology, population ecology and epidemiology of the virus vector, as well as risk assessment of the use of genetically engineered organisms in the Australian landscape.

An ideal immunocontraceptive vaccine must evoke a sustained immune response which blocks a key reproductive process (e.g. fertilization), be species-specific, be delivered effectively throughout the pest population on a broad scale and be cost-effective, environmentally benign and publicly acceptable – a big challenge.

The components of the fertility control approach for the wild house mouse are mouse zona pellucida protein 3 (mZP3) as the reproductive antigen and mouse cytomegalovirus (MCMV) as the candidate delivery vector. This virus is highly prevalent in wild mice in Australia and is species-specific. It spreads by close contact and animals can become infected with multiple strains, which means that super-infection with a recombinant virus is feasible. The virus persists in the salivary gland and lung and can be reactivated during periods of stress. Since it is a DNA virus it can be engineered to carry additional genetic information.

Efficacy of an infertility vaccine.
We tested the effects of inoculating mice with an engineered Australian strain of MCMV expressing the mZP3 gene. Intraperitoneal (i.p.) inoculation with the recombinant virus resulted in stimulation of the host immune system with the

production of antibodies to both the virus and mouse ZP3. Treated mice remained infertile for up to 250 days. Three host strains of MCMV, G4 and N1 from Western Australia and K181, originally from USA, were engineered. All three recombinant MCMV-mZP3 vaccines induced reproducible infertility in laboratory mice following i.p. inoculation. Infertility, resulting from complete loss of primordial ovarian follicles is permanent. Two other recombinant MCMV vaccines expressing mouse zona pellucida protein 1 (mZP1) and a modified form of mouse ZP3 (ubi-mZP3), also caused infertility in female mice after infection. However, the recombinant MCMV-ZP3 derived from the Australian G4 isolate was chosen to be the first mouse vaccine product because it causes consistent and reproducible infertility. The final vaccine is being formulated using strict quality control protocols to remove all non-essential transgenic gene sequences.

Transmissibility of the vaccine.
The ability of a recombinant MCMV-mZP3 vaccine to spread and infect large numbers of mice in the field is critical for its success. We had shown only limited transmission from mice experimentally infected with the wild type MCMV strain G4 to uninfected wild mice within social groups. We are also investigating the transmission dynamics of an MCMV strain from wild-caught mice in eastern Australia. When naturally infected mice were placed in social groups with uninfected mice, this new strain of MCMV spread rapidly. We are currently isolating the strain for further characterisation and to use it as starting material for second-generation vaccines with enhanced transmission ability.

Species specificity and safety.
Following discussions with stakeholders, two major hazards were identified. First, the risk of inadvertently exporting a genetically modified virus overseas in infected live mice and, second, the species-specificity of the recMCMV-mZP3. To address the first concern, a mathematical model is being developed to assess the export risk during mouse plague conditions. For the second, Lewis rats were infected experimentally with a laboratory standard prototype vaccine, recMCMV-mZP3, using 20 times the dose used to sterilize mice. All the rats remained fertile and no recombinant virus was recovered from them by plaque assay or PCR of tissues. Similarly, 3 Australian native rodents have been infected with wild type MCMV and have not become infected.

Practicality in the field.
The ability to introduce a sterilizing virus that can spread effectively among wild mice is critical for the success of the vaccine. The use of non-toxic baits is being explored, and two oral inoculations with strain G4 recMCMV-mZP3 will effectively sterilize laboratory mice. The recombinant vaccine can be freeze-dried and/or applied to bait, with subsequent recovery of infectious recMCMV-mZP3. These results encourage the belief that bait delivery of infectious freeze-dried virus could be an effective means of inoculating field populations of mice. Further trials using freeze-dried

recombinant vaccine delivered on baits are in progress.

To determine the level of infertility required to reduce recruitment in mouse populations, enclosure studies using surgical sterilisation of varying proportions of the adult females are being undertaken to determine the rate of growth and the structure of confined populations. Surgical sterilisation of 67% of adult females significantly reduced the growth rate of the population. Mathematical models have also been used to simulate fertility control. These indicate that a level of 33% infertility for the duration of a breeding season, with each cohort of young being affected at this level, will reduce mouse numbers and maintain them below plague densities (< 200 mice per hectare in grain growing areas).

Conclusions.
Field and laboratory results, as well as computer modelling, all show excellent prospects for the use of viral vectored vaccines based on MCMV for managing eruptions of mouse populations. However, public acceptability of the technology has yet to be confirmed. The issues of species specificity, delivery system stability and other potential or perceived risks require open and wide-ranging debate, nationally and internationally, before field trials of a genetically modified virus to control populations of mammals could occur.

Translocation as a management tool for control of elephant populations

M Hofmeyr

Veterinary Wildlife Services, Kruger National Park, Skukuza 1350, South Africa

Background
Elephant translocation within South Africa has increased significantly in the last decade. Until 1993 only orphaned elephants from the Kruger National Park (KNP) culling operations were translocated in significant numbers. A number of newly established smaller reserves in South Africa such as Pilanesberg, Umfolozi/Hluhluwe and Madikwe were stocked with these juvenile elephants but, after a few years, aberrant social behaviour was noted in the reserves containing introduced elephants.

In 1993 Clem Coetzee developed a method to move adult elephant in Zimbabwe. He came to KNP in 1994 to help the local capture team develop the technique, after which South Africa National Parks (SANParks) adopted his method and refined the equipment to be able to move large numbers of elephants. Since then only complete family units and adult bulls have been translocated from KNP and this change of policy seems to have solved the behavioural problems seen previously in the populations introduced as youngsters. Over 750 elephants in family units and almost 100 mature bulls have been moved by the KNP capture team in the last 9 years.

Capture technique
Elephant capture should only be attempted by experienced personnel using the right equipment. Immobilisation of such a large mammal is a very specialist process, and this is followed by the considerable practical difficulty of raising the adult elephant off the ground and into the recovery vehicle so it can be transported to the new destination safely and humanely and without danger to people or traffic. The basic equipment required includes; i) a truck with a heavy-duty crane; ii) a recovery trailer and winch; iii) a recovery chamber for the elephant to wake up in; iv) a well-constructed transport container.

Experienced personnel should accompany elephants being transported over long distances as fighting may occur so that tranquilisation could be necessary.

Most elephants translocated currently from the KNP go to relatively small, but well fenced, reserves in Zimbabwe and South Africa. This means they must be exposed to electrification before they can be released onto the property. Initially they are

released into a small holding camp or “boma” of about 1-2 hectares in area so that they can become familiar with, and learn to respect, the electric fencing. The boma must be well constructed, securely fenced with cables and have a good and functional electrification system in place. The elephants should stay in the boma for at least 24 h but not so long that they become hungry or bored. The gates must be sturdy and should slide rather than swing open. They should also be electrified at all times. Supplementary food may be needed if more that one group are to be released from the same boma over a short period of time.

In summary, the capture and translocation of elephants can only be done by experienced personnel using specialised equipment. It is expensive (+/-R10,000 per elephant, excluding transport) and areas available for translocation are limited, both by ecological size and accessibility to the heavy equipment needed. A good management plan, a release boma and functional fences are prerequisites before elephants can be released into a reserve. Furthermore, planning for future population control should be in place. KNP cannot control its elephant population by translocation alone since there are not enough accessible areas available to absorb the numbers necessary to reduce the population sufficiently to avoid ecological damage.

For the future, few options are available to the KNP to reduce its elephant population before serious ecological damage is done. Expansion of the conservation area through well-managed Transfrontier Conservation Areas is one option being developed currently, but the fences have not yet been removed and the local population do not support the concept of large numbers of elephant moving back into the areas they now occupy. Application of practical contraceptive methods is a second option but this still needs research and refinement. Improved translocation equipment able to move large numbers of elephants to areas outside South Africa that have had their indigenous elephant population reduced by poaching would be desirable although the security of such areas still remains doubtful. Finally, organised and controlled culling must almost certainly be re-introduced to quickly stabilise the rapidly expanding population of elephant.

Elephant population trends and the challenges facing protected area managers

P Kahumbu

P.O. Box 1403, Limuru, Kenya.

The decline of Kenya's elephant population due to runaway poaching for ivory was halted in 1989 after the country's herds had been reduced to only 12% of their former numbers. Since then, protection, legislation and conservation of habitat have all been effective, such that Kenya's elephants today number approximately 30,000, up from 19,000 in 1989.

So successful have been these measures that the challenge of managing elephants nowadays involves conflict resolution where elephants are returning to traditional migrations in areas now occupied by people. Fencing elephants into protected areas and out of inhabited lands has resulted in damage to fragile and unique habitats in some areas, and it is now necessary to manage elephant numbers to protect biodiversity.

Unlike the situation in other parts of Africa, culling of elephant is not an option in Kenya. Meat and other products cannot be sold in local or international markets and elephant meat is not eaten by most local communities. Moreover, Kenya is home to some of the most intense elephant research in Africa, which has revealed the complex social and behavioural world of this species. The country is heavily dependent on tourism for foreign revenue and the negative impact of culling could damage this fragile industry.

To date, Kenya's policy on elephant management has involved the creation of corridors, elephant sanctuaries and barriers to elephant movement, where human lives and property are at risk. Translocation has been adopted as a humane alternative to culling, to reduce numbers or to remove problem animals, and contraception has been proposed for specific elephant populations.

Recent research in the Shimba Hills area revealed that the damaging effects of elephants are exaggerated by human activity in the form of logging. This population of forest-living elephants is divided into a distinct bull area in the dry forest, where habitat degradation from tree pushing is most severe, and a family area in the rain forest. The density of elephants in this one small protected area ranged from ± 6 per km2 to < 1 per km2.

In rain forest patches, the elephants induced changes in the composition and

structure of species beneath the canopy. Thus, while rain forests were not being converted to grasslands, there were concerns that elephant activity beneath the canopy would eventually prevent its re-establishment when old trees died. This effect was demonstrated in an experimental design in which exclusion and inclusion of elephants was compared. In forests in which gaps had been created by logging, elephant activity was intense due to the flush of re-growth.

In dry forest, elephant activity was much more dramatic and their debarking and pushing over of trees had resulted in complete change from forest to open bushland. Analysis of aerial photographs revealed that the decline in forest was due to elephant activity at the edges, especially by bulls.

The Shimba Hills is the first protected area in Kenya to be completely surrounded by a fence, and this has caused artificial concentration of elephants into a small area. Research findings recommended a multi pronged approach to reduce the impact of elephants. Namely; 1) Reduction of the population by translocation; 2) Contraception or complete sterilisation of females, because of the lack of poaching and the unique biodiversity in the area; 3) Expansion of the protected areas by acquisition of more land and the creation of corridors; 4) The cessation of logging.

Towards this end, an experimental translocation of 30 bulls in 1999 proved successful and a small expansion of the protected area was achieved concomitantly. Logging was prohibited, but the contraception work was not initiated, partly due to a lack of follow up and partly because the technology was unproven at that time.

Following the work in South Africa, it is now realistic for Kenya to initiate immuno-contraception in elephant populations. However, such a project would require a level of scientific sophistication that the government may not be able to provide. For example, the work would require individual recognition of the elephants, intense monitoring of their movements, behaviour and reproductive status, and it would involve radio-tracking, sample collection and analysis, aerial transport and staff accommodation.

Perhaps the most effective way to achieve successful contraception of elephants in Kenya would be a partnership between Kenya Wildlife Services and a respected non-governmental organisation like Save the Elephants. At least three populations of varying size living in different habitats could be used initially, including Sweetwaters, Shimba Hills and Mwea. This would give the opportunity to explore the application of different contraceptive methods under different conditions. Hopefully, a collaboration between Kenya and southern African countries could quickly provide guidance for other African countries with similar problems of high elephant density and different government policies for elephant management.

The public perception of contraception may be more difficult to accommodate in

South Africa than Kenya. Revenue from tourism and related activities is the key to community support for conservation in Kenya. For example, communities in the Shimba Hills made a commitment to conservation and the development of tourism in 1997 by setting aside land for conservation in the Mwaluganje Elephant Sanctuary, an area adjacent to the Shimba Hills Reserve. They now have a game lodge and two restaurants and they are responsible for running the sanctuary in conjunction with the KWS, a local NGO and the Forest Department. This could become Kenya's showcase for ethical management of elephant populations, with the consequent boost to tourism.

Hormonal approaches to male contraception

A Kamischke and E Nieschlag

Institute of Reproductive Medicine, University of Münster Domagkstr. 11, D - 48129 Münster, Germany

A potential male contraceptive has to fulfil certain prerequisites before it can be considered as a reliable alternative for use in human patients (see Table 1: Nieschlag et al. 2000). Current male contraceptive approaches are either highly effective but potentially irreversible (vasectomy) or relatively ineffective (condom). For this reason, there is considerable interest in developing alternative, testicular and post-testicular, methods for male contraception. Of the various theoretical approaches considered, the closest to practical implementation is the administration of exogenous hormones.

Table 1: Prerequisites of an ideal male contraceptive

An ideal male contraceptive should:

- be administered independently of the sexual act
- be acceptable to both partners
- not interfere with libido, potency or sexual activity
- have no short or long-term toxic side-effects
- have no impact on any eventual offspring
- be rapidly effective and fully reversible
- be more effective than condoms

The aim of the hormonal approach to male contraception is to suppress spermatogenesis and sperm release from the testis, and thus induce azoospermia (no sperm in the ejaculate) or a severe oligoasthenozoospermia (few, predominantly immotile or poorly motile sperm in the ejaculate). The general principle of this approach is to interfere with the endocrine regulation of spermato-genesis. In contrast to rodents, normal spermatogenesis in primates is both quantitatively and qualitatively strongly dependent on the pituitary gonadotropins LH and FSH which, in turn, depend on hypothalamic GnRH for their secretion. FSH acts directly on spermatogenesis via specific FSH receptors in the Sertoli cells, whereas LH acts indirectly by stimulating testosterone production in the Leydig cells. For successful

male hormonal contraception, secretion of both gonadotropins needs to be suppressed profoundly, so as to arrest spermatogenesis at the spermatogonial stem cell level. On the other hand, the resulting extra-testicular androgen deficiency also needs to be addressed in order to maintain other androgen dependent functions. For this reason, androgens are an essential component of all hormone based male contraceptives (Nieschlag et al. 2000).

With these principles in mind, testosterone was an obvious first candidate as a hormonal contraceptive for men; it not only suppresses pituitary LH and FSH secretion but simultaneously corrects the circulating testosterone deficiency. Initial studies in the 1970s demonstrated that although the oligozoospermia (< 3 x 106/ml) induced by testosterone administration was not as effective as azoospermia in preventing pregnancy, it still offered better protection than condoms (World Health Organization, 1996). However, as in later studies of androgen-only hormonal contraceptives, azoospermia was induced in almost all East Asian men but only two thirds of Caucasians.

In an attempt to enhance the efficacy in Caucasians, testosterone was combined with other gonadotropin-suppressing substances, such as progestins or GnRH antagonists. The combination of testosterone and a GnRH antagonist leads to a more rapid onset and complete suppression of sperm production. Unfortunately, the preparations currently available are considered unacceptable for practical use. On the other hand, new depot preparations and studies suggesting that the GnRH antagonist may be needed only during the induction phase, mean that this approach may eventually become feasible in practice.

A combination of androgen and depo-medroxyprogesterone acetate (DMPA) has also shown good suppression of spermatogenesis in Caucasian males in some studies, but up to 12 % inadequate responders in others. In more recent studies using 300 mg DMPA (injected every 3 months) combined with testosterone implants (800 mg every 4 months), a rapid initial suppression of spermatogenesis and azoospermia was achieved in 49 out of 53 volunteers and no pregnancies (upper 95% confidence interval for contraceptive failure is 8%) have occurred in 35.5 person years (Turner et al. 2003). On the other hand, 15% of subjects discontinued the study because of failed suppression or problems with the implants, and the recovery to normal semen production appears to be much slower than with other progestins.

Nineteen-noresthisterone was one of the earliest progestins derived from testosterone, has the strongest androgenic activity of all 19-nortestosterone derivatives (approximately 10% that of testosterone) and induces profound, rapid and sustained suppression of serum FSH and testosterone concentrations in normal men. When norethisterone enanthate (NETE) or orally active norethisterone acetate (NETA) were combined with injectable testosterone undecanoate (TU), azoospermia was achieved in 51 out of 56 volunteers and sperm production dropped below 1 x

106/ml in a further 4 subjects (Kamischke et al. 2001, 2002). Since TU and NETE can be combined in a single injection (both are dissolved in castor oil), a combination of these 2 hormones injected at 6 - 10 weekly intervals offers great potential as a male contraceptive.

Orally administered desogestrel (DSG) and its implantable active substance etonorgestrel (ENG) have also been shown to powerfully suppress spermatogenesis when combined with short-acting testosterone enanthate (100 mg weekly) or testosterone pellets (400 mg every 12 weeks). And although azoospermia was achieved in only 78% of 102 Caucasian volunteers, the high proportion of men (92%) that achieved sperm concentrations < 1 x 106/ml compensated for the relatively low rate of azoospermia and confirmed ENG combined with implantable testosterone preparations as an interesting approach to male contraception (for review see Kamischke and Nieschlag, in press).

In conclusion, because the contraceptive efficacy of all self-administered androgen preparations so far tested has been disappointing, recent studies have focused on a combination of either androgen implants or long-acting injectable testosterone esters such as TU with potent progestins. In terms of general long-term acceptance, the ideal would be to combine both medications in a single application. To date, however, the combination of testosterone implants or long-term injectable esters with the progestins NET, DSG and DMPA have proven effective in small clinical trials and offer most potential for licensing.

Elephant contraception: looking beyond the pharmacology

JF Kirkpatrick

The Science and Conservation Center, ZooMontana, 2100 South Shiloh Road, Billings, MT 59106, USA

It is easy to pharmacologically inhibit fertility in virtually any wildlife species. It is not easy to establish how to administer those pharmacological agents into a sufficient number of intelligent, mobile and often dangerous animals in any given population, such that biological goals are achieved in a publicly acceptable manner. Thus, the starting point for any wildlife contraceptive programme must be the development of a set of “ideal” characteristics for the theoretical antifertility drug for each particular species. Such “ideal” characteristics were developed for wild horses in North America in 1991 and, over the past 16 years, porcine zona pellucida (PZP) immunocontraception has been tested against those characteristics. Its efficacy in wild horses and elephants is based on 16 years of treatment of wild horses in > 12 distinct herds and from 4 years treatment of 31 female elephants in The Kruger National Park and 23 cows in Makalali Wildlife Park, both in South Africa.

For the wild horse herds in North America, and elephant groups in Africa, the “ideal” characteristics include i) an efficacy of > 90%; ii) the ability to deliver the drug remotely in 1.0 cc darts so as to reduce or eliminate handling or capture-related stress; iii) reversibility of contraceptive action to preserve the reproductive and genetic integrity of the target animals; iv) safety of administration to pregnant animals; v) inability of the agent to pass through the food chain to predators, scavengers and humans; vi) lack of significant effect upon social organization or behaviour; vii) a lack of harmful or debilitating long-term health side effects; viii) low cost. All these “ideals” have been met in both horses and elephants.

In addition, three levels of progress in the development of a practical wildlife contraceptive have been noted; i) demonstration that the contraceptive agent (PZP) is pharmacologically effective in the target species (proven for horses and elephants, as well as more than 100 other mammalian species), ii) demonstration that the contraceptive agent can be delivered to free-ranging wildlife under field conditions and, iii) demonstration that a sufficiently large portion of a population can be treated to achieve a true population goal.

It appears that by 2003, the only significant scientific hurdle left to overcome with the use of PZP vaccine is the need to deliver a year or more of contraceptive in a single inoculation. Currently, animals are treated twice during the first year, once annually

for the next 2 years and once in alternate years or every third year thereafter. This shortcoming can be overcome in two ways. First, a single “primer” dose of vaccine can be given in Year 1, without subsequent contraceptive action in that year but with the benefit that each animal so treated needs only a single annual booster inoculation thereafter. This is the simplest approach and its utility has been proven with wild horses. A second approach is to place the immunogen in a slow release matrix, and several materials exist which enable this to be accomplished. We have used lactide-glycolide pellets that fit into the 14-gauge needle of the dart with some success. In wild horses in Nevada, a single treatment resulted in 90% contraception in the first year, 83% in the second year and 60% in the third.

Wildlife contraception, particularly in wild horses and elephants, is attended by significant public scrutiny, concern and scepticism, which mean the research team must pay close attention to a proactive public education programme. Despite its high score in terms of “ideal” characteristics, PZP may not be the optimum contraceptive agent for elephants. The natural history, behaviour and even the prevailing public attitudes towards the target species, not to mention the logistic problems of administering the contraceptive agents to identifiable individuals in the field, must all be weighed carefully when attempting to construct a set of working characteristics with which to measure the utility of the product in the chosen target species.

Progestagen depot with or without testosterone: a strategy for regulating fertility in male elephants

GA Lincoln, R Anderson and H Andersson

MRC Human Reproductive Sciences Unit, Centre of Reproductive Biology, 49 Little France Crescent, Edinburgh EH16 4SB, UK

Progestins, notably medroxy-progesterone acetate (MPA), are potent inhibitors of gonadotrophin secretion and have been used widely in steroid-based contraceptive regimens in both man and animals. Moreover, we believe that MPA depot treatment represents a potentially effective method for controlling fertility and/or aggressive musth-related behaviour in male elephants (Loxodonta africana and Elephas maximus). MPA is cheap and readily available in large quantities, its actions are very well characterised and long lasting, and the contraceptive effects are reversible.

In man, MPA given as a subcutaneous depot (150-300mg in oil every 3 months) induces testicular regression, infertility and low androgen status. MPA can also be given in combination with testosterone to enhance effectiveness and maintain male sexual behaviour and other androgen-dependent characteristics, as is desired in human male contraception (Wu and Aitken 1989; Brady et al. 2003). MPA acts primarily through the progesterone receptor to suppress gonadotrophin secretion. In red deer (Cervus elaphus), a 150mg depot of MPA given to males in the sexually active phase of the annual reproductive cycle blocks gonadotrophin release and results, within a month, in the antler casting indicative of testicular inactivity (Muir et al. 1982; Suttie et al. 1995). The effect lasts for several months, as evidenced by reduced LH/testosterone responses to challenge with gonadotrophin releasing hormone (GnRH). The anti-androgenic progestin, cyproterone acetate (CPA), also blocks expression of overt rutting characteristics in red deer stags, but is less effective than MPA in suppressing testicular activity (Suttie et al.). MPA is used in veterinary practice to chronically block testosterone secretion, but may be less effective in some species (e.g. the dog; Paramo et al. 1993).

To date, there have been no robust studies of the long-term efficacy of MPA for inducing oligo/azoospermia in male elephants (MedLine Search). However, the anti-androgen flutamide (2500-7500mg/adult male) has been shown to suppress musth behaviour in captive/working Asian elephant bulls (Chandrasekharan and Cheeran 1996). Not only did the highest dose totally block musth behaviour, but the

subsequent musth did not occur until the normal time in the following season, thereby illustrating that it is possible to control the complete annual cycle with a single treatment. This has implications for the humane management of elephant bulls in captivity (Taylor and Poole 1998). Furthermore, we predict that a single dose of MPA (5000mg) would block the musth cycle and render a male elephant infertile for many months. A combined MPA and androgen/oestrogen treatment might be a more refined method to induce infertility but maintain male behaviour, allowing bulls to remain socially dominant.

The possible contraceptive/management protocol in the wild would take advantage of several aspects of elephant physiology and behaviour: 1) Bull elephants are very large and it is possible to follow musth cycles in individuals in the wild (Poole 1994). 2) Most matings are performed by the larger, older (30-50 year old) male elephants during the musth phase of the annual reproductive cycle (Poole 1994). Thus, only the big, dominant males need to be targeted for steroid-based contraception. 3) Dominant bulls suppress musth behaviour in younger subordinates (Slotow et al. 2000); this favours a treatment that does not affect dominance behaviour of the older bulls. 4) Musth appears to be driven by an endogenously generated circannual rhythm (Lincoln and Ratnasooriya 1996), which means that blocking the sexually active phase of the cycle should not affect the overall timing of an individual's cycle, thus simplifying long-term management. 5) Male elephants may be especially sensitive to the negative feedback effects of MPA, since females produce 5 alpha-reduced progestins, rather than progesterone, to regulate gonadotrophin secretion during the oestrous cycle and pregnancy (Hodges et al. 1997).

We propose that two types of experiments should be conducted:
A. Phase 1; in captive working/zoo adult Asiatic elephants. An experimental group of adult bulls that express musth cycles (e.g. n=10; 20-50 years old animals) would be treated with a MPA depot (e.g. 5000mg). Thereafter, the effects on the musth/testis cycles could be monitored by regular blood sampling to measure gonadotrophin and testosterone secretion (Lincoln and Ratnasooriya 1996; Niemuller and Liptrap 1991), ultrasonography to measure testis and accessory organ development (Hildebrandt et al. 1998), and behavioural observations to examine the expression of musth. To prove an effect of treatment, the same animals could be monitored in the preceding or following year as their own controls. In subsequent years, the efficacy of combined MPA and testosterone therapy could be examined.

B. Phase 2; would be based on the data from the captive Asian elephants, and performed in a well-monitored population of wild African elephants. A group of adult bull elephants that express musth cycles (e.g. n=10; 20-50 year old animals in a single area) would be identified and treated with a MPA depot (e.g. 5000 mg). The effects on musth and other social behaviours would be monitored. The treatment

would be continued for a minimum of 3 annual cycles, with additional data on birth rates in the local elephant population analysed to determine whether treatment was having the desired contraceptive effect.

Evaluation of GnRH conjugated to a cytotoxic agent as a reproductive sterilant in mammals

T.M. Nett[1], L.M. Glode[2] and B.A. Ball[3]

[1]Animal Reproduction and Biotechnology Laboratory, Colorado State University, Fort Collins, CO 80523; [2]Department of Medicine, University of Colorado Health Sciences Center, Denver, CO 80220; [3]Department of Population Health and Reproduction, University of California, Davis 95616

The goal of our research is to develop a treatment for chemically sterilizing animals that is both safe and effective. Ideally, we would like to identify a compound that: 1) is effective in males and females, 2) is effective in many species, 3) has permanent effects, 4) is easy to administer, e.g. injectable, and 5) will not sterilise predators of the target species.

With these characteristics in mind, the hypothalamus and anterior pituitary gland were considered more appropriate targets than the gonads. Not only are there obvious sex differences between the gonads, but there are also species differences in the structure of the hormones that stimulate them, i.e. follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Of course, the hypothalamus is protected by the blood-brain barrier and might not be accessible to compounds designed to inhibit reproduction. We therefore decided to target the gonadotropin-secreting cells of the anterior pituitary gland, which have receptors for gonadotropin-releasing hormone (GnRH), a decapeptide identical in structure across all mammalian species and that has been used to regulate reproductive processes in a wide range of species. A compound that interrupted reproduction at the level of the gonadotropes would satisfy criteria 1 and 2 above, i.e. it would work in both males and females across a range of species. The challenge was rather to find a method of permanently disabling gonadotrope function.

Several long-acting formulations of GnRH (or GnRH agonists) have been developed that suppress reproduction for as long as they are administered. Shortly after treatment ends, however, reproductive function recovers. Our approach was instead to conjugate a cytotoxic agent to an analogue of GnRH, and thereby target the cells for destruction. If all the gonadotropes could be destroyed, there would be no more stimulation to the gonads and the animal would become sterile. After considering several cytotoxic agents, we chose a ribosome-inhibiting protein derived from pokeweed (Phytolacca americana), pokeweed antiviral protein (PAP). PAP inhibits protein synthesis by inactivating 28S rRNA and, in turn, this inhibition of protein synthesis leads to cell death. If PAP could be delivered specifically to the gonadotropes by conjugation to a GnRH analogue it should allow specific elimination

of the gonadotropes (other pituitary cell types do not have GnRH binding capacity), and thereby act as a chemical sterilizing agent. Because the GnRH-PAP conjugate would be digested if administered orally, it would have to be injected. Overall, a GnRH-PAP conjugate would thus meet all 5 of our original criteria.

To test our hypothesis, we first conjugated a superagonist of GnRH (D-Lys6-GnRH) to PAP and examined the ability of the conjugate (GnRH-PAP) to bind to GnRH receptors in membranes isolated from bovine anterior pituitary glands. Although conjugation to PAP reduced the affinity of the superagonist for GnRH receptors by ~80%, the conjugate still bound to the receptor at a higher affinity than native GnRH. Next, we examined the ability of the conjugate to inhibit protein synthesis in an in vitro translation system. Conjugation only slightly reduced the ability of PAP to inhibit protein synthesis. At this point, we evaluated the ability of the conjugate to specifically inhibit synthesis of LH in cultured pituitary cells; the synthesis of LH was inhibited by > 95% by GnRH-PAP while the synthesis of prolactin was not affected. In short, the conjugate was able to prevent protein synthesis by gonadotropes, but did not appear to affect other pituitary cells. Since it was difficult to accurately evaluate cytotoxicity in a mixed population of pituitary cells, we next examined the effect of GnRH-PAP on Chinese Hamster Ovary (CHO) cells transfected with cDNA for the GnRH receptor. The conjugate was cytotoxic to GnRH receptor transfected cells in a dose and time dependent manner, whereas it had no effect on CHO cells lacking the GnRH receptor.

To examine the effects of GnRH-PAP in vivo, we treated rats with an amount of conjugate equivalent to 20ng of GnRH binding activity. In males, this led to a loss of spermatocytes and spermatids and a 50% reduction in testis weight, compared to vehicle treated controls ($p < 0.05$). Peripubertal females treated similarly failed to have estrous cycles and, 60 d after treatment, their ovaries contained only atretic follicles. Next, we used ovariectomized ewes to determine whether GnRH-PAP could reduce secretion of LH in vivo. After a single administration of GnRH-PAP, GnRH-induced LH secretion was reduced to approximately 50% of that in untreated sheep ($p < 0.05$) for at least 6 months. Finally, we examined the effect of GnRH-PAP on testis size, LH and testosterone secretion in male dogs. Four dogs received 0.0042 mg/kg GnRH-PAP hourly for 36 h (Hourly), while another four dogs were treated with a single daily bolus injection of 0.1 mg/kg GnRH-PAP for 3 consecutive days (Bolus). One further dog received a single bolus injection of GnRH-PAP (0.1 mg/kg; Single), and three control dogs were treated with GnRH alone (Controls). Twenty-five weeks after the initial treatment, all treated dogs were given a further single injection of 0.1 mg/kg GnRH-PAP while controls were injected with 0.0045 mg/kg of GnRH analogue. For nine months after treatment, testis size was measured and serum samples collected to monitor testosterone and LH concentrations by radioimmunoassay. To evaluate LH release capacity, the area under the serum LH concentration curve was examined after stimulation with 5 mg/kg GnRH. In summary, post-treatment serum testosterone concentrations and testicular volume were

significantly lower in Bolus and Hourly groups than in Controls ($p < 0.05$). In addition, basal LH concentrations during weeks 1 - 33 after treatment ($p < 0.05$) and LH release after GnRH stimulation were lower in the Bolus and Hourly than the Control group ($p < 0.05$). It is concluded that GnRH-PAP offers considerable promise as an agent for inducing chemical sterilization in a wide variety of mammalian species.

The efficacy of GnRH vaccines in controlling reproductive function in horses

TAE Stout[1], JA Turkstra[2], RH Meloen[2] and B Colenbrander[1]

[1]Department of Equine Sciences, Faculty of Veterinary Medicine, Utrecht University, Yalelaan 12, 3584 CM Utrecht, The Netherlands; [2]Pepscan Systems, Edelhertweg 15, 8219 PH Lelystad, The Netherlands

There are a number of situations in which suppressing the reproductive endocrine system in horses may be desirable. These include the competing animal whose tractability during training, or performance during athletic competition, is compromised by the expression of sexual or aggressive behaviour. Suppression of circulating testosterone concentrations has also been proposed as a treatment for stallions that shed equine arteritis virus (EAV) in their semen, because persistence of the virus in the accessory sex glands is testosterone-dependent, and continued shedding disqualifies that stallion and its semen from export to any of the important horse-breeding countries. Ablation of endogenous gonadotrophin stimulation may also provide a user-friendly means of preparing mares as sex steroid-inducible 'teasers' for semen collection or as recipients for embryo transfer (ET), and could, in the future, also represent a means of increasing the efficacy and reducing the variability in the response to superovulatory treatment of ET donor mares. In practice, the most important current indication for endocrine suppression is behavioural control, for which the alternative treatments include long-term progestagen therapy and surgical gonadectomy. Of course, the former is banned in athletic competition as potentially anabolic, whereas gonadectomy involves the risks of surgery and, if the animal in question turns out to be a gifted athlete, the loss of valuable genetic material from the breeding pool. In this light, the possibility of reversibly shutting down the reproductive endocrine system with a vaccine that induces anti-GnRH antibody formation is an attractive prospect. Unfortunately, while initial oil-based GnRH vaccines were effective in suppressing hormone production, they were unregistrable because of the severe local reactions that they induced. More recent vaccine formulations are water-based and induce less reaction, albeit at the cost of reduced reliability and a shorter duration of action.

Our own studies have involved the use of an ovalbumen conjugated GnRH-dimer vaccine (Oonk et al. 1998) to examine the efficacy and reversibility of GnRH vaccination in young stallions and in adult stallions and mares. In young stallions (3 years old), a course of two injections induced, from 2 weeks after the 'booster' injection, a dramatic increase in anti-GnRH antibody titres and an accompanying fall in systemic testosterone concentrations to baseline values. Treated stallions also showed mark reductions in testicle size, sperm production and sperm quality, and

depressed libido. However, while approximately 75% of treated animals responded to vaccination, the precise magnitude and duration of the effect differed markedly between individuals. Reversibility of treatment was demonstrated 11 months later when sperm quality and production parameters were similar to those in control animals. When the vaccine was tested in retired breeding stallions, only 4 of 8 responded with the expected fall in circulating testosterone concentrations after the initial course of two injections. And while two further stallions responded partially after a third injection 12 weeks later, the remaining two failed completely to respond even after a 4th vaccination. On the other hand, in the animals that did respond properly, testis size, sperm production capacity and sperm quality were reduced below those of both control stallions and poor responders. Disappointingly but not unexpectedly, response to vaccination had little effect on the intensity of sexual or aggressive behaviour in these older stallions. Eight months after the last vaccination, sperm production capacity had returned to pre-treatment levels, but sperm quality had yet to recover completely.

In adult mares, 3 successive vaccinations at 3-4 week intervals were needed to induce ovarian inactivity. Nevertheless, within 4 weeks after the third injection, 6 out of 7 mares entered a deep anoestrus characterized by a total absence of ultrasonographically visible ovarian follicular activity and circulating progesterone concentrations < 1ng/ml. Three of these mares restarted follicular development within 8 weeks (6-8 weeks) and one ovulated at this time. The remaining 3 mares were still completely acyclic 12 weeks after the final vaccination, although the onset of winter meant that it was not possible to distinguish clinically between a vaccine and a seasonal effect. The following spring, all 3 mares showed renewed ovarian activity. In a follow up trial aimed at ablating reproductive cyclicity for the entire breeding season, vaccination was performed in early March and repeated 3, 6 and 17 weeks later. As previously, 3 of 4 naive mares entered anoestrous within 2 weeks of the third vaccination. More surprisingly, while 2 of 4 previously vaccinated mares entered anoestrus soon after the first seasonal vaccination and remained acyclic for the entire breeding season, one previous responder failed totally to respond and another was rendered acyclic for only 4 weeks, shortly after the 3rd vaccination. In addition, treated mares showed irregular but occasionally strong oestrous behaviour, despite complete ovarian inactivity.

In conclusion, these studies confirm earlier reports that GnRH vaccination is a successful and reversible way of suppressing reproductive endocrine activity and sex-steroid induced behaviour in young horses. In older animals, the response rate tends to be lower and to require more injections to elicit a clinical effect of shorter duration. In addition, significant injection site reactions have been noted in older animals that would reduce its suitability in competing animals. Finally, older animals continued to exhibit sexual behaviour despite baseline gonadal steroid hormone

production. In terms of the utility of this treatment as a contraceptive, responding mares would be rendered temporarily infertile whereas, despite lowered sperm production and quality, most stallions would have remained capable of getting mares pregnant. In practical terms, the need for repeated injections to induce a clinical response would limit the use of this vaccine to only those feral or wild populations where individuals are readily tracked and identified.

Effects of vaccination against gonadotropin releasing hormone (GnRH) on sexual development and fertility in mammals

JA Turkstra, WMM Schaaper and RH Meloen

Pepscan Systems, Edelhertweg 15, 8219 PH, Lelystad, The Netherlands

Successful immunization against gonadotropin releasing hormone (GnRH) results in the production of antibodies that bind to and inactivate the native hormone, and thereby suppresses fertility in mammals. Inactivation of GnRH results, in turn, in reduced production and secretion of luteinising hormone (LH) and, to a lesser degree, follicle-stimulating hormone (FSH). In female mammals, the reduced levels of FSH and LH lead to a failure of follicle growth and ovulation, respectively, while in males low LH and FSH levels lead to reduced testis function, e.g. suppressed testicular steroid production, and a resulting fall in both libido and sperm production.

However, because GnRH is a small ‘self’ molecule, it is difficult to induce an immune response sufficient to neutralize the release of GnRH from the hypothalamus. Consequently, vaccines based on native GnRH are only moderately effective, and induction of an acceptable response requires aggressive adjuvants and multiple injections. To solve this problem of low intrinsic antigenicity, we extended the GnRH antigen into a tandem dimer molecule, introduced foreign amino acids and conjugated the resulting peptide to a carrier protein.

Most of the clinical trials of the GnRH immunosterilization vaccine were performed on male piglets, for which there is a practical desire to prevent the development of “boar taint”, a phenomenon induced by testicular steroid hormones. These trials demonstrated that, after two immunisations, testosterone concentrations are reduced to undetectable levels, and the development and function of the genital glands is halted completely. Efficacy of the vaccine in young male piglets is almost 100%, and poorly responding pigs can easily be distinguished by the larger size of their testes and scrotum. In female piglets, vaccination resulted in lowered circulating LH concentrations and a cessation of ovarian function, as evidenced by low inhibin levels and the absence of follicles and corpora lutea on the ovaries.

In sexually mature pony stallions, a primary course of 2 injections was sufficient to reduce testosterone concentrations to baseline values in all 4 treated stallions for the duration of the experiment (13 weeks). In addition, testis function was suppressed in 3 out of the 4 stallions, as witnessed by reduced sperm motility, a lower Johnson score (a measure of spermatogenic activity), a reduction in seminiferous tubule

diameter and a substantial decrease in testis size.

Recently, we modified the GnRH immunosterilization vaccine for the treatment of prostate cancer in men. In fact, it transpired that the prostate cancer vaccine (PCV) was superior to the original immunosterilization vaccine (ISV) for suppressing reproductive function in sexually mature boars and male rats. In both of the latter species, the PCV induced a rapid suppression of serum testosterone levels and atrophy of the genital glands in all treated animals. In the pig study, 3-5 years old boars were immunized twice at a 4-week interval. None of the boars treated with ISV had responded after an initial course of 2 immunizations, whereas two out of four boars treated with PCV exhibited baseline serum testosterone concentrations within three weeks after the second injection. A third immunization caused the serum testosterone concentrations to drop to zero in all four boars in the PCV group. By contrast, a measurable biological response was effected in 3 out of 4 boars in the ISV group only after a fourth consecutive immunization. In the early responding (PCV) boars, GnRH antibody titres rose rapidly and remained high until the end of the study. Twenty-five weeks after the initial immunization, the boars were slaughtered and their testes and accessory genital glands were weighed. Testes of control boars consistently weighed in excess of 550 grams, whereas testes of all boars treated with PCV weighed less than 400 g. By contrast, only three of the boars treated with ISV had testes that weighed less than the control animals and the testes of the non-responder reached 580 g. Examination of seminal vesicle development revealed an even more pronounced effect of successful vaccination. Six out of 8 vaccinated boars (4 PCV and 2 ISV), had seminal vesicles weighing less than 200 g, whereas the seminal vesicles of control boars exceeded 800 g. In addition, libido was suppressed in 3 of the vaccinated boars (2 PCV and 1 ISV), while sperm quality was reduced in 3 other vaccinated animals (2 PCV and 1 ISV). In rats, similar results were observed with circulating testosterone concentrations beginning to drop 2 weeks after the second immunization with PCV (4-week interval between vaccinations) and reaching baseline levels a further 4 weeks later.

In conclusion, immunisation with the modified GnRH tandem-dimer vaccine leads to a rapid suppression of circulating testosterone concentrations. This vaccine, therefore, represents a promising potential treatment for hormone-dependent prostate cancer, and for suppressing fertility.

The feasibility of current options for the management of wild elephant populations

IJ Whyte

Kruger National Park, Skukuza 1350, South Africa

There is now ample evidence that in game reserves in which elephants are adequately protected from poaching their numbers will increase to the point where they begin to have negative impacts on biodiversity. Initially this may only affect the structural diversity of habitats but as elephant numbers continue to increase, some other species will be lost from the system. Generally, woodlands are changed to grasslands so that all species which are dependant upon woodland habitats may be extirpated.

The decision whether elephant numbers in any reserve should be limited must be based on the management priorities set for the reserve. If biodiversity is a priority, something must be done to limit the elephant population to a level at which their impacts will not have negative consequences for other species. And if the priorities for such reserves have not been clearly defined, management will be directionless and muddled.

In reserves in which biodiversity has been defined as the management priority, what options are available for managing elephants? Three only – translocation, contraception and culling. While the first two non-lethal options seem more ethically acceptable, they have their problems.

Translocation
Opportunities for translocations are now very limited. Most areas in Southern Africa that could potentially accommodate elephants now have them, while those that still can (e.g. Limpopo National Park in Mozambique), will not be able to take the numbers that need to be moved. While this method of population management may seem to be ethically acceptable it can seldom be established with certainty whether family units are moved intact or some members are left behind. The effects of such separation are not yet well understood.

Contraception
Current contraception technology is of limited value for controlling large populations. While porcine zona pellucida (pZP) vaccines have been shown to be effective and acceptable in elephants, oestrogen (oestradiol-17ß) implants caused behavioural aberrations and other unacceptable post-treatment effects. But regardless, the logistics of both techniques preclude their use. To stabilize an elephant population,

75% of all breeding females (i.e. 35% of the total population) must be constantly under treatment. These animals all require “boosters” at specific times, which means they must be individually locatable and therefore fitted with a radio collar. These requirements all push the financial and logistic costs to an unaffordable level for most conservation agencies.

Sterilization has the major drawback of irreversibility. Any population being regulated in this manner would be severely at risk from epidemics of either poaching or disease and its ability to recover would be greatly impaired if most of the adults (females or males) had been permanently sterilized.

A final problem with all contraception techniques is that they cannot reduce a population in the short term. Once a population has been stabilized by contraception, there will be a time lag before natural mortalities will eventually begin to reduce it.

Culling

Culling is the third option and, currently, is the only one that can solve the problems of over-abundance in a large population. However, it is an extremely emotive subject, particularly when applied to elephants. While culling elephants may be an anathema to some, it is usually seen by those concerned with the maintenance of biodiversity as a necessary evil – one which must be used in situations where translocation and contraception are not implementable.

The advantages of culling are that, in large populations, the over-population problem can be addressed successfully. Also, the processed by-products of culling (meat, hides, ivory, etc.) can be sold profitably to provide conservation activities, such as anti-poaching, with much needed funding. Disadvantages? a certain amount of disturbance to nearby related groups, the degree of which will depend on proximity and will be worst when a large group must be split. However, such disturbance is identical to that which accompanies translocation. The impacts come from the disturbances of the operation itself and from the longer-term effects of the loss of bond group or family members.

The major ethical question associated with culling is: Is it morally justifiable to kill elephants? Some Western cultures may find culling ethically unacceptable. But the question must be asked, whose ethics should apply? To a rural African with little access to protein, an average Westerner, or an animal rights campaigner, ethical elephant management will mean very different things.

While many believe that culling is not ethical, it must be understood that the culling option has to be weighed up against the losses of whole populations of other species. Loss of a species from a system will have its effects on biodiversity and the system’s food webs, and such a loss may even mean the complete extinction of that species. These species losses will occur if elephant numbers are not limited by some

means. Therefore one must ask, is it ethical to allow species to be lost from a system when prevention is possible

Report

The First International Workshop on the “Control of Wild Elephant Populations” was convened at the Golden Tulip Hotel in Beekbergen, The Netherlands, during 7th and 8th November 2003. This workshop was initiated by Mr. Paul Fentener van Vlissingen, sponsored by the Prince Bernhard Nature Fund and organised by the Faculty of Veterinary Medicine of Utrecht University. The twenty-one experts that participated in the workshop were drawn from 9 countries and included veterinary scientists, biologists and wildlife managers. A total of 20 papers were presented on a range of topics that included: 1) management strategies and population control mechanisms already in place in major game parks in South Africa, Zimbabwe and Kenya; 2) ongoing experiments in Kruger National Park and Makalale Reserve in Northern Transvaal to suppress conception rates in female elephants by dart-delivered active immunisation against ZP3, the principal sperm binding protein in the zona pellucida; 3) current research programmes in academic institutions worldwide on immunocontraception in female and male large domestic and wild animal species, using various preparations of ZP3 or gonadotrophin-releasing hormone (GnRH) as immunogen and a range of synthetic oil or water based preparations as adjuvant; 4) novel methods of achieving contraception or infertility in pest species, such as the house mouse in Australia and possum in New Zealand, based on the incorporation of a reproductive immunogen into either the genetic material of a species-specific non-lethal virus or into bacterial ghosts; and 5) the actions of specific chemicals on the morphology and functionality of spermatozoa while in the epididymis, and the effects of exogenous androgens and progestagens or GnRH antagonists or vaccines on testicular function and libido in prepubertal and mature men and male animals.

In frank and wide-ranging discussion sessions that followed each group of papers, differing views and strategies were debated rigorously and, wherever possible, a consensus opinion was reached. As a result of the great deal of new information presented and the ensuing discussions, a number of broad conclusions and recommendations were reached:

1. Preliminary experiments to induce contraception in adult female elephants have yielded promising results. Selected females in the large herd of 11,000 elephants within the boundaries of the Kruger National Park and all 18 adult females in the much smaller herd of 60 elephants maintained in the Makalale Reserve, have been actively immunised against ZP3. At the same time, challenges with regard to immunogen delivery, preparation of the optimum adjuvant and recognition of immunised animals for monitoring and revaccination, are being actively investigated. The Workshop is unanimous in recommending strongly that adequate funding and practical help be made available to ensure that further vaccination field trials planned for Kruger Park and other smaller public and private game parks in South Africa and neighbouring Botswana can be undertaken.

2. Despite the considerable success of the relocation strategy used by Kruger

National Park in recent years, and justified optimism that an efficacious method for inducing harmless and reversible contraception in larger elephant herds will be developed in coming years, organised culling remains a necessary method for controlling unwanted increases in, or achieving rapid reductions in, certain elephant populations. Most notably, those populations in Kruger Park, Hwange Park and surrounding areas in Zimbabwe and in clearly defined areas in Botswana need urgent attention. The Workshop recommends that the expertise of the relocation teams in Kruger Park be made available to other game parks and countries in southern and eastern Africa to assist necessary culling operations. The Workshop is also very aware and approving of the considerable potential benefits that may and should accrue to local populations and park management authorities as a result of well-organised culling operations, including the provision of food and cash from the sale of ivory and other by-products.

3. The Workshop was much alarmed to learn of the dangerous elephant overpopulation of Hwange National Park and surrounding areas in Zimbabwe, and of the huge scale “die-off” that will almost certainly occur if drastic action is not taken to reduce the population by some 20,000 animals over the next 2-3 years. The negative effects of such an “elephant holocaust”, in terms of animal welfare and biodiversity of plant and other animal species in the area, are too horrendous to contemplate and the impending disaster simply cannot be allowed to occur. The Workshop therefore urges that every possible and necessary political, financial and logistic step be undertaken urgently to enable a major culling operation in Zimbabwe to relieve this intense overpopulation pressure.

4. The Workshop appreciates greatly the many university, research institute and industry-led research groups worldwide that are actively investigating novel methods for inducing effective contraception in male and female humans and domestic and wild animal species. Much of this work was presented and/or discussed at the Workshop and many useful scientific contacts were made. It is important that these “other species” research groups remain aware of, and interested in, the problems faced in elephant population control and continue in their willingness to share new ideas and techniques with colleagues at the “elephant coal-face”. It is, therefore, essential that non-elephant contraceptive experts remain an active part of the Workshop in future years.

5. In view of the practical and logistical difficulties associated with the identification and location of individual animals, which is a vital step in implementing existing contraceptive methods which require multiple carefully-timed injections of immunogen, the Workshop urges that time and money be devoted to developing and refining a method of multiple time-delayed repeated immunogen delivery within a single dart. The Workshop was also greatly impressed by recent advances in the technique for permanently and specifically ablating gonadtroph cells in the pituitary glands of target species using a single injection of a potent GnRH agonist conjugated to a cytotoxin such as the ribosome inhibiting protein, pokeweed anti-viral protein

(PAP). Such a single-administration, minimally invasive treatment that has the potential to induce permanent sterility in targeted animals could be applicable to wild elephants. For example, it could potentially be employed to ablate reproductive function and suppress oestrous cyclicity in every 3rd or 4th adult female in elephant family groups, thereby lowering overall fertility of the population while maintaining the necessary broad base to the pyramidal family structure. The Workshop thus suggests that, as soon as practically and scientifically possible, this strategy of gonadotroph ablation be tested in a suitable, small game park elephant population.

6. Although a variety of useful treatment regimes for inducing temporary infertility and down-regulating libido in adult males of large animal species like the horse and cow are available, the Workshop does not currently foresee an application of such techniques for contraceptive purposes in large herd situations. Ablation of musth and reproductive function in large mating bulls, even if it were possible, may simply mean that younger, less genetically desirable bulls quickly rise up and assume the mating role within that population. On the other hand, these treatments do offer considerable potential for controlling fertility in small herds, or sexual and aggressive behaviour in problem bulls.

7. Clearly, computer models based on available population growth and demographic data need to be created to accurately predict the number or proportion of animals that need to be removed, permanently or reversibly sterilised in order to maintain numbers in a given elephant population within desired limits for a prolonged period of time. These models should also take into account the fact that the chosen strategy must allow the population in question to retain the flexibility to respond to unpredictable challenges, such as severe drought or disease. Ideally, any new model should also be able to predict the effect of a given contraceptive strategy on family structure and social or sexual interactions.

In conclusion, the First Workshop on the Control of Wild Elephant Populations was a resounding success, both scientifically and socially. A mood of enthusiasm and scientific cooperation pervaded the meeting and there was unanimous agreement amongst the participants that considerable benefits could be gained from a further meeting in 2-3 years time. In the interim, the members are resolved to maintain close collaborative links and to do everything possible to further the aims expressed in the recommendations made above. Warm and very generous appreciation is extended to Mr. Paul van Vlissingen and the Prince Bernhard Nature Fund for their foresight and generosity in creating this useful gathering.

Conclusions

MANAGING AFRICAN ELEPHANT POPULATIONS: ACT OR LET DIE?

In several African countries, elephant populations are growing at an alarming rate, as high as 5-10% per annum. Such population expansion is not sustainable and, despite the huge tracts of land open to elephants, it is already having a devastating effect on a number of unique ecosystems and the biodiversity (plant and animal) within them. To avoid an ecological catastrophe culminating in a mass die-off of elephants, urgent action is needed to reduce elephant numbers. Even then, further long-term population control strategies must be implemented if the apocalypse is to be prevented rather than just postponed. With this in mind, an expert consultation on the "Control of Wild Elephant Populations" was organised by Utrecht University's Faculty of Veterinary Medicine in Beekbergen, The Netherlands on 7th – 8th November, 2003. Twenty-one international experts in fields ranging from reproductive physiology and contraception to population dynamics and game-park management attended the meeting, and came to the following conclusions:

1. In many of the more then 35 African countries that are home to wild elephants, populations are or have historically been endangered by poaching and habitat destruction. However, in several parks where the elephants are well protected, populations are now growing at such a rate that other animal species and plants are being driven to extinction and, due to destruction of the vegetation, a mass die-off of elephant is fast becoming inevitable.

2. The approach to controlling elephant numbers depends primarily on the aim of a given park; i.e. is it primarily an elephant sanctuary or an area dedicated to conserving as great as possible a diversity of species and habitats. If the aim is biodiversity and the elephant population density is already well above the carrying capacity, immediate population reduction is the only answer. Although this could, in theory, be achieved by translocating groups of elephants to new areas, translocation is expensive, time-consuming and logistically complex and, moreover, there are very few areas left to accommodate the large numbers of animals involved. Indeed, in some areas, the numbers of elephants are so large, that the only realistic way of bringing the population under control is culling.

3. Contraceptive techniques have been developed that successfully control population growth in feral horses and are being developed for pest species such as mice and possums. While such anti-fertility treatments are very useful for reducing the rate of population growth in the longer term, they are certainly not suitable for reducing numbers of a long-lived and late reproducing species, like the elephant, in the short term.

4. Techniques exist to exert reversible or irreversible contraception on male and/or female animals. Indeed, there are already encouraging results from field trials of anti-

zona pellucida vaccination of female elephants (a treatment that should block fertilisation) and pilot trials have begun with a GnRH vaccine in male elephants (vaccination should block sperm production and suppress sexual behaviour in males and prevent follicle development and ovulation in females). Further studies are needed to examine the effects, efficacy, reversibility and in-field practicality of these and other putative contraceptives. Ideally, the bulk of this development will be achieved using in vitro or other-species models, since the 4-year calving interval in elephants means that field trials yield meaningful results only slowly.

5. The way in which the presence and behaviour of a dominant bull suppresses reproductive activity in other male elephants and, at least in captivity, can lead to temporary infertility should be investigated. This may lead to novel contraceptive approaches tailored to male elephants.

6. Demographic models need to be developed, using existing and new, targeted field data, to predict the effects of elephant removal and/or contraception on population growth and conservation targets. Field data on the natural factors, such as food resources, that affect population growth will improve the accuracy of these models, which could then be used to identify the best strategy, and the proportion of animals that need to be included, to control a given population.

7. The expert group makes a call for international political will and financial support to:

a. Preserve eco-systems in Africa

· By protective measures for animals and plants,

· By urgent reduction of elephant numbers where needed, through translocation and culling.

· By reducing elephant population growth via fertility control

b. Study population dynamics in elephants and the factors that affect it, so as to enable reliable modelling of the effects of protective and control measures on population growth, social structure and behaviour.

c. Improve existing and develop novel methods of contraception for the elephant.

Disclaimer

The Conclusions are based on the general consensus of opinion reached during the

workshop and may, therefore, not express the personal opinion of all the individual participants.

ABSTRACT

Contraceptive vaccines are used to reduce birth rates in wild and feral animal populations. While the immunocontraceptive GonaCon-Equine has proven effective in reducing fertility among female feral horses, there is individual variation in the duration of infertility following treatment. To identify genetic factors influencing the effectiveness of GonaCon-Equine, we conducted a genome-wide association study of 88 mares from a feral population genotyped using the Illumina GGP Equine 70k SNP array. Contraceptive treatment schedules and long-term foaling rates have been recorded for each individual. We used mixed linear models to control for relatedness among mares. We found a significant association ($p < 5 \times 10^{-8}$) with a locus on equine chromosome 18. The most likely candidate genes in this region are *STAT1* and *STAT4*, which are both involved in immune system function. Variation in STAT function could affect the immune response to the vaccine, leading to variation in contraceptive efficacy. Additional SNPs reaching a less stringent threshold of significance ($p < 5 \times 10^{-6}$) were located on other chromosomes near known immune system genes, supporting the hypothesis that variation in immunocontraceptive efficacy can be attributed to genetic variation in immune response rather than fertility genes.

1. Introduction

Immunocontraception has been used effectively to decrease birth rates in many different animal species, wild and domestic, with contraceptive vaccines targeting one of two proteins that are required for reproduction. Some vaccines use porcine zona pellucida protein (PZP) as an antigen (Kirkpatrick et al., 2009). Antibodies to PZP bind to the zona pellucida and block fertilization in immunized females. The second target protein is gonadotropin-releasing hormone (GnRH), a key hypothalamic hormone that regulates synthesis and secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary gland.

Immunization against GnRH has been increasingly used to manage wild populations. The National Wildlife Research Center (USDA-APHIS Wildlife Services) developed an immunocontraceptive named GonaCon, which consists of a GnRH peptide combined with an adjuvant to trigger an immune response (Miller et al., 2004). This generates neutralizing antibodies against GnRH, thereby inhibiting FSH and LH synthesis and secretion. In females this vaccine blocks ovulation and estrus, resulting in infertility (Miller et al., 2004). In male white-tailed deer, GonaCon vaccination leads to reduced testosterone levels, reduction of testes size, and inhibition of reproductive behavior (Killian et al., 2005). However, infertility is temporary in both males and females, lasting only as long as GnRH-antibody titers remain high enough to block GnRH activity (Miller et al., 2000; Pinkham et al., 2022). The efficacy of GonaCon in reducing reproduction has been evaluated in a wide variety of mammalian species, such as prairie dogs and fox squirrels, wild boar, feral cats, and elk (Krause et al., 2014; Massei et al., 2012; Powers et al., 2014; Vansandt et al., 2017; Yoder and Miller, 2010).

GonaCon has also been considered for use in feral horse herds. Feral horses on public lands exhibit a high population growth rate with about 20% increase per year (National Research Council, 2013) and cause ecological damage when they reach high densities (Eldridge et al., 2020), necessitating some form of population control. Public sentiment favors contraception as a horse management tool over lethal methods or capture and removal, yet the public often responds poorly to permanent sterilization of horses. Reversibility of the GonaCon vaccine provides an appealing option for management of feral horse populations.

Baker et al. (2018) began research on the long-term effectiveness of GonaCon-Equine in free-roaming feral horses in Theodore Roosevelt

National Park (TRNP) in 2009, with 25 mares receiving a primary vaccination that fall and a secondary vaccination four years later, by hand-injection at a roundup. Due to the success of the treatment, the study was expanded. To determine optimal reimmunization interval, 40 additional mares in three treatment groups were treated by remote delivery via dart, with the last group receiving their secondary vaccination in 2016 (Baker et al., manuscript in prep). Collectively, the reimmunization treatments were divided into groups based on the interval between primary and secondary injections: 4-year intervals, 2-year intervals, 1-year intervals, and 6-month intervals. A control group was treated with a saline injection on the same schedule as the 4-year group. Foaling rates of these mares were monitored from 2009 through 2021. While the vaccine was shown to be effective in reducing foaling rates, the duration of infertility was variable; some mares had one or two years of infertility while others remained infertile for the duration of the study. Factors influencing individual mares' responses to treatment are as yet unknown.

Individual variation in reproductive rates following immunocontraception could be due to many factors, both environmental and/or genetic. Some genetic components of fertility are known, but many aspects of reproduction are complex and not fully understood. In humans, genes have been identified for some female reproductive disorders/diseases as well as markers contributing to fertility traits such as reproductive lifespan and ovarian function (Gajbhiye et al., 2018). The genetics of fertility traits in dairy cattle has also been a subject of interest, with several candidate markers identified (Ma et al., 2019). However, genes that influence fertility in horses have yet to be identified (Laseca et al., 2021; Raudsepp, 2020).

Variation in efficacy of immunocontraceptives could also be due to variation in genes underlying immune responses. As with fertility, immune responses are complex and difficult to attribute to any single gene. Research into human disease-resistance has demonstrated that epigenomic changes in gene expression play a role beyond purely genetic factors (Yamamoto et al., 2021). In cattle, some quantitative trait loci have been associated with immune response to vaccination (Leach et al., 2012). However, no previous studies have identified genetic factors in response to any immunocontraceptive agent in horses or response to GonaCon in any other species.

Here, we use SNP genotypes to conduct a genome-wide association study (GWAS) in search of loci associated with variation in the long-term effectiveness of GonaCon-Equine vaccine. We hypothesize that genes involved with fertility and/or immune response will impact the duration of infertility following vaccination. This research will improve our understanding of the mechanism by which the vaccine works and inform future use of GonaCon-Equine in other feral herds. More broadly, findings from this study may also provide insight into why vaccine induced immunity persists or wanes over time, which is an outstanding question in immunology (Kennedy et al., 2020).

2. Materials and methods

2.1. Sample and data collection

Hair samples were collected from all study mares during a regularly scheduled gather in 2013. Individual horses were identified by coat color, markings, and conformation. In 2017, tissue samples were collected via biopsy dart from four mares that had evaded the 2013 capture and were included in the later GonaCon treatment groups. We collected an additional 18 tissue samples from young study mares born in 2014 by biopsy dart under research permit number THRO-2020-SCI-0013 and NPS IACUC approval (ND_THRO_McCann_HorseBiopsyDarting_2020.A1). This resulted in a total of 88 samples, which included all treated and control mares that had received both injections (Table 1). We used foaling data as collected by Baker et al. (2018), consisting of annual pregnancy status of all mares for the duration of the study. We also generated pedigrees from records for the herd going back to the 1980 s. Many pedigree relationships of the past two decades have been confirmed through genetic testing, and older relationships were recorded from behavioral observations of familial relationships of mares and their offspring.

Table 1
GonaCon treatment groups, named for time interval between primary and booster GonaCon injection. Control group received saline injections at the same schedule as 4-year group.

Treatment Groups	Number of Individuals
Control	25
4-year	25
2-year	11
1-year	14
0.5-year	13

2.2. DNA extraction and genotyping

Genomic DNA was extracted from hair follicle and tissue samples by the Animal Genetics Laboratory at Texas A&M University using Gentra Puregene Tissue kits (Qiagen) following manufacturer's protocols. Individuals were then genotyped at Neogen Genomics Laboratory (Lincoln, NE) for over 70k SNPs located evenly across the horse genome using the Illumina Equine GGP 70k BeadChip (Illumina Inc., San Diego, CA).

2.3. Data pruning

We performed quality control filtering of the genotypes using SNP & Variation Suite v8.9.0 (SVS) (Golden Helix, Inc., Bozeman, MT, www.goldenhelix.com). We removed markers with call rate ≤ 0.95 and with a minor allele frequency (MAF) of 0.05 or less. We removed markers with Hardy-Weinberg equilibrium (HWE) P-values $< 1 \times 10^{-6}$ as recommended by Marees et al. (2018). All samples had a call rate ≥ 0.90 and all but three had a call rate ≥ 0.98, so we retained all individuals due to the already limited sample size. We mapped the remaining SNPs to the horse reference genome EquCab3.0 (https://www.ncbi.nlm.nih.gov/assembly/GCF_002863925.1/). Since our dataset only included females, we retained the SNPs on the X-chromosome. The dataset contained a total of 47,495 SNPs after pruning.

2.4. Data analysis

We conducted a single-locus mixed linear model (MLM) GWAS using SVS's implementation of EMMAX (Kang et al., 2010; Vilhjalmsson, 2012). Infertility following GonaCon booster was treated as a quantitative trait. Because treatment groups had variable durations since the booster, we calculated a normalized measure of infertility as the proportion of years infertile: (# years infertile)/(total # of years since booster). Infertility values ranged from 1 for those mares that exhibited complete infertility to 0 for mares that exhibited complete fertility since the booster (Fig. 1). We included Treatment Group as a fixed effect interaction with genotype in the model. Because many of the mares were related to each other, we computed a relationship matrix in SVS using pedigree data. This kinship matrix was included as a random effect to account for relatedness among mares. The final model can be represented as Infertility = Genotype x Treatment Group + Kinship. The MLM analysis used an additive genetic model and included Bonferroni multiple testing corrections and false discovery rate (FDR) calculations. SVS also estimated narrow-sense heritability (h^2) of Infertility for each model following the method of Kang et al. (2010). We used $p = 5 \times 10^{-8}$ for a genome wide significance threshold but also considered SNPs with a less stringent threshold of $p = 5 \times 10^{-7}$ as suggested by Chen et al. (2021). We referenced EquCab3.0 to identify genes that contained significant SNPs and genes within broader regions of multiple significant SNPs. We

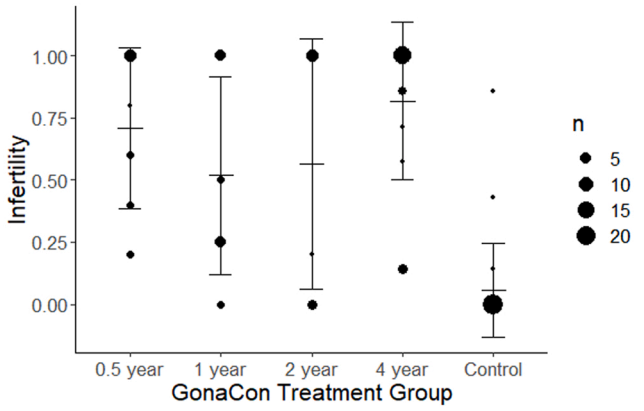

Fig. 1. Infertility after treatment with GonaCon-Equine for mares in each reimmunization group, with error bars indicating mean and standard deviation. Infertility was calculated as the proportion of years infertile following booster injection.

included genes found within 200 kb of significant SNPs as candidate loci (Brodie et al., 2016). To investigate biological function of these candidate genes we referenced The Human Gene Database (www.genecards.org).

We also evaluated several other variations of the MLM to test for potentially confounding variables. To verify that significant genetic associations were due to the treatment group by genotype interaction, we dropped the interaction from the model and only included main effects, summarized as Infertility = Genotype + Treatment Group + Kinship. To determine whether there were any fertility differences among mares prior to assignment to treatment groups, we tested an MLM with infertility prior to GonaCon immunization as the dependent variable. Infertility prior to the first injection was calculated in the same manner as infertility following the booster: (# years infertile)/(total # of years between sexual maturity and initial injection). Sexual maturity was defined as 3 years of age for the purposes of this study, based on age at first foaling typical for the herd. However, a few mares produced a foal as 2-year-olds, so their age at sexual maturity was considered 2 years. The model included the same interaction term and kinship matrix as above, summarized as Infertility Before Injection = Genotype x Treatment Group + Kinship. We also analyzed several models with additional covariates such as age at first injection and injection delivery method (hand injection or dart delivery). These covariates had minimal impact on the results of the simpler model reported below (Fig. S1).

3. Results

The mixed linear model GWAS for infertility after GonaCon treatment using the treatment group by genotype interaction yielded 10 significant SNPs at the $p = 5 \times 10^{-7}$ threshold, with one SNP significant at $p = 5 \times 10^{-8}$ (Table 2). These 10 SNPs were located within a 2.10 Mb region on chromosome 18 of the horse reference genome (Fig. 2). All 10 SNPs were also significant using a very stringent Bonferroni multiple testing correction, with corrected p-values < 0.05. The FDR for each was < 0.005. A Q-Q plot of observed versus expected p-values shows deviation of significant SNPs from values expected when assuming no association, with multiple SNPs deviating from the otherwise linear relationship (Fig. 3). This relationship strongly suggests that genetic variants truly influenced GonaCon effectiveness. Heritability of the Infertility trait was 0.277604 (SE = 0.238108) for this model, while heritability in the model evaluating infertility prior to treatment was 4.53979×10^{-5} (SE = 0.171988).

None of the significant SNPs were located within coding regions of genes, however one was located within an intron of NGFI-A binding protein 1 (*NAB1*) (Table 2). The region of ECA18 with significant SNPs contained ten annotated genes and two uncharacterized protein coding regions (Table 3). Two of those genes, signal transducer and activator of transcription 1 (*STAT1*) and signal transducer and activator of transcription 4 (*STAT4*), have known roles in the immune system.

Inspection of the Manhattan plot in Fig. 2 suggests additional regions of interest on chromosomes 4, 5, and 15, despite SNPs falling below the most stringent thresholds for genome-wide significance. Five SNPs within those regions had p-values $< 5 \times 10^{-6}$ (Table 4) and fourteen genes were located within a 200 kb window around those loci (Table 5). One of the SNPs on ECA4 is located within an intron of the IKAROS family zinc finger 1 (*IKZF1*) gene, which regulates lymphocyte differentiation. The nearest annotated gene to the SNP on ECA5 is protein tyrosine phosphatase non-receptor type 22 (*PTPN22*), which regulates T-cell receptor signaling. There were no annotated genes located within the 200 kb window surrounding SNPs on ECA15.

Results from the alternate models yielded no significant SNPs for infertility. When the treatment group by genotype interaction was dropped from the model, SNPs on ECA4, ECA5, ECA15, and ECA18 were no longer significant (Fig. 4a). In addition, the SNPs identified in Fig. 2 were not associated with infertility in mares prior to their treatment with GonaCon (Fig. 4b). Addition of other covariates (e.g., age at immunization) to the model did not appreciably change the GWAS results, and so were not included in the final model described above (Fig. S1).

4. Discussion

This study demonstrates that genetic variants influenced the response of TRNP mares to GonaCon vaccination. The difference between models including vs. excluding the genotype by GonaCon interaction and models before vs. after GonaCon immunization strongly indicate that genetic variants specifically influence GonaCon efficacy. The lack of significant SNPs resulting after elimination of the interaction between GonaCon treatment and genotype from the model indicates that these associations cannot simply be explained by genotype or by GonaCon vaccination alone. In addition, there were no associations between genotype and infertility prior to GonaCon vaccination. The near-zero heritability of infertility prior to vaccination in contrast with moderate heritability after vaccination also points to genetic variation in

response to the vaccine. Taken together, these findings indicate that individual differences in infertility are the results of genetic variation in the immune response to the GonaCon vaccine. Indeed, genetic variants are a major factor influencing immune responses to pathogens and vaccines in humans (Scepanovic et al., 2018).

The most likely candidate genes to influence GonaCon effectiveness in TRNP mares are *STAT1* and *STAT4* on ECA18. The STAT family of genes are transcription activators with a wide range of functions, some of which include innate and adaptive immune response to a variety of pathogens (Horvath, 2000). Together with Janus kinases (JAK) they form the JAK-STAT signaling pathway by which cell surface receptors trigger transcription in the nucleus (Stark and Darnell, 2012). *STAT1* and *STAT4* variants have been shown to influence disease risk and immune responses in humans (Hedl et al., 2020). *STAT1* is involved in the signaling pathway that activates antiviral responses and reduced activity of *STAT1* is connected to increased infection susceptibility (Katze et al., 2002; Najjar and Fagard, 2010). Mutations in *STAT1* cause different clinical disorders depending on whether the mutations are recessive or dominant and whether they result in *STAT1* deficiency or *STAT1* gain-of-function (Mizoguchi and Okada, 2021). Loss of *STAT1* function leads to increased susceptibility to mycobacterial and viral infection, and gain-of-function is associated with autoimmune disease in addition to increased infection susceptibility (Boisson-Dupuis et al., 2012). *STAT1* plays a key role in inhibition of the IL-17 pathway, which can result in impaired immunity (Liu et al., 2011). The cytokine IL-17 induces tissue inflammation and is produced by Th17 memory cells (Korn et al., 2009), which are themselves a major cause of autoimmune disease in mice and humans when dysregulated (McGeachy, 2013). In horses, *STAT1* was upregulated following infection with African horse sickness virus (Wall et al., 2021). *STAT4*, which is adjacent to *STAT1* on ECA18, is also an important component in immune response to many diseases and is linked to inflammation and T-cell differentiation (Yang et al., 2020).

Genetic variation in *STAT1* and/or *STAT4* function within the TRNP herd could affect the mares' ability to mount a strong and long-lasting immune response to the GnRH peptide. However, the significant SNPs on ECA18 are not found within any of the candidate genes. The Equine GGP 70k chip only included one SNP within an intron of *STAT1* and one SNP within an exon of *STAT4*, neither of which reached the threshold for genome-wide significance ($p = 9.60\text{x}10^{-4}$ and $p = 5.21\text{x}10^{-2}$ respectively). In human response to an influenza vaccine, *STAT1* expression levels were linked to antibody response, with increased antibody titers strongly correlated with higher *STAT1* expression on the first day after vaccination (Bucasas et al., 2011). Thus, we hypothesize that the causal SNP or SNPs in the TRNP mares are likely to influence expression of *STAT1* and/or *STAT4* in basal conditions and/or in response to GonaCon vaccination. Future studies could test this hypothesis by drawing blood from mares and measuring *STAT1* and *STAT4* expression and activation in white blood cells under basal condition and in response to signaling molecules that activate STATs during immunization.

The observation that two of three suggestive loci on other chromosomes also contain genes related to immune function (Table 4) supports our initial hypothesis. *IKZF1* and *PTPN22* have both been implicated in a

Table 4
SNPs on other chromosomes which are above the threshold of $P = 5 \times 10^{-6}$. Asterisks mark genes with known immune system function and parentheses indicate a gene located ~34 kb away from that SNP.

range of immunodeficiencies (Kuehn et al., 2021; Tizaoui et al., 2021). In humans, variants in *IKZF1*, *PTPN22*, and *STAT4* are associated with risk of developing the autoimmune disorder systemic lupus erythematosus (Ebrahimiyan et al., 2018; Hu et al., 2013; Kyogoku et al., 2004; Mohan and Putterman, 2015). There is some evidence of epistasis between *IKZF1*, *STAT4*, and other loci (Dang et al., 2014), and *IKZF1* may be a regulator of *STAT4* in human T cells (Hu et al., 2013). *PTPN22* has roles in both the adaptive and innate immune system as a signal inhibitor of T-cell activation and a signal enhancer promoting production of type I interferon in myeloid cells, respectively (Stanford and Bottini, 2014).

While we think that genetic variation in immune response to GonaCon vaccination is the most plausible hypothesis for variation in contraception, STAT family genes have also been associated with reproductive traits in cattle. *STAT1* and *STAT4* are located together on chromosome 2 in the cattle genome and were within a genome window associated with age at first calving in cattle (Dubon et al., 2021). *STAT1* and the paralog *STAT3* were linked to embryonic survival in cattle (Khatib et al., 2009). Several members of the STAT family, as part of the JAK-STAT pathway, have also been shown to play a role in milk production in dairy cattle (Khan et al., 2020). In horses, STAT genes were found to be differentially expressed in adult versus fetal ovaries (Hall et al., 2017), but not much is known about the association of STAT gene variation with horse reproductive traits. In mice, the JAK-STAT pathway has been shown to play a critical role in normal reproductive development and function. Cytokine receptors activate JAK-STAT signaling in GnRH neurons, which regulate the secretion of GnRH peptide. Knockout of the *JAK2* gene resulted in impaired fertility (Wu and Wolfe, 2012). Thus, altered STAT expression/activity in GnRH neurons could also potentially affect reproductive function in the mares. This hypothesis could be tested through experiments measuring STAT expression and activity in GnRH neurons in a rodent model of GonaCon immunocontraception.

Further work needs to be done to identify the specific locus responsible for the genetic association as well as the mechanism causing phenotypic variation in the long-term efficacy of GonaCon. Future studies should use a higher density of markers on a SNP chip or whole genome sequencing to fine map causal variant(s). If possible, future studies should also aim to use unrelated individuals to minimize the

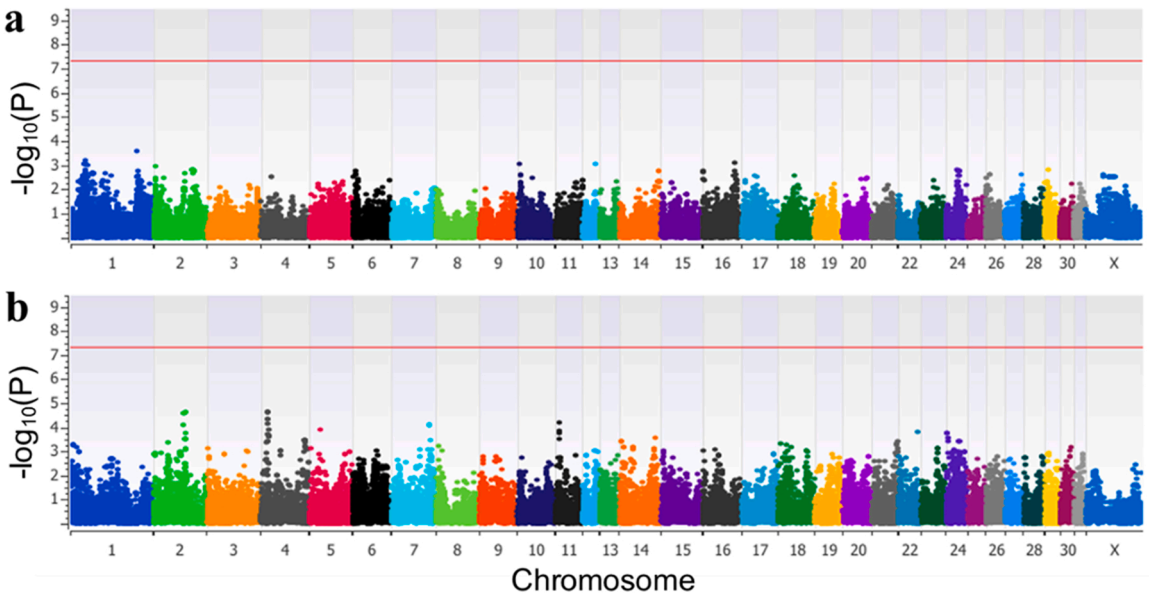

Fig. 4. Manhattan plots from other MLMs to test for SNP association with infertility in TRNP mares following treatment with GonaCon-Equine. Red line denotes the genome wide significance threshold of $p = 5 \times 10^{-8}$. a) SNP significance in infertility after GonaCon treatment when treatment group is included as a covariate rather than an interaction with genotype. b) SNP significance when infertility before first injection is used as dependent variable.

potential impact of family and population structure. Such studies would shed light on whether cause variants are within coding sequences (affecting protein sequence, structure, and function) or in cis-acting regulatory regions (affecting gene expression).

Given that this vaccine induces an immune response to the body's own reproductive hormone, it is reasonable to assume that genes in immune pathways are involved in either the initial response to GonaCon injection or the maintenance of immunity over time (i.e., Th17 memory cells). Although other loci did not cross the more stringent genome-wide thresholds of significance, the presence of other immune related genes within noticeable peaks suggests that genetic variation across multiple loci affects the immune response to GonaCon vaccination.

Finally, there are additional factors not explored here which may also be influencing efficacy of GonaCon injections. Baker et al. (manuscript in prep) evaluated differences between injection method and found that the two-year dart injection treatment group had a more variable response than the 4-year hand injection treatment group, though the difference was not statistically significant. Neither of the other dart injected groups (0.5-year and 1-year) were significantly different from the hand injected group. The use of darts does have the potential for greater tissue trauma at the injection site due to the velocity of both the dart impact and the expulsion of the dart's contents (Hampton et al., 2021). Differences in dart placement, ballistics, injection force, the animal's behavioral response, and individual physiological variation could influence the response to vaccine delivered via darting. In contrast, the placement and force of the injection can be more carefully regulated when vaccine is administered by hand. Baker et al. hypothesize that variation in contraceptive success between treatment groups is due to booster interval rather than injection delivery method; however, it is possible that tissue trauma caused by darting may influence the strength of the immune response to vaccination.

4.1. Implications

Our findings have important implications for population management plans, which should be aware of a significant genetic influence on the effectiveness of GonaCon in reducing foaling rates in feral mares. Over multiple generations the continued use of an immunocontraceptive within a population could result in unintended artificial selection for alleles that decrease responsiveness to the vaccine, reducing its effectiveness over time and potentially weakening the immune response to pathogens (Cooper and Larsen, 2006; Magiafoglou et al., 2003). Those managing feral horse herds should take into consideration their long-term goals for population management. Immunocontraception will likely need to be used in combination with other management techniques, balancing the benefits of slowing population growth with the potential for reduced efficacy of the vaccine over time.

While GonaCon immunocontraception is currently effective, selection for a reduced immune response to GonaCon may necessitate new approaches in the future. The genetic variants associated with GonaCon response may or may not affect response to the immunocontraceptive PZP, which is prepared using a different adjuvant to trigger immune response (Naz and Saver, 2016). A similar GWAS could be performed on mares treated with PZP to test whether the same loci are associated with PZP response. If PZP response is associated with different genetic variants than those identified in this study, selection pressure could be reduced by alternating GonaCon and PZP use in the population.

4.2. Conclusions

Genetic variants are influencing individual variation in infertility duration following treatment of feral horses with GonaCon. Rather than fertility-specific factors, this variation in immunocontraceptive efficacy can be attributed to genetic variation in immune response.

Remotely delivered immunocontraception in free-roaming feral burros (*Equus asinus*)

J. W. Turner, Jr[1], I. K. M. Liu[2] and J. F. Kirkpatrick[3]

[1]*Department of Physiology and Molecular Medicine, Medical College of Ohio, Toledo, OH 43699 USA;* [2]*Department of Population, Health and Reproduction, School of Veterinary Medicine, University of California, Davis, CA 59616, USA; and* [3]*Science and Conservation Biology Program, ZooMontana, Billings, MT 59108, USA*

Regulation of local overpopulations of free-roaming feral equids is in demand worldwide for ecological balance and habitat preservation. Contraceptive vaccines have proven effective in feral horses, which breed seasonally, but no data are available for equids such as the burro, which is reproductively active all year round. In the present study, 27 individually identified female feral burros (*Equus asinus*) roaming free in Virgin Islands National Park (St John, US Virgin Islands; Lesser Antilles) were remotely treated with pig zonae pellucidae (PZP) vaccine. Between January and May, 16 burros were darted with a 1 ml emulsion of PZP plus Freund's adjuvant. Ten to twelve months later each treated burro was given a single booster injection of PZP plus adjuvant to maintain contraception through a second year. Eleven adult untreated jennies served as controls. Beginning one year after initial vaccination, these burros were monitored for pregnancy and foal production. Collection of data to determine treatment effect was not begun until 12 months after initial treatment to ensure that pregnancies existing before vaccination were not included. Pregnancy was assessed using previously validated methods for steroid metabolite measurement in fresh faecal samples. None of the PZP-treated burros produced foals between 0 and 12 months after the last inoculation. One PZP-treated burro tested positive for pregnancy at 10 months after the final inoculation. During this same period, six of 11 untreated burros tested pregnancy-positive, and four were observed with foals. There was no difference in pregnancy rates among treated, control and randomly sampled jennies between 12 and 24 months after the last inoculation. The results demonstrate that, in free-roaming feral burros that are reproductively active all year round: (1) burros can be accessed for remotely delivered PZP vaccination; (2) PZP contraception is effective; (3) PZP contraception is reversible; and (4) pregnancy can be reliably detected by faecal steroid analysis.

Introduction

Reducing fertility among free-roaming horses (*Equus caballus*) and feral burros (*Equus asinus*) has been the goal of numerous studies in the United States over the past two decades. Initial experiments focused on contraceptive steroids which were delivered as injectable, sustained-release (microencapsulated) compounds (Kirkpatrick *et al.*, 1982; Turner and Kirkpatrick, 1982) or Silastic® implants (Plotka *et al.*, 1989). All of these methods resulted in various degrees of pharmacological success but the microencapsulated steroids required extremely large doses and the Silastic® implants required restraint and surgery. In addition, there is concern about steroid-induced pathologies, alteration of behaviour, and the passage of steroids through the food chain when they are used to prevent conception in free-roaming animals (Turner and Kirkpatrick, 1991).

Received 13 November 1995.

An alternative to steroid-induced fertility control in equids is immunocontraception. Solubilized pig zonae pellucidae (PZP) injections delivered remotely inhibited fertility in captive feral mares (Liu *et al.*, 1989), and free-roaming wild mares (Kirkpatrick *et al.*, 1990a). In a follow-up experiment, 14 previously treated mares were given a single PZP booster inoculation, and 13 of the 14 failed to produce foals (Kirkpatrick *et al.*, 1991a). These studies also showed that immunosuppression, which usually accompanies pregnancy in mammals, does not interfere with the contraceptive effects of the vaccine and that the vaccine is safe for use in animals that are already pregnant.

Another advantage of the PZP vaccine is the protein nature of the contraceptive antigen. This characteristic precludes the possibility of passage of the antifertility agent through the food chain. In any realistic management by contraception, some treated animals will die from natural causes and a variety of scavengers will feed upon the carcasses. Protein, unlike steroids (particularly synthetic steroids), cannot be passed

0022–4251/96 $08.50

along intact to the predators' tissues and cannot accumulate therein. This is an important environmental consideration where large-scale management of wild or feral equids is contemplated (Turner and Kirkpatrick, 1991).

The success of PZP vaccine in suppressing fertility appears to be via its ability to inhibit fertilization (Sacco *et al.*, 1984). The PZP consists of four glycoproteins. At least one of these, ZP3, is the receptor molecule for sperm surface molecules (Florman and Wassarman, 1985). Antibodies raised against PZP are thought to block the sperm receptor sites on the equine zona pellucida, possibly by steric hindrance (Skinner *et al.*, 1984), therefore preventing fertilization.

An equid that has not been tested for effectiveness of PZP contraception is the burro. This hardy equid, with a gestation of 11 months, has been a successful reproducer in many harsh environments (McKnight, 1958), and is a problem feral animal in several parts of the world including North America, Australia and Africa (Woodward, 1979). Presently there is a feral burro population inhabiting the island of St John, United States Virgin Islands, which is the site of Virgin Islands National Park. The burros in this population, locally referred to as 'donkeys', are *Equus asinus*, and no mules are known to be present. The population is reportedly in excess of 250 and is expanding (Nellis *et al.*, 1986). The circumstances of fixed land mass and expanding populations, both human and burro, have raised interest on the part of the National Park Service to investigate means of regulating feral burro numbers on St John. This situation offered an opportunity to evaluate PZP immunocontraception in an equid that is reproductively active throughout the year (Nellis *et al.*, 1986). An additional opportunity available with this burro population was to determine whether pregnancy could be detected via measurement of concentrations of specific steroid metabolites in faecal samples. Previous studies have shown that pregnancy is consistently associated with high concentrations of oestrone sulfate, a group of progesterone metabolites, and total oestrogens in extracts of fresh faeces in free-roaming feral horses (Kirkpatrick *et al.*, 1990b, 1991b) and in several other species (Loskutoff *et al.*, 1982; Lasley and Kirkpatrick, 1991).

The goals of the present study of immunocontraception of feral burros inhabiting Virgin Islands National Park (VINP) were to determine: (1) the accessibility to feral burros for remote vaccination; (2) the deliverability of PZP vaccine to feral burros by dart; (3) the contraceptive effectiveness of the PZP vaccine in feral burros; (4) the reversibility of the contraceptive effect in feral burros; and (5) the capability for pregnancy testing of feral burros through faecal steroid measurement.

Materials and Methods

Study area

The study was carried out on the Caribbean island of St John in the US Virgin Islands, a part of the Lesser Antilles island group, located at 18°20'N latitude and 65°45'W longitude. St John is approximately 11 km × 5 km, covering an area of 5180 ha. The majority of the burros included in the study inhabit Virgin Islands National Park, which, in somewhat checkerboard fashion, comprises 57% of the land area of St John. The climate is relatively constant throughout the year with steady trade winds, temperatures normally ranging from 18° to 32°C, and an average 75% humidity. The topography is rugged, characterized by deep valleys, high ridges and several major drainage basins. Sixty-three per cent of the island is covered by four types of dry evergreen forest, and the remainder is covered by moist forest, vegetation secondary to recent human activity, pasture and urban development. Burros tend to be concentrated in basin areas, but can be found in every habitat type, including urban areas. The drainage basins contain fresh and brackish water ponds, which the burros use for drinking water.

Burro identification and access

The present study used 27 adult female burros ranging in weight from approximately 90 kg to 115 kg. Sixteen of these were treated with contraceptive, and 11 were untreated controls. Half of the control jennies were in the same family groups as treated jennies. Individual burros were identified on the basis of coat colour and shading, body and head size and shape, and unique markings or permanent scars (Turner *et al.*, 1981). This method of identification was initially time intensive but proved highly reliable and consistent across the study period. Access to burros to provide treatment via remotely delivered dart was accomplished by the establishment and regular use of bait stations. These 'stations' were merely ground sites along paths frequented by burros, usually in flat areas and within 10 m of brushy sanctuary. A mixture of grain, hay and molasses was placed at the sites daily. Regular use of these bait stations occurred within 2 weeks.

Pig zonae pellucidae vaccine preparation

The pig zonae pellucidae vaccine was prepared as described by Liu *et al.* (1989) and stored frozen in 0.5 ml aliquots until used. Burros were given an initial one- or two-injection PZP treatment and, after 10–12 months, were given a one-injection PZP booster treatment. Initial treatment consisted of: (1) two separate injections (3 weeks apart) of a 1.0 ml emulsion, containing 65 μg PZP plus Freund's complete (first injection) or incomplete (second injection) adjuvant ($n = 13$); or (2) a single injection containing 130 μg PZP emulsified in Freund's complete adjuvant. The PZP for the single injection was present in two forms: 65 μg unsequestered and 65 μg sequestered in 10–50 μm diameter microspheres of biodegradable lactide and glycolide in a 1:1 ratio ($n = 3$). The polymer microspheres were prepared by R. Linhardt and D. Flanagan (University of Iowa) using a coacervation method described by Wang *et al.* (1991). Release rates were projected to be continuous across 4 weeks, with greatest release in weeks 1 and 4 (Wang *et al.*, 1990). Booster treatment format consisted of a single injection of 65 μg PZP (0.5 ml) emulsified with 0.5 ml Freund's incomplete adjuvant.

Each treatment was administered remotely by a dart fired from a rifle. The most reliable delivery was obtained using the Pneu-Dart system (Williamsport, PA), which uses a .22 caliber rifle with scope and powder-charged, 1.0 cc, self-injecting darts. All darts were recovered after injection.

Pregnancy testing and foal counting

All burros in the study were monitored for effectiveness of treatment and reversibility of treatment as determined by foal counts and by pregnancy testing. Collection of data to determine treatment effect was not begun until 12 months after initial treatment to ensure that pregnancies existing before vaccination were not included. Collection of data to determine reversibility of treatment effect was between 12 and 24 months after the last treatment. Pregnancy was assessed via measurement of concentrations of total faecal oestrogens (TFE), oestrone conjugates (E_1C) and immunoreactive pregnanediol-glucuronide-like metabolites (iPdG) in extracts from fresh faeces (Kirkpatrick *et al.*, 1991b). Individually identified treated and control jennies were monitored until they defecated, and samples were immediately collected and kept frozen until assayed. Pregnancy data were generated for up to five faecal collection periods, which were approximately 12, 21, 24, 36 and 48 months after initial PZP vaccination. Pregnancy data are presented as means ± SEM. Statistical hypothesis testing for foaling data used binomial probability distribution (BPD) and, for pregnancy-test data, used Student's *t* test or Tukey's test for multiple proportions (Zar, 1984).

Results

Concentrations of steroid metabolites indicative of pregnancy were compared between burros that produced foals and burros that did not produce foals during the period from February 1993 to February 1994 (Table 1). Two non-foaling burros, one PZP-treated and one control, showed conflicting steroid results (pregnant versus nonpregnant) among sample periods. It is possible that a pregnancy occurred between samplings, but no foals were produced by these burros during the sampling period. The average concentrations (ng g^{-1} faeces ± SEM) of faecal steroids in samples from nonfoaling burros ($n = 10$) were 15.4 ± 1.6 for TFE, 24.2 ± 1.8 for E_1C, and 849.9 ± 289.1 for iPdG. In contrast, burros that produced foals ($n = 6$) exhibited average faecal steroid concentrations during pregnancy of 286.5 ± 100.2 for TFE, 145.4 ± 57.6 for E_1C, and 2950.7 ± 160.7 for iPdG. The differences between foaling and nonfoaling burros were significant ($P < 0.05$, Student's *t* test) for all three steroid measures. In PZP-treated and control burros for which reproductive status was known for at least one full gestation period ($n = 18$), pregnancy test data correlated 100% with eventual presence or absence of foals.

At the beginning of the study (before any treatments), six of the 16 burros scheduled for PZP treatment had offspring ranging from approximately 2 to 12 months of age. By 1 year after treatment, when monitoring for treatment effect was begun, an additional four jennies had produced foals. In the period from 12 to 24 months after PZP treatment, none of the 16 treated burros was observed with a foal, and one burro tested positive for pregnancy at 22 months after immunization (Table 2). In contrast, four of the 11 control burros were observed with offspring, and six (including three of the above four) of the 11 tested positive for pregnancy during this period. In the four jennies that had been given a booster inoculation after 1 year, there were no positive pregnancy tests and no foals were produced. The proportions of burros producing foals in the PZP-treated versus control groups were different ($P < 0.01$; BPD) in the 11–24 months after treatment. In addition, the proportion of burros producing foals before treatment and during the test period for treatment effectiveness (12–24 months) was different ($P < 0.01$; BPD). All burros in the study appeared subjectively to remain healthy for the entire study period, based on physical appearance, demeanour and general behaviour as indices of condition.

Reversibility of treatment effect was assessed by faecal pregnancy testing only. For reversibility testing we were able to locate only 13 of 16 treated burros, and six of 11 control burros. Six of 13 (46.1%) PZP-treated and three of six (50.0%) control burros tested pregnancy positive (Table 3). Faecal samples were also collected from 33 randomly chosen jennies that were not in the study. Fifteen of these 33 jennies (45.5%) tested pregnancy positive.

Mating behaviour, which included courtship, female oestrous behaviour, and male mounting and copulatory behaviour (intromission with or without ejaculation) were observed on 21 occasions during the study period. No subjectively discernible differences in reproductive behaviour were observed between PZP-treated and control burros. Breeding was recorded in all months studied. Across 3 years, the approximate frequency of reproductive behaviour occurrence per 100 h of observation was 7.5 in January, 7.5 in February, 12 in April and 4.5 in November. Observations were not made in other months.

Table 1. Correlation of foal production and total faecal oestrogens (TFE), oestrone conjugates (E_1C) and progesterone metabolites (iPdG) concentrations in feral burros

		Faecal steroid concentration (ng g^{-1} dry mass ± SE)		
Condition[a]	*n*	TFE	E_1C	iPdG
Burros that produced foals[b]	6	286.5 ± 100.2	145.4 ± 57.6	2950.7 ± 160.7
Burros that did not produce foals	10	15.4 ± 1.6	24.2 ± 1.8	849.9 ± 289.1

[a]Samples were collected over 12 months.
[b]Samples were collected from 3–9 months before foal was first observed.

Table 2. Effect of pig zonae pellucidae (PZP) immunocontraception on the incidence of pregnancy in free-roaming feral burros

Condition	*n*	Number (%) of burros that were pregnant
PZP-treated (2 injections)	13	0 (0)[a]
PZP-treated (1 injection)	3	1 (33.0)[b]
Untreated control	11	6 (54.4)[b]

Pregnancy was determined via measurement of concentrations of total faecal oestrogens (TFE), oestrone conjugates (E_1C) and progesterone metabolites (iPdG) in extracts of faecal samples obtained from individually identified burros. Samples were taken 0–12 months after the last PZP treatment.
Values with different superscripts are significantly different from each other; $P < 0.05$ Tukey's test for multiple proportions.

Table 3. Reversibility of pig zonae pellucidae (PZP) immunocontraception in free-roaming feral burros

Condition	*n*	Number (%) of burros that were pregnant
PZP-treated[a]	13	6 (46.1)
Untreated control	6	3 (50.0)
Random sampling	33	15 (45.5)

Pregnancy was determined via measurement of concentrations of total faecal oestrogens (TFE), oestrone conjugates (E_1C) and progesterone metabolites (iPdG). Samples were taken 12–24 months after the last PZP treatment.
No significant differences across groups; $P > 0.05$, Tukey test for multiple proportions.
[a]Values for jennies given one injection and two injections were pooled, since pregnancy incidence did not differ in these groups.

Discussion

The results of this study demonstrate that PZP immunocontraception can be delivered to free-roaming feral burros, is highly effective in preventing pregnancy in this species, and is reversible in its effect. As stated previously, the first 12 months after immunization were not included in the assessment of treatment efficacy on the premise that some burros were already pregnant at immunization time. This turned out to be the case for four burros which foaled in the 12 months following immunization. The foals were nursed and grew normally. Since the gestation period is approximately 11 months in burros (McKnight, 1958), these pregnancies had begun prior to the PZP treatment. Thus, in burros, as in other species studied to date (Turner and Kirkpatrick, 1991), PZP contraception does not disrupt existing pregnancies.

The two-injection protocol was more effective than the single-injection, controlled-release PZP protocol in preventing pregnancy. These results are similar to contraceptive effects of the two-injection PZP protocol reported for horses (Kirkpatrick *et al.*, 1990a) and for white-tailed deer (Turner et al., 1992). The refinement of a high-efficacy, single-injection treatment, which is underway, will be necessary before immunocontraception can be used for routine management of burros.

It appears that burros on St John exhibit reproductive behaviour throughout the year. However, the data from the present study showed that breeding frequency is greater in spring than in other seasons. November was a breeding nadir among the months studied. Assuming that the contraceptive effect is of similar duration across treated individuals, the year-round nature of burro reproduction on St John makes it necessary to consider spreading contraceptive treatment across the year. This would prevent the bunching of foal production at one time of year, and ensure a more natural temporal pattern in foaling.

Obtaining access to the burros for treatment was accomplished with high success by the use of bait stations. It was necessary to maintain a regular daily baiting schedule to ensure regular return of burros to the site, and even with a regular baiting schedule, almost 40% of the burros were not daily visitors. However, over 4–5 days, most study burros would visit their respective bait stations at least once. While almost all burros consumed bait when it was available, a definite pecking order developed regarding consumption of limited bait. At a given station, a few burros would eat the bait while the remainder of the group watched. Placing two or three piles of bait several metres from each other permitted access for more individuals.

Burro family groups appeared to prefer certain limited areas (home ranges) of the island and showed fairly regular patterns of movement within these areas. This is consistent with the findings of Nellis *et al.* (1986). Among burros in the present study, each home range included at least one drainage basin with a clearing, fresh water supply, and at least 1 km of dirt or paved road. Some burro groups moved back and forth regularly between two different drainage basins and were observable in the clearings. Many road areas were lined with vegetation that appealed to burros, and they were often observable along the roads. All except two of the jennies in the study remained throughout the 3 year study within the home range where they were first observed. The home-range stability and frequent use of roads and bait stations by burros facilitated the determination of burro identification, movement patterns and habits.

The use of counts of young offspring has been a classic approach to determining fecundity (Seber, 1982; Wolfe *et al.*, 1989). Unfortunately, counts of young can often yield underestimates of reproductive rates and productivity, since fetal losses and neonatal losses, respectively, may be missed (Berger, 1986). On St John, the jennies rarely bring young foals out of the dense bush. Most foals are not seen until they are 2–4 months of age. Thus, counting of foals is not an optimal method for assessing contraceptive effectiveness in St John burros.

In contrast, burro pregnancy testing via measurement of steroid metabolites in faeces appears to be reliable. The differences in faecal steroid concentrations between pregnant and nonpregnant burros were large, ranging from an average of 3.5-fold for iPdG to 18.5-fold for TFE. These differences were similar to those reported in horses (Kirkpatrick *et al.*, 1990b, 1991b). All burros that produced foals had previously tested positive for pregnancy, and none of the burros that tested negative for pregnancy have produced foals. This

reliability in testing for pregnancy in burros suggests potential usefulness for assessing various aspects of burro reproduction, including population fertility rates, fetal loss rates, seasonal reproductive patterns and individual oestrous cycles. In two burros showing both pregnancy-positive and pregnancy-negative steroid data across their samples, the pregnancy-positive data were late in the sample period. These burros may have become pregnant between early and late samples.

In summary, the present study has demonstrated in free-roaming feral burros on St John, which breed all year round that: (1) burros are accessible for PZP treatment by use of bait stations; (2) PZP vaccine can be remotely delivered by dart; (3) PZP vaccine is effective in preventing pregnancy; (4) PZP treatment effect is reversible; and (5) pregnancy can be detected reliably by faecal steroid analysis.

The execution of this project has involved a cooperative effort on the part of the Virgin Islands National Park, The Humane Society of the United States, the Medical College of Ohio, and the Virgin Islands Environmental Resource Station of the University of the Virgin Islands. Special thanks are accorded T. Kelley and J. Bjork of Virgin Islands National Park for their project coordination efforts and field assistance on site. Funding of the project was undertaken by Virgin Islands National Park and the Humane Society of the United States. Special thanks to M. Bernoco for preparation of the PZP vaccine and to E. V. Berkeley for faecal steroid analysis.

IMMUNOCONTRACEPTION LIMITS FOAL PRODUCTION IN FREE-ROAMING FERAL HORSES IN NEVADA

JOHN W. TURNER, JR., Department of Physiology and Molecular Medicine, Medical College of Ohio, Toledo, OH 43699, USA

Abstract: We determined contraceptive effectiveness and duration of effect after porcine zona pellucida (PZP) vaccination in free-roaming feral horses in Nevada. We captured, freeze-branded, treated and subsequently released 132 adult feral mares. Treatment consisted of 1 or 2 injections (1 month apart) of vaccine emulsion consisting of aqueous PZP and Freund's complete adjuvant (Sigma, St. Louis, Mo.; FCA; inj. 1) or Freund's incomplete adjuvant (FIA; inj. 2). We gave controls saline and Freund's adjuvant as above. Among 1-injection mares, we gave one group a single dose of raw antigen, and we gave the other group raw antigen plus a second dose of antigen sequestered in controlled-release microspheres. We also studied 63 untreated mares. We administered inoculations in December 1992, and monitored the mares via fecal analysis for pregnancy and via helicopter and ground survey for foal production through September 1994. We determined pregnancy via measurement of estrone sulfate, progesterone metabolites and total estrogens, in fresh feces collected from the ground. Among antigen-treated mares, reproductive success across 1 year was 4.5% (2-inj.), 20.0% (1-inj. + microspheres) and 28.6% (1-inj., no microspheres). Reproductive success in placebo (55.0%) and untreated (53.9%) mares was significantly greater than in treated groups. The following year, without further treatment, reproductive success was 44.0% (2-inj.), and 54.5% (untreated) and these values were not different. Data from other groups were insufficient for comparison. The results of this study confirm the feasibility of capturing large numbers of mares in the field for treatment and demonstrate: (1) 1-year contraceptive efficacy of several PZP vaccine protocols, (2) greater effectiveness in 2-injection protocols than in 1-injection protocols, and (3) a return to fertility in the second year after vaccination.

J. WILDL. MANAGE. 61(3):873–880

Key words: antibody titers, contraceptive vaccine, controlled-release, equids, feral horses, fertility, horse immunocontraception, mares, microspheres, population control, reversibility.

Since the late 1970s, fertility control has been investigated as a potential tool for regulating feral horse (*Equus caballus*) numbers. In early studies, various steroids were the focal contraceptive agents, with controlled-release androgens used in stallions (Turner and Kirkpatrick 1982, Kirkpatrick et al. 1982) and estrogenic and progestagenic steroids used in mares (Plotka et al. 1988, 1992). Despite contraceptive efficacy obtained with some steroids, interest in these agents waned in the face of undesirable behavioral effects and potential environmental hazards of such steroids (Turner and Kirkpatrick 1991, Kirkpatrick and Turner 1991). In 1987, the antifertility effect of a PZP vaccine was tested successfully in free-roaming feral mares on Assateague Island National Seashore (Kirkpatrick et al. 1990*a*). Previously this PZP vaccine had prevented pregnancy in 13 of 14 domestic or captive feral mares (Liu et al. 1989). In the Assateague study the dart-delivered vaccine was >95% effective and had no apparent effects on pregnancies in progress, the health of offspring, or the behavior of treated mares.

The effectiveness of the vaccine appears to reside in the antigen-stimulated production of anti-PZP antibodies in the vaccinated animal. These antibodies bind to the zona pellucida surface of the recipients' ovulated egg, presumably preventing sperm attachment (Liu et al. 1989). In ungulates studied to date, 2 separate exposures to PZP in one month have been used to obtain maximal, sustained anti-PZP titers for the first year of contraception (Kirkpatrick et al. 1990*a*, Turner et al. 1992*a*). Thereafter, a single annual booster injection has been sufficient to maintain fertility from year to year (Kirkpatrick et al. 1991*a*, 1992*a*).

Because it is impractical on a management scale to give a 2-injection sequence to free-roaming wildlife, the potential use of polymers that permit a controlled, gradual, or pulsed release of the vaccine has been investigated. One

approach involves forming a homogenous mixture of the drug with a biodegradable nontoxic material, in the form of microspheres (Eldridge et al. 1989, Wang et al. 1990). Upon intramuscular injection and contact with tissue fluids, the biodegradable material erodes and releases the drug over a predetermined period of time (Wang et al. 1991). One goal of the present study was to compare the efficacy of PZP vaccine administered as 2 separate injections with the efficacy of PZP vaccine administered as a single injection with and without a controlled-release PZP component.

Federal agencies have considered contraception for a potential management role in regulating some Western feral horse populations. While barrier-island feral horses and Western feral horses are the same species, there are many regional differences in horse behavior and habitat (Turner and Kirkpatrick 1982, Keiper and Houpt 1984, Berger 1986, Rutberg 1990), as well as agency differences in horse management techniques (T. Pogacnik, Bur. Land Manage., pers. commun.; B. Underwood, Natl. Park Serv., pers. commun.). Techniques for accessing and contracepting barrier-island horses may not be effective with Western horses. Therefore, an additional goal of the present study was to determine field accessibility to Western feral horses for PZP contraception.

We thank: M. Bernoco for PZP preparation and anti-PZP antibody titer analysis, and B.L. Lasley for E_1C antibodies; U.S. Bureau of Land Management (BLM) personnel and associates for the gathering, holding and releasing the horses, with appreciation to W. Baker, R. Brown, D. Cattoor, B. Dawson, C. Heaverne, J. Hicks, K. McKinstry, S. Luttrell, T. Pogacnik, M. Ravnikar, R. Sanford, J. Smith, K. Walker, and F. Wyatt. This study was performed under the guidelines of (1) BLM-approved procedures for the gathering and handling of feral horses as detailed in the Capture/Removal Plans for the Antelope and Antelope Valley Herd Management Areas, and (2) animal welfare protocol #91–58, approved by the Medical College of Ohio. Primary funding for this study was provided by BLM Cooperative Agreement #1422F950A20002, U.S. Department of Interior, with additional support by the Humane Society of the United States.

METHODS

Experimental Design

The study examined the antifertility effectiveness and duration of effect of 3 variations of injected PZP contraceptive vaccine in comparison to placebo and untreated control conditions. We (the research team) randomly assigned to groups, adult mares previously identified by freeze-branding. Investigators inoculating the animals were unaware of the content of a given injection. From previously identified individuals, we determined treatment effectiveness and duration of effect by foal counts and pregnancy testing of fecal samples collected upon defecation. Mare groups consisted of: (1) 2 separate injections 4 weeks apart of vaccine containing adjuvant and native PZP, (n = 60); (2) 1 injection of vaccine containing adjuvant and native PZP (n = 21); (3) 1 injection of vaccine containing adjuvant and native PZP plus an additional, controlled-release PZP (no controlled-release adjuvant) dose (n = 22); (4) 2-injection placebo (adjuvant and saline, without PZP) (n = 19), and (5) 1-injection placebo (n = 10). In addition to these groups, we tested for pregnancy or observed for presence of a foal 63 unmarked and untreated mares (that had not been captured) during the study. To prevent duplication of data collection among these 63 mares, we identified the mares by coat color, face markings, and by association with other horses in their family band (Turner et al. 1981). Contraceptive treatment was administered in December 1992. We collected fresh feces for pregnancy testing in September–October 1993 and 1994. We counted foals in May, August, September, and October of 1993 and 1994.

STUDY AREA

The study area encompassed about 1,825 km^2 in northeastern Nevada centered at 40°15′N and 113°30′W near the Dolly Varden Mountains. Elevations ranged from 1,600 to 2,400 m. Vegetation on the study area was composed largely of shrub-steppe communities with sagebrush (*Artemisia* sp.), rabbitbrush (*Chrysothamnus* sp.), and bitterbrush (*Purshia tridentata*) dominating. Areas of pinyon pine (*Pinus edulis*) were present at higher elevations. Average annual precipitation was 25 cm at 1,500-m elevation, with increasing amounts (mostly as snowfall) at higher elevations. Water was available from permanent springs scattered throughout the study area. The northern and southern portions of the study area were administered by the Elko and Ely districts of the Nevada BLM.

Horse Population

The study area was inhabited by about 700 horses with a harem band social structure (Turner et al. 1981, Berger 1986). The peak breeding period was May and June, and the peak foaling period was April and May. We subjectively estimated the physical condition of the mares according to the condition scale (1–10) developed by Henneke et al. (1983). Mare condition ranged from fair (3) to very good (7) during the study. We rated well-fleshed animals with a sleek coat in very good condition. We rated animals with noticeable ribs, mild hip and shoulder bone protrusion and low quality coat in fair condition.

PZP Vaccine Preparation

We prepared PZP from porcine ovaries (Liu et al. 1989). The vaccine consisted of 0.5-cc standard phosphate buffer solution containing 65-μg PZP, which was emulsified with 0.5-cc FCA. We emulsified PZP with FIA for the second injection. We prepared the emulsion within 12 hours of injection, using 2 10-cc glass syringes joined with a plastic connector. After 100 plunger strokes, we loaded the emulsion into a 3-cc plastic syringe for injection via a 19-gauge, 3.7-cm needle. The needle and injection site were prewashed with 70% ethanol.

In an attempt to mimic the 2-injection condition with a single injection, we gave one group of mares an injection, with an additional component of controlled-release microspheres containing 65-μg PZP with no adjuvant. While we recognized that the presence of adjuvant was desirable in the microspheres for maximizing the immune response, the technology for preparing adjuvant-containing microspheres was unavailable. The microspheres were 10–50 μm in diameter and composed of bioerodable lactide and glycolide polymers. They were prepared by D. Flanagan, R. Linhardt and E. Schmitt at University of Iowa using a coacervation method (Wang et al. 1991). We projected release rates to be continuous over about 4 weeks, with greater release in weeks 1 and 4 (Wang et al. 1990, 1991).

Accessing, Handling, and Inoculating of Horses

The BLM gathered horses by helicopter, permitting injection by hand. We chose this method because access to the horses was possible as a part of scheduled roundup for the BLM horse adoption program.

Between 2 and 12 December 1992, the BLM gathered about 500 horses by helicopter into portable corrals. In a cooperative effort, we and the BLM: (1) separated the gathered stallions and mares, (2) moved them singly through a chute, (3) determined aged and physical condition, (4) gave a 1-cc prophylactic Strepguard® (Miles Lab., Shawnee Mission, Kans.) injection intramuscularly, and (5) permanently marked healthy mares (n = 132) between the ages of 5 and 15 (prime reproductive age) with consecutive numbers by freeze-branding. The brands were located on the upper left hip, were 10-cm in height and were readable from a helicopter and through a spotting scope at >500-m distance on the ground.

We hand-injected intramuscularly 1 cc of freshly prepared emulsion of buffered PZP (or buffer alone) and adjuvant into the left gluteus muscle and photographed each marked mare. The BLM maintained mares given a single injection in the portable corrals on grass-hay and water ad libitum for up to 72 hours and then released them into the range area from which they had been gathered. Before release, the BLM separated the mares and their foals and retained the foals for eventual adoption. They separated mares in the 2-injection protocol from the foals and transported them by truck to the Palomino Valley BLM corral facility. The BLM maintained the mares, under observation, for 4 weeks on a grass-hay and water (ad libitum) diet until we gave the second PZP injection. The BLM then returned the mares to their home range area and released them. Members of the same harem band, previously marked with a same-color grease pencil, were released together. Within 24 hours of the release, representatives of the BLM and the research team surveyed the study area by helicopter to determine the well-being and dispersal of the mares.

Antibody Titers

Before release from captivity and after the second inoculation, we examined each mare for possible injection-site abscess, and obtained a 10-cc blood sample by jugular venipuncture for antibody titer analysis from randomly chosen PZP-treated (n = 19) and placebo (n = 8) mares. We harvested the serum and froze it at −20 C until assay. We determined anti-PZP antibody titers in the above serum samples by an

enzyme-linked immunosorbent assay (ELISA; Voller et al. 1986), with modification reported previously for horses (Liu et al. 1989). We assayed the sera in duplicate and expressed the results as a percentage of the horse positive reference serum, which consisted of a pool of sera that had demonstrated near-maximal titers, about 4–6 weeks after an initial PZP injection (Liu et al. 1989). Pooled preimmunization sera served as a control (no anti-PZP antibody).

Pregnancy Testing by Fecal Steroid Analysis

Pregnancy testing avoids the potential problem of incorrectly assessing contraceptive effectiveness due to undetected stillbirths or mortality of neonates. In the study area, most foaling occurs in April and May, and breeding is uncommon after mid-June. Pregnancy can be detected reliably with fecal analysis within 80 days of conception (Kirkpatrick et al. 1991*b*). We sampled mares for pregnancy detection in fall 1993 (to determine treatment efficacy) and fall 1994 (to determine duration of effect). Between mid-September and mid-October of 1993 and 1994, we observed mares for defecation using binoculars and 20–40× spotting scopes. We insured that each sample collected was from the desired mare by pairing observers such that one person maintained view of the sample through the scope while hand-signalling the other observer to the sample. In any case where the location or specificity of the sample was in questions, none was collected. We collected freshly dropped fecal balls (2–3) in a sealable plastic bag, labelled them, and stored them on ice until they could be placed in a freezer (within 72 hr). We determined pregnancy in each sample via measurement of estrone sulfate (E_1C) and immunoreactive progesterone metabolites (iPdG) by ELISA (Kirkpatrick et al. 1991*b*) and total estrogen (TE) by radioimmunoassay (Kirkpatrick et al. 1990*b*). The combined measures have proven nearly 100% accurate in pregnancy diagnosis in several species (Lasley and Kirkpatrick 1991), including the feral horse. We considered a mare pregnant when values for a given sample were $E_1C > 27.9$, iPdG > 4000.0 and TE > 250.0 ng/g of dry-weight feces.

Foal Counts

We determined the presence of a foal with a given marked mare by helicopter and ground observations in May and September of 1993 and 1994. We verified which foal was with which mare in ground surveys by observing the horses until the foal clearly associated with a given mare by its repeated proximity to her during grazing and travelling and/or by nursing from her. In the helicopter surveys we verified parentage by maintaining sufficient helicopter distance from the family groups of horses to permit foals to associate closely with the mother as they moved away from the helicopter. The latter verification method has correlated well with subsequent ground survey data in previous studies (Turner et al. 1992*b*). We considered a mare to be successful reproductively if she tested positive for pregnancy and/or was verified to have a foal.

Statistical Analysis

Where appropriate, we have presented data as mean ±SE. We employed Student's *t*-test for statistical analysis of fecal and titer data. We determined possible group differences among reproductive success rates using a Tukey-type multiple comparison test for proportions or a binomial probability distribution (BPD; Zar 1984).

RESULTS

During one month of captivity and at the time of their release in January 1993, none of the 60 2-injection mares showed abscesses. None of the mares observed in the field thereafter showed injection-site marks, suggesting that abscesses had not occurred. Following the treatment of mares in December 1992, severe winter conditions prevailed in northern Nevada through March 1993. However, we observed 93 of the 130 marked mares (71.5%) between May and October 1993. We found an additional 8 marked mares not seen in 1993 between May and October 1994, yielding a total reidentification rate of 77.7% during the study.

In 1993 we collected fecal samples from 51 marked mares. In the 1993 samples obtained from mares that were reidentified and had produced foals in 1994 ($n = 9$) the average values for E_1C, iPdG, and TE were 18.9, 38.7, and 22.2 × greater than the respective average values associated with mares that did not produce foals ($n = 19$) in 1994 (Table 1). For each of the 3 steroids measured, the average value for mares that did produce foals was significantly greater ($P < 0.01$) than for mares that did not

Table 1. Association of fecal steroid metabolite levels in feral mares with subsequent presence or absence of foals[a]

Mare condition	No. of mares	Steroid metabolites concentration[b] (ng/g feces dry wt ± SE) E_1C	iPdG	TE
Without foal	19	14.6 ± 8.3	378.0 ± 217.4	53.9 ± 21.4
With foal[c]	9	276.2 ± 69.8	14,637.1 ± 2,250.0	1,197.1 ± 214.0

[a] Fecal samples collected in Sep 1993, foal counts performed May–Sep 1994.
[b] E_1C = estrone sulfate, iPdG = immunoreactive pregnanediol glucuronide, TE = total estrogens.
[c] Values between conditions for all steroids are significantly different; $P < 0.01$, Student's t-test.

produce foals. Among the mares tested, the values for all 3 steroids were consistent, i.e., all were elevated or all were depressed. All mares that were diagnosed as pregnant (by fecal steroids) and were reidentified the following spring were observed to have a foal. We observed that 2 of 19 mares that were diagnosed as not pregnant had a foal the following spring. Overall accuracy was 26/28 (93%).

Of 44 reidentified mares in the 2-injection PZP group, only 2 mares were reproductively successful in the 1993 breeding season. Eleven of 20 mares were reproductively successful in the 2-injection placebo group. In the 1-injection groups reproductive success occurred in 4 of 14 mares (PZP, no microspheres), 3 of 15 mares (PZP plus PZP microspheres), and 2 of 4 mares (placebo). Reproductive success was achieved in 34 of 63 unbranded mares that were studied (Table 2). The proportion of reproductively successful mares in all treatment groups was significantly lower ($P < 0.05$) than in both placebo and untreated control groups, the proportions of which were not different from each other. In addition, the proportion of reproductively successful mares in the 2-injection PZP group was significantly lower ($P < 0.05$) than the proportions in both 1-injection PZP groups. The proportions in the 1-injection PZP groups were not different.

Table 2. Effect of PZP immunocontraception on fertility of free-roaming feral mares in Nevada.

Treatment[a]	No. of mares located[b]	No. of mares reproductively successful[c]	% of mares reproductively successful[c,d]
Untreated	63	34	53.9[q]
Placebo (1- or 2-inj.)	20	11	55.0[q]
PZP (2-inj.)	44	2	4.5[r]
PZP (1-inj. + microspheres)[e]	15	3	20.0[s]
PZP (1-inj.)	14	4	28.6[s]

[a] A given treatment (Dec 1992) consisted of i.m. injection of an emulsion of 0.5-cc Freund's adjuvant and 0.5-cc phosphate buffer solution with or without (placebo) 65-μg PZP.
[b] Mares that were located for sample collection and/or observation between May 1993 and Oct 1994.
[c] A positive fecal pregnancy test or presence of a foal were criteria for reproductive success.
[d] Values with different superscript ([q,r,s]) are significantly different from each other; $P < 0.05$, Tukey-type multiple comparison test for proportions.
[e] One dose of microspheres contained 65-μg PZP for controlled release and was incorporated into the injection.

Anti-PZP antibody titers in 2-injection mares at 4 weeks after initial inoculation averaged 86.2% of positive reference control titers in 19 PZP-treated and 0.9% in 8 placebo-treated animals ($P < 0.01$). Control titers were 0–2%. Thirteen of the PZP-treated mares showed titers >90%, and 6 were between 46 and 75%. Sixteen of the titer-tested PZP mares were reidentified for subsequent fertility evaluation. All of these had shown titers >52% at 4 weeks posttreatment, and all were infertile in the first year after treatment.

We determined duration of treatment effect on the basis of 1994 pregnancy testing only. This basis was considered acceptable, because the 1993 correlation between pregnancy-test and foal-count data reported was 0.93 ($n = 28$). In the 2-injection PZP group (treated Dec 1992) fecal samples from 11 of 25 mares showed pregnancy-positive levels of steroid metabolites in the second year (Sep 1994) after treatment. We obtained a positive pregnancy test in fecal samples from 12 of 22 unbranded mares that we had sampled during the same period as for branded mares. The pregnancy rates were not different ($P > 0.05$, BPD) between these groups (Table 3). Among 2-injection placebo mares, samples (Sep 1994) from 2 of 4 indicated pregnancy. In the 1-injection PZP and 1-injection PZP-plus-PZP microspheres groups, samples (Sep 1994) from 1 of 2 and 1 of 2 mares, indicated pregnancy. We did not obtain samples from mares in the 1-injection placebo group. Sample sizes for 1-injection groups were insufficient for statistical analysis.

Table 3. Reversibility of PZP contraception in free-roaming feral mares.

Condition	No. of mares sampled[a]	No. of pregnant mares[b]	% of mares pregnant[c]
PZP (2-inj.)	25	11	44.0
Untreated	22	12	54.5

[a] Treatment in Dec 1992; fecal samples collected in Sep 1994.
[b] Based on pregnancy test criteria as presented in Table 1.
[c] No differences among groups; ($P > 0.05$) binomial probability distribution.

DISCUSSION

Inoculation of captured and released feral mares with PZP vaccine resulted in a marked suppression of fertility across one breeding season. While a fertility rate of 4.5% occurred with use of the 2-injection protocol, fertility rates in both single-injection groups were higher (20–28%). Nonetheless, single-injection fertility rates were only 1/3–1/2 of fertility rates observed in control (placebo and untreated) mares, and this difference was statistically significant. Fertility rates among control mares were similar to those reported for other feral horse populations (Wolfe et al. 1989).

The results indicate that the controlled-release microspheres neither mimicked the condition of 2 separate injections, nor produced significantly greater infertility than a single injection alone. Exposure of the mares to PZP via microspheres differed from a second vaccine injection in that the PZP in the former was not released as a bolus and was not accompanied by adjuvant. In a previous equid study employing FCA (Kirkpatrick et al. 1990*a*), we observed abscesses in 3 of 26 treated mares. However, abscesses occurred only in mares given 3 injections of vaccine (1 = FCA, 2 = FIA, 3 = FIA), not in mares given 2 injections (1 = FCA, 2 = FIA). Had there been abscesses in 2-injection mares in the present study, the abscesses should have appeared during the month of captivity. Thus, it appears that, in the 60 mares given 2 injections, abscesses did not occur. Abscesses seemed unlikely in mares given a single injection, since they received less exposure to adjuvant than 2-injection mares.

The presence of well-elevated anti-PZP antibody titers in all of the PZP-treated mares and in none of the placebo-treated mares that were sampled is consistent with previous reports in horses (Liu et al. 1989). Also, these titers were consistent with fertility data, i.e., no mares with elevated titers produced foals in all of the mares ($n = 16$) for which the assessment could be made.

The presence of anti-PZP antibody titers and infertility are not necessarily related. However, elevated titers consistently have been associated with infertility in the horse. In a previous study, none of 13 mares exhibiting peak (4–6 weeks post-inoculation) titer levels >65% of positive reference serum titers before the breeding season became pregnant (Liu et al. 1989). In the present study, none of 16 mares showing titers >52% at 4 weeks post-inoculation was reproductively successful during the subsequent breeding season.

The effect of PZP treatment in 2-injection mares was sustained through 1, but not 2, breeding seasons, indicating a return to fertility after 1 year. Forty-four percent of 2-injection, PZP-treated mares that were relocated in the fall of 1994 were pregnant. This finding is similar to the pregnancy rates in placebo and untreated control mares, which averaged 56 and 54% in 1993, and 50 and 54% in 1994. We focused the reidentification effort to test duration of infertility on the 2-injection mares, since they were exposed to the greatest stimulation by PZP. We expected that the possibility of extended infertility would be greatest in this group. Also, the 2-injection mares composed the largest group in the study, offering the best chances for reidentifying a large number of these mares. Although the 1-injection data are consistent with the 2-injection data regarding reversibility, the small number of reidentified mares in the 1-injection groups precludes conclusions in these groups.

This study confirms the high accuracy of pregnancy diagnosis via fecal steroid metabolites in feral horses (Kirkpatrick et al. 1991*b*). The minimum 18-fold difference observed between non-pregnant and pregnant state in the measured metabolite levels favors reliable differentiation of pregnant and non-pregnant state. Although no discrepant values were observed in the present study, an occasional (<2%) discrepant high or low value is possible among the 3 metabolites we have used (Lasley and Kirkpatrick 1991). By measuring all 3 metabolites (E_1C, iPdG and TE), we minimized the chances of misdiagnosis. Among 28 mares for which we obtained both pregnancy and foaling data, agreement was 93%. Both cases of disagreement were false negatives, i.e., pregnancy

diagnosis was negative but a foal was present. We were unable to determine whether the pregnancy test was incorrect or whether we mismatched the foal with the mare or whether conception occurred too late in the year to be detectable at the time of fecal collection.

MANAGEMENT IMPLICATIONS

The study was carried out in Nevada, where more than 60% of Western feral horses reside. Helicopter roundup of horses is a well-established method for accessing feral horses in Nevada and other Western states for roundup/adoption programs, and has been used for other contraception studies (Eagle et al. 1992, Plotka et al. 1992). Incorporation of PZP vaccination into the existing roundup procedures greatly reduces the cost of accessing horses for immunocontraception in years when gathers are performed. In the BLM roundup/adoption program, mares more than 5 years of age are returned to the range. An added advantage of using scheduled periodic roundups for administering immunocontraception is that only mares destined to remain on the range will be treated; i.e., treatment will not be wasted on mares aged 3–5 years, which will be removed and adopted. Options for horses for single-injection immunocontraception in years when adoption roundups are not performed include gathering by helicopter, and remote delivery by dart from helicopter (Turner and Kirkpatrick 1991).

The use of contraception for management purposes has the potential to reduce management costs by reducing the frequency of roundups and eliminating the need to maintain unadoptable horses in captivity. Contraception can also enhance the humaneness of management, since roundups and extended captivity are stressful to the horses. However, Garrott (1991) has concluded from feral horse modelling studies that each population (herd area) is unique and must be considered individually for potential use of contraception. We agree with this point. Also, as suggested by Garrott (1991), the issues of both cost-effectiveness and limitation of population growth must be included in assessing long-term contraceptive management potential.

A 2-injection protocol presents logistical and economic problems for routine use in feral horses, because of the need to keep gathered horses for 3–4 weeks. However, single-injection methodology presently could be used in the field, with the caveat that the first year after treatment the expected fertility rate will be 20–28%. An annual booster in subsequent years should yield >90% efficacy, because Kirkpatrick et al. (1992*a*) have observed <5% fertility in year 3 among mares given a single injection of PZP vaccine in years 1 and 2. In other words, despite a submaximal response to antigen in year 1, the response to booster antigen in year 2 can be maximal.

Porcine zona pellucida (PZP) immunocontraception of wild horses (*Equus caballus*) in Nevada: a 10 year study

J. W. Turner, Jr[1], I. K. M. Liu[2], D. R. Flanagan[3], K. S. Bynum[1] and A. T. Rutberg[4]

[1]*Physiology and Molecular Medicine, Medical College of Ohio, 3035 Arlington Avenue, Toledo, OH 43614-5804, USA;* [2]*University of California at Davis, Davis, CA 95616, USA;* [3]*University of Iowa, Iowa City, IA 52242, USA; and* [4]*Tufts University School of Medicine, North Grafton, MA 01536, USA*

Porcine zona pellucida (PZP) immunocontraception was investigated for possible use in free-roaming wild horses in the western USA. A protocol of two injections (3–4 weeks apart) of vaccine lasting 1 year was first used and a single-injection controlled-release vaccine of 1 year duration was developed and tested in the field. Studies of a presumptive vaccine of 2 year duration were initiated. The parameters of anti-PZP antibody titre response, pregnancy testing and offspring production were used, and PZP vaccine was found to provide up to 94% infertility in free-roaming wild mares. In addition, a single-injection PZP vaccine of 1 year duration and containing a controlled-release component of PZP in a polymer matrix can provide infertility equivalent to the two-injection PZP vaccine. All the PZP vaccine preparations tested were associated with a return to normal fertility within 1 year. During the course of these studies, attention was given to practical aspects of management application of PZP contraception. Preparation of the controlled-release portion of the vaccine in pellets, which fit into the needle of a dart or syringe, has simplified vaccine handling and permitted long-term storage of the controlled-release component. Vaccine delivery is now performed using a jabstick on captured mares restrained in a field stock chute during routine horse gathers. Provision of a vaccine-training programme has maximized personnel safety during vaccine preparation and use.

Introduction

The first study of immunocontraception of free-roaming wildlife took place in 1988 on wild horses (*Equus caballus)* on Assateague Island National Seashore (ASIS) off the Maryland coast. Successful contraception was achieved with a porcine zona pellucida (PZP) vaccine on ASIS (Kirkpatrick *et al.*, 1990) and in captive mares (Liu *et al.*, 1989). These studies encouraged pursuit of immunocontraception as a humane and cost-effective tool for managing wild horses in the western USA. Since 1991, with funding provided by the US Department of the Interior,

© 2002 Society for Reproduction and Fertility

Bureau of Land Management (BLM), we have investigated long-term fertility control of free-roaming wild horses using PZP immunocontraception.

This research has focused on three primary criteria that must be satisfied to enable practical wildlife contraception: (i) high efficacy with reversibility; (ii) access to animals in the field; and (iii) ability to limit population growth. The specific aims of these studies were: (i) to convert the existing two-injection (1 month apart) vaccine with a 1 year duration into a single-injection vaccine with high efficacy and 2–3 years duration; (ii) to ensure return to fertility in treated animals; and (iii) to design the vaccine for practical application in wild horse management. In this article, research toward these aims in the period from 1991 to 2001 is presented.

Materials and Methods

General

This work has involved several sets of laboratory experiments followed by field trials in free-roaming wild horses. Laboratory work involved: (i) vaccine formulation; (ii) *in vitro* testing of controlled-release vaccine characteristics; and (iii) monitoring of *in vivo* antibody production in response to immunization. Subjects for laboratory studies were horses (captive-wild or domestic) and rabbits, with group size ranging from 5 to 10 unless stated otherwise. Field trials used specific herds of free-roaming wild horses in Nevada, the location of approximately 65% of wild horses in the western USA. The reference immunization for all studies consisted of two i.m. (gluteus) PZP (65 μg)–adjuvant injections, 1 cc each, administered 3–4 weeks apart as described by Liu *et al.* (1989). All treated mares in field studies were freeze-marked on the left hip for future identification from the ground or helicopter, and subsequent foals were counted by ground and aerial survey. Efficacy and reversibility of contraceptive treatment was determined by antibody titres in captive mares using a serum ELISA specific for anti-PZP antibodies (Liu *et al.*, 1989) and by pregnancy determination in free-roaming mares based on faecal steroid assay (Kirkpatrick *et al.*, 1991) or foal counts or both.

Controlled-release vaccine

The high costs and formidable logistics of maintaining wild horses in captivity for the required 3–4 weeks between injections make a two-injection vaccine protocol impractical. Thus, a primary aim was to develop a single-injection PZP vaccine. Initially, it appeared that controlled-release technology, already used for the delivery of a number of agents, including cancer chemotherapeutics and various vaccines (Chang, 1976; Carter *et al.*, 1988; Linhardt, 1989; Wang *et al.*, 1990), could be applied to the PZP vaccine to meet the requirement for a single-injection vaccine. This technology was used to sequester PZP or adjuvant or both within inert, non-toxic poly L-lactide co-glycolide (PLG) polymer microspheres or pellets (mini-rods), which would release their contents upon injection and exposure to an aqueous environment in a fashion dependent on the formulation.

PLG controlled-release preparations were performed using a coacervation technique (Wang *et al.*, 1991). PZP comprised 1% of final microsphere weight, and duration of delay in PZP release (1, 3 or 12 months) was adjusted by altering the lactide:glycolide ratio (from 50:50 to 100:0). Initial studies focused on microspheres of several types, including microspheres with slow, continual release and microspheres showing a delayed bolus release at 1–6 months, as desired.

Preliminary *in vitro* studies were performed with controlled-release preparations. Although release characteristics of these preparations were not likely to be identical *in vivo* and *in vitro*,

the latter provided reasonable, inexpensive estimates of release patterns. The release of PZP from the controlled-release PZP preparations was monitored by solid-phase protein assay (SPA) ELISA of biweekly aliquots of an incubation medium of phosphate-buffered saline kept at 37°C under gentle, continuous shaking.

For immunization of animals with appropriate releasing preparations, microspheres were suspended in an inert liquid carrier (carboxymethylcellulose) and injected by hand or dart. Controlled-release vaccines consisted of a standard, 1 cc PZP–Freund's complete adjuvant (FCA) emulsion plus the controlled-release component. Initial microspheres did not contain adjuvant, as the requirement for water solubility for incorporation into the polymer preparations precluded the use of Freund's adjuvant. Later microspheres were prepared containing the water-soluble adjuvant Carbopol 934 (CAR) (B. F. Goodrich, Cleveland, OH).

In addition to microspheres, controlled-release PLG pellets containing PZP or adjuvant or both were also prepared and tested. Pellets were prepared using a physical compression or thermal extrusion method (Sanders *et al.*, 1986) and were approximately 6.0 mm × 1.5 mm in diameter, and designed to fit into the barrel of a 14-gauge hypodermic syringe. Pellets contained 70–90 µg PZP or 150–175 µg QS-21 (water-soluble saponin adjuvant; Aquila Biopharmaceuticals, Framingham, MA) or both and exhibited a bolus release similar to that observed in bolus-release microspheres.

Conjugate vaccine

Conjugate vaccines may provide an ideal way to increase T-cell activation and cytokine production essential for B-cell activation and antibody production after immunization. As most carrier proteins are stronger T-cell stimulators than are zona pellucida antigens, conjugation of antigen to carrier protein can potentially increase antibody affinity maturation and duration of immunological memory. It was hypothesized that the effects of conjugation could play a key role in developing a single-injection vaccine of 1 year duration.

For this study, captive wild mares were immunized (left hip, 1 cc, by syringe) with PZP conjugated to keyhole limpet haemocyanin (KLH) at a 1:1 mass ratio (Pierce Chemical Company, Rockford, IL) prepared by R. Fayrer-Hosken (University of Georgia). The study compared several combinations of conjugated PZP–KLH and non-conjugated PZP (each emulsified with FCA or Freund's incomplete adjuvant (FIA)) against the standard two-injection PZP–FCA/FIA vaccine.

Results and Discussion

Vaccine efficacy

Controlled-release studies. An example of release data obtained from *in vitro* incubation of a PZP microsphere formulation (Turner *et al.*, 2001) and an example of a PZP pellet release pattern are shown (Fig. 1a and 1b, respectively). Release characteristics have been examined for microspheres and pellets with 1–3 and 3–6 month release delays. Assessment of PZP release from pellets designed for release after 12 months is still in progress.

Rabbits were used for initial *in vivo* testing to determine antibody titre response, with subsequent field testing of early microsphere preparations in 132 mares of the Antelope Valley Herd Management Area (HMA) in Nevada (Turner *et al.*, 1997). A summary of various controlled-release vaccines and their contraceptive efficacy in the field, including Antelope Valley HMA, is shown (Table 1).

The results of the Antelope Valley HMA study were encouraging in several aspects. Firstly, they established the feasibility of treating large numbers of mares in the field during routine

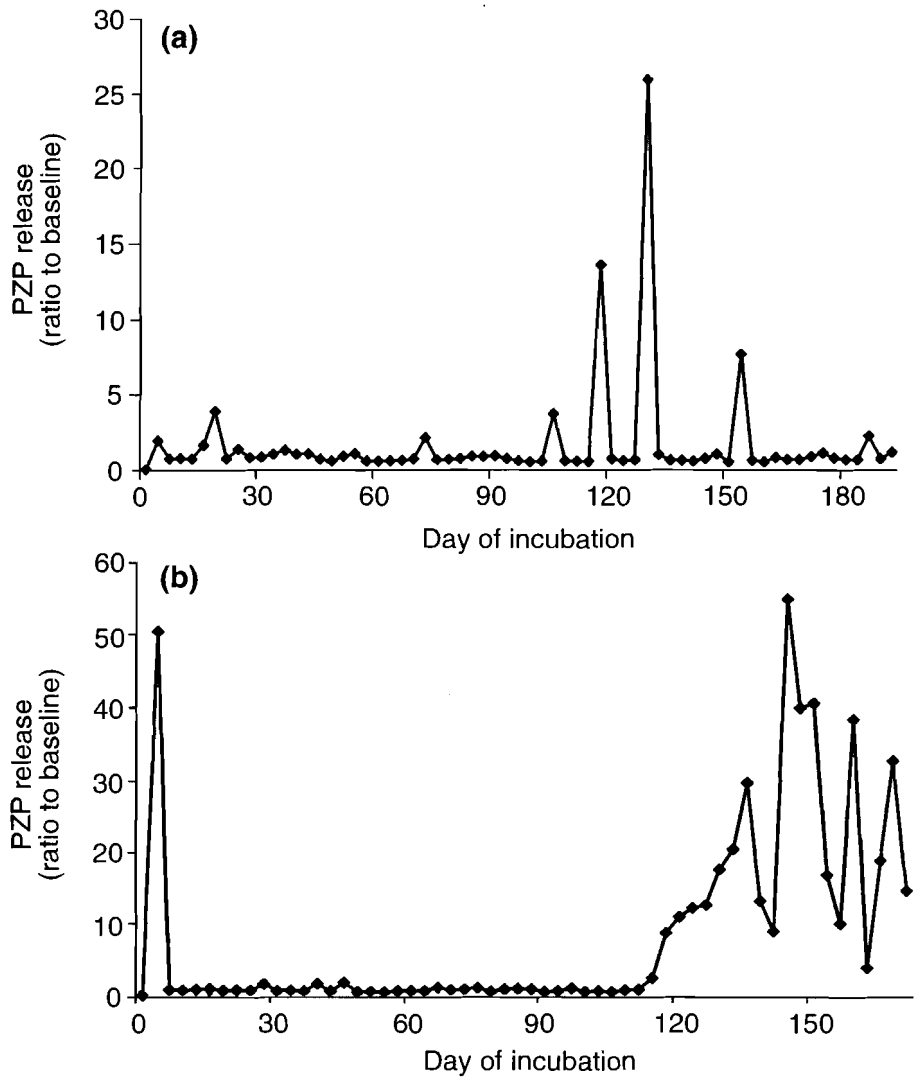

Fig. 1. (a) *In vitro* release pattern for three identical, separately incubated lactide:glycolide (ratio 65:35) microsphere populations containing 80 μg porcine zona pellucida (PZP) per population. Each microsphere population exhibited one major bolus release during the incubation. (b) *In vitro* release pattern for a single lactide:glycolide (85:15 ratio) pellet containing 80 μg PZP incubated at 37°C in phosphate buffered saline and designed to release after approximately 3 months. Note initial release associated with PZP on or near pellet surface.

BLM horse gathers. Secondly, they demonstrated that the fertility rate in mares given the single-injection microsphere vaccine was lower than in untreated controls. Finally, they demonstrated that treated mares showed infertility of one breeding season in duration, with a return to fertility in the second year after vaccination (Turner *et al.*, 1997).

However, the single-injection (with microspheres) treatment was less effective than the standard two-injection vaccine. There were two likely shortcomings of the original microsphere formulation. Firstly, continuous release rather than bolus release of antigen was a poor mimic of a second injection. Secondly, the absence of adjuvant in the second exposure resulted in a submaximal response. Therefore, the microspheres were reformulated to allow for bolus release of antigen and inclusion of adjuvant, and these were tested. As water-

Table 1. Effects of various PZP vaccine formulations on fertility in free-roaming feral horses in Nevada

Vaccine type[a]	Injection type	Adjuvant[b]	Study site (HMA)	Number of mares	Fertility rate[c] (%)

Pellets (bolus 1, 3 and 12 month)	Jabstick	QS-21	Clan Alpine	32	6	–

[a]All vaccines contained an initial injection with porcine zona pellucida–Freund's complete adjuvant (PZP–FCA) emulsion. Controlled-release pattern was gradual for Antelope Valley and bolus for all sites thereafter.

[b]Adjuvant for second exposure to PZP (FIA: Freund's incomplete adjuvant).

[c]Based on foal counts or faecal steroid-based pregnancy test or both.

[d]Pregnancy rates in treated mares were determined 2 years after treatment, and sample size ranged from 16 to 38.

[e]Composite value comprised untreated horses from each Herd Management Area (HMA) listed in this Table.

[f]Some treated marked populations included mares given the standard two-injection vaccine.

soluble adjuvants show similar solubility to PZP, no testing of these adjuvants *in vitro* was performed.

Revised microsphere formulations were evaluated in horse and rabbit studies that lasted up to 68 weeks using anti-PZP antibody titres as an indicator of vaccine efficacy (J. W. Turner, Jr and I. K. M. Liu, unpublished). These studies showed that: (i) some animals respond vigorously and others only moderately to the same dose of PZP vaccine; (ii) increasing PZP doses by up to three times in rabbits or up to six times in horses did not increase either antibody titre response or the percentage of animals responding; and (iii) microspheres given alone, without a PZP–FCA priming dose, did not elicit sufficient antibody titres.

On the basis of the above studies, a field trial was initiated in January 1996 in Nevada to test a presumptive single-injection, 1 year PZP vaccine using bolus-release PZP–CAR microspheres against the standard two-injection vaccine (Turner *et al.*, 2001). Adult wild mares ($n = 267$) were captured, freeze-marked, treated and released. Reproductive success across 1 year was 12.8% in mares receiving the two-injection vaccine, 11.3% in mares given the single-injection vaccine containing microspheres and 62.5% in untreated control mares. This study revealed equivalent 1 year contraceptive efficacy between single- and two-injection PZP vaccines, indicating that controlled-release technology can replace a second injection.

Despite the contraceptive success of the controlled-release vaccine, some disadvantages of CAR adjuvant and of microspheres became evident during field trials. As previously stated, microspheres were delivered by suspending them in an inert liquid in a syringe. Unless the injection was made within 30 s of suspension, microspheres clumped at the tip of the syringe

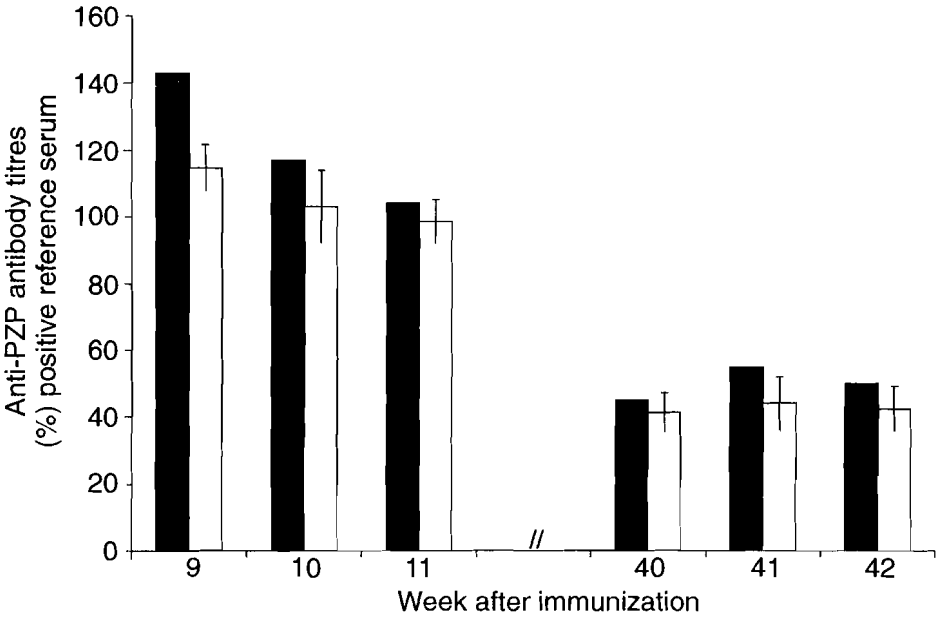

Fig. 2. Comparison of antibody response in domestic mares to standard two-injection porcine zona pellucida (PZP) vaccine (■) versus controlled-release PZP vaccine (□). Two-injection vaccine ($n = 2$) consisted of 65 μg PZP–Freund's complete adjuvant (FCA) followed in 3 weeks by 65 μg PZP–Freund's incomplete adjuvant (FIA). Controlled-release vaccine ($n = 5$) consisted of a single injection containing 65 μg PZP–FCA emulsion plus 1 month pellet (70 μg PZP and 150 μg QS-21 adjuvant) and 3 month pellet (90 μg PZP and 200 μg QS-21 (water-soluble saponin) adjuvant). Reference serum was obtained at 8 weeks after immunization from a mare previously given a standard two-injection vaccine.

and prevented injection. In addition, the CAR adjuvant had to be delivered in mg amounts, which required either overloading the microspheres or using a 2–3 cc injection volume. Thus, the use of pellets as a controlled-release medium and QS-21 as an alternative water-soluble adjuvant was investigated.

In 1998, as part of a 45 week study of 25 domestic mares, the standard two-injection PZP vaccine was compared with a presumptive single-injection vaccine, using PZP and QS-21 pellets in place of the second injection (Fig. 2). The PZP–QS-21 pellet vaccine consistently produced titres similar to the two-injection PZP treatment group during the 45 weeks that were monitored. Importantly, the PZP–QS-21 pellet-treated mares consistently showed titres in the range usually associated with contraceptive effects in mares, as determined in previous experiments by Liu *et al.* (1989). This finding indicated that an effective single-injection contraceptive vaccine with approximately 1 year duration had been developed.

Early in 1999, a series of tests was initiated in five separate wild horse populations to assess the impact of the single-injection, 1 year vaccine containing PZP–QS-21 pellets on population growth. Although the population-impact portion of these tests is still in progress, data from these tests on vaccine efficacy and reversibility are shown (Table 1). It is noteworthy that the fertility rates in treated mares in the Monte Cristo and Dolly Varden populations were higher than in other treated populations. This lower efficacy was purportedly due to a significant incidence of failed injection of vaccine by darts used for remote delivery in these two studies (other studies used hand injection or jabstick). A similar efficacy problem has been encountered in studies using dart delivery of PZP vaccine in white-tailed deer (A. Rutberg and R. Naugle, personal communication).

Results of the studies using a single-injection, 1 year vaccine encouraged exploration of a vaccine containing a controlled-release annual booster. A pellet projected to release PZP–QS-21 at about 12 months after injection was designed, with the amounts of PZP and QS-21 increased to 250 μg and 500 μg, respectively, to account for expected biological degradation and cumulative gradual loss from the pellets across time. In January 2000, wild mares (n = 96) in the Clan Alpine HMA were treated and released using a vaccine consisting of a priming dose of PZP in FCA and 1-month, 3-month and presumptive 12-month releasing pellets of PZP–QS-21. This vaccine was expected to provide 2 continuous years of infertility. Results after 1 year revealed 6% fertility among 32 treated mares that were re-identified and 59% fertility in 33 untreated mares (Table 1). Year 2 data will be available from foal counts in 2002.

Conjugate studies. Captive wild mares (n = 42) were divided into several treatment groups (n = 7–9 per group) to allow comparison of the PZP–KLH conjugate vaccine with standard PZP and control vaccines. All injections were delivered by hand in December 1998, with a booster at week 4 and antigen challenge with PZP alone at week 44. All mares in the study underwent normal ovarian cycles as demonstrated by faecal ovarian hormone concentrations measured from April to June. Delayed-type hypersensitivity skin test results revealed no increase in Th1 T-cell activation as determined by wheal diameter (mm) in response to intradermal injection of PZP, indicating that the risk of autoimmune ovarian disease typically associated with ovary-specific $CD4^+$ Th1 cells (Bagavant *et al.*, 1999) was not increased.

Primary immunization of mares with PZP–KLH in FIA followed by boosts with PZP in FIA resulted in increased, sustained anti-PZP antibody titres that were not significantly different from titres in mares immunized similarly using PZP alone. Mares immunized with the PZP–KLH sequence and mares immunized with PZP alone sequence had significantly ($P < 0.05$, binomial probability distribution) lower pregnancy rates, 33% and 29%, respectively, compared with a KLH–adjuvant control pregnancy rate of 75%.

This study is the first to demonstrate an immunization protocol in horses that is as effective as the standard two-injection PZP vaccine without requiring the use of FCA. As FCA is not indicated for widespread use in the field, the PZP–KLH conjugate used with permissible oil adjuvants or other delivery systems may have high potential for routine management use. The PZP–KLH conjugate may also prove to be an ideal priming dose in deer and other species in which routine testing for tuberculosis (TB) infection is performed, as vaccines that include FCA may result in a false-positive TB test.

The PZP–KLH conjugate may also have potential in controlled-release preparations. As the immune response to PZP is not vigorous, a strong adjuvant such as FCA has been necessary in the priming dose of PZP. However, the oil-based FCA cannot be used in controlled-release pellets, and no water-soluble adjuvants to date have equalled the potency of lipid-based FCA. If PZP–KLH conjugate is proven compatible with existing rapid-release (from hours to days) polymers, an attractive immunization protocol would be a priming dose of lyophilized PZP–KLH and water-soluble dry adjuvant in a rapid-release pellet with secondary PZP doses in delayed-release pellets. This would allow a completely pelletized, dry vaccine of controlled-release components and elimination of soluble vaccine containing FCA. Without a liquid component, the vaccine would have a long shelf life (years) and neither on-site emulsification nor cold storage of components would be required.

Reversibility

Short-term recovery of fertility after administration of anti-fertility treatment has been

determined in our field trials by helicopter and ground surveys (Table 1). In most cases, fertility rates were determined among treated and untreated mares in the year that infertility was elicited, as well as in treated mares in the year after contraceptive effect, to determine reversibility. Fertility rates among different populations were similar, ranging from 44% to 65% in the year of return to fertility. This range was similar among the same populations monitored in the year before contraceptive effect. In addition, in populations containing a percentage of treated mares, the range of fertility rates in untreated mares was from 54% to 67%. These data support the conclusion that a return to normal fertility occurred within 1 year after the period of active contraception.

As routine horse gathers take place a minimum of 3 years apart, the BLM has encouraged the development of a single-injection vaccine with 3 year duration. The theory is that this would ensure continuous contraceptive coverage. However, perspectives on this matter continue to change as a result of the association of consecutive treatment for 3 or more years (to provide continuous infertility) with delayed return to fertility in 69% of treated mares across 4 years in the studies on ASIS (Kirkpatrick *et al.*, 1992).

The development of a PZP vaccine with effects up to 3 years in duration is warranted, but use for management purposes should be contingent on establishment of a strong database on the population impact of treating specific percentages of a population with vaccines of specific duration. To date, our studies have addressed only a 1 year PZP vaccine in this regard and results are incomplete. An additional complicating factor is the size of the population being treated. Hobbs *et al.* (2000) have used computer modelling for ungulate populations to demonstrate that long-lived contraceptives have the potential to reduce small populations to the point that they cannot recover. One way to minimize this risk is to use a contraceptive of shorter duration in smaller populations, which would enable more responsive and adaptable management.

Another important aspect of the reversibility issue related to management is the gene pool and the aim of maintaining genetically viable populations. Unimpeded natural selection will yield the best fit of horse to habitat, and the value of the wild horse gene pool lies in that fit. The current gather programme regularly and permanently removes genes and manipulates the gene pool artificially. In contrast, reversible contraception does not eliminate genes and, thus, leaves more material for natural selection.

Management issues

There are issues other than efficacy and reversibility that are relevant to a viable vaccine for use in the field. These include field access to animals and safety of use for administrator and recipient.

Field access. A highly effective vaccine is worthless until it is in the target animal; thus, access is a critical component of any wildlife fertility control programme. The most common access methods are immobilization or trapping (to enable immunization by direct injection) and remote delivery (via dart or biobullet) in the open field or at bait stations. Oral delivery in feed or bait is also under consideration, although this method is faced with the serious challenge of assuring species specificity in the consumer. Early studies on ASIS involved accessing mares by tracking them on foot followed by darting. This method was also used effectively in a separate project in free-roaming wild burros (Turner *et al.*, 1996). Tracking and darting were so successful that we initially considered remote-delivery darting of western horses from a blind (camouflaged hiding) spot at waterholes or from helicopters.

Although the feasibility of these approaches has been documented (Kirkpatrick *et al.*, 1991), the ongoing gather and adoption programme of the BLM guaranteed access to mares in the field. Horses were gathered by helicopter and placed individually into a stock chute to be aged by dental examination. Mares older than a BLM-specific age were immunized with the PZP vaccine and returned to the range. Several methods were examined for delivery of PZP pellets, including syringe/trocar, self-injecting dart and jabstick, with the PZP–FCA emulsion portion of the vaccine in the syringe or dart propelling the pellets into the muscle in all delivery methods. The jabstick emerged as the most suitable delivery method for use in routine horse gathers. The adoption programme is expected to continue indefinitely, with associated horse gathers guaranteeing access to mares for PZP vaccine delivery. An important advantage of this method of access is that the only cost associated with ongoing fertility control in this situation is the vaccine and its delivery equipment.

Safety and training. The biological safety of the PZP vaccine in target animals has been documented through the observed normality of physiological and behavioural function in treated animals of various species including deer (McShea *et al.*, 1997), elephants (Delsink *et al.*, this supplement) and wild horses (Kirkpatrick *et al.*, 1995; Powell, 1999; Turner and Kirkpatrick, this supplement). Qualitative observations of PZP-treated and control horses in Nevada during the past 10 years have been consistent with these reports. Furthermore, the obvious improved nutritional status of females freed periodically from the metabolic demands of pregnancy and lactation (McShea *et al.*, 1997) has affected individual lifespan and overall health positively (Turner and Kirkpatrick, this supplement).

Ensuring the safety of personnel who prepare and administer the vaccine is important and can best be achieved by training. In early studies, all fieldwork was performed by the investigators. However, the increase in both the number of study sites and number of BLM personnel involved in these studies led to provision of a formal 4 day training programme on the topic of wild horse immunocontraception at ZooMontana (Billings, MT; instructors: J. Kirkpatrick, K. Frank, R. Lyda and F. Deigert) in 1999 and 2000. This training has maximized the assurance of safety and comfort with vaccine preparation and use.

Conclusion

Considerable progress has been made in wild horse contraception since 1991. A single-injection controlled-release PZP vaccine has been developed that provides 1 year of infertility followed by a high return to fertility. Efficient access to wild mares has been demonstrated during routine BLM gathers of wild horses, and reasonable vaccine delivery and safety have been provided for both administrator and recipient. PZP vaccine appears viable for management application, pending results of ongoing studies, which address contraceptive limitation of population growth. While PZP vaccine can be used effectively in its present (1 year) form, it has additional potential pending the outcome of current studies to extend its duration to 2 years and to simplify its preparation and storage.

ABSTRACT Previous studies reported one year of contraception associated with a 1-injection porcine zona pellucida (PZP) vaccine. We have subsequently determined contraceptive effectiveness of a presumptive 1-injection, 2-year-duration PZP vaccine in free-roaming wild horses (*Equus caballus*) in Nevada, USA. In January 2000, we captured, freeze-branded, treated, and subsequently released 96 adult females that received 1) a primary dose of vaccine emulsion consisting of aqueous PZP and Freund's Complete Adjuvant, and 2) booster doses of PZP and adjuvant in controlled-release polymer pellets. We determined PZP release characteristics of pellets in vitro, prior to field use. We determined reproductive success in treated and untreated females through October 2004 via measurement of estrone sulfate and progesterone metabolites in fresh feces collected from the ground and by twice-annual foal counts. Among treated females, annual reproductive success from 2001 though 2004 sequentially was 5.9%, 14.0%, 32.0%, and 47.5%. Untreated females showed average reproductive success of 53.8 ± 1.3% across this period. This study revealed that: 1) PZP acted as an effective contraceptive for 2 years posttreatment; 2) some residual contraceptive effect remained in year 3; and 3) fertility returned to control levels by year 4 posttreatment. It appears that controlled-release technology can replace both the second (1-month) and annual booster injection of PZP vaccine, thereby decreasing cost and increasing efficiency of use of this vaccine in wild horse management. (JOURNAL OF WILDLIFE MANAGEMENT 71(2):662–667; 2007)

KEY WORDS adjuvant, controlled-release vaccine contraception, *Equus caballus,* field study, free-roaming wild horse, pregnancy testing, zona pellucida antigen.

Since the passage of the Free-Roaming Wild Horse and Burro Protection Act in 1971, management of wild horses (*Equus caballus*) on public lands has proven biologically and politically challenging. Under its multiple-use mandate, the Bureau of Land Management (BLM) must maintain healthy, viable wild horse herds in a thriving ecological balance with many competing uses, including wildlife, livestock, and other commercial and recreational activities. With lethal horse population control being illegal and broadly unacceptable to the public, the BLM has relied principally on gathering, removing, and adopting wild horses to control their numbers on the range. However, the supply of wild horses has markedly exceeded adoption demand, forcing the BLM to hold horses in sanctuaries and other long-term holding facilities, primarily at taxpayer expense.

To help reduce population pressure on public lands and the adoption program, the BLM has been supporting horse contraception research since the 1970s (Kirkpatrick 2005). The use of porcine zona pellucida (PZP) immunocontraception for the purpose of safe and cost-effective regulation of free-roaming wild horse populations has been under investigation since 1988 (Turner and Kirkpatrick 1991). Porcine zona pellucida vaccine use in the horse was first reported by Liu et al. (1989). The vaccine appears to act by stimulating anti-PZP antibodies that bind to the surface of the ovulated egg, preventing sperm attachment (Liu et al. 1989).

In initial studies, a vaccination protocol of 2–3 separate inoculations about a month apart yielded reversible infertility for one breeding season in a number of species including horses (Liu et al. 1989, Kirkpatrick et al. 1990), burros (*Equus asinus*; Turner et al. 1996), white-tailed deer (*Odocoileus virginianus*; Turner et al. 1992), and African elephants (*Loxodonta africana*; Fayrer-Hosken et al. 1997). However, for managing free-ranging wildlife a 1-injection vaccine effective for 1–3 years is desirable.

One approach to a one-injection, multiple-year vaccine is to mimic the effects of booster injections by incorporating vaccine into controlled-release polymers. This methodology has involved forming a homogenous mixture of bioactive ingredients with a biodegradable, nontoxic lactide-glycolide polymer in the form of microspheres (Eldridge et al. 1989, Wang et al. 1990). Upon intramuscular injection and contact with tissue fluids, the polymer material gradually erodes and releases the bioactive contents (Wang et al. 1991).

In previous studies with free-roaming wild horses, a single injection containing primer PZP adjuvant and booster PZP (no adjuvant) in controlled-release preparations of lactide-glycolide microspheres reduced fertility but was less effective than 2 separate inoculations (Turner et al. 1997). Since an important function of adjuvant is to enhance immuno-

[1] *E-mail: jturner@meduohio.edu*

recognition of antigen and consequent antibody production, we expected that adjuvant presence in the controlled-release component of the vaccine would boost the effectiveness of this component. In a subsequent study, a vaccine preparation in which a carbomer adjuvant was added to the PZP-containing polymer microspheres proved as effective as 2 separate injections of PZP adjuvant (Turner et al. 2000). Further refinement of controlled-release components led to replacement of gradual-release polymer microspheres with bolus-release polymer mini-rods (pellets) in the 1-injection, 1-year vaccine (Turner et al. 2002). We hypothesized that these conditions would resemble multiple, separate injections of vaccine and would yield infertility similar to that obtained with multiple booster inoculations.

Our present objective was to test the effectiveness of a presumptive 2-year PZP vaccine that utilized a controlled-release PZP adjuvant component to provide multiple bolus-release booster events.

STUDY AREA

The study area was part of the Clan Alpine Herd Management Area in central Nevada, USA, and comprised about 7,800 km^2 centered at 39°32′N latitude and 117°55′W longitude. Elevations ranged from 1,300 m to 3,066 m. Vegetation on the portion of the range most used by study horses was composed largely of sagebrush (*Artemisia* sp.) communities, with pinyon pine (*Pinus edulis*) and juniper (*Juniperus* sp.) occurring at higher elevations. Grasses commonly utilized by horses in these communities were Indian rice grass (*Achnatherum hymenoides*), galleta (*Pleuraphis jamesii*), and desert needlegrass (*Achnatherum speciosum*). Average annual precipitation (2000–2004) was <22 cm at 2,000 m elevation. Water was available from several permanent springs in the study area. During the study period, we made >80% of the observations by aerial and ground surveys in 4 distinct areas comprising <3,000 km^2 and favored by the horses due to feed and water availability. The Carson City (Nevada) District of the Bureau of Land Management (BLM), United States Department of Interior administered the study area.

METHODS

Experimental Design

The study examined the antifertility effectiveness and longevity of a single-injection PZP vaccine containing a controlled-release component exhibiting several release windows. Every vaccine treatment contained an emulsion of aqueous PZP, Freund's Complete Adjuvant (FCA), and a controlled-release component containing PZP and the saponin adjuvant QS-21. We applied contraceptive treatment in the field (Jan 2000) after we randomly assigned >200 captured adult wild females to a vaccine treatment group ($n = 96$) or to an untreated control group ($n > 100$). We did not include a sham control group because we have previously shown (Turner et al. 1997) that wild females captured, handled, and given a placebo injection exhibited fertility rates that did not differ from those of untreated females not captured. We estimated fertility rates in the absence of contraceptive effects from foal counts made among treated and untreated females in May and October of 2000 (i.e., foals born to both were conceived before treatment in Jan 2000). We determined the effectiveness and duration of treatment by assessing reproduction via ground and aerial foal counts and fecal-hormone pregnancy tests at various times across the period from autumn 2000 through autumn 2004. We considered a female to have successful reproduction if she tested positive for pregnancy or was observed with her foal or both.

Horse population.—We performed this study under auspices of Animal Care and Use protocol (no. 100742) of the Medical University of Ohio and the standard animal management practices of the Bureau of Land Management. The study area was inhabited by about 600 horses with a harem-band social structure (Turner et al. 1981, Berger 1986). The peak breeding period was May and June, and the peak foaling period was April and May. We estimated the physical condition of females in the corral prior to inoculation and in the field during subsequent observations using the condition scale (1–10) developed by Henneke et al. (1983). Initial female condition ranged from fair (3) to good (6). Condition-3 females comprised <30% of those treated. None of the females appeared to deteriorate in condition across the study and many apparently improved, possibly due to increased feed availability after a January 2000 permanent removal of 233 (329 initially removed, 96 returned to range) horses from the range.

Because BLM selective-removal policies in place at the time dictated the removal of all females under 10 years of age, all females receiving treatment were >10 years of age. Six treated females were aged >20 years. In some wild horse herds, reproduction may be reduced in females >20 years old (T. Pogacnik, BLM Wild Horse and Burro Program files, unpublished data). However, data for the Nevada Wild Horse Range in central Nevada, where female physical condition was generally inferior to the Clan Alpine herd, showed fertility rates in females aged 10–20 were similar to those rates in females >20 (Turner et al. 2000).

PZP vaccine emulsion preparation.—We prepared PZP from porcine ovaries as previously described (Liu et al. 1989). The primer portion of the vaccine consisted of an emulsion of 0.5 cc FCA with 65 μg PZP in 0.5 cc phosphate buffer solution (PBS). We prepared the emulsion, 8 doses at a time within 24 hours of injection using 10-cc glass syringes joined with a plastic connector. After 100 plunger strokes, we loaded the emulsion into 10-cc plastic syringes for injection via a 14-gauge, 3.7-cm needle. We prewashed the needle (new needle each injection) and the injection site with 70% ethanol. The emulsion was kept chilled, but we hand-warmed it prior to injection.

Controlled-release pellet preparation.—We prepared the pellets by a heat–extrusion process employing a Dynisco extruder (Dynisco, Morgantown, PA). The pellets consisted of lyophilized PZP and QS-21 (a water-soluble saponin adjuvant) matrixed in homogenous lactide and glycolide

Table 1. Polymer pellet composition and in vitro bolus controlled-release characteristics for porcine zona pellucida (PZP) vaccine used in female wild horses in Nevada, USA, in 2000.

Pellet type based on exp release delay (months)	No. of pellets tested	Pellet mass (mg)	Polymer ratio[a] (lactide:glycolide)	PZP mass (μg)	QS-21[b] mass (μg)	Loading rate (PZP + QS-21) polymer (%)	Obs in vitro release delay[c] (months)	
							$\bar{x}$	Range
1	6	7	65:35	70	175	3.5	1.5	0.9–2.1
3	6	7	85:15	90	200	4.1	3.9	3.0–5.2
12	6	8.5	100:0	250	500	9.4	11.5	10.3–14.2

[a] Lactide used is a mixture of dextro- and levo-rotatory forms.
[b] QS-21 is a water-soluble saponin adjuvant.
[c] $\bar{x}$ and range are based on when >80% of total PZP release occurred during entire in vitro incubation period.

polymers. Pellet preparation and release characteristics (Table 1) are summarized below. We regulated the delay period for release of active ingredients from pellets by altering the ratio of lactide to glycolide. We chose to release windows at approximately 1 month and 3 months to mimic a second and third inoculation, which had yielded effective contraception for one breeding season in an earlier study (Kirkpatrick et al. 1990). Likewise, we chose an approximate 12-month window to mimic an annual booster inoculation shown previously to provide a second year of contraception (Kirkpatrick et al. 1992). We extruded pellets from a melted (<95° C) mixture of lactide and glycolide containing micronized PZP and QS-21. The cylindrical pellets, designed to fit inside the barrel of the 14-gauge hypodermic needle, were approximately 0.6 × 1.5 mm with an average weight of 7.5 mg. Pellets were of 3 types (Table 1), and we determined characteristics of PZP release at several polymer ratios in vitro by measuring PZP concentrations in the incubation medium across time using a sandwich-type enzyme-linked immunosorbent assay (ELISA) for PZP (Turner et al. 2002). The in vitro environment for a given pellet consisted of 3 cc of 37° C bacteriostatic PBS – 1% horse serum gently and continuously shaken (2 back-and-forth motions/sec). Every 5–7 days for up to 14 months, we removed the medium for assay and added 3 cc of new medium to the pellet vial. We performed the ELISA on 100 μl of each sample of medium. We did not measure the release of QS-21 from pellets. However, we expected release characteristics to be similar to PZP, based on similar water solubility (C. Kensil, Antigenics, Inc., personal communication).

Accessing, handling, and inoculating of horses.—The BLM gathered horses by helicopter, which permitted injection by hand. We chose this method because access to the horses was possible as a part of scheduled roundup for the BLM horse adoption program. Between 2 January and 9 January 2000, the BLM gathered 329 horses by helicopter into portable corrals. In the corral system the BLM 1) separated the gathered males and females, 2) moved them singly through a stock chute, 3) estimated age through dentition and physical condition, 4) gave a 1-cc prophylactic Strepguard® (Miles Laboratories, Shawnee Mission, KS) injection intramuscularly, and 5) permanently marked 96 healthy females >10 years of age with consecutive numbers by freeze-branding. The brands were located on the upper left hip, were 8 cm in height, and were readable from a helicopter and through a spotting scope at >500 m distance on the ground.

We used a jabstick to inject 1 cc of freshly prepared emulsion of buffered PZP adjuvant (described above) into the left gluteus muscle and we simultaneously injected 1-month, 3-month, and 12-month pellets, which were sequestered in the needle barrel. We examined each needle postinjection to ensure pellet delivery. Three of the 96 deliveries by this method failed, and in those cases, we delivered the pellets by a second injection using PBS to propel the pellets. We photographed each marked female prior to release. The BLM maintained all females (treated or untreated) in portable corrals on grass–hay and water ad libitum for up to 4 days, and then released them into the range area from which they had gathered them. Before release, the BLM separated the females and their foals and retained the foals for eventual adoption. Within 24 hours of the release, representatives of the BLM surveyed the study area by helicopter to determine the horses' well-being and dispersal.

Pregnancy testing by fecal steroid analysis.—In the study area, most foaling occurs in April and May, and breeding is uncommon after mid-June. Pregnancy can be detected reliably with fecal analysis within 80 days postconception (Kirkpatrick et al. 1991). We sampled females for pregnancy detection in autumn 2001 to determine treatment efficacy for year 2 and to verify for this herd the validity of foal counts for assessing reproductive rates, as previously reported for other herds (Turner et al. 1996, Turner and Morrison 2001). Between mid-September and mid-October of 2001, we observed females for defecation using binoculars and 20–40× spotting scopes. We took photographs of untreated females at observation when possible to enable later identification for foal presence or absence. We ensured that each sample collected was from the desired female by pairing observers such that one person maintained view of the sample through the scope while hand- or radio-signaling the other observer to the sample. If the location or specificity of the sample was in question, we did not collect the sample. We collected 2 freshly dropped fecal balls in a sealable plastic bag, labeled it, and stored it on ice until it could be placed in a freezer (within 72 hr). We determined pregnancy in each sample via measurement of estrone sulfate (E1C) and immunoreactive progesterone metabolites (iPdG) by ELISA (Kirkpatrick et al. 1991). The combined measures

Table 2. Association of steroid metabolite levels in fecal samples collected in September and October 2001 with the presence of foals the following summer in female wild horses in Nevada, USA.

F condition	n[a]	Fecal metabolite concentration[b] E_1C[c] (pg/g feces wet wt) $\bar{x} \pm$ SE	iPdG[c] (ng/g feces wet wt) $\bar{x} \pm$ SE
Without foal	24	3.0 ± 0.1	649.3 ± 107.6
With foal	14	6.8 ± 0.9	10,083.0 ± 2,153.1

[a] F included freeze-marked ($n = 17$) and unmarked, but uniquely identifiable ($n = 21$), individuals.

[b] E_1C = estrone sulfate, iPdG = immunoreactive pregnanediol glucuronide.

[c] Values with vs. without foal were different ($t = 2.74$, $P < 0.01$).

Table 3. Hormonally determined pregnancy rates in the second year of treatment for free-roaming female wild horses in Nevada, USA, given in 2000 a single-injection porcine zona pellucida (PZP) contraceptive vaccine of presumptive 2-year duration.[a]

Condition	Total no. F	No. pregnant	No. not pregnant	Pregnancy rate (%)
PZP-treated[b]	17	3	14	16.6
Untreated control	21	11	10	55.0

[a] We immunized F in January 2000 and we collected fecals for pregnancy testing in September and October 2001. We considered a F to be pregnant if fecal estrone conjugates were >3.0 ng/g and immunoreactive pregnanediol glucuronide was >2,400 ng/g.

[b] Vaccine treatment consisted of intramuscular injections of liquid (PZP/Freund's Complete Adjuvant) plus 3 controlled-release pellets (PZP/QS-21 [a water-soluble saponin adjuvant]; 1-month, 3-month, or 12-month delay in release).

have proven >93% accurate in pregnancy diagnosis in several species (Lasley and Kirkpatrick 1991), including the wild horse. We considered a female pregnant when values for a given sample were E1C > 3.1 ng wet feces and iPdG > 2,400 ng/g wet feces.

Foal counts.—The presence of a foal with a given marked female was determined by ground observations in May and October of 2000–2004. We concurrently counted foals among untreated, unmarked females. Double-counting of a given unmarked female was unlikely in the context of unique color and marking patterns across a given band of horses. In questionable cases, we compared our immunization-day photo-identification file with video of target females taken during field collections. We verified which foal was with which female in ground surveys by observing the horses until the foal clearly evidenced association with a given female by its repeated proximity to her during grazing and traveling or by nursing from her or both. We performed aerial counts of horses using a Bell 47 (Ft. Worth, TX) or Hughes Jet Ranger (Seattle, WA) helicopter, with both pilot and observer (1 or 2) having prior experience in aerial survey of horses. We established maternity by applying minimal pressure on a given band of horses initially, which permitted foals to pair with mothers as the band formed up and moved away from the helicopter. We approached more closely to permit reading of freeze-mark numbers, and then withdrew to permit reobservations of mother–foal pairings. We determined reliability of mother–foal pairing behavior as a basis for contraceptive assessment to be >95% when we reidentified and verified marked females with and without foals in ground surveys.

Statistical analysis.—Where appropriate, we have presented data as mean ± standard error. We employed Student's *t*-test for statistical analysis of fecal data. We determined possible group differences among reproductive success rates using a Tukey-type multiple-comparison test for proportions or a binomial probability distribution (BPD; Zar 1984).

RESULTS

In vitro incubation of PZP-containing pellets yielded some PZP release (<10% of total) in the first 10 days, with no detectable release thereafter until a primary release event (72–85% of total release) for a given pellet. Considerable variation occurred in delay of release onset among pellets of a given type (Table 1). Duration of release averaged 8 days, 14 days, and 20 days for 1-month, 3-month, and 12-month pellets, respectively.

Among marked females, 18% ($n = 17$) were both pregnancy tested (Oct 2001) and assessed by foal counts (May and Oct 2002). In addition, among unmarked (untreated) females that were uniquely identifiable (from photographs taken during fecal collections), we assessed 21 individuals by both pregnancy test and foal presence or absence. Thus, we assessed 38 females both hormonally and by foal observation (Tables 2, 3). Average values for E_1C and iPdG were 2.3-fold and 15.5-fold, respectively, greater among females that produced foals than corresponding values for these metabolites in females that did not produce foals (Table 2). For both steroids measured, the average value for females that did produce foals was significantly greater ($t = 2.74$, $P < 0.01$) than for females that did not produce foals. In the spring of 2002, we were able to locate and reidentify 12 of the females that had tested pregnancy-positive and 8 of the females that had tested pregnancy-negative in October 2001. We observed all 12 of the pregnancy-positives and 1 of the 8 pregnancy-negatives to have a foal the following spring. Thus, diagnostic accuracy of hormone versus observation-based fertility assessment among these females was 19/20 (95%).

The percentages of reproductive success in 2001 were 5.2% for treated and 53.6% for untreated females (Table 4). These rates in 2002 were 14.9% (treated) and 58.5% (untreated) by observation, and 16.6% and 55.0%, respectively, by pregnancy test (Table 3). Statistics applied to observational rates revealed a significant difference between treated and untreated averages in both years (2001: $z = 5.66$, $P < 0.001$; 2002: $z = 4.81$, $P < 0.001$; Table 4). Reproductive success rates in treated females remained 19.5% below rates in untreated females in 2003, but this was not significant ($z = 1.15$, $P = 0.252$). In 2004, reproductive success rates in treated and untreated females were nearly identical (Table 4). Among untreated females,

Table 4. Fertility rates from 2000–2004 for free-roaming female wild horses in Nevada, USA, given a single-injection porcine zona pellucida (PZP) contraceptive vaccine of presumptive 2-year duration.

Yr[a]	Total ad observed[b]	Total foals observed	Untreated F		Treated F		Fertility rate (%)	
			With foal	No foal	With foal	No foal	Untreated	Treated
2000	107	27	11	9	16	17	52.4	48.5[c]
2001	127	40	37	32	3	55	53.6	5.2[d]
2002	236	41	31	22	10	57	58.5	14.9[d]
2003	128	28	22	21	6	13	51.1	31.6
2004	187	46	28	26	18	21	51.8	46.2

[a] Treatment was in Jan 2000; assessment period was approx. 2 weeks between May and Oct of each yr.
[b] No. includes M and F, representing the base population from which foal data were obtained each yr.
[c] No treatment effect expected on 2000 foal counts, because F were bred 6–8 months prior to treatment.
[d] Values for treated vs. untreated were different (2001: $z = 5.66$, $P < 0.001$; 2002: $z = 4.81$, $P < 0.001$).

the reproductive success rate averaged 53.5% across the entire study period. Females observed for foal presence across seasons and years were not necessarily the same individuals.

DISCUSSION

Inoculation of captured and released wild females with PZP vaccine resulted in a marked suppression of fertility that was significant across 2 breeding seasons, although year-2 infertility was not as great as in year 1. Although the reproductive rate in year 3 for treated females was not significantly below the rate in untreated females, the 19.5% absolute rate difference suggests a partial contraceptive carryover through year 3. The vaccine format employing controlled-release pellets was as effective in year 1 as that reported previously (Turner et al. 2000) for 2 separate inoculations. Fertility rates among both treated and untreated females foaling in 2000 (before vaccine effects) and among untreated females in other years were similar to those reported for other wild horse populations (Wolfe et al. 1989, Turner et al. 2000).

This study reconfirms the high accuracy of pregnancy diagnosis via fecal steroid metabolites in wild horses (Kirkpatrick et al. 1991, Turner et al. 2000), with pregnancy data versus foaling data in 95% agreement. These data are also evidence that fetal loss was unlikely to have inflated infertility rates since pregnancy diagnosis was well-correlated with foal counts. By measuring both E_1C and iPdG (Table 2), we minimized the chances of misdiagnosis.

Polymer pellet composition and characteristics (Table 1), and data obtained from in vitro incubation of PZP-containing pellets (previously reported by Turner et al. 2002) showed that all 3 pellet types released PZP in an approximately bolus fashion, with up to 80% of the PZP being released across a 7–10-day period for a given 1-month pellet and across a 12–30-day period for 3-month and 12-month pellets. While the in vitro pellet-release data may provide a reasonable approximation of in vivo activity, we cannot precisely extrapolate it to in vivo conditions (Sanders et al. 1986, Tracy et al. 1999); that is, actual release characteristics of the previous pellets in the females of this study are undetermined. However, the marked infertility in both years 1 and 2 indicate that pellet content release was sufficient to engage immune system memory of the PZP antigen (Kirkpatrick et al. 1992, Newman and Powell 1995).

Despite an increase in reproductive success across years 1–3 posttreatment in the population of treated females, the average reproductive success rate in treated females remained below untreated females. In year 4 posttreatment, the rates in treated and control females were nearly identical, indicating complete return to fertility. It is likely that slower return to fertility in some females reflects individual differences in immune system responsiveness or sensitivity across the population.

MANAGEMENT IMPLICATIONS

As suggested by Garrott (1991), the issues of cost-effectiveness and limitation of population growth must be included in assessing long-term contraceptive management potential. The availability of a 1-inoculation, multi-year PZP vaccine allows contraception to be incorporated at low cost into standard BLM management practices, which include the regular round up (gather) of wild horses for the purpose of removing some from the range. Administering a single-injection, multi-year contraceptive to females being returned to the range has the potential to limit management program costs by reducing frequency of horse roundups, number of horses entering the adoption program (or maintained in long-term holding facilities), and the number of horses using the range (Gross 2000). Associated benefits will include improved range quality and reduced stress to wild horse populations (due to better habitat and less human intervention).

ACKNOWLEDGMENTS

The authors wish to thank the following people for their assistance in enabling this study: M. Bernoco (University of California, Davis) for aspects of vaccine preparation; D. Kivlahan, S. Sloan, and R. McCoy for assistance in field data collection; R. Lyda (Science and Conservation Cneter, Billings, MT) for hormonal pregnancy testing; J. Gianola (BLM) and J. Axtell (BLM) for logistical and tactical support, High Desert Helicopters, Inc. for aerial survey services; and D. Catoor and staff (commercial contractor) for accessing and handling horses. The Assistance Agreement number FAA040011 of the United States Department of Interior, BLM funded this work.

Abstract. Successful immunocontraception of wildlife relying on repeated access to individuals for boosters has highlighted the need to incorporate primer and booster immunisations into one injection. We have investigated use of controlled-release polymers (lactide–glycolide) in small pellets to provide delayed *in vivo* delivery of booster porcine zona pellucida (PZP) antigen and adjuvant. This report reviews pellet-making methodology, *in vitro* testing of controlled-release pellets and *in vivo* effects of controlled-release PZP vaccine. We assessed 3 different manufacturing approaches for producing reliable, cost-effective pellets: (1) polymer melting and extrusion; (2) solvent evaporation from polymer solution; and (3) punch and die polymer moulding. *In vitro* testing of release patterns of controlled-release formulations, towards development of a 3-year duration vaccine, provided estimates for *in vivo* use of pellet preparations. These *in vitro* studies demonstrated protein release delay up to 22 months using 100% *l*-lactide or polycaprolactone polymers. For *in vivo* tests, pellets (1-, 3-, and 12-month release delay) serving as boosters were administered intramuscularly with PZP/adjuvant liquid primer to wild horses (*Equus caballus*), white-tailed deer (*Odocoileus virginanus*) and African elephants (*Loxodonta africana*). Horse field studies assessed fertility via offspring counts and/or faecal-hormone pregnancy testing. Treatment decreased fertility 5.3–9.3-fold in Year 1 and 3.6-fold in Year 2. In preliminary testing in deer, offspring counts revealed treatment-associated fertility reduction of 7.1-fold Year 1 and 3.3-fold Year 2. In elephants, treatment elevated anti-PZP titres 4.5–6.9-fold from pretreatment (no fertility data).

Introduction

Contraception has become a substantive means of managing several species of free-roaming wildlife and captive exotics. In the light of growing interest in this area, the need for agents that are maximally both user and recipient friendly has become apparent. Two agent characteristics that partially address this need are efficient agent delivery and extended duration of effectiveness in a single treatment. The impetus for developing a controlled-release, extended-duration immunocontraceptive originated from studies with free-roaming wild horses. Early studies employed a protocol of two or three separate immunisations (primer plus one or two boosters) about 1-month apart (Kirkpatrick *et al.* 1990). This protocol was necessary to satisfy requirements for optimal and sustained immune response with maximal immunomemory for subsequent annual boosters. Although the treatments were effective, the high costs and daunting logistics of (1) multiple accessing of wild horses for darting or (2) maintaining wild horses in captivity between injections made the multiple-injection protocol impractical for most circumstances. Since controlled-release polymer technology was already in use for delivery of cancer chemotherapeutics and some vaccines (Chang 1976; Carter *et al.* 1988; Linhardt 1989; Wang *et al.* 1990, 1991), we began investigations of this technology for possible application in a single-injection porcine zona pellucida (PZP) immunocontraceptive.

This report reviews and updates salient aspects of the testing of a one-injection, multi-year immunocontraceptive that employs controlled-release polymer components to achieve efficient vaccine delivery and extended vaccine effect. The vaccine utilises PZP antigen plus adjuvant to provide contraception (Kirkpatrick *et al.* 1990, 1991*b*). Polymer-based controlled-release vaccine delivery has been studied predominantly in horses to date (Turner *et al.* 2001, 2002, 2007), and this is reflected in the present report. However, preliminary data applying this technology to white-tailed deer and African elephants are also presented for broader perspective. The

content of this review is divided into three sections: (1) *in vitro* studies; (2) *in vivo* studies; and (3) research assessment and management implications.

In vitro studies

Methods

The endpoint for *in vitro* testing has been the temporal pattern of protein release from controlled-release formulations into incubation medium. Early *in vitro* studies (1992–1996) focussed on controlled-release polymers mixed with vaccine and formulated as microspheres suspended in liquid for delivery (Turner *et al.* 2002). However, repeated difficulties were encountered with delivery of microspheres, due to the tendency of these particles to settle out of the liquid vehicle, clump in the syringe needle and clog it. This persistent and unresolvable problem led to development of solid pellets as the delivery medium, and all subsequent studies have utilised pellet formulations.

Polymers and pellets

The polymers used to make pellets (and information regarding their projected release attributes) were obtained from Birmingham Polymers (Birmingham, AL; now Lactel/Durect, Inc., Pelham, AL). Polymer information is presented in Table 1. Lyophilised PZP and water-soluble saponin adjuvant (QS-21, human-grade; QA-21, veterinary-grade Vrbac Corp., Brussels, Belgium) were mixed by trituration to form a homogeneous matrix with the inert, non-toxic polymers. The mixture was then pelletised by one of three methods briefly described below: heat/extrusion (H/X), cold/evaporation (C/V) or pressure/moulded (P/M).

The H/X method involved melting the polymer–vaccine mixture in a Dynisco extruder (Morgantown, PA) and pushing it through a small aperture to form a long strand of diameter 0.6 mm (to fit inside a 14-gauge hypodermic needle). The strand was then cut to ~1.6-mm length pellets. This method had the advantage of bulk pelleting capability, but ~50% of the ingredients were lost during manufacture, and the heat (100–113°C) could partially degrade the PZP. For this reason we examined two alternate methods that did not employ heat. In assessing the viability of these two methods, we used H/X pellets (of proven efficacy) as a reference base.

The C/V pellets were formed at <20°C by homogeneous suspension of vaccine ingredients in polymer that was rendered as a viscous liquid in the organic solvent dichloromethane. This liquid was then injected into 14-gauge Silastic tubing moulds 5 cm each in length. Gradual evaporation of solvent from the moulded polymer–vaccine mixture across 48 h at 4°C yielded a firm strand inside the tubing. The mould was cut away, and the cylindrical strand was then cut into 1.6-mm lengths, yielding 26–30 pellets. Loss of ingredients during pellet manufacture was 15–20%. This method required ~3-fold more personnel time per pellet than the H/X method.

The P/M pellet-making method employed a low-pressure punch-and-die system. We designed an aluminum mould with 40-pellet capacity that was based on a standard mould used for small-scale pharmaceutical tablet/suppository production. Each half of the mould contained a row of half cylinders, which became whole cylinders for pellets when the mould halves were clamped together. We had the mould manufactured locally (Bollinger Tool and Die Co., Toledo, OH). The pellet-making process consisted of (1) thorough mixing (trituration) of finely powdered vaccine ingredients, polymer and colour dye, (2) loading the powder into the mould, (3) warming the mould in an incubator for 20–30 min while periodically applying pressure to the die chambers by a spring-loaded punch array. This method employed a temperature of 80–85°C, which was well below the denaturation temperature for this vaccine (J. Turner, unpubl. data). The polymer–vaccine mixture became pliable at this temperature, allowing pressure from the punch array to form the pellets in the die cylinders. The halves of the multi-pellet mould were then separated, and the exposed pellets were removed. Relative to H/X pellets, these product pellets were of similar hardness (based on force required to cut with a single-edged razor blade and to crush in a mortar and pestle) and similar physical appearance at 10× magnification (similar translucence and lack of air bubbles or fracture lines). The loss of materials was 8–14% (compared with >50% for H/X method), and the per-pellet personnel time was ~1.5-fold greater than for H/X pellets. An advantage of the P/M method is that no minimum number of pellets must be produced to obtain reasonable production efficiency (the H/X method requires a 100-pellet minimum of each type). Thus, the P/M method can be advantageous for short-notice production and for application to small numbers of animals.

Table 1. Characteristics of polymer pellets employed in one-injection controlled-release porcine zona pellucida (PZP) vaccine of known effectiveness

Pellet type (expected release delay)	Actual release delay (days)	Polymers	Ratio (%)	PZP (μg)	Adjuvant (μg) (QA-21)
1 month	30–60	Lactide : glycolide	65 : 35	100	200
3 months	75–100	Lactide : glycolide	85 : 15	100	200
12 months	340–370	*d*, *l* lactide	100	250	500

Controlled-release pellet contents

Three polymer–vaccine formulations were prepared by the H/X method and tested *in vitro*. Contents of the various pellets are presented in Table 1. Lyophilised PZP was prepared as previously described by Liu *et al.* (1989). The adjuvant was QS-21 or QA-21. Dyes for colour coding were commercial non-toxic food dyes. Polymers were finely ground and passed through a #60 sieve (250 μm). These were projected to release respectively in windows of 1–3 months, 3–5 months and 10–12 months. For all pellets, homogeneity was assured by trituration mixing of powdered ingredients (polymer, PZP, adjuvant, dye) using a mortar and pestle and examination of produced powder by microscope (10–20×). The cylindrical pellets (~0.6 mm × 1.6 mm) weighed 7.5–10.0 mg and the ratio of vaccine ingredients to polymer (termed '% loading') was <9%. For optimal pellet performance maximal loading should be <10% (D. Flanagan, pers. comm.). Pellets were stable at room

temperature but were nonetheless refrigerated for extended storage.

Since the pellet-making process involved potential protein-denaturing conditions (heat for H/X process; organic solvent for C/E process), we assessed viability of PZP exposed to these pellet-making conditions (P/M-type pellets have not been tested to date). We determined conservation of immunoreactivity by Ochterlony immuno-diffusion and titre response of mares immunised with these PZP preparations. No significant effect on PZP of heat or solvent exposure was observed (Liu *et al.* 2005; Turner *et al.* 2007).

In vitro *testing methods*

For all pellets, we determined characteristics of PZP release by measuring PZP concentrations in the incubation medium across time using a sandwich-type enzyme-linked immunosorbent assay (ELISA) for PZP (Turner *et al.* 2002). The *in vitro* environment for a given pellet consisted of 1–3 cc of 37°C bacteriostatic PBS gently and continuously rocked back and forth (one motion per second). Every 3–5 days for up to 23 months, we removed the medium for assay and added the same volume of new medium to the pellet vial. We performed the ELISA on 100 µL of each medium sample. We did not measure the release of adjuvant from pellets, but expected release characteristics to be similar to PZP based on similar water solubility (C. Kensil, Antigenics, Inc., pers. comm.). Some testing of pellets employed bovine serum albumin (molecular weight similar to PZP) in place of PZP. Protein release in those tests was measured by commercial protein assay (Pierce BCA Kit, Rockford, IL). Protein assay sensitivity was 0.5 µg mL^{-1} incubation fluid.

In vitro group data are presented as mean values ± standard error (s.e.). However, statistical analysis was not applied, since the purpose of these studies was to examine release patterns, which were visually obvious.

In vitro *findings*

Release patterns for PZP vaccine-containing pellets have been previously reported (Turner *et al.* 2002). However, in light of the focus of this report on pellets, relevant details are provided in Table 1, and a sample *in vitro* PZP release pattern is presented in Fig. 1.

C/V pellets

We examined the C/V method towards avoiding the disadvantages of H/X method: heat denaturation of PZP and high materials loss. Although the C/V method did achieve these goals, C/V pellets performed suboptimally *in vitro*, releasing ~80% of the total PZP before the desired release window (Fig. 2). Nonetheless, these studies included release characteristics of extremely water-resistant polymers (100 *l*-lactide and polycaprolactone) in pellets that could theoretically delay vaccine release by up to 2 years. One useful outcome of the *in vitro* testing of these polymers in C/V-type pellets was the finding during a 23-month incubation of presumptive 20-month pellets that both polymers can delay some protein release for up to 20 months (Fig. 2). Although only ~20% of the protein remained in these pellets after the first 18 months of incubation, across the next 5 months more than half of the remaining protein was released during only 1 month (Month 20 for polycaprolactone; Month 21 for 100 *l*-lactide).

P/M pellets

In vitro protein-release testing of 1-month P/M-type pellets containing bovine serum albumin (an inexpensive stand-in for PZP) was carried out as previously described for H/X pellets. The protein release pattern showed <12% initial release followed by <5% thereafter (except 7% on Day 20), with the major release (45.2%) occurring across Days 40–48 (Fig. 3). Release returned to pre-surge values thereafter.

***In vivo* studies**

Animals

These studies report effectiveness of controlled-release PZP vaccine in domestic and free-roaming wild horses (*Equus caballus*) and in free-roaming white-tailed deer (*Odocoelius virginanus*) and African elephants (*Loxodonta africana*). The principal investigators were J. Turner (horse), A. Rutberg (deer) and H. Bertschinger (elephant). Horse study sites were USA Department of Interior Bureau of Land Management (BLM) Herd Management Areas in Nevada (USA) for free-roaming horses and University of California, Davis (I.K.M. Liu) for domestic horses. The deer study site was Fripp. Island, SC (USA). The elephant study site was in Limpopo Province, South

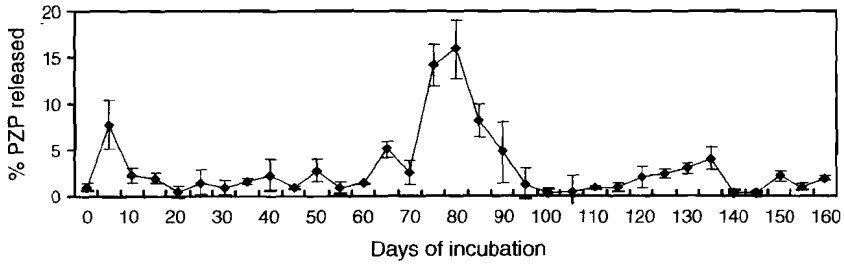

Fig. 1. *In vitro* release pattern of porcine zona pellucida (PZP) from heat/extrusion (H/X) pellets of presumptive 3-month release delay. Each point is the average of 6 pellets (8 mg per pellet). Each pellet was a matrix of lactide : glycolide polymer and PZP (100 µg) incubated at 37°C in phosphate-buffered saline (PBS; pH 7.2) with gentle rocking motion (one per second). Assay was by enzyme-linked immunosorbent assay (ELISA).

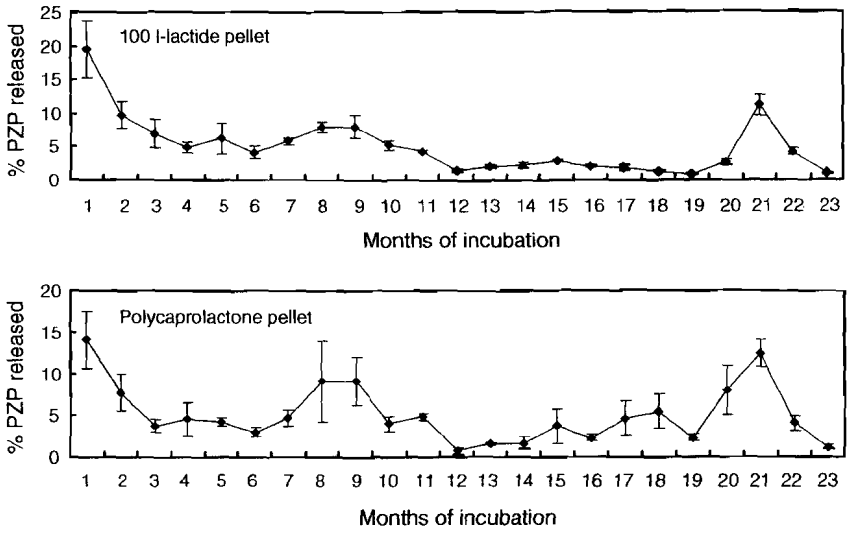

Fig. 2. *In vitro* porcine zona pellucida (PZP) release (as percentage of total pelleted PZP) from polymer pellets of cold/evaporation (C/V) type with presumptive release delay of up to 20 months. Each pellet contained PZP (400 μg) plus QA-21 adjuvant (500 μg). Each monthly value is the average from 10 pellets across four separate 7-day samplings of incubation medium and is presented as % of total PZP placed in each pellet. Lower limit of detection was 0.5 μg protein per mL phosphate-buffered saline (PBS) measured by bicinchoninic acid (BCA) protein assay kit (Pierce, Rockford, IL).

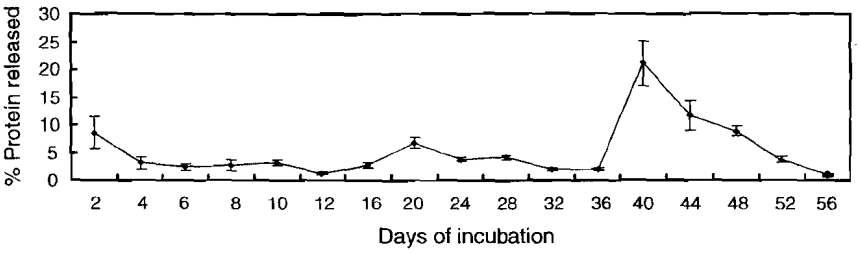

Fig. 3. Percentage of total pelleted bovine serum albumin (BS) released from P/M-type pellets. Each point is the average of 6 pellets (mass = 10 mg/pellet), which were derived from a mixture of lactide : glycolide (50 : 50) and bovine serum albumin (BSA; 750 μg), incubated at 37°C in phosphate-buffered saline (PBS; pH 7.2) with gentle rocking motion (one per second).

Africa. All animals were studied under auspices of respective specific Animal Care and Use protocols for each organisation. Data for horses include both new and previously published files, with the latter clearly referenced. Deer and elephant data represent preliminary studies.

Vaccine

PZP controlled-release vaccine was delivered via hip i.m. injection composed of (1) a primer dose of 100-μg PZP in 0.5 cc phosphate-buffer solution (PBS) emulsified with 0.5 cc Freud's adjuvant (complete = FCA or modified = FMA) and (2) 1-month and 3-month pellets (for 1-year vaccine) or 1-month, 3-month and 12-month pellets (for 2-year vaccine). All pellets used *in vivo* were prepared by the H/X method (except C/V type in one deer group) and contents of each pellet type were as previously described.

Statistics

Titre data are presented as mean value ± s.e. Domestic horse titre data for treatment *v.* control were sufficiently different to obviate statistical assessment. Wild horse data were previously published and statistically assessed in those reports (Turner *et al.* 2002, 2007). Elephant titre data were assessed by *t*-test and deer fertility data were assessed for treated *v.* control differences by binomial probability distribution, (Zar 1984).

Horse studies

Subsequent to *in vitro* testing and before testing in free-roaming horses, *in vivo* assessment of presumptive 1-year and 2-year controlled-release vaccine was performed in captive mares at U.C., Davis. Mares were titre tested via periodic jugular blood sampling across 42 weeks (for 1-year vaccine) and 24 months (for 2-year vaccine). Anti-PZP antibody titres were measured using an

ELISA developed for this purpose and previously described (Liu *et al.* 1989). The positive reference titre was produced by standard two-injection vaccine averaged across six mares from a prior study (Liu *et al.* 1989).

We previously reported *in vivo* anti-PZP titre response to 1-year vaccine containing 1- and 3-month pellets (Turner *et al.* 2002). To summarise those data: relative to a standard two-injection protocol (known to provide 1 year of infertility), the 1-year vaccine was not different in titres across a 42-week monitoring period. By Week 3, the titre response to both vaccine types was >100% of positive reference control and remained so through Week 10. By Week 42, levels were 49–55%. Previous studies comparing titres and fertility in the same mare have shown excellent contraception associated with titres near or above 60% of positive reference control (Turner *et al.* 2002). In a subsequent study, not previously reported, we assessed titre response pattern in domestic mares given 2-year vaccine (containing 1-, 3-, 12-month pellets). Treated mares exhibited a rapid anti-PZP titre rise across 3 weeks to reach 1.4 × positive reference control titre (Fig. 4). These titres gradually decreased but remained above or near positive reference control (100%) for 45 weeks. Thereafter titres declined more rapidly, but remained elevated (54%) at 53 weeks. Control mares, given saline plus blank pellets, showed titres near or below reliable detection throughout the study.

In addition to studies in domestic horses, free-roaming wild mares were field-tested with PZP vaccine. Several herds in Nevada were given 1-year controlled-release vaccine between 1995 and 2001, and these studies have been previously reported (Turner *et al.* 2001, 2002). Likewise, a field test of 2-year controlled-release vaccine was performed in Nevada from 2000 to 2005 (Turner *et al.* 2007). Methods and Results of these studies are summarised below in the context of controlled-release vaccine efficacy. All studies utilised adult horses captured in routine BLM gathers, and mares scheduled for return to the range were treated, by hand-injection or by darting in field corrals. The 1-year and 2-year PZP vaccine used in these studies was the same as described elsewhere in this review. Fertility was determined by foal counts and/or faecal-sample pregnancy test (Turner *et al.* 2001). Pregnancy was assessed by the concentrations of oestrone conjugates and immunoreactive pregnanediol glucuronide in aqueous extracts of faecal material from individually identified mares. These conjugates were measured via ELISA as described by Kirkpatrick *et al.* (1991*a*).

Summary data compiled from our previously reported field studies with 1-year vaccine (Turner *et al.* 2001, 2002) are presented in Table 2. Mares given 1-injection, 1-year vaccine by hand or by dart had fertility rates 0.19 and 0.39, respectively, compared with those of untreated mares (0.61–0.63). Mares given standard two-injection, 1-year vaccine averaged 0.12 of the fertility of untreated mares. All treated groups returned to normal fertility the following year.

More recently, in our field study of hand-injected 2-year PZP vaccine effectiveness in 96 mares (Turner *et al.* 2007), we observed fertility rates of 53.6% for pretreatment and 5.2, 14.9, 31.6 and 46.2% across the ensuing 4 years, evidencing marked infertility effect of 2-year vaccine in Years 1 and 2, partial infertility remaining in Year 3 and return to normal fertility in Year 4.

Deer study

As part of a larger study of one-injection PZP preparations performed on Fripp. Island, white-tailed deer were treated with pellet-based controlled-release PZP vaccine. In February and March (2005, 2006), adult female deer were captured via chemical immobilisation, ear-tagged, measured, weighed, blood-sampled and hand-injected with one of several PZP

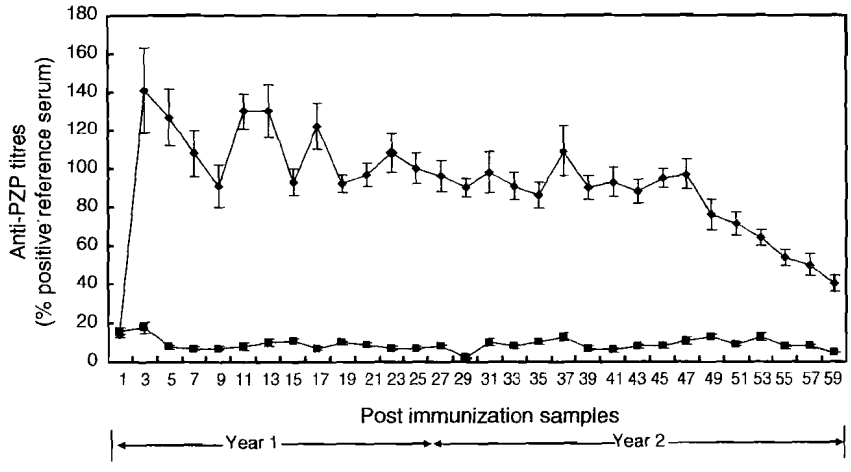

Fig. 4. Antibody response in domestic mares to controlled-release porcine zona pellucida (PZP) vaccine of presumptive 2-year duration. Treatment was standard PZP/adjuvant primer injection plus 1-, 3-, 12-month pellets ($n = 10$; ◆). Control was saline injection plus blank pellets ($n = 5$; ■). Positive reference serum (100%) was highest titre average of six previously studied mares given standard two-injection PZP vaccine. First sample was on the day of immunisation.

Table 2. Survey of field tests of 1-year controlled-release vaccine in wild horses[A]

No. of mares[B]	Vaccine type[C]	Delivery format[D]	Fertility (% foaling) Year-1	Year-2
295	Untreated	None	64	61
376	Standard 2-injection (no pellets)	Hand injection	8	60
48	Primer plus 1-, 3 months pellets	Hand injection	12	58
114	Primer plus 1-, 3 months pellets	Dart	25	50

[A]Modified from Turner *et al.* (2002).
[B]Data are composite of 1–4 separate study sites in Nevada.
[C]Adjuvant in all pellets was a saponin (QS-21).
[D]All mares treated in field corrals or stock chute during routine horse gathers associated with US government wild horse and burro program.

preparations. At capture, females received a priming injection of 100-μg PZP/FMA and a set of one each 1-month, 3-month and 12-month H/X or C/V pellets, hand-injected via trocar. Treated deer that could be located again were recaptured 1 and 2 years later (2006, 2007), and blood was drawn for pregnancy testing via an ELISA for pregnancy-specific protein B (Biotracking, Moscow, ID).

In 160 adult white-tailed does that were captured and pregnancy tested before the treatment period, 133 (83%) were pregnant (Table 3). Of 32 does given 2-year vaccine containing H/X-type pellets, nine were recaptured 1 year later and none of these was pregnant (0% fertility). Of 12 does given 2-year vaccine with C/V-type pellets, two of eight recaptured were pregnant (25.0% fertility). Four does (three H/X, one C/V) were recaptured in Year 2, and one doe (H/X) was pregnant (overall 25.0% fertility). Thus, among all does given pellet-containing 2-year vaccine, fertility rates were 11.7% in Year 1 and 25.0% in Year 2. Relative to pretreatment, Year-1 fertility rates were reduced in treated deer ($P<0.01$ for H/X, $P<0.05$ for C/V; binomial probability distribution). Year-2 data were insufficient for analysis. Return to fertility remains to be determined.

Elephant study

Two groups of elephant cows were treated in South Africa. One ($n=6$) was given standard two-injection PZP vaccine, albeit using 400-μg PZP (instead of 100 μg) in the primer dose and 200 μg (instead of 100 μg) in the booster. The larger doses were used in consideration of large elephant bodyweight. These free-roaming animals were accessed by remote darting from a helicopter. The second group ($n=3$) was captive and hand injected with 1-year controlled-release vaccine consisting of primer (400-μg PZP/FMA) plus two pellets each of the 1-month, 3-month and 12-month type per cow.

Titres were calculated as percentage of positive reference control value. A peak titre value of 100% was assigned to the six two-injection elephant cows in the present study, since the same vaccine dose and protocol provided up to 80% contraceptive efficacy in previous elephant studies (Fayrer-Hosken *et al.* 2000). Thus, these two-injection cows averaged anti-PZP titres of 100%, at 3 months post immunisation. In the three cows given 1-year (pellet-containing) PZP vaccine, anti-PZP titres were 162.1 after 3 months (Table 4). The titre difference was significant ($P<0.01$, *t*-test), giving preliminary indication of more vigorous effect of pelleted vaccine than standard two-injection vaccine in this species. Titre monitoring remains in progress and fertility has not been assessed.

Research assessment and management implications

Considerable progress has been made in the use of controlled-release technology to improve PZP immunocontraception for wildlife. A major technical development in this area has been the

Table 3. Effect of one-injection, 2-year controlled-release porcine zona pellucida (PZP) vaccine on fertility in white-tailed deer

Condition	Doe fertility[A] Year 1		Year 2	
Untreated[B]	133/160	(83.1%)	–

[D]Different from two-injection value and pretreatment value ($P<0.01$, *t*-test).

transition from microspheres to pellets. A major functional development has been the use of pellet-based vaccine boosters to enable 2 years of contraception in a single injection, thus limiting the need to re-access animals for treatment. *In vitro* assessment of various controlled-release polymer formulations has been a beneficial and cost-efficient weeding-out step in pellet development. Despite the inability to project *in vivo* performance from *in vitro* data, reasonable estimates can be made. The need for *in vivo* testing remains essential and should include both antibody titre measurement in blood and actual fertility assessment via pregnancy test and/or offspring counts. *In vivo* assessment should include pretreatment, treatment (contraceptive effect) and follow-up (return to fertility) data. To date, positive outcomes of *in vitro* release-delay studies and *in vivo* titre studies associated with controlled-release pellets have correlated well with field-treatment contraceptive success in horses (Turner *et al.* 2002; Liu *et al.* 2005) and deer (Turner *et al.* 1992; Rutberg *et al.* 2004). Although controlled-release pellet technology has shown promise for eventual routine management use, several obstacles remain to be surmounted. An issue that faces use of controlled-release, multi-year PZP vaccine is possible delay in return to fertility (Kirkpatrick *et al.* 1995; Turner *et al.* 2007). Thus, controlled-release PZP vaccine must be assessed regarding population-level effects of both initial treatment and retreatment. If controlled-release capability can eventually extend infertility to 3 or 4 years, this issue will likely become even more pressing. Another, perhaps simpler, issue is the reliable delivery of vaccine by remote darting. Currently available darts cannot reliably provide sufficient or rapid enough pressure to propel both vaccine primer emulsion and two pellets into muscle tissue. Partial loss of vaccine ingredients sometimes occurs owing to backflow from the injection site or incomplete expulsion from the dart needle or both. This is evidenced by data in Table 2 showing half the contraceptive efficacy in dart-injected *v.* hand-injected mares given 1-year PZP vaccine. This circumstance for darting is both costly and time consuming. In treating wild horses gathered in routine BLM horse management, the delivery problem has been surmounted by separate hand-injections of primer emulsion by syringe and pellets by trocar. The latter has been 100% effective in pellet delivery in >200 horses (J. Turner, unpubl. data). Development of a trocar-containing dart (now in progress) may resolve this issue. In addition to delivering primer vaccine emulsion, this dart also propels the pellets in the needle barrel with a metal rod upon dart firing.

The database for pellet use in horses indicates that controlled-release PZP vaccine is a viable option in this species. Because controlled-release pellets of the 2-year vaccine provide <24 months (21–22 months) of contraceptive-level titres (Fig. 4), application of vaccine is best done in the autumn or winter of a given year to maximise infertility for two breeding seasons. The same preference may eventuate for 3-year vaccine, since the longest-term pellets for this version of vaccine release at 19–21 months rather than 24 months. Although effectiveness of PZP contraception has been previously established for deer (Turner *et al.* 1992; Rutberg *et al.* 2004) and elephants (Fayrer-Hosken *et al.* 2000; Delsink *et al.* 2002), use of controlled-release pellets as boosters has not been reported. Controlled-release vaccine data for deer and elephant in this report are preliminary but encouraging. In deer the limited evidence shows markedly reduced fertility in Year 1 with controlled-release, 2-year vaccine. Although the finding of only one in four recaptured does with fawns in Year 2 is promising, no conclusions can be drawn from this small '*n*'. Interestingly, C/V pellets, which did not maintain anti-PZP titres in mares, yielded a 58% reduction in doe fertility. The reason for this difference is unknown but may lie in species differences in responsiveness to a given PZP exposure pattern. Elephant data to date are insufficient for conclusions regarding pelleted vaccine, but the vigorous titre response (62% greater than for 2-injection vaccine) is encouraging. It is unlikely that this difference was due to incomplete two-injection vaccine delivery by dart, since previous studies of PZP vaccine delivered to elephants by dart have shown effective (2–4-fold) fertility reduction (Fayrer-Hosken *et al.* 2000; Delsink *et al.* 2002).

Although controlled-release technology is not new, the extended release-delay intervals to which PZP vaccine use has aspired are unexplored territory. Much of the field success has stemmed from trial and error forays and *in vitro* inferences. However, emergent from this has been the efficacious transition from a two-injection contraceptive lasting 1 year to a one-injection contraceptive lasting 2 years. Continued efforts should target refinements in controlled-release capabilities, ease of use and more extended contraceptive duration through controlled-release technology.

Effects of immunocontraception on population, longevity and body condition in wild mares (*Equus caballus*)

A. Turner[1] and J. F. Kirkpatrick[2]*

[1]*Assateague Island National Seashore, 7206 National Seashore Drive, Berlin, MD 21811, USA; and* [2]*Science and Conservation Center, ZooMontana, 2100 South Shiloh Road, Billings, MT 59106, USA*

Contraception is becoming a common approach for the management of captive and wild ungulates yet there are few data for contraceptive effects on entire populations. Management-level treatment of mares with porcine zona pellucida (PZP) vaccine resulted in zero population growth of the Assateague Island wild horse population within 1 year of initiation of treatment. Contraceptive efficacy was 90% for mares treated twice in the first year and annually thereafter. For mares given a single initial inoculation, contraceptive efficacy was 78%. The effort required to achieve zero population growth decreased, as 95, 83 and 84% of all adult mares were treated in each of the first 3 years, compared with 59 and 52% during the last 2 years. Mortality rates for mares and foals after the initiation of management-level treatments decreased below historic and pretreatment mortality rates of approximately 5%. Two new age classes have appeared among treated animals (21–25 years and > 25 years), indicating an increase in longevity among treated animals. Body condition scores for all horses, all adult mares and non-lactating mares increased significantly between summer 1989 and autumn 1999 but did not change significantly in lactating mares. These results provide reliable data for the construction of realistic models for contraceptive management of free-roaming or captive ungulate populations.

Introduction

The management of free-roaming and captive ungulate populations often relies on some form of contraception. The use of porcine zona pellucida (PZP) vaccine to inhibit fertility among various free-roaming wildlife (Kirkpatrick *et al.*, 1990a, 1991a, 1992, 1995a; Kirkpatrick, 1995) and captive exotic (Kirkpatrick *et al.*, 1995b, 1996) species has been well documented. Until 1994, studies had focused on contraceptive efficacy and short-term (< 3 years of treatment) safety of the vaccine, and they did not address the larger issue of changes among entire populations and long-term safety (> 3 years of treatment). One of the ultimate goals of any wildlife contraceptive effort, whether captive or otherwise, is to alter entire populations in some manner, which will positively affect habitat, other species or the target population itself.

In the case of Assateague Island National Seashore, MD (ASIS), the National Park Service (NPS) sought to protect fragile barrier island habitat from a rapidly growing wild horse population (Rodgers, 1985; Stribling, 1989, 1990; Furbish, 1990, 1994) and to protect the health of the wild horses themselves, by limiting population growth, while at the same time protecting the genetic integrity of the population.

From 1988 to 1993, between 10 and 34 mares in a total population that ranged from 129 to 156 animals were treated annually to test the efficacy and safety of the PZP vaccine. In 1994, ASIS began management-level application of PZP immunocontraception with the short-term goal of stabilizing the population at or near 166 animals. This paper reports the efficacy of PZP contraception over an 11 year period, population changes over 5 management years, and associated changes in mortality, the percentage of mares treated annually, and the occurrence of increased longevity and body condition among treated animals. The working hypotheses were that: (i) the population could be stabilized in < 5 years; (ii) the body condition scores of treated mares would increase; and (iii) that annual effort to achieve these goals would decrease over the 5 years.

Materials and Methods

Management plan

In 1994, a management plan was developed by the ASIS Resource Management staff to maximize the potential population-level effects of immunocontraception while protecting the genetic integrity of the wild horse herd. A treatment priority was established: (i) to inhibit older mares (those with three living offspring or two or more surviving generations) from breeding for the remainder of their lives; (ii) to limit treatment of mares with fewer than two living offspring to no more than 3 consecutive years of treatment, after which they would be permitted to have a foal; and (iii) to prohibit any treatment of older mares with no living offspring. The 3 year limit was imposed because it was clear in 1994 that PZP contraception was reversible after a few consecutive annual treatments (Kirkpatrick *et al.*, 1995a), but fewer data were available for reversibility after treatment for longer periods. The long-term treatment of mares was liberalized in 1998 to two surviving offspring or two generations, where offspring was defined as a foal that survived through its first winter. At the onset of management-level contraceptive treatment in March 1994, the population was 166.

Immunocontraception

Contraception was carried out with PZP vaccine, as previously described (Liu *et al.*, 1989; Kirkpatrick *et al.*, 1990a, 1991a, 1995a; Kirkpatrick, 1995). The vaccine consisted of 0.5 ml PZP, at a concentration of 65 μg protein per 0.5 ml phosphate-buffered saline (PBS), emulsified in 0.5 ml of either Freund's complete adjuvant (FCA) or Freund's incomplete adjuvant (FIA). FCA was used for the initial inoculation only and FIA was used exclusively thereafter. The total 1.0 ml of PZP–adjuvant was administered via a barbless 1.0 cc dart with a 14 g, 3.8 cm needle, and was delivered by a Model 193 Pneu-Dart® capture gun (Pneu-Dart, Inc., Williamsport, PA). Each mare was located on foot or by vehicle and darted at a range of 20–50 m to inject the antigen i.m. in the hip or gluteal muscles. Darts were recovered and inspected to make sure they had injected all their contents. All mares on ASIS are identified by physical markings and colour patterns, and the locations and band affiliations of each animal are monitored monthly by ASIS personnel. Initial treatments were carried out in March of each year, or in August or September in the case of mares that had already been treated for at least 2 years.

In March 1994, there were 82 mares aged ≥ 2 years. Of these mares, 41 had never been treated during the previous 6 years of contraceptive research; 33 had been treated previously in the course of the research; and eight mature mares had been treated previously but were not to be treated again until after they had foaled. The 41 untreated mares were given a single PZP–FCA inoculation, the aim of which was not to achieve contraception, but rather to establish antigen recognition and thereby make them 'single-inoculation' animals in preparation for subsequent management-level application of the vaccine. One year later, in March 1995, all mares designated for treatment under the management plan were treated with the PZP vaccine as described above. Two-year-old mares received only a single dose treatment in 1995, but in 1996, the 2-year-olds received an initial PZP–FCA inoculation followed by a second PZP—FIA inoculation approximately 2 weeks later. All other mares included in the management plan received a single booster inoculation of PZP–FIA.

Reproductive success was determined as the birth of a foal in the year after treatment, or a positive pregnancy test during the autumn months after treatment, by analysing concentrations of hormone metabolites in urine and faecal samples (Kirkpatrick *et al.*, 1990b, 1991b; Lasley and Kirkpatrick, 1991). Contraceptive effectiveness was measured by the lack of reproductive success during the 12 months after each mare was treated.

Body condition scores

The body condition score of each mare was assessed on a scale of 0 to 5 according to the shape of the rump and, therefore, the amount of fat deposited in the rump area: 0 indicated an animal in very poor condition and 5 represented extreme fat deposits (Rudman and Keiper, 1991). These scores were assessed between July and November in 1989 and again in 1999 by the same method, and the findings were compared.

Results

Overall contraceptive effectiveness during 1988–1999 for the animals given either the standard double-inoculation protocol, then given a single booster inoculation, and the 41 mares given a single-inoculation initial treatment only in 1994, was 88.7% (43 foals produced after 381 treatments). The effectiveness of contraception was 90% (34 foals produced after 340 treatments) when the 41 single-inoculation mares were excluded. The contraceptive effectiveness among the 41 mares treated with single-inoculation treatment in 1994 was 78% (nine foals produced after 41 treatments).

From 1994 to March 1999, the original population of 166 horses remained stable, ranging between 172 and 164 (Fig. 1). On the basis of historic population increases of 5% annually (Keiper and Houpt, 1984), the number of horses in this herd would have increased to 240–260 by March 2000 had immunocontraception not been used.

The percentage of the total number of mares of all ages that required treatment under the ASIS management plan decreased from 95% to 52% in 1999. This decrease was brought about by cessation of treatment of mares after they had finished their third consecutive treatment, as dictated by the management plan, and by not inoculating other animals that had already been treated for several consecutive years.

The mortality rate in the total population of mares and foals decreased between 1990 and 1999 despite an overall increase in population during that period (Fig. 2). During the 4 years preceding the introduction of management-level contraception, the mortality rate for all adult horses was > 10% and was approximately 3% for foals. During the 4 years after the start of the management-level contraception, overall adult mortality decreased to < 4%; mare mortality dropped to < 4% and foal deaths were only about 1%. The unusually high mortality rates in

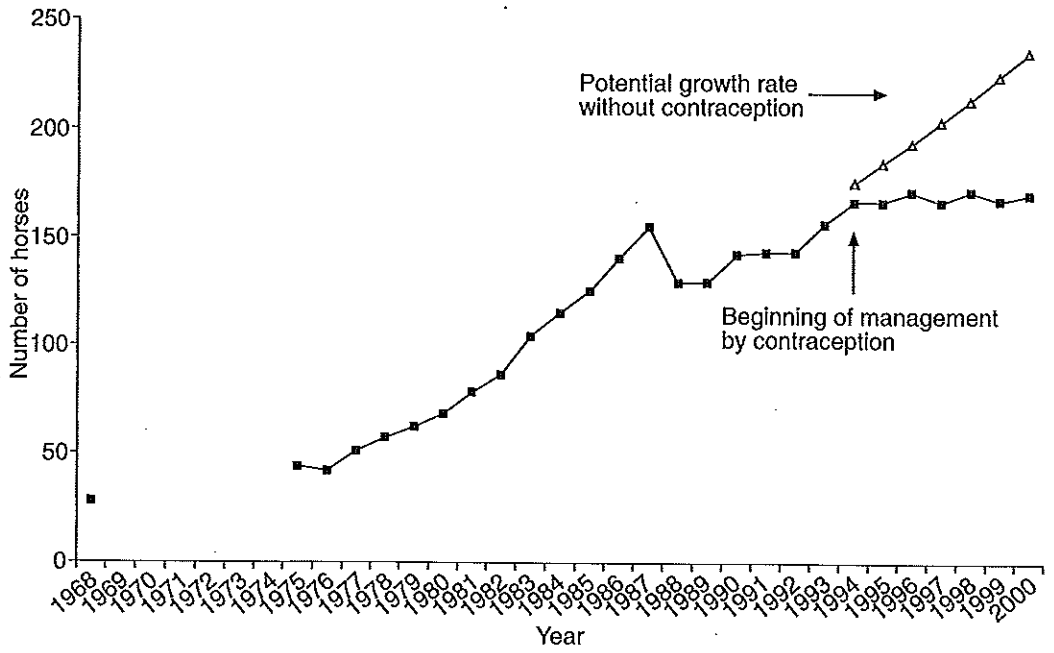

Fig. 1. Population growth curve for the Assateague wild horses. The sharp decrease between 1988 and 1990 was caused by an outbreak of Eastern equine encephalitis. The absence of growth between 1990 and 1993 was the result of additional mares being treated during the research phase of the study and storm-related deaths. The projected increase in population without contraception, beginning in 1994, was based on historic foaling and mortality data.

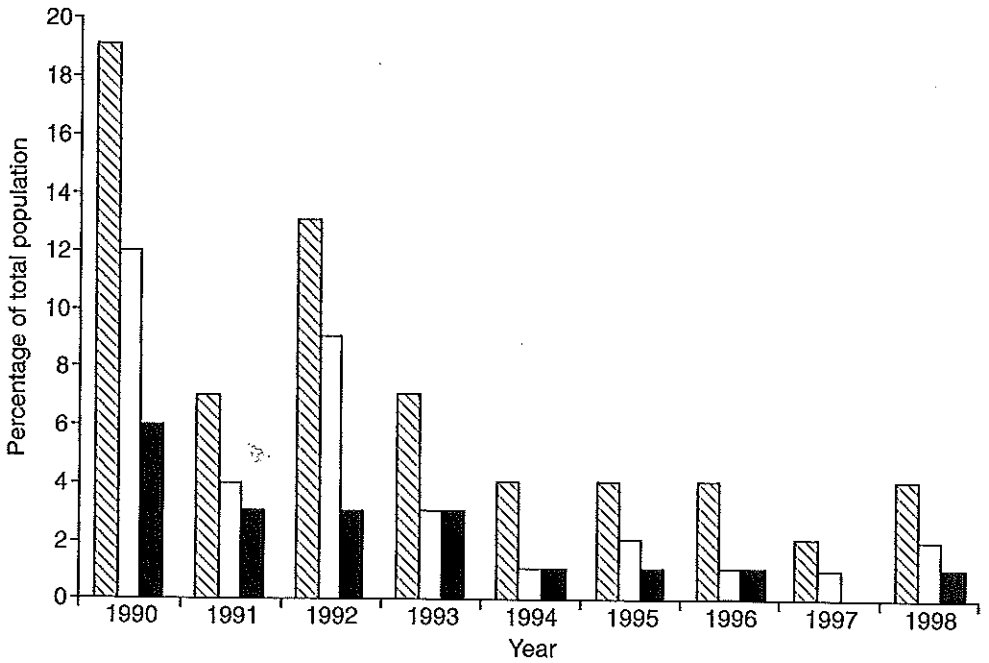

Fig. 2. Mortality rates among Assateague wild horses. The unusually high rates in 1990 and 1992 were the result of an Eastern equine encephalitis outbreak and a large number of storm-related deaths, respectively. ⧅: Total population; □: mares only; ■: foals only.

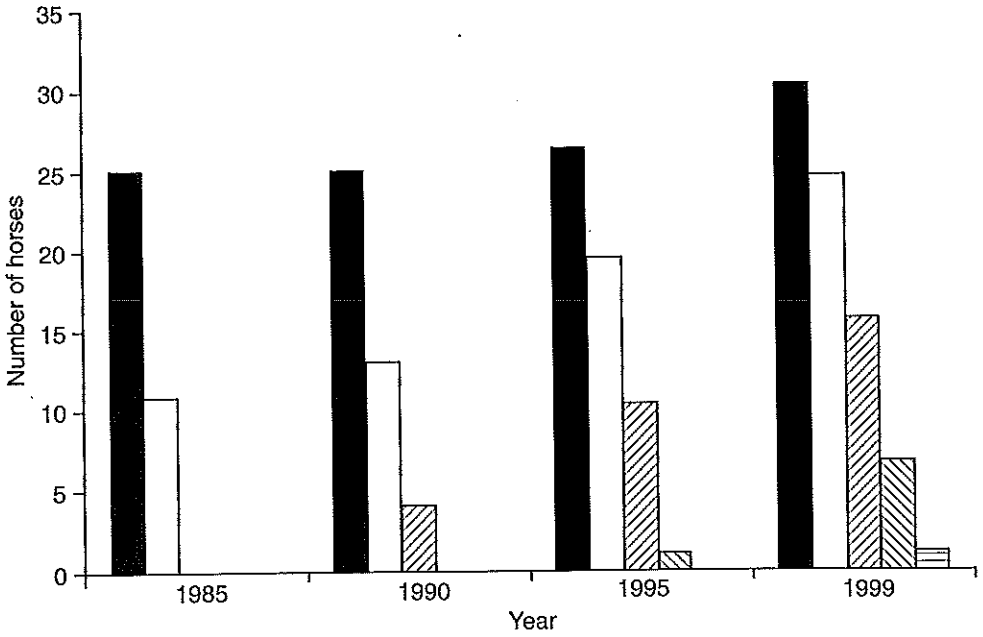

Fig. 3. Changes in the age class structure of the Assateague wild horse herd. The marked change in population trends between 1986 and 1990 was the collective result of horse removals, an outbreak of equine encephalitis, contraception of 26–33 mares for research purposes and storm-related deaths. ■: Age 6–10 years; □: age 11–15 years; ▨: age 16–20 years; ▧: age 21–25 years; ⊟: age > 25 years.

1990 and 1992 were the result of an outbreak of Eastern equine encephalitis on the island in 1990 and severe storms in 1992. The 1991 and 1993 mortality rates were normal and representative of the 8-year period before the start of immunocontraception (Keiper and Houpt, 1984).

Changes in the age classes of the entire herd shifted upwards, indicating increased survival (Fig. 3). These changes were not just an expected increase in the age profiles of the treated herd, but rather animals were reaching new and older age classes, indicating increased longevity. The change was greater among mares than stallions, with the former accounting for 83% of the animals reaching the 16–25 year group in 1995, and 67.7% of the animals reaching the same age group in March 1999.

Body condition scores were significantly higher in 1999 than 1988. For example, the mean ± SEM scores for all horses in 1999 and 1988 were 3.04 ± 0.06 and 2.47 ± 0.43, respectively ($t = 2.85$, 46 df, $P = 0.0064$).

For all adult mares, the mean body condition scores were 2.96 ± 0.08 and 2.33 ± 0.35, respectively ($t = 4.01$, 31 df, $P = 0.0004$) for these 2 years, and for non-lactating mares the scores were 3.07 ± 0.05 and 2.42 ± 0.38, respectively ($t = 5.71$, 18 df, $P = 0.0001$). However, the body condition scores for lactating females did not differ significantly between 1999 and 1988 (2.0 ± 0.55 and 1.96 ± 0.60, respectively; $t = 1.0$, 4 df, $P = 0.373$).

Discussion

Contraceptive efficacy after management-level treatment with PZP was about the same, approximately 90%, as in earlier research trials with the ASIS horses (Kirkpatrick *et al.*, 1990a, 1991a, 1995a) and captive and wild cervids (Turner *et al.*, 1992, 1996; McShea *et al.*, 1997).

The high degree of efficacy of the single-inoculation treatment given to the 41 previously untreated mares in 1994 (78%) was unexpected, and was probably a result of three factors. Firstly, the initial inoculations were given in March, just before the breeding season. Keiper and Houpt (1984) showed that 75% of ASIS foals are born between April and June, so that the single inoculation of the PZP vaccine in March would only need to stimulate contraceptive antibody titres for a period of 3 months to achieve significant inhibition of fertility. A second factor is that wild horses, unlike white-tailed deer, do not appear to have an extended breeding season after contraception. McShea *et al.* (1997) demonstrated that the breeding season of PZP-treated white-tailed deer can be extended by as much as 2 months. In contrast, it was demonstrated that wild horses have a very discrete breeding season that does not appear to lengthen even when nutritional planes are increased or pregnancy does not result (Kirkpatrick and Turner, 1983). Thus, the onset and cessation of the breeding season for ASIS mares are rigidly set and were not extended by contraception.

A third possible reason for the success of the single-inoculation treatment was the use of FCA as the adjuvant. This particular adjuvant is considered widely to be the best available with regard to the ability to stimulate significant antibody titres (Leenaars *et al.*, 1994). The use of FCA is contra-indicated in some other animal species because it may cause false positive tuberculosis tests, but as no definitive test exists for equids, FCA has no health testing implications in horses. Some concern has been expressed over possible abscess formation resulting from the use of FCA. However, after 381 treatments, only two abscesses were noted among the treated ASIS animals, one of which occurred after treatment with FIA rather than FCA. In both cases, the abscesses were < 2.5 cm in diameter and they drained and reduced within a week of formation. We attribute the low rate of abscess formation to the exclusive inoculation into hip and gluteal muscles rather than the neck muscles. In other species, the adjuvant of choice is modified Freund's Adjuvant (Calbiochem, La Jolla, CA), which no longer results in false tuberculin tests and which appears to impart contraceptive effectiveness when given with PZP (J. F. Kirkpatrick, unpublished).

Both the 90% effectiveness of the PZP contraception over 5 years and the unexpected high efficacy of the single-inoculation PZP–FCA treatment regimen in 1994 are important observations when considering the development of population models for captive or wild ungulate fertility control. Estimates of contraceptive efficacy in the past have been theoretical (Garrott *et al.*, 1992; Hone, 1992; Garrott, 1995; McCullough, 1996; Muller *et al.*, 1997), but these data provide a sound factual basis for using a 90% effectiveness figure. In addition, herds of wild horses will exist where the administration of two inoculations in the first year is not easy or even possible, whereas a single inoculation may be feasible. The contraceptive efficacy achieved by the single inoculation, if given in March, provides additional data for population models.

The effect of contraception on the total ASIS population has been marked, with achievement of zero-population growth within the first year of management, and continued over 5 years. Even within an extremely conservative management plan that permits a certain level of successful reproduction for genetic reasons, it was possible to stabilize growth of the herd and thereby meet the first management objective.

The failure to reduce the size of the population after 5 years of management-level treatment has three obvious causes. The first is the fairly conservative treatment schedule, which permits a low level of successful reproduction to ensure genetic integrity of the herd. It ensures that all mares have an equal opportunity to make a genetic contribution to the herd by permitting some reproduction. A second cause is the increased longevity occurring among the treated mares. It is to be expected that the mean age of a population undergoing management by contraception will increase and that the percentage of animals in older age classes will

increase. However, the creation of entirely new age classes within the population was unexpected. The cessation of foaling and lactation as a result of contraception, particularly among older mares, which were already losing body mass as a result of the ageing process, was associated with the attainment of new and older age classes, which, in turn, will delay mortality. This increase in longevity has important implications for the use of immunocontraception in wild and captive ungulates. Basically, contraception can still be used to decrease the size of a herd, but the time needed to achieve a significant decrease will be longer than originally thought, particularly when there is concern about the genetic integrity of the herd. In the case of the ASIS herd, significant mortality due to ageing has been delayed and significant decreases in population size will not occur until a new 'age of mortality' is reached. On the basis of available data, this new mortality peak will probably occur between 20 and 25 years of age, rather than at 15–20 years.

The third reason for failing to reduce the size of the population rapidly relates to mortality rates. Normally, as population size increases in most mammalian species, mortality, and particularly mortality of the young, also increases (Christian, 1971; Krebs, 1978). The opposite scenario has occurred on ASIS. During the years of management-level contraception (1994–1999), the population remained static, but between 1988 and 1994 it increased from 126 to 166. Thus, mortality rates should have increased correspondingly or at least remained the same. The tendency for reduced mortality was primarily among mares, indicating that the reduction in physiological stress from not undergoing pregnancy or lactation underlies the higher survival rates in this group. The reduction in foal mortality is harder to explain, but may be related to better body condition of the mothers. Assateague Island is a harsh environment and an earlier study of body condition of all ASIS horses (Rudman and Keiper, 1991) showed that adult females and non-lactating adult females were in fair to good condition, whereas lactating females were classed as thin. In 1999, by comparison, scores had improved to fat for all horses, including adult females and non-lactating females. Clearly, something had improved body condition in the ASIS horses, despite an increase in the number of animals. This finding indicates that continued contraception had a positive effect on body condition scores and, by implication, the health of the horses.

The effort necessary to achieve the desired degree of change in the population within the context of this management plan is clearly intense during the first 3 years, but after this time the effort necessary to maintain the effect decreases as a result of the long interval between the last of the three consecutive treatments in younger mares and the time at which they produce their first post-treatment foal. Apart from a reduction in the number of animals to be treated, the timing of the treatments (March versus August) increases efficiency. In March, there are few humans on ASIS and even fewer on the marshes of the island, where the horses spend most of their time. At this time of year the horses are extremely wary of humans, so successful treatment requires hours of effort for each horse. It appears that after 2 consecutive years of treatment, the third treatment can be carried out in August or September, or probably at any time of the year, and the contraceptive effect will extend throughout the following breeding season. In August and September the horses spend much of their time on the beaches to avoid insects and even in the camping areas in close association with humans. Thus, treatment requires much less effort than in March.

The reduction in effort may be temporary. The management plan was liberalized to permit the long-term treatment of mares with only two surviving offspring to avoid resurgent breeding. However, even with that added burden, the new and older mortality age of an increasing number of mares is approaching and the death of these animals should reduce the annual effort so as to balance the increase from the need to treat a greater number of younger mares.

Conclusion

This study of 5 years of treatment under a management plan provides the first population-level data for contraception in wild horses, and may be useful in developing new models. Previous models have not accounted for changes in age class structure, mortality or the degree of effort required to achieve particular goals. Models can now be refined and improved on the basis of these data.

This project was funded in part by Assateague Island National Seashore and the Science and Conservation Center of ZooMontana, and carried out under the Humane Society of the US Investigational New Animal Drug (INAD) file 8857-G002 with the US Food and Drug Administration. Federal Docket No. FWS–R8–ES–2015–0049

90-Day Finding on a Petition to List a Distinct Population Segment of North American Wild Horses on all U.S. Federal Public Lands as an Endangered or Threatened Species

Background

Section 4(b)(3)(A) of the Act requires that we make a finding on whether a petition to list, delist, or reclassify a species presents substantial scientific or commercial information indicating that the petitioned action may be warranted. We are to base this finding on information provided in the petition and supporting information submitted with the petition.

Our standard for substantial scientific or commercial information within the Code of Federal Regulations (CFR) with regard to a 90-day petition finding is "that amount of information that would lead a reasonable person to believe that the measure proposed in the petition may be warranted" (50 CFR 424.14(b)).

Petition History

On June 17, 2014, we received a petition, dated June 10, 2014, from Friends of Animals and The Cloud Foundation, requesting that the distinct population segment (DPS) of North American wild horses on all U.S. Federal public lands be listed as an endangered or threatened species under the Act. The petition clearly identified itself as such and included the requisite identification information for the petitioner(s), as required by 50 CFR 424.14(a). In an October 3, 2014, letter to the petitioner, we responded that we reviewed the information presented in the petition and did not find that the petition warranted an emergency listing. This finding addresses the petition.

Evaluation of Petition to List the Distinct Population Segment of North American Wild Horses on all U.S. Federal Public Lands

Species and Range

Does the petition identify an entity that is eligible for listing (i.e., is the entity a species, subspecies, or DPS)?

☐Yes

X No

The petitioners requested that we list the North American wild horse on all U.S. Federal public lands as a DPS. The petition classifies the North American wild horse as a population of the species *Equus caballus*.

The petition requests that the Service list the DPS of North American wild horses on all U.S. Federal public lands (intended to encompass those lands owned or administered by the Bureau of

Land Management (BLM), the Service, the National Park Service (NPS), and the U.S. Forest Service (USFS). However, the information provided in the petition appears to focus on the wild horses covered under the Wild Free-Roaming Horse and Burro Act of 1971 (WHBA).

The WHBA defines ""wild free-roaming horses and burros" to mean "all unbranded and unclaimed horses and burros on public lands of the United States" and defines "public lands" to mean "any lands administered by the Secretary of the Interior through the Bureau of Land Management or by the Secretary of Agriculture through the Forest Service." (16 USC 1332 (b) and (e)). The WHBA does not apply to management of feral horses or burros within National Wildlife Refuges, which are managed by the Service, or management of feral horses or burros in National Parks, which are managed by the NPS.

However, because the petition requested that we consider North American wild horses on all U.S. Federal public lands, we are evaluating the petition based on this request. Our evaluation considers whether the petition presents substantial information that the North American wild horse found on U.S. Federal public lands may meet the criteria to be considered a distinct population segment.

Evaluation of the Population of North American Wild Horse Found on Public Lands as a Distinct Population Segment

To interpret and implement the DPS provisions of the Act, the Service and the National Oceanic and Atmospheric Administration published the Policy Regarding the Recognition of Distinct Vertebrate Population Segments Under the Endangered Species Act in the Federal Register on February 7, 1996 (61 FR 4722). Under the DPS Policy, three elements are considered in the decision regarding the establishment and classification of a population of a vertebrate species as a possible DPS: (1) The discreteness of a population segment in relation to the remainder of the species to which it belongs; (2) the significance of the population segment to the species to which it belongs; and (3) the population segment's conservation status in relation to the Act's standards for listing, delisting, or reclassification. Both discreteness and significance are used to determine whether the population segment constitutes a valid DPS. If it does, then the population segment's conservation status is used to consider whether that DPS warrants listing. We address these elements with respect to the North American wild horse found on public lands.

Discreteness

Under the DPS policy, a population segment of a vertebrate species may be considered discrete if it satisfies either one of the following conditions: (1) It is markedly separated from other populations of the same taxon as a consequence of physical, physiological, ecological, or behavioral factors (quantitative measures of genetic or morphological discontinuity may provide evidence of this separation); or (2) it is delimited by international governmental boundaries within which differences in control of exploitation, management of habitat, conservation status, or regulatory mechanisms exist that are significant in light of section 4(a)(1)(D) of the Act.

Markedly Separated

Information Provided in the Petition

The petitioners assert that the population of North American wild horses on U.S. Federal public lands is markedly separated from other populations of horses throughout its range due to physical separation as well as ecological, physiological, and behavioral factors.
The petitioners assert that the BLM-designated Herd Management Areas (HMAs) separate the population of wild horses on public lands from domestic horses on private property as well as wild horses occurring on tribal lands. In 2012, there were 179 HMAs that occurred in ten states – Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, and Wyoming; 171 of the HMAs were occupied by either horses or burros (National Research Council, 2013, p.21-24). Some HMAs are connected to other HMAs and the animals can move between these areas; these areas often managed as a complex (National Research Council, 2013, p.22). The BLM often removes horses from HMAs and places them in short-term or long-term holding areas (National Research Council, 2013, p.2). These animals may be adopted out to private owners. The horses that are removed may also be gelded or treated with a contraceptive and returned back to an HMA (National Research Council, 2013, p. 25).

The horses occurring on HMAs may disperse or migrate out of the HMA. According to the 2013 National Research Council report: "A designated HMA may constitute the core range of a herd or population, but dispersal movements outside the HMA are possible" (p. 84).

Although the citations provided by the petitioner speak to horses occurring on BLM-lands, it is not clear that they apply to all North American horses that occur on U.S. Federal public lands. Therefore, we find the petition does not provide substantial information that the population of North American wild horse on Federal public lands may be discrete based on physical separation.

The petitioners assert that the wild horses occurring on Federal public lands in the Western States occupy a unique ecological setting. The petition describes the horses on Federal lands in the west as living in areas that "can be extremely harsh with very hot summers, cold winters, sparse vegetation." The petition asserts that domesticated horses that live on private properties are provided food and water by humans and do not face the same conditions that horses on private lands do. We note that the consideration of a population occurring in a unique ecological setting is generally addressed under the evaluation of Significance (see below). However, in evaluating discreteness, we consider how physiological and behavioral differences may result in the marked separation of populations of the taxon. Thus, although there may be physiological or behavioral differences between populations, these differences are only relevant for discreteness if they are a cause of the population being markedly separate from other populations of the taxon.

The petition asserts that wild horses have physiological differences that make them more suitable for living in the wild when compared to domestic horses. For example, the petition asserts that wild horses may be able to survive longer without water than domestic horses; however, the citation to support this claim indicates that this contention "has not been demonstrated with empirical data" (Beever 2003, p. 892). The petition also points to a 2008 article by Jaime Jackson that discusses the differences between wild and domestic horse hooves. Although the article provides a description of common characteristics of the wild horse foot, we find that it does not provide substantial information that the North American wild horse on Federal public lands may be markedly separate from other populations of the taxon based on physiological

factors related to hoof structure. The petition also identifies the "long limbs and single-unit soliped hooves" of wild horses that allow them to move long distances in order to obtain food and water. The provided citation (Downer 2014) does not indicate that this is a physiological difference between the wild horse on Federal public lands and other populations of the taxon. In fact, all equids have soliped (single) hooves on each foot. Therefore, based on our review of the petition and information provided by the petitioner, we find that the petition does not provide substantial information indicating that the wild horse occurring on Federal public lands may be markedly separate from other populations of the taxon based on physiological differences.

The petition asserts that wild horses have different behaviors than domestic horses. Specifically, the petition asserts that wild horses live in family groups (or bands) consisting of a lead stallion and several mares. The petition provides a discussion of the behavior of the bands, as well as a discussion of the communication patterns of wild horses and aggressive encounters between stallions of wild horses. However, the petitioner does not provide citations to indicate that these communication patterns or aggressive encounters do not occur with wild horses occurring outside of Federal lands or among domesticated horses. The petitioner asserts that a wild horse has a "highly refined fight or flight reaction," but the citation provided (Nock, 2010) does not discuss how or why the fight or flight response differs between North American wild horses and other populations of horse. While the petitioner provides a quote from a 2014 perspective piece (Marshall, Dobney, Denham & Capriles) that states domestication "has resulted in diverse phenotypic and behavioral changes to wild animals, including decrease flight responses, increased sociality, earlier reproduction, and modification of endocrine and metabolic systems," the article's authors cite four additional articles associated with the quote. These articles were not provided to the Service by the petitioners. Furthermore, the focus of the Marshall, et al. 2014 article is on assumptions of gene flow between wild and domestic stocks of animals (including horses, donkeys, cats, dogs, etc.) and the new data that are showing such gene flow existed for longer periods of time than previously thought. Although behaviors between domestic and wild (or feral) animals of the same species may differ, based on our review of the information in the petition, we find that the petition does not present substantial information that the North American wild horse may be markedly separate from other populations of horse as a consequence of behavioral differences.

The petition asserts that the population of wild horses is discrete because the WHBA applies regulations to horses on public lands that are not applied to horses on private or tribal lands. The petition asserts that this difference in management is important with regard to section 4(a)(1)(D) of the Act. Under our discreteness analysis, we consider whether a population is delimited by international governmental boundaries within which differences in control of exploitation, management of habitat, conservation status, or regulatory mechanisms exist that are significant in light of section 4(a)(1)(D) of the Act. The discreteness analysis does not consider whether a regulatory mechanism might apply to only specific populations of a species or subspecies that occur within the United States. Because the horses addressed in the petition occur within the United States and are not delimited by international governmental boundaries, the second condition of discreteness is not met.

Following a review of the petition and the sources provided, we find that the petition does not present substantial information that the population of North American wild horse may be discrete under our DPS policy.

Significance

Under the DPS policy, a discrete population segment of a vertebrate species may be considered significant if there is: (1) Persistence of the discrete population segment in an ecological setting unusual or unique for the taxon; (2) evidence that loss of the discrete population segment would result in a significant gap in the range of the taxon; (3) evidence that the discrete population segment represents the only surviving natural occurrence of a taxon that may be more abundant elsewhere as an introduced population outside its historical range; or (4) evidence that the discrete population segment differs markedly from other populations of the species in its genetic characteristics.

We concluded in the previous section that the population of North American wild horse did not meet the discreteness criteria. Therefore, we do not need to evaluate the significance criteria. Based on our review of the petition and the information provided, we find there is not substantial information that the North American wild horse occurring on Federal public lands may meet the discreteness criteria outlined in our 1996 policy, and therefore the petitioned entity is not a DPS.

Petition Finding

Based on our review of the petition and sources cited in the petition, we find that the petitioned entity is not a listable entity under the Act.

In summary, the petition does not present substantial information supporting the characterization of North American wild horses on all U.S. Federal public lands as a DPS, because the discreteness criteria were not met. Therefore, this population is not a valid listable entity under section 3(16) of the Act.

On the basis of our determination under section 4(b)(3)(A) of the Act, we conclude that the petition does not present substantial scientific or commercial information to indicate that listing North American wild horses on all U.S. Federal public lands as a DPS as a threatened or endangered species under the Act may be warranted at this time.

Human Health and Ecological Risk Assessment
for the Use of Wildlife Damage Management Methods
by APHIS-Wildlife Services

Chapter XXIV

Use of GonaCon

in Wildlife Damage Management

June 2017

USE OF GONACON IN WILDLIFE DAMAGE MANAGEMENT

EXECUTIVE SUMMARY

Gonadotropin releasing hormone (GnRH) is a naturally occurring hormone that stimulates production of sex hormones such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH regulate gamete and steroid hormone production by the ovaries and testes and are critical in the reproduction of vertebrates. USDA APHIS Wildlife Services has developed an immunocontraceptive vaccine against GnRH, called GonaCon, when injected into a target animal, GonaCon induces the body to make antibodies against its own GnRH, resulting in infertility. GonaCon is an effective tool in managing wild and feral animal fertility.

GonaCon is preloaded into syringes which is injected into target animals by hand, or transferred into jab stick hypodermic needles or darts for remote delivery. GonaCon is registered for use in female wild or feral equids and white-tailed deer, and shows potential use in bison and feral swine as well as other mammals where it may eventually be registered for use.

USDA APHIS evaluated the potential human health and ecological risks from the proposed use of GonaCon in this assessment and determined that the risks to human health and the environment are negligible. Risks to workers as well as the general population, including hunters who may harvest injected animals, are low based on the method of application, the mode of action of GnRH, and label requirements. Similarly, risks are negligible for nontarget fish and wildlife based on how GnRH is applied, its fate, and label requirements.

Since GnRH is mostly used from preloaded syringes, with the contents discharged into the target animal, adverse exposure potential is reduced. Remote delivery and jab sticks have an increased risk because the jab stick and darts have to be loaded from preloaded syringes with a potential, albeit low, for exposure. When a remote delivery application misses the intended target or when a syringe or dart is dislodged from an animal, potential exposure increases. The label requires personnel to attempt to be retrieve all darts that miss or fall out of animals. Thus, retrieving darts, the low volume of GnRH in each syringe or dart, the expected short half-life of GnRH, and the infrequent occurrence of a remote delivery miss would be expected to result in negligible risk to human health and nontarget fish and wildlife. Risk to humans and nontarget organisms that may consume animals injected with GonaCon is also negligible due to the low toxicity of GnRH, its short half-life, and its degradation in the gut.

1 INTRODUCTION

GonaCon is an immunocontraceptive vaccine that was developed and could be used operationally by the U.S. Department of Agriculture (USDA), Animal and Plant Health Inspection Service (APHIS), Wildlife Services (WS) in the management of certain wildlife and feral vertebrate animal populations. This risk assessment provides a qualitative evaluation of potential risks and hazards to human health, nontarget fish and wildlife as a result of exposure to GonaCon under the proposed uses in the APHIS and WS Program. The results of this human health and ecological risk assessment will help WS determine an appropriate risk management strategy to achieve its program management goal.

The methods used to assess potential human health effects follow standard regulatory guidance and methodologies (National Research Council 1983, USEPA 2017). The methods used to assess potential ecological risk to nontarget fish and wildlife follow U.S. Environmental Protection Agency (USEPA) methods, as well as other published methodologies where appropriate. Data used in this risk assessment were obtained from USEPA registration-related and other peer-reviewed documents, other published literature, and online searches for relevant data.

The following risk assessment is divided into four sections: problem formulation (identifying hazard), toxicity assessment (the dose-response assessment), exposure assessment (identifying potentially exposed populations and determining potential exposure pathways for these populations), and the integration of the exposure and toxicity assessments, or risk characterization.

2 PROBLEM FORMULATION

Wildlife and feral animals can reach population levels that are harmful to ecosystems or the human environment. WS employs several lethal and nonlethal methods for managing these populations depending on the particular problem. GonaCon is one nonlethal population control option -- an immunocontraceptive vaccine that renders female animals temporarily infertile. To date, APHIS has obtained USEPA pesticide registrations for use of GonaCon to control populations of white-tailed deer[1], wild and feral horses (*Equus caballus*); and burros (*Equus asinus*). APHIS is also investigating the potential for obtaining USEPA registrations to use GonaCon to manage populations of bison and feral swine. In experimental studies, GonaCon has also been shown to prevent pregnancy in other species including elk, domestic and feral swine, bison, domestic cats, California ground squirrels, prairie dogs and brown (Norway) rats (Miller et al. 2008).

2.1 Chemical Description and Product Use

GonaCon is an injectable immunocontraceptive vaccine, containing the active ingredient mammalian gonadotropin releasing hormone (GnRH), developed by the WS National Wildlife Research Center (NWRC) (Eisemann et al. 2006). GnRH is a 10 amino acid peptide hormone with the same amino acid sequence conserved across most mammals (USEPA 2009a). The U.S. Food and Drug Administration (USFDA) formerly regulated GonaCon as an investigational new animal drug, but the regulatory jurisdiction for the product changed to USEPA once research and development of the product by APHIS WS moved forward as a registered wildlife management method. After interagency discussions between USFDA and USEPA, responsibility for regulatory approval was moved to the USEPA, Office of Pesticide Programs (OPP). USEPA regulates GonaCon as a pesticide for contraceptives in wild and feral animals (USEPA 2009a). APHIS is the registrant of two GonaCon end-use products:

- USEPA Reg. No. 56228-40: GonaCon Immunocontraceptive Vaccine for white-tailed deer (registered in September 2009)[2]

[1] Scientific names are given in the Risk Assessment Introduction Chapter I, or given if not in that Chapter.

[2] Latest label @ https://iaspub.epa.gov/apex/pesticides/f?p=PPLS:8:::NO::P8_PUID,P8_RINUM:496016,56228-40.

- USEPA Reg. No. 56228-41: GonaCon Equine (registered in January 2013)[3]

Both products are GnRH-based water-in-oil emulsions with the same active ingredient (0.03% GnRH). GnRH (also known as luteinizing hormone-releasing hormone (LHRH)) is a reproductive hormone produced in the arcuate nuclei of the hypothalamus. GnRH stimulates production and secretion of two gonadotropins (luteinizing hormone (LH) and follicle-stimulating hormone (FSH)) by the anterior pituitary gland. LH and FSH regulate gamete and steroid hormone production by the ovaries and testes (i.e., estrogen, progesterone, and testosterone).

The formulation is comprised of two primary components that are mixed together to form an emulsion for injection. The first component is AdjuVac™ (a mineral oil-based adjuvant that contains killed *Mycobacterium avium*) to induce a localized inflammatory response that triggers a rapid, strong, and sustained immune response. The second is a mollusk stabilizing buffer (Gionfriddo et al. 2011) containing GnRH conjugated to a mollusk-derived carrier protein (i.e., keyhole limpet hemocyanin or blue protein) (Bender et al. 2009). Three additional amino acids are added to the GnRH to act as a spacer and to facilitate conjugation to the carrier protein. Despite GnRH being a "self" protein, GnRH conjugated to the mollusk carrier protein causes the body to recognize GnRH as "foreign," stimulating an immune response and production of specific antibodies against it. This immune response prevents GnRH from stimulating production of additional sex hormones (LH and FSH) and blocks ovulation. The targeted animals become temporarily infertile, and because the production of sex steroids is also reduced, reproductive behaviors are also often suppressed. (USEPA 2009b, Killian et al. 2006).

For deer, 1-mL doses of GonaCon are packaged and pre-loaded in 3-mL plastic syringes. Applicators (limited to APHIS WS personnel, state wildlife management personnel, or persons working under their authority) administer GonaCon by hand injection.

According to the label for USEPA registration No. 56228-40, GonaCon Immunocontraceptive Vaccine induces temporary infertility in female white-tailed deer to control its populations. On the current deer label, application is by hand-injection only. Studies are ongoing to investigate remote darting as another application method. If approved, issues relating to risks of darting application would be similar to those discussed below for the equine label, and discussed further in the Use of Immobilization and Euthanasia and Firearms Risk Assessments.

Applicators inject a single dose (1 mL) of GonaCon at least 2 to 3 months prior to the onset of rut (USEPA 2009b). Applicators administer GonaCon by hand injection in a large muscle mass using an 18G (gauge) or 19G stainless steel hypodermic needle (USEPA 2009b). In studies, researchers injected GonaCon into the upper hind limb of deer (Gionfriddo et al. 2011). In deer, a single vaccination can induce infertility for multiple years.

GonaCon Equine is approved for fertility control in female wild or feral horses and burros according to the label for USEPA Reg. No. 56228-41 dated January 2013. Horses and burros receive a single dose (2 mL) of GonaCon Equine at least 2 to 3 months prior to the onset of breeding. A single vaccination can induce infertility for multiple years in equine and other ungulates (Gray et al. 2010, Fagerstone et al. 2010). GonaCon Equine is administered by hand injection, jab stick, or remote delivery (darting) under the following directions:

- Hand injection: Inject 2.0 mL of GonaCon by intramuscular injection into a large muscle mass (e.g., rump, neck) using the preloaded syringe and a 1.5-inch 18G or 19G stainless steel hypodermic needle

- Jab Stick: Transfer 2 mL GonaCon from the preloaded syringe. Inject intramuscularly using a 1.5-inch 14G stainless steel hypodermic needle

[3] Latest label @ https://iaspub.epa.gov/apex/pesticides/f?p=105:8:::NO::P8_PUID,P8_RINUM:508549,56228-41.

- Remote Darting: Recommended dart specifications are 2 cc dart with a 1.25- or 1.5-inch 14G gelatin barb needle. The 2 mL GonaCon in a preloaded syringe must be transferred into the dart. Deliver intramuscularly using the appropriate projection device.

- If remote delivery is used, the applicator must make every attempt to recover the dart, whether it missed or fell out of the equid. If "weathered-out" such as inclement weather, darkness, or safety concerns, the applicator can make note of the location and retrieve the dart at a later date.

GnRH potentially causes injection-site reactions and in lymph nodes, which includes abscesses, nodules, swelling and stiffness from the water-in-oil emulsions containing mycobacteria such as AdjuVac (Gionfriddo et al. 2011), but not in all studies (Gray et al. 2010). Injection site and lymph node reactions may be a necessary factor of the immune response that causes infertility (Gionfriddo et al. 2011). Vacuoles in the lymph nodes were found in cytoplasm or among macrophages and multinucleated giant cells, which were likely mineral oil droplets from the AdjuVac. However, injection site reactions to the vaccine did not result in observed differences in an animal's range of movement or locomotor patterns. Thus, a side effect can be injection site reactions, but did not have any noted physical effects.

The method of drug delivery may be responsible for some injection-site reactions. More injection-site reactions were observed in remote delivery compared to syringe injection with porcine zona pellucida (PZP) (Roelle and Ransom 2009), another immunocontraceptive agent. Rifle darts caused less injuries than blowpipes. Roelle and Ransom (2009) determined that the method of delivering the drug was likely the cause of injuries since hand injection resulted in few injuries whereas dart trauma was much higher.

Both GonaCon products are classified by USEPA as restricted-use pesticides. The labels prohibit GonaCon from direct use in water, in areas where surface water is present, or in intertidal areas below the mean high water mark. Since these products are restricted-use, all users must be certified pesticide applicators or be under the supervision of a certified pesticide applicator. For both USEPA approved GonaCon labels, use of the deer label is further restricted to USDA APHIS Wildlife Services or state wildlife management agency personnel or persons working under their authority, and for the equine label employees of USDA APHIS Wildlife Services and Veterinary Services, U.S. Bureau of Land Management, U.S. Fish and Wildlife Service, U.S. National Park Service, U.S. Department of Defense, federally recognized Indian Tribes, state agencies responsible for wild or feral horse and burro management, public and private wild horse sanctuaries, or persons working under their authority (equine label). In addition, the labels specify that applicators are not to use these products near humans, domestic animals, or pets. Use of these pesticide products also requires pesticide registration by States. As of April 2017, New Jersey, North Carolina, and North Dakota have approved use of the deer label (EPA Reg. No. 56228-40) and Arizona, Louisiana, Nevada, North Dakota, and Pennsylvania of the equine label (EPA Reg. No. 56228-41). The labels also specify that users must consult State regulations to determine whether they need additional permits or approval prior to use.

2.2 Physical and Chemical Properties

GnRH (CAS Number: 9034-40-6, and molecular formula: $C_{55}H_{75}N_{17}O_{13}$) is a white odorless powder, solid at room temperature (USEPA 2009b), with a molecular weight of 1182.31 (Merck 2013). Melting point, boiling point, stability to normal and elevated temperatures, metal and metal ions, oxidation/reduction action, flammability, explodability and vapor pressure are not available (USEPA 2009b, Merck 2013). Preliminary testing of the GnRH peptide used in GonaCon indicates that it is very water-soluble (≥100 mg/mL) (Warren and Stephens 2008). Storage stability and corrosion characteristics are not applicable for GnRH because the product's shelf life is less than 6 months (USEPA 2009b).

2.3 Environmental Fate

As part of the data package required by USEPA for registration of GonaCon, APHIS submitted waivers for the environmental fate studies because, when used according to label instructions, there is limited potential for

environmental release from direct injection of the product into the target animal. USEPA-OPP granted waivers for environmental fate sturolledies including hydrolysis, photolysis, soil dissipation, aerobic soil metabolism, and adsorption/desorption due to the low potential for release to soil and water (USEPA 2009b).

2.4 Hazard Identification

The role of GnRH within the reproductive system has been intensively studied. However, mammalian toxicology data on GnRH is limited to a few acute toxicity studies. The toxicity study in deer performed during the safety and toxicity evaluation of GonaCon showed no significant contraindications or toxic effects in female deer in weeks following vaccination with GonaCon, except for the formation of granulomata at the injection site (Killian et al. 2006). Behavioral studies in white-tailed deer showed that treated animals are not permanently sterilized, but they exhibit fewer breeding behaviors due to the decline in serum sex steroids (Killian and Miller 2001). A field study in free-roaming feral horses showed that GnRH vaccine can significantly reduce fertility for several years with a single injection. However, no significant effects were noted from contraceptive treatment on the sex ratio of foals, birthing season, or foal survival (Gray et al. 2010). With elk, male precopulatory behavior rates toward cows treated with a GnRH vaccine was greater than controls and could be problematic; treatment did not affect existing pregnancies or calf survival (Powers et al. 2011)

Acute oral and dermal studies in the rat showed that all tested animals survived a 1-mL exposure. A primary eye irritation study in rabbits did not show corneal opacity or iritis. Treated eyes exhibited conjunctival redness and discharge within one-hour after treatment, but there were no "positive" grade irritations at 24 hours. Rabbits were free of all eye irritation after 72 hours. A primary skin irritation study in rabbits did not show swelling at any treated site. Initially, treatment resulted in a very slight superficial reddening of skin that dissipated within 72 hours. For these reasons, USEPA-OPP classified GnRH as a Toxicity Category IV (no precautions required) for acute oral/dermal toxicity and eye and skin irritation exposures (USEPA 2009b). Chronic toxicity of GnRH is not expected since it is rapidly metabolized in animals.

When GonaCon is used according to the label, human exposure to GnRH is unlikely. First, certified applicators deliver GonaCon while wearing personal protective equipment, which includes long-sleeved shirts, long pants, gloves, and shoes with socks. Secondly, GonaCon is pre-packaged in syringes and the preloaded syringes significantly reduce exposure or transferring it to jabstick syringes or darts presents minimal potential for exposure. Lastly, certified applicators apply GonaCon through hand injection (most equids are actually injected with from a syringe since they are in chutes following roundups) or remote delivery. As a result of these attributes, certified applicators are unlikely to make dermal contact with GnRH or inhale it during its intended use. Even so, remote delivery poses minimal risks. Thus, USEPA-OPP waived several study requirements, including:

- The acute inhalation study in the rat, because inhalation is unlikely to occur;
- The dermal sensitization study, because dermal contact is not expected;
- The studies on gene mutation, structural chromosomal aberration, and other genotoxic effects, because the intended use precludes human exposure;
- The acute delayed neurotoxicity study in the hen, because GonaCon is not an organophosphate pesticide and its structure is not similar to products causing delayed neurotoxic effects; and
- The chronic dietary toxicity studies for mammalian and non-mammalian species, because GonaCon use will not result in repeated human exposure during its intended use.

USEPA-OPP applied a Category IV to the acute inhalation toxicity, the same category as the acute oral toxicity.

If a pesticide is categorized as a food-use product by USEPA and it accumulates in animal or plant materials that will be consumed by humans, data to determine a safe level for consumption (a tolerance) are required for registration. A tolerance is not required for this product because it is not a food-use product and it does not accumulate in the tissues of treated animals.

The previously described use pattern for GonaCon also resulted in the waiver of ecological effects studies required by USEPA-OPP for pesticide registration including (USEPA 2009c):

- Seedling Germination/Vegetative Vigor (Guideline 122-1)
- Aquatic Plant Growth (Guideline 122-2)
- Avian Oral Toxicity (LD50) (Guideline 850.1200)
- Avian Dietary Toxicity (LC50) (Guideline 850.2200)
- Acute Toxicity Freshwater Invertebrates (EC50) (Guideline 850.1010)
- Freshwater Fish Toxicity (LC50) (Guideline 850.1075)

USEPA granted waivers for these studies due to the low potential for environmental release of GnRH from the proposed use pattern in this assessment.

3 DOSE-RESPONSE ASSESSMENT

3.1 Human Health Dose-Response Assessment

A dose-response assessment evaluates the dose levels (toxicity criteria) for potential human health effects including acute and chronic toxicities.

USEPA did not establish a reference dose for GnRH. USEPA assigned GnRH to the low toxicity Category IV for acute oral, dermal, inhalation, and ocular exposure routes. USEPA-OPP waived the requirement for an acute inhalation study during the registration of GonaCon (USEPA 2009b); thus, these studies are not available. With the use pattern of GonaCon, inhalation exposure is not expected to occur.

3.2 Ecological Exposure Dose-Response Assessment

USEPA-OPP waived the aquatic and terrestrial ecological effects data requirements for GonaCon due to its restricted use, method of application, mode of action, and lack of potential exposure to nontarget fish and wildlife. Currently the only available toxicity data applicable to the effects analysis for nontarget wildlife is an acute oral limit toxicity study using the rat. No lethal or sublethal effects were noted during a 14-day period at a dose of 1-mL solution containing 0.03% gonadotropin releasing hormone (Eurofins 2008). GnRH belongs to a large group of peptide-based endocrine-related hormones that are present in all vertebrates and are critical for proper reproductive function (Somoza et al. 2002). Sublethal effects would be expected in nontarget vertebrates under the appropriate exposure pathway and in cases where GnRH is non-specific to binding receptors; however, this is unlikely in nontarget fish[4] and wildlife since exposure would have to occur through intramuscular injection. GnRH and similar peptides have been noted in some invertebrates; however, their role in reproduction and other physiological functions is not fully understood (Tsai 2006). Studies regarding these peptides are conducted *in-vitro* and no dose-response data for invertebrates appear to be available in the literature.

4 EXPOSURE ASSESSMENT

4.1 Human Health Exposure Assessment

Exposure assessment estimates the potential exposure of humans to GnRH. The exposure assessment begins with the use and application methods of the GnRH products. A complete exposure pathway for GnRH includes (1) release from a GnRH source, (2) an exposure point where human contact can occur, and (3) an exposure route for the contact such as ingestion, inhalation or dermal contact (USEPA 1989). In this way, the potentially exposed human populations and complete exposure pathways are identified and qualitatively evaluated.

4.1.1 Identification of Potentially Exposed Human Populations and Complete Exposure Pathways

Exposure of certified pesticide applicators to GnRH is unlikely during proper use; however, there are potential exposures for trained applicators during an accidental event, or if the product is not used according to label directions and precautions.

The public would not have access to the GnRH vaccine. Exposure through consumption of treated animals by the public or hunters who consume a recently injected animal is unlikely because GnRH is rapidly metabolized and has a short half-life (under one hour) so dietary ingestion of GnRH from treated animals is expected to be minimal (see discussion below in Exposure Evaluation for additional information on oral exposure). If remote delivery is used, the label requires that applicators make every attempt to recover all darts. In addition, the applicators examine all fired darts after recovery to determine if the charge fired and the plunger fully expelled its vaccine content. Therefore, the

[4] Fish utilize a different form of GnRH, which reduces the risk even further.

potential for the general public to encounter a loaded dart, either from failing to recover darts that fall out of treated animals or missing the animal with the dart, is low.

Release of GnRH vaccine into soil is unlikely because the vaccine is contained within syringes and is injected directly into target animals. The lack of product reaching the soil means that subsequent movement and impacts to groundwater via leaching, surface water via runoff, or plant uptake are not expected. This in general excludes the exposure pathway for soil, groundwater, and surface water media or plant uptake. Loaded darts may occasionally fall out of or miss target animals and remain on the ground if applicators fail to locate and remove them. If this happens, a dose may leak onto the soil, but the volume released would be small. These events would be infrequent because not all animals are treated using remote delivery methods such as darts, but when they are, the chance that WS employees would miss their target is small because employees are trained and skilled in remote delivery methods.

4.1.2 Exposure Evaluation

This section qualitatively evaluates the worker exposure in direct contact pathways associated with applying GnRH formulations. It also discusses exposure through dietary consumption for hunters.

As discussed in Sections 2.4 and 3.1, GnRH has low toxicity (Category IV) via the oral, dermal, ocular, and inhalation routes of exposure. The direct contact exposures via incidental ingestion, inhalation, and dermal contact to trained workers wearing personal protective equipment (PPE) are minimal. PPEs for applicators include long-sleeved shirts and pants, gloves, and shoes with socks. In addition, the label prohibits pregnant women from handling or injecting GonaCon.

There is potential for humans to eat a GonaCon-treated animal harvested through hunting. However, little likelihood of exposure through dietary ingestion of game animals is expected for humans based on the short half-life (less than 1 hour) of GnRH in the animal relative to the harvest date and degradation in the digestive tract prior to absorption. The half-life of synthetic luteinizing hormone-releasing hormone (LH-RH) was reported as 4 to 12 minutes (Warren 2006). A short half-life indicates that GnRH is rapidly metabolized in treated animals and would not be available for human exposure by the time of dietary consumption. The half-life of the conjugated GnRH is expected to be longer at the injection site when compared to GnRH, but conjugated GnRH would not be biologically active and still degrade prior to the animal being harvested. Even if a human consumed a treated game animal shortly after administration, it is unlikely that he or she would be adversely affected because the active ingredient GnRH is a protein that is digested into its component amino acids instead of absorbed intact in the digestive tract of mammals. Therefore, oral exposure to GonaCon products is not an effective exposure route for humans and animals compared to the injection route (USEPA 2009a).

It is possible that the public could encounter a dart that has fallen on the ground from a targeted animal (either the dart falls out of the animal or the applicator misses the animal with the dart); however, the active ingredient would likely be contained within the syringe or have been evacuated as a result of contact.

4.2 Ecological Exposure Assessment

Aquatic exposure to GnRH is unlikely based on the method of application and short half-life once animals are injected. A scenario where an animal is injected and subsequently dies, due to other causes, no residues are expected that could runoff or leach into sediment or water. Secondary exposure to terrestrial nontarget wildlife should be considered. However, the extremely short half-life and the lack of effects from ingestion of GnRH due to breakdown in the gut would not result in an exposure pathway that could impact endocrine function in vertebrates. The short half-life would also reduce the potential for exposure to any invertebrates that may feed on injected animals or carcasses. Loaded darts may fall out of or miss target animals and remain on the ground if applicators fail to locate and remove them. Loaded darts that fall out of an animal would not be expected to contain GnRH since it would most likely have been discharged when the dart made contact with the target animal. In cases where the contents from a remote delivery are not

discharged, for example if the target animal is missed, the probability of exposure would also be low since it would be unlikely that nontarget wildlife would ingest the syringe and it is likely the contents would have been evacuated when the dart strikes the ground or other object.

5 RISK CHARACTERIZATION

This section qualitatively characterizes risks associated with human health and nontarget fish and wildlife. Under the anticipated uses, GonaCon should pose minimal risks to human health as well as nontarget fish and wildlife.

GonaCon products contain only 0.03% GnRH as active ingredient, and the remaining 99.97% of the formulations are other ingredients that cause an immune response and enhance the stability of the vaccine in the treated animal. Applicators administer the vaccine by injection (hand, jab stick, or remote darting). Trained applicators must use required PPE and follow other label directions to minimize exposure and risk. GnRH has a Toxicity Category IV for the registered uses regarding acute oral, dermal, inhalation, and ocular and skin irritation toxicities. The low potential for exposure to GnRH during intended use combined with the use of PPE and low toxicity suggest that adverse health risk to applicators is not expected.

Risks to consumers of hunted game animals are minimal based on the exposure evaluation discussed in Section 4.1.2.

GonaCon products pose negligible risk to terrestrial and aquatic nontarget plants and animals. The lack of ecological risk is due primarily to the proposed use pattern of GonaCon, which includes hand injection, jab stick, or remote darting, which greatly reduces the potential for any exposure to nontarget fish and wildlife either directly or from residues on soil, water, or plant material. The requirement for intramuscular injection for activation as well as the short half-life further reduces the risk to nontarget organisms. Direct risk to nontarget fish and wildlife and any impacts to habitat or prey items (indirect risk) would not be expected to occur under the proposed use pattern for GonaCon.

6 UNCERTAINTIES AND CUMULATIVE IMPACTS

The uncertainties associated with this risk evaluation arise primarily from the unpredictability associated with human behavior, and can only be discussed qualitatively. Accidental release of a small amount of GonaCon from a hand application may occur when GonaCon in the preloaded syringe is not accurately delivered to the target animal or the loaded syringe becomes detached. Accidental self-injection when administering GonaCon to the target animal may also occur. However, the potential for these accidental exposures is very low with trained and experienced applicators. Accidental exposure from transferring the contents of a preloaded syringe into a jab stick hypodermic needle or a dart could occur with similar risks as accidental self-injection. These risks are expected to be very low. Finally, accidental injection could occur as a result of the dart missing its target. However, this would be negligible since WS applicators are well-adept at using firearms (certified) and know what their backstop is should the dart miss.

WS does not necessarily record the application method (hand injection, jab stick, or dart) used to treat target animals with GnRH or other drugs, just that it was treated with GnRH. As this is unknown, and data is unavailable on the frequency with which darts fall from or miss target animals, and how often applicators are able to recover these darts, APHIS WS cannot exactly determine how much GnRH would end up in the environment. However, the amount is expected to be small because APHIS applicators make every attempt to recover all darts. In addition, the low volume of GnRH in each syringe, the expected short half-life, and the infrequent occurrence of a remote delivery miss where the dart is not collected, would equate to minimal amounts of GnRH in the environment; in all likelihood discharges in the environment would be expected to quickly result in undetectable residues. Any GnRH that would occur in the environment from this type of release would be localized to the area immediately adjacent to a compromised syringe and would be expected to quickly dissipate.

The potential impacts to human health and the environment of the GonaCon formulation have not been determined in toxicity studies. Previously discussed inert ingredients in the formulation occur in minor quantities. Other inert materials that occur in larger quantities have been evaluated and determined to be practically nontoxic to humans and nontarget organisms. In addition, potential exposure of humans and nontarget organisms to the formulation, due to the low volume and method of application, as discussed is low, and therefore the risk from the formulation is expected to be negligible.

Potential cumulative effects could be associated with: (1) repeated worker exposure to GnRH, (2) co-exposures to other pesticides within the program with respect to their toxicity, and (3) exposures to other chemicals affecting the toxicity of GnRH. Repeated exposure to GnRH by applicators wearing appropriate PPE is not expected. In addition, vaccinations are injected using prefilled syringes. An accidental exposure may occur if a syringe breaks and the contents spill. However, this occasional accidental exposure will not lead to accumulation in the human body. WS does not use other pesticides with the same active ingredient as GnRH, so exposure by applicators to multiple pesticides with the same mode of action will not occur. Cumulative effects involving other chemicals such as endocrine disruptors are possible for human and ecological exposures. However, it is highly unlikely for WS personnel to be simultaneously exposed to GonaCon and these other types of agents. Similarly, the low potential for GnRH to occur in soil, water, or plants makes cumulative impacts from exposure to other endocrine modulating chemicals and GnRH highly unlikely for nontarget fish and wildlife.

7 SUMMARY

This risk assessment has determined that the potential human health and ecological risks from the proposed use of GonaCon are low and that the risks to human health and the environment are negligible. Risks to workers as well as the general population, including hunters who may harvest treated animals, are low based on the method of application, the mode of action of GnRH, and label requirements. Similarly, risks are negligible for nontarget fish and wildlife based on how GnRH is applied, its fate, and label requirements.

9.0 PREPARERS

9.1 APHIS-WS Methods Risk Assessment Committee

Writers for "Use of GonaCon in Wildlife Damage Management Risk Assessment":
Writer: Thomas Hall
Position: USDA-APHIS-WS, Operational Support Staff, Staff Wildlife Biologist, Fort Collins, CO
Education: BS Biology (Natural History) and BA Psychology – Fort Lewis College; MS Wildlife Ecology – Oklahoma State University
Experience: Special expertise in wildlife biology, identification, ecology, and damage management. ThirtyoneThirty-one years of service in APHIS Wildlife Services including in CO and WY for research and OR, GU, CA, OK, and NV for operations conducting a wide variety of programs including bird damage research and management, livestock protection (predators and birds), invasive species management, wildlife hazard management at airports, property and natural resource protection from wildlife.

Primary Writer: Fan Wang-Cahill –
Position: USDA-APHIS-Policy and Program Development (PPD), Environmental and Risk Analysis Services (ERAS), Environmental Health Specialist, Riverdale, MD
Education: BS Biology and M.S. Hydrobiology - Jinan University, Guangzhou, China; Ph.D. Botany (Ultrastructure/Cell Biology) – Miami University
Experience: Joined APHIS in 2012, preparing human health risk assessments and providing assistance on environmental compliance. Prior experience before joining APHIS includes 18 years environmental consulting experience specializing in human health risk assessments for environmental contaminants at Superfund, Resource Conservation and Recovery Act (RCRA), and state-regulated contaminated facilities.

Primary Writer: Jim Warren
Position: USDA-APHIS-Policy and Program Development (PPD), Environmental and Risk Analysis Services (ERAS), Environmental Toxicologist, Little Rock, AR
Education: B.S. Forest Ecology and M.S. Entomology – University of Missouri; Ph.D. Environmental Toxicology – Clemson University

Experience: Seven years of experience working for APHIS preparing ecological risk assessments and providing assistance on environmental compliance. Prior experience before joining APHIS includes other government and private sector work regarding ecological risk assessments related to various environmental regulations.

Editors/Contributors for "Use of GonaCon™ in Wildlife Damage Management Risk Assessment":

Editor: Nikeeya Ali
Position: USDA-APHIS-WS, Operational Support Staff, Fort Collins, Colorado, 2017 Sumer Intern
Education: BS in Communications, South Carolina State University
Experience: Three years as a staff writer for The Collegian Newspaper, one year as Editor-in-Chief. Skilled in production, video editing. Previously edited two Risk Assessments for USDA-APHIS-WS.

Editor/Contributor: Jeanette O'Hare
Position: USDA-APHIS-Wildlife Services (WS), National Wildlife Research Center (NWRC), Registration manger, Fort Collins, CO
Education: B.S. Biology – College of Saint Mary; M.A. Biology – University of Nebraska - Omaha
Experience: 13 years of experience working for WS NWRC providing regulatory compliance support for the development of wildlife damage management tools. Prior experience before joining APHIS includes assessing the environmental fate of pesticides and providing the agency guidance on water quality issues at the state government level, and laboratory experience in the fields of pharmacology and toxicology, and immunology.

Editor: Andrea Lemay
Position: USDA-APHIS-Policy and Program Development (PPD), Environmental and Risk Analysis Services (ERAS), Biological Scientist, Raleigh, NC
Education: BS Plant and Soil Science (Biotechnology) - University of Massachusetts; MS Plant Pathology -North Carolina State University
Experience: Twelve years of service in APHIS conducting risk analysis. Four years of experience in preparing environmental analyses in compliance with the National Environmental Policy Act.

Editor: Emily Ruell
Position: USDA-APHIS-WS, NWRC, Registration Specialist, Fort Collins, CO
Education: B.S. Zoology and Biological Aspects of Conservation – University of Wisconsin - Madison; M.S. Ecology – Colorado State University (CSU); M.A. Political Science – CSU
Experience: Three years of experience with APHIS WS NWRC preparing and reviewing vertebrate pesticide registration data submissions and other registration materials, and providing pesticide regulatory guidance to WS, WS NWRC, and collaborators. Prior experience before joining APHIS includes seven years of conducting field and laboratory wildlife research at CSU, and environmental policy research for the U.S. Geological Survey.

Editor: Ryan Wimberly
Position: USDA-APHIS-WS, Operational Support Staff, Staff Wildlife Biologist, Madison, TN
Education: BS Wildlife Management and Ecology – Northwest Missouri State University
Experience: Special expertise in wildlife biology, ecology, and damage management. Sixteen years of service with APHIS Wildlife Services, including operations and research, conducting a wide variety of programs, including bird damage research and management, livestock protection, invasive species management, wildlife hazard management at airports, property, and natural resource protection. Expert in preparing environmental documents for WS programs to comply with the National Environmental Policy Act and the Endangered Species Act.

9.2 Internal Reviewers

USDA-APHIS Wildlife Services

Reviewer: Douglas Eckery, PhD
Position: USDA-APHIS-WS National Wildlife Research Center, Researcher, Fort Collins, CO
Education: BS and MS Animal Science – Brigham Young University; PhD Physiology – Colorado State University

Experience: Special expertise in reproductive biology and development of tools for fertility control of overabundant wildlife species. Current species of interest include horses, feral swine, dogs, and macropod marsupials. Joined WS NWRC in 2013 as a research physiologist and leader of fertility control project. Oversees manufacture and product support for GonaCon Immunocontraceptive Vaccine. Prior experience includes 17 years in New Zealand leading basic and applied research focused on fertility control of the brushtail possum and other marsupials.

USDA-APHIS Veterinary Services

Reviewer: Albert Kane, DVM
Position: USDA-APHIS-VS Surveillance Preparedness and Response Services, Senior Staff Veterinarian and Epidemiologist, Fort Collins, CO
Education: BS Biology – Notre Dame, South Bend, IN; DVM - Virginia-Maryland Regional College Veterinary Medicine, Blacksburg, VA; MPVM & PhD - University California, Davis
Experience: Special expertise in veterinary medicine, wild equids, and horse roundups with the APHIS/Bureau of Land Management Horse and Burro Partnership. Have assisted with the use of GonaCon.

9.3 External Reviewers

U.S. Department of Interior- Geological Survey

Reviewer: James (Butch) Roelle

THEORIES OF EVOLUTION

One of the major incentives in the pioneer studies of heredity and variation which led to modern genetics was the hope of obtaining a deeper insight into the evolutionary process. Following the rediscovery of the Mendelian mechanism, there came a feeling that the solution of problems of evolution and of the control of the process, in animal and plant breeding

and in the human species, was at last well within reach. There has been no halt in the expansion of knowledge of heredity but the advances in the field of evolution have, perhaps, seemed disappointingly small. One finds the subject still frequently presented in essentially the same form as before 1900, with merely what seems a rather irrelevant addendum on Mendelian heredity.

The difficulty seems to be the tendency to overlook the fact that the evolutionary process is concerned, not with individuals, but with the species, an intricate network of living matter, physically continuous in space-time, and with modes of response to external conditions which it appears can be related to the genetics of individuals only as statistical consequences of the latter. From a still broader viewpoint (compare LOTKA 1925) the species itself is merely an element in a much more extensive evolving pattern but this is a phase of the matter which need not concern us here.

The earlier evolutionists, especially LAMARCK, assumed that the somatic effects of physiological responses of individuals to their environments were transmissible to later generations, and thus brought about a directed evolution of the species as a whole. The theory remains an attractive one to certain schools of biologists but the experimental evidence from genetics is so overwhelmingly against it as a general phenomenon as to render it unavailable in present thought on the subject.

DARWIN was the first to present effectively the view of evolution as primarily a statistical process in which random hereditary variation merely furnishes the raw material. He emphasized differential survival and fecundity as the major statistical factors of evolution. A few years later, the importance of another aspect of group biology, the effect of isolation, was brought to the fore by WAGNER. Systematic biologists have continued to insist that isolation is the major species forming factor. As with natural selection, a connection with the genetics of individuals can be based on statistical considerations.

There were many attempts in the latter part of the nineteenth century to develop theories of direct evolution in opposition to the statistical viewpoint. Most of the theories of orthogenesis (for example, those of EIMER and of COPE) implied the inheritance of "acquired characters." NÄGELI postulated a slow but self contained developmental process within protoplasm; practically a denial of the possibility of a scientific treatment of the problem. Differing from these in its appeal to experimental evidence and from the statistical theories in its directness, was DE VRIES' theory of the abrupt origin of species by "mutations." A statistical process, selec-

tion or isolation, was indeed necessary to bring the new species into predominance, but the center of interest, as with Lamarckism, was in the physiology of the mutation process.

The rediscovery of Mendelian heredity in 1900 came as a direct consequence of DE VRIES' investigations. Major Mendelian differences were naturally the first to attract attention. It is not therefore surprising that the phenomena of Mendelian heredity were looked upon as confirming DE VRIES' theory. They supplemented the latter by revealing the possibilities of hybridization as a factor bringing about an extensive recombination of mutant changes and thus a multiplication of incipient species, a phase emphasized especially by LOTSY. JOHANNSEN'S study of pure lines was interpreted as meaning that DARWIN'S selection of small random variations was not a true evolutionary factor.

A reaction from this viewpoint was led by CASTLE, who demonstrated the effectiveness of selection of small variations in carrying the average of a stock beyond the original limits of variation. This effectiveness turned out to depend not so much on variability of the principal genes concerned as on residual heredity. As genetic studies continued, ever smaller differences were found to mendelize, and any character, sufficiently investigated, turned out to be affected by many factors. The work of NILSSON-EHLE, EAST, SHULL, and others established on a firm basis the multiple factor hypothesis in cases of apparent blending inheritance of quantitative variation.

The work of MORGAN and his school securely identified Mendelian heredity with chromosomal behavior and made possible researches which further strengthened the view that the Mendelian mechanism is the general mechanism of heredity in sexually reproducing organisms. The only exceptions so far discovered have been a few plastid characters of plants. That differences between species, as well as within them, are Mendelian, in the broad sense of chromosomal, has been indicated by the close parallelism between the frequently irregular chromosome behavior and the genetic phenomena of species crosses (FEDERLEY, GOODSPEED and CLAUSEN, etc.). Most of DE VRIES' mutations have turned out to be chromosome aberrations, of occasional evolutionary significance, no doubt, in increasing the number of genes and in leading to sterility of hybrids and thus isolation, but of secondary importance to gene mutation as regards character changes. As to gene mutation, observation of those which have occurred naturally as well as of those which MULLER, STADLER, and others have recently been able to produce wholesale by X-rays, reveals characteristics which seem as far as possible from those required for a directly adaptive evolutionary process. The conclusion nevertheless seems warranted by

the present status of genetics that any theory of evolution must be based on the properties of Mendelian factors, and beyond this, must be concerned largely with the statistical situation in the species.

VARIATION OF GENE FREQUENCY

Simple Mendelian equilibrium

The starting point for any discussion of the statistical situation in Mendelian populations is the rather obvious consideration that in an indefinitely large population the relative frequencies of allelomorphic genes remain constant if unaffected by disturbing factors such as mutation, migration, or selection. If $[(1-q)a+qA]$ represents the frequencies of two allelomorphs, (a, A) the frequencies of the zygotes reach equilibrium according to the expansion of $[(1-q)a+qA]^2$ within at least two generations,[1] whatever the initial composition of the population (HARDY 1908). Combinations of different series are in equilibrium when these are combined at random, but as WEINBERG (1909) and later, in more detail, ROBBINS (1918) have shown, equilibrium is not reached at once but is approached asymptotically through an infinite number of generations. Linkage slows down the approach to equilibrium but has no effect on the ultimate frequencies.

Mutation pressure

The effects of different simple types of evolutionary pressure on gene frequencies are easily determined. Irreversible mutation of a gene at the rate u per generation changes gene frequency (q) at the rate $\Delta q = -uq$. With reverse mutation at rate v the change in gene frequency is $\Delta q = -uq+v(1-q)$. In the absence of other pressures, an equilibrium is reached between the two mutation rates when $\Delta q = 0$, giving $q = v/(u+v)$.

Migration pressure

The frequency of a gene in a given population may be modified by migration as well as by mutation. As an ideal case, suppose that a large population with average frequency q_m for a particular gene, is composed of subgroups each exchanging the proportion m of its population with a random sample of the whole population. For such a subgroup, $\Delta q = -m(q-q_m)$.

The conditions postulated above are rather artificial since, in an actual species, subgroups exchange individuals with neighboring subgroups rather

[1] This statement assumes that there is no overlapping of generations which may bring about some delay in the attainment of equilibrium.

than with a random sample of the whole species and the change in q will be only a fraction of that given above. The fraction is the average degree of departure of the neighboring subgroups toward the population average. The formula may be retained by letting q_m stand for the gene frequency of immigrants rather than of the whole species.

Selection pressure

Selection, whether in mortality, mating or fecundity, applies to the organism as a whole and thus to the effects of the entire gene system rather than to single genes. A gene which is more favorable than its allelomorph in one combination may be less favorable in another. Even in the case of cumulative effects, there is generally an optimum grade of development of the character and a given plus gene will be favorably selected in combinations below the optimum but selected against in combinations above the optimum. Again the greater the number of unfixed genes in a population, the smaller must be the average effectiveness of selection for each one of them. The more intense the selection in one respect, the less effective it can be in others. The selection coefficient for a gene is thus in general a function of the entire system of gene frequencies. As a first approximation, relating to a given population at a given moment, one may, however, assume a constant net selection coefficient for each gene. Assume that the genes a and A tend to be reproduced in the ratio $(1-s):1$ per generation. The gene array $[(1-q)a+qA]$ becomes $[(1-s)(1-q)a+qA]/[1-s(1-q)]$. The change in the frequency of A is $\Delta q = [sq(1-q)]/[1-s(1-q)]$ or with sufficiently close approximation $\Delta q = sq(1-q)$ if the selection coefficient is small.

A second approximation may be obtained by considering the zygotic frequencies. Assume that the types aa, Aa, and AA reproduce in the ratio $(1-s') : (1-hs') : 1$ per generation. The change in the frequency of A to a sufficiently close approximation is $\Delta q = s'q(1-q)[1-q+h(2q-1)]$ (WRIGHT 1929). In the case of selection for or against a complete recessive ($h=0$, s' negative or positive respectively), $\Delta q = s'q(1-q)^2$.

The case of no dominance ($h=\frac{1}{2}$) is the same as the case of genic selection except that the selection against the gene is $s'/2$ instead of s.

The two factor case in which the phenotypes aabb, $aaB-$, $A-bb$ and $A-B-$ reproduce at the rates $(1-s_{ab}):(1-s_a):(1-s_b):1$ respectively yields (for low values of the selection coefficients):

$$\Delta q_A = q_A(1 - q_A)^2[s_a + (s_{ab} - s_a - s_b)(1 - q_B)^2].$$

The frequency of A depends on the frequency and selection of B, becom-

ing independent only if $s_{ab} = s_a + s_b$, that is, if the two series of genes are cumulative with respect to selection. It does not seem profitable to pursue this subject further for the purpose of the present paper, since in the general case, each selection coefficient is a complicated function of the entire system of gene frequencies and can only be dealt with qualitatively. Attention may, however, be called to HALDANE'S (1924–1927) studies of selection rates and of the consequent number of generations required for unopposed selection to bring about any required change in gene frequency under various assumptions with respect to mode of inheritance and system of mating.

Equilibrium under selection

There may be equilibrium between allelomorphs as a result wholly of selection, namely, selection against both homozygotes in favor of the heterozygous type. Putting $\Delta q = s'q(1-q)[1-q+h(2q-1)] = 0$ gives $q = [1-h]/[1-2h]$ as the condition.[2] This includes the case of selection against both homozygotes and also that in favor of them, but examination of the signs of Δq above and below the equilibrium point shows that only the former is in stable equilibrium in agreement with FISHER (1922). The linkage of a favorable dominant with an unfavorable recessive of another series is a case in which selection would be against both homozygotes as JONES (1917) has pointed out, and stressed as a factor in the vigor of heterozygosis. In a population produced by the intermingling of types in which different deleterious recessives have become fixed, there will be a temporary selection in favor of the heterozygotes even without any linkage at all. Unless the linkage is very strong, however, this effect does not persist long enough to have much effect on gene equilibrium. The extreme case of equilibrium of the sort discussed here is, of course, that of balanced lethals, found in nature in Oenothera.

In the two factor case, discussed in the preceding section,

$$\Delta q_A = 0 \text{ if } q_B = 1 - \sqrt{\frac{s_a}{s_a + s_b - s_{ab}}}$$

$$\text{and } \Delta q_B = 0 \text{ if } q_A = 1 - \sqrt{\frac{s_b}{s_a + s_b - s_{ab}}}.$$

[2] The condition can be expressed in a more symmetrical form by using a different form of statement of the selection coefficients. Assume that the rates of reproduction of the three types aa, Aa and AA are as $(1-s_a):1:(1-s_A)$. The value of q at equilibrium comes out $q = \frac{s_a}{s_A + s_a}$ with stable equilibrium only for positive values of the two selection coefficients.

There may be equilibrium here, if s_a and s_b are alike in sign, and s_{ab} is either opposite in sign or of the same sign and smaller, but it is an unstable equilibrium. Of more general importance, perhaps, is the equilibrium reached by a deleterious mutant gene. For mutation opposed by genic selection $\Delta q = -uq+sq(1-q)=0$, $q=1-u/s$. For mutation opposed by zygotic selection (aa, Aa and AA reproducing at rates $(1-s'):(1-hs'):1$ it is easily shown that $q=1-u/hs'$ (WRIGHT 1929), unless h approaches 0. Thus with no dominance, $q=1-2u/s'$, and for selection against a dominant mutation, $q=1-u/s'$. The important case of selection against a recessive is that in which $h=0$. The formula becomes $q=1-\sqrt{u/s'}$. All of these cases are illustrated in figure 1 in which the ordinates show the selection pressure as related to factor frequency, under the different conditions of selection. The intersections with the straight line representing mutation pressure give the points of equilibrium. If deleterious dominant and recessive mutations occur with equal frequency and are subject to the same degree of selection, the frequency of the recessive mutant genes will be greater than that of the dominant ones in the ratio $\sqrt{u/s'}$ to u/s'. The corresponding figure for factors lacking dominance is $2u/s'$, where s' is the selection against the homozygote. These considerations alone should lead to a marked correlation in nature between recessiveness and deleterious effect. This correlation is further increased by the greater frequency of recessive mutation which seems to be a general phenomenon. It is this correlation which gives the theoretical basis for the immediate degeneration which usually accompanies inbreeding, a process which increases the proportion of recessive phenotypes.

The amount to which gene frequency in a subgroup may depart from the species average as a result of local selection held in check by population interchange with other regions may be calculated by solving the quadratic $\Delta q = sq(1-q)-m(q-q_m)=0$. If the local selection coefficient is much greater than the proportion of migration ($s > m$), $q=1-\frac{m}{s}(1-q_m)$ or $-mq_m/s$ depending on the direction of selection, formulae analogous to those for the equilibrium between mutation and selection. If, on the other hand, selection is weak compared with migration ($s < m$), the departure from q_m is small and $q=q_m[1+\frac{s}{m}(1-q_m)]$. This case is doubtless the more important in nature. Large subgroups living under different selection pressures should show gene frequencies clustering about the average according to this expression. The effect of small size of the subgroups in bringing about random deviation in this and other cases is not here con-

sidered. The case in which s and m are of the same order of magnitude may be illustrated by the case of exact equality. Here $q = \sqrt{q_m}$ or $1 - \sqrt{1 - q_m}$ depending on the direction of selection.

Multiple allelomorphs

The foregoing discussion has dealt formally only with pairs of allelomorphs, a wholly inadequate basis for consideration of the evolutionary pro-

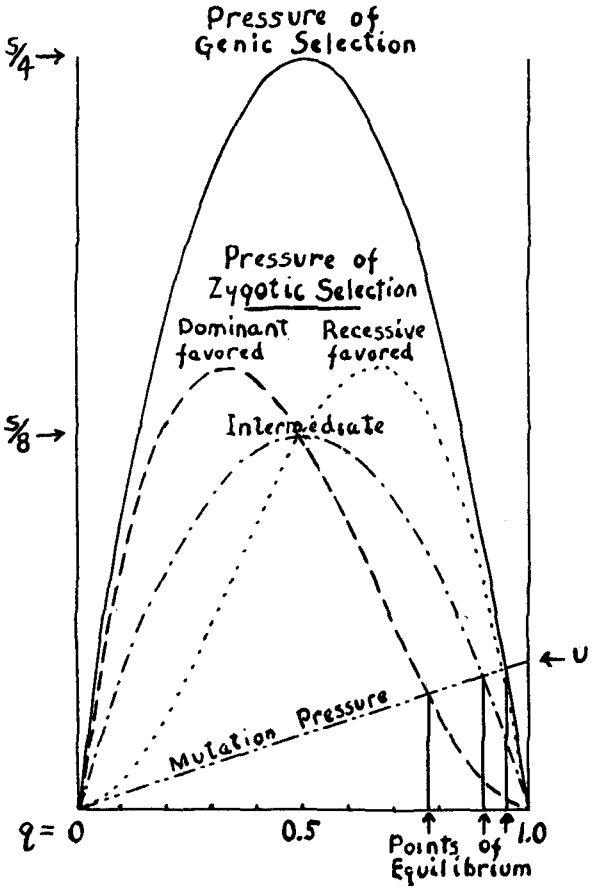

FIGURE 1.—Rate of change of gene frequency under selection or mutation. Genic selection (A, a reproducing at rates 1:1−s); Zygotic selection: dominant (B-, bb at rates 1:1−s), recessive (cc, C− at rates 1:1−s), intermediate (DD, Dd, dd at rates $1:1-\frac{1}{2}s:1-s$), Mutation such that $u = -0.05$ s. Intersections of line of mutation pressure with those for selection pressure determine the equilibrium frequencies.

cess unless extension can be made to multiple allelomorphs. Among the laboratory rodents some 40 percent of the known series of factors affect-

ing coat color are already known to be multiple. The number of multiple series is large in other organisms, for example, Drosophila (MORGAN, STURTEVANT and BRIDGES 1925). It is not unlikely that further study will indicate that all series are potentially multiple. In this case, each gene has a history which is not a mere oscillation between approximate fixation of two conditions but a real evolutionary process in its internal structure. Presumably any particular gene of such an indefinitely extended series can arise at a step from only a few of the others[3] and in turn mutate to only a few. Since genes as a rule have multiple effects and change in one effect need not involve others, it is probable that in time a gene may come to produce its major effects on wholly different characters than at first. Continuing this line of thought, it indeed seems possible that all genes of all organisms may ultimately be traced to a common source, mitotic irregularities furnishing the basis for multiplication of genes.

The relative frequencies of all allelomorphs in a series tend, of course, to remain constant in the absence of disturbing forces. The zygotes reach the equilibrium of random combination of the genes in pairs by the second generation from any initial constitution of the population. The effects of the various kinds of evolutionary pressure on the frequency of each gene may be treated as before by contrasting each gene with the totality of its allelomorphs. In the binomial expression $[(1-q)a+qA]$, A may be understood as representing any gene, and a as including all others of its series. Such treatment, however, requires further qualification with regard to the constancy of the various coefficients. It may still be assumed that the rate (u) of mutational breakdown of the gene in question (A) is reasonably constant, but its rate (v) of mutational origin from allelomorphs must be expected to change. This may be expected to rise to a maximum, as genes closely allied to A in structure become frequent, and to fall off to zero as changes accumulate in the locus. Even at its maximum, however, the rate of formation should in general be of the second order compared with the rate of change to something else, simply because it is one and its alternatives many. Moreover, there is an indication that the genes which become more or less established in a population are not a random sample of the types of mutations which occur. It has been the common experience that mutations are usually recessive. Recessiveness is most simply interpreted physiologically as due to inactivation which may well be the commonest type of mutational change. But the evolutionary process presumably involves in-

[3] Those most closely related genetically, however, need not always be closest in effect. The complete inactivation of a gene in a particular respect may for example occur more freely than a partial inactivation.

crease in activity of genes at least as frequently as inactivation with the consequence that the rate of formation (v) of genes of evolutionary significance becomes negligibly small in comparison with rate of breakdown (u) of such genes. It should be said that FISHER has advanced an alternative hypothesis according to which genes originally without dominance become dominant through a process of selection of modifiers (FISHER 1928, 1929, WRIGHT 1929, 1929a).

The selection coefficient, s, relating to a gene A cannot be expected to be constant if the alternative term a includes more than one gene. The coefficient should rise to a maximum positive value as A replaces less useful genes but should fall off and ultimately become negative as the group of allelomorphs comes to include still more useful genes. But as already discussed, even if A has only one allelomorph, the dependence of the selection coefficient on the frequencies and selection coefficients of non-allelomorphs keeps it from being constant. The existence of multiple allelomorphs merely adds another cause of variation.

Random variation of gene frequency

There remains one factor of the greatest importance in understanding the evolution of a Mendelian system. This is the size of the population. The constancy of gene frequencies in the absence of selection, mutation or migration cannot for example be expected to be absolute in populations of limited size. Merely by chance one or the other of the allelomorphs may be expected to increase its frequency in a given generation and in time the proportions may drift a long way from the original values. The decrease in heterozygosis following inbreeding is a well known statistical consequence of such chance variation. The extreme case is that of a line propagating by self fertilization which may be looked upon as a self contained population of one. In this case, 50 percent of the factors with equal representation of two allelomorphs (that is, in which the individual is heterozygous) shift to exclusive representation of one of the allelomorphs in the following generation merely as a result of random sampling among the gametes. From the series of fractions given by JENNINGS (1916) for the change in heterozygosis under brother-sister mating (population of two) it may be deduced that the rate of loss in this case is a little less than 20 percent per generation. A general method for determining the decrease in heterozygosis under inbreeding has been presented in a previous paper (WRIGHT 1921). It can be shown from this that there is a rate of loss of about 1/2N in the case of a breeding population of N individuals whether equally divided between males and females or composed of monoecious individ-

uals, assuming pairs of allelomorphs. HAGEDOORN (1921) has urged the importance of such random fixation as a factor in evolution.

Another phase of this question was opened by FISHER (1922) who attempted to discover the distribution of gene frequencies ultimately reached in a population as a result of the above process. He studied a number of conditions relative to mutation and selection. He does not state the rate of decrease in heterozygosis (where any) which would follow from the solutions which he reached but this can be deduced very directly from them. It comes out 1/4N for a population of N breeding individuals in the absence of selection or mutation. This is just half the rate indicated by the method referred to above.

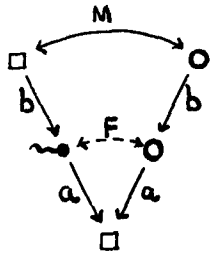

FIGURE 2.

Rate of decrease in heterozygosis

The following symbols and formulae were used in the previous paper in determining the consequences of systems of inbreeding. Primes were used to indicate the number of generations preceding the one in question. Only pairs of allelomorphs are considered here.

M correlation between genotypes of mates

b $(=\sqrt{\tfrac{1}{2}(1+F')})$ path coefficient, zygote to gamete

a $\left(=\sqrt{\dfrac{1}{2(1+F)}}\right)$ path coefficient, gamete to fertilized egg

F $(=b^2M)$ correlation between uniting egg and sperm, also, total proportional change in heterozygosis.

P $(=2q(1-q)(1-F))$ proportion of heterozygosis.

The general formula for the correlation between uniting gametes is easily deduced and has been used as a coefficient of inbreeding in dealing with complex livestock pedigrees (WRIGHT 1922, 1923, 1925, MCPHEE and WRIGHT 1925, 1926),

$$F = \Sigma\left[\left(\tfrac{1}{2}\right)^{n_s+n_d+1}(1 + F_A)\right].$$

Here F_A is the coefficient of inbreeding of any common ancestor that

makes the connecting link between a line of ancestry tracing back from the sire and one tracing back from the dam. The numbers of generations from sire and dam to such a common ancestor are designated n_s and n_d respectively. The contribution of a particular tie between the pedigrees of sire and dam is $(\frac{1}{2})^{n_s+n_d+1}(1+F_A)$ and *the total coefficient is simply the sum* of all such contributions. This formula makes it possible to compare quantitatively the statistical situation in actual populations with that in ideal populations.

In dealing with regular systems of mating the method of analysis consists in expressing the correlation between mated individuals in terms of path coefficients and correlations pertaining to the preceding generation ($M=\phi(a,'b,'M')$ and from this obtaining expression for F in terms of the F's of the preceding generations.

Consider a population in which there are N_m breeding males and N_f breeding females, and random mating. The proportion of matings between full brother and sister will be $1/(N_mN_f)$, that between half brother and sister $(N_m+N_f-2)/(N_mN_f)$, and that between less closely related individuals $(N_m-1)(N_f-1)/(N_mN_f)$. The correlation between mated individuals may be written as follows, giving due weight to these three possibilities:

$$M = a'^2b'^2\left[\frac{1}{N_mN_f}(2+2M') + \frac{N_m+N_f-2}{N_mN_f}(1+3M') + \frac{(N_m-1)(N_f-1)}{N_mN_f}4M'\right].$$

This leads to the following formula for proportional change in heterozygosis since the foundation period:

$$F = F' + \left(\frac{N_m+N_f}{8N_mN_f}\right)(1-2F'+F'').$$

The proportion of heterozygosis may be written, relative to that of preceding generations:

$$P = P' - \left(\frac{N_m+N_f}{8N_mN_f}\right)(2P'-P'').$$

It is to be expected that the proportional change per generation will reach approximate constancy. This rate may be found by equating P/P' to P/P''

$$-\frac{\Delta P}{P'} = \tfrac{1}{2}\left(1+\frac{N_m+N_f}{4N_mN_f}\right) - \tfrac{1}{2}\sqrt{1+\left(\frac{N_m+N_f}{4N_mN_f}\right)^2}.$$

This gives $(1/8N_m+1/8N_f)(1-1/8N_m-1/8N_f)$ as a close approximation even for the smallest populations while for reasonably large ones the form $1/8N_m+1/8N_f$ is sufficiently accurate.

The simplest case is that of continued mating of brother with sister ($N_m=N_f=1$). The rate of loss of heterozygosis comes out $\frac{1}{4}(3-\sqrt{5})$ or 19.1 percent per generation. The formula for proportion of heterozygosis takes the form $P=\frac{1}{2}P'+\frac{1}{4}P''$ as given in the previous paper, with results in exact agreement with those derived by JENNINGS (1916) by working out in detail the consequences of every possible mating from generation to generation.

Another simple case is that in which one male is mated with an indefinitely large number of half-sisters. This is approximately the system of breeding continuously within one herd, headed always by just one male. In this case $N_m=1$, $N_f\doteq\infty$, with rate of loss of heterozygosis of 11.0 percent per generation in agreement with previous results (WRIGHT 1921).

With a relatively limited number of males but unlimited number of females, the rate becomes approximately $1/8N_m$.

An especially important case is that in which the population is equally divided between males and females. Here $N_m=N_f=\frac{1}{2}N$ and the rate of loss is approximately $1/2N$ (or somewhat more closely $1/(2N+1)$) where N is the total size of the breeding population.

It is not, perhaps, clear at first sight that a population of N monoecious organisms, in which self fertilization is prevented, should show a decrease in heterozygosis exactly equal to that in a population of the same size equally divided between males and females. The chance that uniting gametes come from full sisters is $2/[N(N-1)]$, the chance that they come from half sisters is $4(N-2)/[N(N-1)]$ while the chance that they come from less closely related individuals is $(N-2)(N-3)/[N(N-1)]$ giving

$$M=\frac{a'^2b'^2}{N(N-1)}[2(2+2M')+4(N-2)(1+3M')+(N-2)(N-3)4M']$$

$$P=P'-\frac{1}{2N}(2P'-P'')$$

exactly as in the preceding case.

The somewhat arbitrary case in which the gametes produced by N monoecious individuals unite wholly at random is that which can be compared directly with FISHER'S results. The gametes have a chance $1/N$ of coming from the same individual and of $(N-1)/N$ of coming from different individuals. The correlation between uniting gametes may thus be written

$$F = \frac{1}{N}b^2 + \left(\frac{N-1}{N}\right)4b^2a'^2F'$$

$$P = \frac{(2N-1)}{2N}P'.$$

As might be expected, the result does not differ appreciably from that of the preceding case. The rate of loss of heterozygosis is exactly 1/2N instead of merely approximately this figure. The simplest special case is, of course, continued self fertilization in which N = 1 and the formula gives the obviously correct result of 50 percent loss of heterozygosis per generation.

From the mode of analysis it might be thought that the loss in heterozygosis is wholly the consequence of the occasional matings between very close relatives. This, however, is not the case. If instead of random sampling of the gametes produced by the population it is assumed that all individuals reproduce equally and that inbreeding is consistently avoided as much as possible, the percentage of heterozygosis still falls off. The rate of loss is, however, only about half as rapid (approximately 1/4N) in a reasonably large population equally divided between males and females. The cases of N = 2, 4, 8 and 16 have been given previously (WRIGHT 1921).

In dealing with heterozygosis in the foregoing, it has been assumed for simplicity that each locus was represented by only two allelomorphs in the population in question and that either complete fixation or complete loss of a particular gene means homozygosis of all individuals with respect to the locus. But in any case beyond that of self fertilization, more than two allelomorphs may be present and complete loss of the gene no longer implies homozygosis of the locus. The initial rate of loss of heterozygosis in a large population may thus be only 1/4N with gradual approach to 1/2N as the number of loci with only two remaining allelomorphs increases. The rate of decay of the distribution of gene frequencies is 1/2N regardless of number of allelomorphs.

The population number

It will be well to discuss more fully, before going on, what is to be understood by the symbol N used here for population number. The conception is that of two random samples of gametes, N sperms and N eggs, drawn from the total gametes produced by the generation in question (N/2 males and N/2 females each with a double representation from each series of allelomorphs). Obviously N applies only to the breeding population and not to the total number of individuals of all ages. If the population fluctu-

ates greatly, the effective N is much closer to the minimum number than to the maximum number. If there is a great difference between the number of mature males and females, it is closer to the smaller number than to the larger. In fact, as just shown, a population of N_m males and an indefinitely large number of females is approximately equivalent to a population of $4N_m$ individuals equally divided between males and females.

The conditions of random sampling of gametes will seldom be closely approached. The number of surviving offspring left by different parents may vary tremendously either through selection or merely accidental causes, a condition which tends to reduce the effective N far below the actual number of parents or even of grandparents. How small the effective N of a population may be is indicated by recent studies of SMITH and CALDER (1927) on the Clydesdale breed of horses in Scotland, in which they find a steady increase in the degree of inbreeding (Coefficient F) equivalent to that in population headed by only about a dozen stallions. Even more striking is the rapid increase in the coefficient of inbreeding in the early history of the Shorthorn breed of cattle (MCPHEE and WRIGHT 1925).

THE DISTRIBUTION OF GENE FREQUENCIES AND ITS IMMEDIATE CONSEQUENCES

No mutation, migration or selection

On making a cross between two homozygous strains a population is produced in which the members of each pair of allelomorphs in which the strains differ are necessarily equally numerous. The proportional frequency of each allelomorph in unfixed series is $q = 0.50$. In an indefinitely large population, there should be no change in this frequency in later generations (except by recurrent mutation or selection). In any finite population, however, some genes will come to be more frequent than their allelomorphs merely by chance. This means a decrease in heterozygosis, since the proportion of heterozygosis under random mating is $2q(1-q)$, and this quantity is maximum when $q = 0.50$. As time goes on, divergences in the frequencies of factors may be expected to increase more and more until at last some are either completely fixed or completely lost from the population. The distribution curve of gene frequencies should, however, approach a definite form if the genes which have been wholly fixed or lost are left out of consideration. This can easily be seen by considering a case opposite in a sense to that considered above. Suppose that a large number of different mutations occur in a previously pure line. The frequency ratio of mutant to type allelomorphs is initially $(1/2N):(2N-1)/2N$ where N is the number of individuals. The great majority of such muta-

tions will be lost, by the chances of sampling, as FISHER (1922) points out. Those which persist are largely those for which there has been a chance increase in frequency. The distribution curve of frequencies of persisting mutations will thus continually spread toward higher frequencies. There must be a position of equilibrium as far as form is concerned between this situation and that first considered, although a uniform decline in absolute numbers.

As noted above, decrease in heterozygosis takes place in the early generations following a cross without any appreciable fixation or loss of genes. But after equilibrium has been reached in the form of the distribution curve, further loss in heterozygosis must be identical in rate with fixation plus loss.

In simple cases, the equilibrium distribution of gene frequencies can easily be worked out directly. Under brother-sister mating, for example, the following relative frequencies of the 4 possible types of mating involving unfixed factors are in equilibrium although the absolute frequencies of all are falling off 19.1 percent ($=\frac{1}{4}(3-\sqrt{5})$) each generation as new genes enter the fixed states, AA × AA or aa × aa.

Mating	*Relative Frequency*
	Percent
AA×Aa	$7-3\sqrt{5}=$ 29.2
Aa ×Aa	$-22+10\sqrt{5}=$ 36.1
AA×aa	$9-4\sqrt{5}=$ 5.6
Aa ×aa	$7-3\sqrt{5}=$ 29.2
	100.1

Similarly in populations of 2 and 3 monoecious individuals with random union of gametes, the following relative frequencies are in equilibrium although the absolute frequencies are decreasing in each generation by exactly 25 percent and 16⅔ percent respectively verifying the 1/2N of theory.

Gene Frequency	*Class Frequency*	
	Percent	
3A:1a	32	Case of 2 monoecious
2A:2a	36	individuals per gen-
1A:3a	32	eration
Gene Frequency	*Class Frequency*	
	Percent	
5A:1a	18.3	
4A:2a	21.0	Case of 3 monoecious
3A:3a	21.4	individuals per gen-
2A:4a	21.0	eration
1A:5a	18.3	
	100.0	

In order to determine generally the distribution of gene frequencies, consider the way in which genes (A) with frequency q are distributed after one generation of random mating. In a population of N breeding individuals, each of the specified genes will have 2Nq representatives among the zygotes and their allelomorphs $2N(1-q)$. A random sample of the same size will be distributed according to the expression $[(1-q)a+qA]^{2N}$. The contribution of this sample to the frequency class with an allelomorphic ratio of $q_1:(1-q_1)$ will be in proportion to the $2Nq_1$'th term of the above expression and to the number of genes included in the contributing class (f). The sum of contributions from all such classes should give the $2Nq_1$'th term an absolute frequency smaller than its value in the preceding generation (f_1) by the amount $1/(2N+1)$ deduced above. Following is the equation to be solved for f as a function of q.

$$f_1\left(1-\frac{1}{2N+1}\right)=\frac{\lfloor 2N}{\lfloor 2Nq_1 \ \lfloor 2N(1-q_1)}\Sigma q^{2Nq_1}(1-q)^{2N(1-q_1)}f$$

Replacing summation by integration and letting $f=\phi(q)/2N=\phi(q)dq$ we have[4]

$$\frac{\phi(q_1)}{2N+1}=\frac{\lfloor 2N}{\lfloor 2Nq_1 \ \lfloor 2N(1-q_1)}\int_0^1 q^{2Nq_1}(1-q)^{2N(1-q_1)}\phi(q)dq.$$

[3]The cases of 2 and 3 monoecious individuals as worked out by simple algebra suggest an approach to a uniform distribution. As a trial let $\phi(q)=C$. It will be found that this makes the right and left members of the equation identical and is thus a solution.

$$\frac{C}{2N+1}=\frac{C\lfloor 2N}{\lfloor 2Nq_1 \ \lfloor 2N(1-q_1)}\frac{\Gamma(2Nq_1+1)\Gamma(2N-2Nq_1+1)}{\Gamma(2N+2)}=\frac{C}{2N+1}.$$

The case of loss at rate 1/2N should not differ appreciably from that at rate $1/(2N+1)$. It would appear that after a cross, the gene frequencies will spread out from 50 percent toward fixation and loss until a practically uniform distribution is reached. The frequencies of all classes will then slump at a rate of about 1/2N as 1/4N of the genes become fixed and the same number lost per generation. Figure 3 is intended to illustrate this situation.

[4] f must be equated to $\phi(q)/2N$ here, rather than $\phi(q)/(2N-1)$, if the convenient limits 0 and 1 are to be used for integration in place of the limits 1/2N and $(2N-1)/2N$ of the summation with its $2N-1$ terms.

Before finally accepting this solution, however, it will be well to examine the terminal conditions. The amount of fixation at the extremes if N is large can be found directly from the Poisson series according to which the chance of drawing 0 where m is the mean number in a sample is e^{-m}. The contribution to the 0 class will thus be $(e^{-1}+e^{-2}+e^{-3}\cdots)f = \frac{e^{-1}}{1-e^{-1}} f, = 0.582f.$

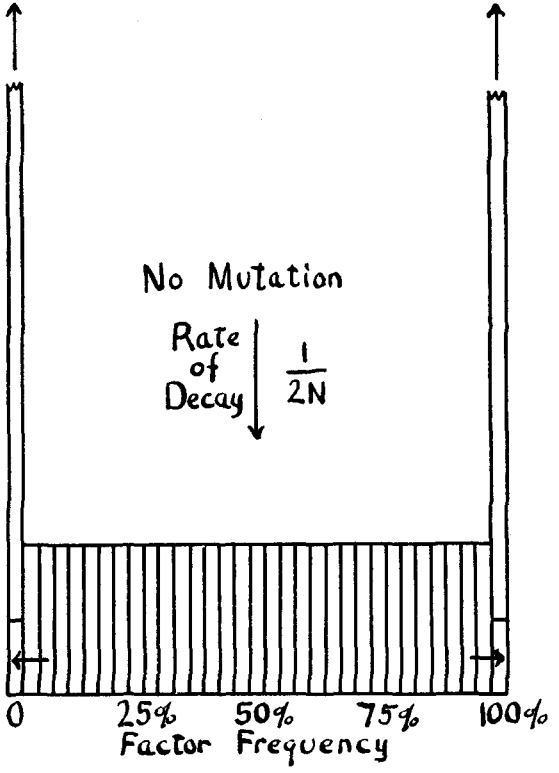

FIGURE 3.—Distribution of gene frequencies in an isolated population in which fixation and loss of genes each is proceeding at the rate 1/4N in the absence of appreciable selection or mutation. $y = L_0 e^{-T/2N}$.

This is a little larger than the $\frac{1}{2}f$ deduced above and indicates a small amount of distortion near the ends due to the element of approximation involved in substituting integration for summation. The nature and amount of this distortion are indicated by the exact distributions obtained in the extreme cases of only 2 and 3 monoecious individuals.

Letting L_0 be the initial number of unfixed loci (pairs of allelomorphs) and T the number of generations we have approximately

Unfixed loci in the T 'th generation $L_T = L_0 e^{-T/2N}$

An analogous formula holds for genes in multiple series, but in this case, as previously noted, the rate of fixation of loci is only half that given above.

The amount of genetic variation with respect to cumulative characters is easily calculated assuming for simplicity pairs of allelomorphs. The contribution of each factor pair to variance, in the case of no dominance, is $2a^2q(1-q)$ where a is the average difference in effect between plus and minus allelomorphs. The general formula for variance in this or any other distribution is thus $\sigma^2 = 2a^2\int_0^1 q(1-q)\phi(q)dq$. In the present case in which $\phi(q) = L$ this reduces to $\sigma^2 = \frac{1}{3}La^2$. PEARSON'S β_2 comes out with a value 2.8 a slightly platykurtic distribution. Since the percentage of heterozygosis for a given factor frequency, q, is $2q(1-q)$, the formula for heterozygosis is the same as that for variance except that a^2 is to be omitted.

Similarly in the case of dominance, the contribution of a single factor pair to variance is $4a^2(1-q)^2(2q-q^2)$ where a is half the average difference in effect between dominant and recessive zygotes. The total variance with perfect dominance is thus in general

$$\sigma^2 = 4a^2 \int_0^1 (1 - q)^2(2q - q^2)\phi(q)dq.$$

In the case of a uniform distribution this gives $\sigma^2 = 8/15\ La.^2$

FISHER (1918) has emphasized the importance of a characteristic of the population which he calls the dominance ratio. He analyzes the variance of characters into three portions, that due to genetic segregation (τ^2) that due to dominance, as something which causes deviations of the phenotype from the closest possible linear relation with the genotype (ϵ^2), and that due to environment. Assuming environment constant, $\sigma^2 = \tau^2 + \epsilon^2$. The simple formulae for the correlations between relatives, to be found if there is random mating and no dominance, must be modified, if dominance is present depending on the value of the dominance ratio defined as ϵ^2/σ^2. Following are examples which he gives:[5]

[5] The author wishes here to correct an error in his 1921 paper which was written without knowledge of FISHER'S results cited above. In this paper it was assumed that the correlation with no dominance needed merely to be multiplied by the squared correlation between genotype and phenotype, the same as FISHER'S $\tau^2/\sigma^2 = (1-\epsilon^2/\sigma^2)$, to obtain that with dominance. This gives correct results (if there is no assortative mating) in the case of offspring with parents, all other ancestors and also in the case of collaterals where one of the individuals is related to the other through only one parent but it is more or less in error in other cases, the fraternal correlation being that most affected. The reasoning followed was not exact because a correlation in the deviations due to dominance in the cases indicated was overlooked.

	Correlation	
	No dominance	*Dominance*
Parent and offspring	$\frac{1}{2}$	$\frac{1}{2}(1-(\epsilon^2/\sigma^2))$
Brothers	$\frac{1}{2}$	$\frac{1}{2}(1-(\epsilon^2/2\sigma^2))$
Uncle and nephew	$\frac{1}{4}$	$\frac{1}{4}(1-(\epsilon^2/\sigma^2))$
Double first cousins	$\frac{1}{4}$	$\frac{1}{4}(1-(3\epsilon^2/4\sigma^2))$

FISHER has shown that the contribution of a single factor to ϵ^2, if there is complete dominance, may be written $\delta^2 = 4q^2(1-q)^2a^2$ where q is the frequency for dominant allelomorphs. Whether a particular dominant gene has a plus or minus effect on the character under consideration is immaterial. The contribution due to genetic segregation he gives as $\beta^2 = 8q(1-q)^3a^2$ thus

$$\frac{\epsilon^2}{\sigma^2} = \frac{\Sigma\delta^2}{\Sigma(\delta^2+\beta^2)} = \frac{\int_0^1 q^2(1-q)^2\phi(q)dq}{2\int_0^1 q(1-q)^3\phi(q)dq + \int_0^1 q^2(1-q)^2\phi(q)dq}.$$

In the present case this reduces to $\frac{1}{4}$ as given by FISHER who also obtains a uniform distribution of factor frequencies for the case of no mutation or selection, although a different rate of decay.

Nonrecurrent mutation

If mutation is occurring, however low the rate, the decline in heterozygosis, following isolation of a relatively small group from a large population, cannot go on indefinitely. There will come a time when the chance elimination of genes will be exactly balanced by new genes arising by mutation. The equation to be solved is obviously as follows:

$$\frac{\phi(q_1)}{2N} = \frac{\lfloor 2N}{\lfloor 2Nq_1 \ \lfloor 2N(1-q_1)} \int_0^1 q^{2Nq_1}(1-q)^{2N(1-q_1)}\phi(q)dq.$$

It may be found by trial that the expression $\phi(q) = C_1q^{-1} + C_2(1-q)^{-1}$ is a solution. The terminal condition, reduction of the class of fixed genes ($q=1$) by an occasional mutation (contributing to the class $q=(2N-1)/2N$ necessarily involves the appearance of new genes (contributing to the class $q=1/2N$) and therefore means that only the symmetrical solution $\phi(q) = Cq^{-1}(1-q)^{-1}$ can be accepted as descriptive of the distribution of the entire array of genes at equilibrium (under the rather arbitrary postulated condition, no selection, no migration, no recurrence of the same mutations). Letting $f = (C/2N)\ q^{-1}(1-q)^{-1}$ and making $\sum f = 1$,

$$C = \frac{1}{2[(0.577 + \log(2N-1)]}$$

or approximately $C = 1/(2 \log 3.6N)$ (compare figure 5).

Before attainment of equilibrium with respect to heterozygosis the distribution will pass through phases of approximately the form $\phi(q) = C_1 q^{-1}(1-q)^{-1} + C_3$ in which the term C_1 gradually displaces C_3 as the number of temporarily fixed genes approaches equilibrium with mutation.

Each particular gene has a probability distribution for the future which spreads in time from the initial frequency in curves which are at first approximately normal in form but later (if the initial q was not too close to 1) become flat, the chances of complete fixation or complete loss each increasing by 1/4N each generation. As the chances of complete fixation increase, the chance of mutation must be taken into account. The distribution passes through phases of the type $C_2(1-q)^{-1} + C_3$, C_2 gradually displacing C_3, relatively, but itself beginning to decline as the chance of complete loss increases. With initial q equal (or close) to 1, equilibrium with mutation, and hence the hyperbolic distribution, is reached directly. The ultimate result in any case is complete loss of the gene in question (still assuming no recurrence of the same mutation and hence mutation *of* the gene but not *to* it). If there is reverse mutation, but at very low rate, a term $C_1 q^{-1}$ must be added to the formula, and an equilibrium will be reached in the form $Cq^{-1}(1-q)^{-1}$. This last formula means that in the long run (assuming no disturbances from selection, migration, etc.) the gene will usually be found either completely fixed or completely absent from the population (with frequencies proportional to the mutation rates to and from the gene respectively) but that occasionally fixation or absence will not be quite complete and that at extremely rare intervals the gene will drift from one state to the other.

The turnover among genes in equilibrium in the distribution $Cq^{-1}(1-q)^{-1}$ can be determined from consideration of the variance of q, and independently by application of the Poisson law.

Let $\sigma_q^2 = \Sigma(q - \frac{1}{2})^2 f / \Sigma f$ be the variance of q, excluding the terminal classes, the summation including $2N-1$ terms. This variance is increased in the following generation by the spreading out of each frequency class as a result of random sampling. The variance from the spreading of a single class is $q(1-q)/2N$ and the average is thus

$$\Delta\sigma_q^2 = \frac{\Sigma q(1-q)f}{2N\Sigma f} = \frac{1}{2N}\left(\frac{1}{4} - \sigma_q^2\right) = \frac{2N-1}{(2N)^2}C.$$

The sum $\sigma_q^2+\Delta\sigma_q^2$ includes the newly fixed factors whose contribution is $\frac{1}{4}K$ where K is the rate of fixation, plus loss, but excludes mutation.

Digressing for a moment to the case of no mutation but equilibrium of form, we have at once

$$\sigma_q^2 + \Delta\sigma_q^2 = K\tfrac{1}{4} + (1 - K)\sigma_q^2$$

$\left(K-\frac{1}{2N}\right)\left(\sigma_q^2-\frac{1}{4}\right) = 0$ giving an independent demonstration that the rate of decay is $1/2N$ in this case.

Returning to the case of equilibrium under mutation, the contribution of new mutations to variance is $K(N-1)^2/(2N)^2$.

$$\sigma_q^2 + \Delta\sigma_q^2 - \tfrac{1}{4}K + K\left(\frac{N-1}{2N}\right)^2 = \sigma_q^2$$

$$K = C = \frac{1}{2\log 3.6N}.$$

The proportion exchanged at each extreme is thus about half the corresponding subterminal class where N is large ($f_1 = f_{2N-1} = 2NC/(2N-1)$ by this method. This compares fairly well with the proportion as determined by the Poisson law, which is 0.46 times the subterminal class instead of 0.50.

The equilibrium frequencies can be worked out algebraically in simple cases. The figures below give the results in the case of a population of 3 monoecious individuals for comparison with the theoretical values deduced above. The rate of exchange at each extreme is actually 10.8 percent in comparison with 11.0 percent as $\frac{5}{12}\left(=\frac{2N-1}{4N}\right)$ the subterminal class, or 11.4 percent from the formula $\frac{1}{4(.577+\log 5)}$. The case of irreversible mutation is also given.

	Reversible Mutation		*Irreversible Mutation*	
Gene frequency	*Exact equilibrium*	$Cq^{-1}(1-q)^{-1}$	*Exact*	$C(1-q)^{-1}$
5A:1a	27.5	26.3	47.7	43.8
4A:2a	15.4	16.4	20.6	21.9
3A:3a	14.1	14.6	14.1	14.6
2A:4a	15.4	16.4	10.2	10.9
1A:5a	27.5	26.3	7.3	8.8
Totals	99.9	100.0	99.9	100.0
Terminal exchange	10.8	11.0	18.0	18.25
Loss			3.6	3.65

The number of unfixed loci (L) which a given mutation rate per individual (μ) will support in a population is easily found, assuming only pairs of allelomorphs. The number of mutations is KL as well as $N\mu$. Therefore $L = N\mu/K = 2N\mu \log 3.6N$. The variance of cumulatively determined characters worked out as in the preceding case comes out $2N\mu a^2$ in the case of no dominance and $10/3\ N\mu a^2$ in the case of dominance, in both cases, directly proportional to the size of population[6] and to the mutation rate. In view of the piling up of new mutations, one might perhaps, expect to find a leptokurtic distribution for characters. This, however, turns out not to be the case: PEARSON'S β_2 comes out exactly 3 in the case of no dominance on substitution in the general formula

$$\beta_2 = 3 + \frac{\int_0^1 q(1-q)[1-6q(1-q)]\phi(q)dq}{\left[\int_0^1 q(1-q)\phi(q)dq\right]^2}$$

FISHER'S dominance ratio comes out 1/5 in this case.

The preceding results differ somewhat from those presented by FISHER (1922). The latter's analysis was based on a transformation of the scale of factor frequencies designed to make the variance due to random sampling uniform at all points. The variance at a given value of q is $q(1-q)/2N$. FISHER assumes that if the ratio of small differences on the q scale to the corresponding differences on a new θ scale be made proportional to the varying standard deviation of q, the standard deviation on the θ scale will be uniform. Letting $dq/d\theta = \sqrt{q(1-q)}$ leads to the transformation $\theta = \cos^{-1}(1-2q)$ with uniform variance of factor frequencies of $1/2N$. Letting $y = F(\theta)$ be the distribution of factor frequencies in one generation, he wrote that in the next as

$$y + \Delta y = \int_0^\pi \frac{1}{\sigma\sqrt{2\pi}} e^{-\delta\theta^2/2\sigma^2}\left(y + y'\delta\theta + \frac{\delta\theta^2}{\underline{|2}}y'' \cdots\right)$$

and measuring time in generations (T) he reached the equation

$$\frac{\partial y}{\partial T} = \frac{1}{4N}\frac{\partial^2 y}{\partial \theta^2}.$$

After noting that the solution for the symmetrical stationary case is

[6] These estimates of number of unfixed loci and of variance depend, of course, on the validity of the conditions on which the formula of the distribution curve is based. How far the mutation rate per locus can be considered negligibly small as size of population increases is discussed later.

$y = L/\pi$, he proceeded to derive the formulae for increasing and decreasing y. Considering the latter, $dy/dT = -Ky$ where K is the rate of decay, giving $1/4N\ d^2y/d\theta^2 = -Ky$ as the equation to be solved. In the symmetrical case this yields $y = C \cos [\sqrt{4NK}(\theta - \pi/2)]$ where $C = \sqrt{4NK}/[2 \sin (\frac{1}{2}\pi\sqrt{4NK})]$ in order to give a total frequency of unity and is to be multiplied further by L_0e^{-KT} to show change from the initial frequency of L_0.

The maximum value which K can take without giving negative frequencies within the range is obviously 1/4N and FISHER found reason for accepting this as the value in the case of no mutation. The formula for the distribution in this case reduces to $y = \frac{1}{2} \sin \theta$. FISHER transformed these equations to the scale $Z = \log [q/(1-q)]$ in which the case of no mutation becomes $y = \frac{1}{4} \operatorname{sech}^2 \frac{1}{2}Z$ and the case of loss balanced by mutation becomes $y = 1/2\pi \operatorname{sech} \frac{1}{2}Z$. This transformation brings the curves into an approach to the form of the normal probability curve. For our present purpose it is preferable to transform to the scale of actual factor frequencies. The case of steady decay becomes $y = 1$ with which my results are in agreement, although in disagreement as to rate of decay. In the case of loss balanced by mutation, FISHER'S formula transforms into $y = 1/[\pi\sqrt{q(1-q)}]$ instead of $1/[2(\log 3.6N)q(1-q)]$ as developed in the present paper. FISHER obtained $\sqrt{\pi/2}N^{3/2}\mu$ for the number of unfixed factors, in contrast with $2N\mu \log 3.6N$; and $\sqrt{\frac{2}{\pi N}}$ for the factor turnover in contrast with $1/[2 \log 3.6N]$. It will be seen that FISHER'S solution leads to a smaller number of unfixed factors with more rapid turnover in very small populations (less than 81) but to a larger number of such factors with slower turnover in larger populations. In a breeding population of one million with one mutation per 1000 individuals, FISHER'S formula gives 1,250,000 unfixed factors with a turnover of 0.08 percent while I get 30,000 unfixed factors with a turnover of 3.3 percent.

The exact harmonizing of the results of the two methods of attack has been a somewhat puzzling matter, but Doctor FISHER, on examination of the manuscript of the present paper, has written to me the following which I quote at his suggestion. ". . . . I have now fully convinced myself that your solution is the right one. It may be of some interest that my original error lay in the differential equation

$$\frac{\partial y}{\partial T} = \frac{1}{4N} \frac{\partial^2 v}{\partial \theta^2}$$

which ought to have been

$$\frac{\partial v}{\partial T} = \frac{1}{4N} \frac{\partial}{\partial \theta}(y \cot \theta) + \frac{1}{4N} \frac{\partial^2 y}{\partial \theta^2}$$

the new term coming in from the fact that the mean value of δp in any generation from a group of factors with gene frequency p is exactly zero,[7] and consequently the mean value of $\delta\theta$ is not exactly zero but involves a minute term $-1/4N \cot \theta$. With this correction, I find myself in entire agreement, with your value 2N, for the time of relaxation and with your corrected distribution for factors in the absence of selection."

Reversible recurrent mutation

It only requires a very moderate mutation rate in a large population for the number of unfixed loci to become enormous. This raises the question as to the effect of a limitation in the number of mutable loci, and recurrence of mutations.

Consider now the case of genes with uniform rates of recurrence of mutation and reverse mutation. Let u be the rate per generation for break down of the gene A and v that for origin from allelomorphs. A class of genes with frequency q (that of all allelomorphs, $1-q$) will be distributed in the following generation under random sampling according to the expansion of the expression

$$\{[(1-q)-v(1-q)+uq]a+[q+v(1-q)-uq]A\}^{2N}f.$$

Equating the total contribution to a given class, to the frequency of this class in the parent generation, reduced by the proportion K, if there is a uniform rate of decay, gives as the equation to be solved:

$$\phi(q_1)\frac{1-K}{2N}=\frac{\underline{|2N}}{\underline{|2Nq_1}\ \underline{|2N(1-q_1)}}\int_0^1[q(1-u-v)+v]^{2Nq_1}$$
$$[1-q(1-u-v)-v]^{2N(1-q_1)}\phi(q)dq.$$

It will be found by trial that the right and left members became identical in certain cases in which $\phi(q)$ is of the form $q^s(1-q)^t$

Let $x=q(1-u-v)+v$

$$q=\frac{x-v}{1-u-v} \qquad dq=\frac{dx}{1-u-v}$$
$$q^s=\frac{x^s-svx^{s-1}\cdots}{(1-u-v)^s} \qquad (1-q)^t=\frac{(1-x)^t-tu(1-x)^{t-1}}{(1-u-v)^t}.$$

[7] p is the q of the present paper. Since the above was written, FISHER has published this revision of his results in *The genetical theory of natural selection*, 1930.

The small amount of spread from a given class will justify retention of the untransformed limits of integration.

Noting that $\Gamma(c+s+1)=\underline{|c}\ c^s\left(1+\frac{s(1+s)}{2c}\right)$ approximately when c is an integer and s is small compared with c, and making use of the following derived relation

$$\frac{2N\underline{|2N}}{\underline{|2Nq_1}\ \underline{|2N(1-q_1)}}\int_0^1 x^{2Nq_1+s}(1-x)^{2N(1-q_1)+t}dx$$
$$=\frac{4N+s(s+1)q_1^{-1}+t(t+1)(1-q_1)^{-1}}{4N+(s+t+1)(s+t+2)}q_1^s(1-q_1)^t$$

the equation may be written as followsf or small values of s and t (compared with N) and values of u and v of a still lower order of size.

$$(1-K)q_1^s(1-q_1)^t$$
$$=\frac{1}{1-(u+v)(s+t+1)}\left[\frac{4N}{4N+(s+t+1)(s+t+2)}q_1^s(1-q_1)^t\right.$$
$$+\left(\frac{s(s+1)}{4N+(s+t+1)(s+t+2)}-\frac{4Nsv}{4N+(s+t)(s+t+1)}\right)q_1^{s-1}(1-q_1)^t$$
$$\left.+\left(\frac{t(t+1)}{4N+(s+t+1)(s+t+2)}-\frac{4Ntu}{4N+(s+t)(s+t+1)}\right)q_1^s(1-q_1)^{t-1}\right]$$

The coefficients of $q_1^{s-1}(1-q_1)^t$ and of $q_1^s(1-q_1)^{t-1}$ must equal 0 either under complete equilibrium or equilibrium merely in form of distribution. Neglecting small quantities:

$$s=0 \quad \text{or} \quad s=4Nv-1$$
$$t=0 \quad \text{or} \quad t=4Nu-1.$$

In the case of complete equilibrium ($K=0$), it turns out that the coefficients of $q_1^s(1-q_1)^t$ *in the left and right members are also satisfied to a* first approximation by $s=4Nv-1$, $t=4Nu-1$. They are also satisfied by letting $s=0$, $t=0$ provided that $u+v=1/2N$. The relation between the fixed terminal and the unfixed subterminal classes, however, requires that $u=v=1/4N$ in this case, which thus becomes merely a special case of the first solution. Similarly, the solutions $s=0$, $t=4Nu-1$ and $s=4Nv-1$, $t=0$ require that $v=1/4N$ and $u=1/4N$ respectively and thus also reduce to special cases of the first solution. It appears then that the distribution of gene frequencies in equilibrium under mutation and reverse mutation may be represented approximately by curves of PEARSON'S Type I,

$$\phi(q) = \frac{\Gamma(4Nu + 4Nv)}{\Gamma(4Nu)\Gamma(4Nv)} q^{4Nv-1}(1 - q)^{4Nu-1}.$$

The terminal conditions are of interest in this and other cases to be considered. The factor turnover at each extreme may be written

$$K_0 = \tfrac{1}{2}f_1 = 2Nvf_0$$
$$K_{2N} = \tfrac{1}{2}f_{2N-1} = 2Nuf_{2N}$$

where the subterminal classes have the frequencies

$$f_1 = \frac{1}{2N}\phi\left(\frac{1}{2N}\right)$$
$$f_{2N-1} = \frac{1}{2N}\phi\left(1 - \frac{1}{2N}\right).$$

In the present case, the terminal classes have the frequencies $f_0 = C/[4Nv(2N)^{4Nv}]$ and $f_{2N} = C/[4Nn(2N)^{4Nu}]$ where C is the coefficient in the expression for $\phi(q)$.

It will be seen that the form of the curve depends not only on the rates of mutation of the genes but also on the size of the breeding population. With small populations or rare recurrence of mutations, the distribution approaches the symmetrical form $y = 1/(2 \log 3.6N)\, q^{-1}(1-q)^{-1}$ already discussed (figure 5). The ratio of the class of temporarily fixed genes (f_{2N}) to the class of complete absence (f_0) must be approximately v:u in this case in order that the number of mutations at each extreme of the symmetrical distribution of unfixed factors may be equal.

With increase in size of the population, the gene frequencies tend in general to be distributed in asymmetrical U— or even I— or J—shaped curves. For example, if the size of population reaches 1/4u and v is much smaller than u, the distribution will be the hyperbola $\phi(q) = Cq^{-1}$ with a piling up of factors with few or no plus representatives.

With sufficient increase in the size of population, the distribution at length takes a form approaching that of the normal probability curve; centered about the point $\bar{q} = v/(u+v)$ which, indeed, is always the mean

$$\left(\bar{q} = \int_0^1 q\phi(q)dq = \frac{v}{u + v}\right).$$

The variance of gene frequencies, $\sigma_q^2 = \int_0^1 (q-\bar{q})^2\phi(q)dq$ is

$$\frac{\bar{q}(1 - \bar{q})}{4N(u + v) + 1}.$$

The amount of genetic variation of cumulative characters may be calculated as before. In the case of no dominance and paired allelomorphs

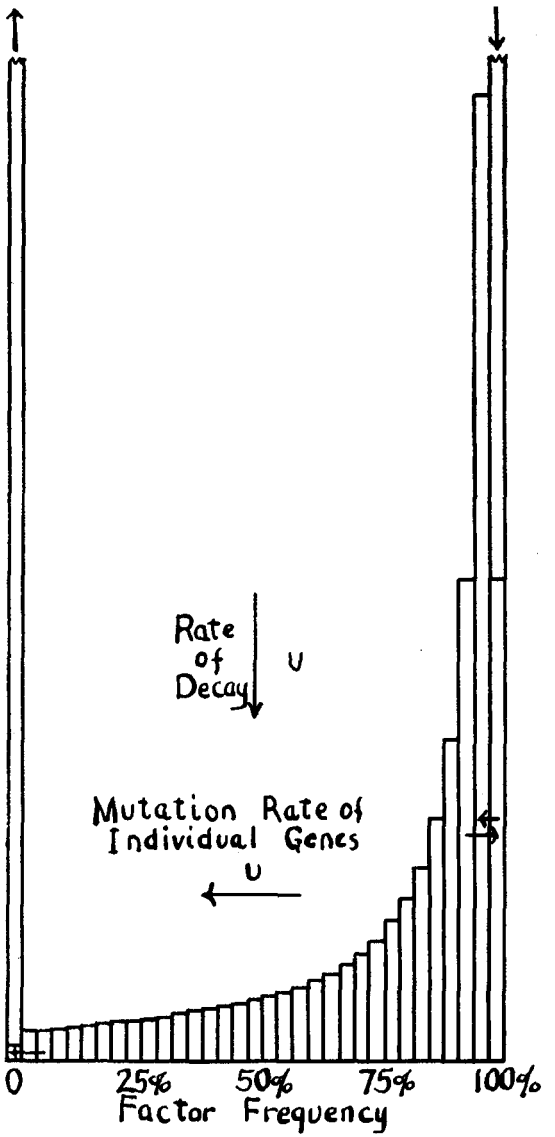

FIGURE 4.—Distribution of type genes in an isolated population in which equilibrium has been reached with destructive mutation but has not been approached with respect to formative mutation. $y=4NuL_0e^{-uT}(1-q)^{4Nu-1}$ with 4Nu much smaller than 1 and the formula approximately $\frac{L_0(1-q)^{-1}}{\log 3.6N}$.

it is $\sigma^2 = 2La^2\ 4Nuq/(4Nu+4Nv+1)$ or $2La^2[\bar{q}(1-q)-\sigma_q{}^2]$. Where u is much greater than v, this can be written approximately $\sigma^2 = 2La^2 4Nv/(4Nu+1)$ approaching $2La^2\bar{q}$ as a limit, as N increases and L comes to include all loci.

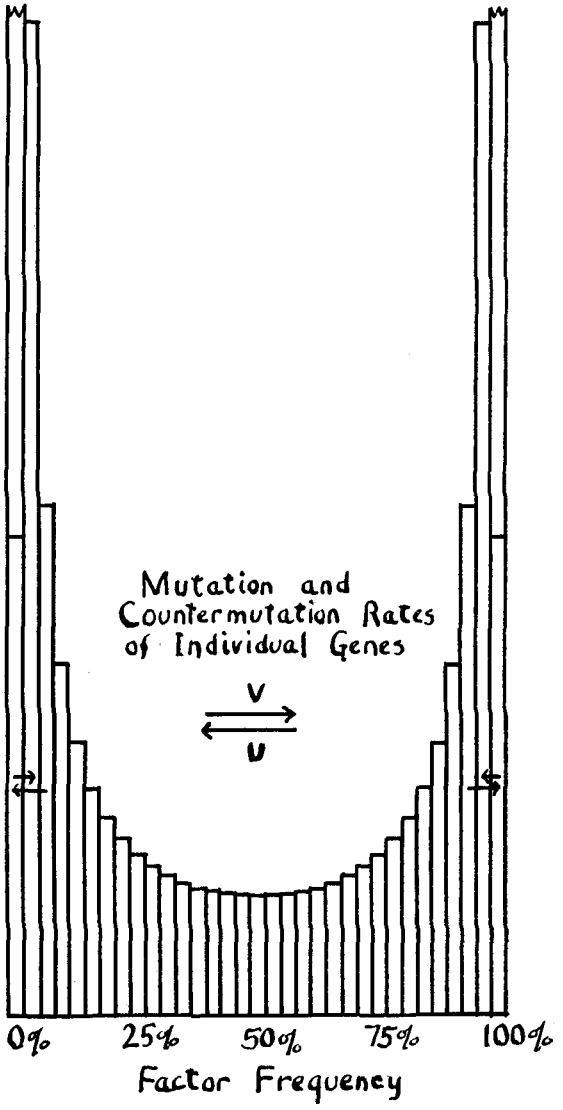

FIGURE 5.—Distribution of gene frequencies (or probability array of gene) where equilibrium with mutation has been attained. Population so small that the terms 4Nu and 4Nv are both much smaller than 1. $y = Cq^{4Nv-1}(1-q)^{4Nu-1}$, approximately $\frac{q^{-1}(1-q)^{-1}}{2 \log 3.6N}$.

As the formula for this case was derived on the assumption of small values of u and v, it is desirable to obtain an independent test of its applicability to large values. This can be done as follows: the increase in variance of q due to random sampling is

$$\frac{1}{2N}\int_0^1 q(1-q)\phi(q)\,dq = \frac{\bar{q}(1-\bar{q})-\sigma^2_q}{2N}.$$

Letting $\Delta q = -uq+v(1-q)$ be, as before, the change in q due to mutation, $q+\Delta q-\bar{q} = (q-\bar{q})(1-u-v)$. Thus the effect of mutation is as if all deviations from the mean were reduced in the proportion $(1-u-v)$. The decrease in the variance of q, due to mutation is therefore $\sigma_q^2[1-(1-u-v)^2]$. At equilibrium the increase in σ_q^2 due to random sampling is exactly balanced by the decrease due to mutation yielding:

$$\sigma^2_q = \frac{\bar{q}(1-q)}{4N(u+v)-2N(u+v)^2+1.}$$

The term $-2N(u+v)^2$ in the denominator is important only when $(u+v)$ has a large absolute value. Omitting this, the formula is identical with that deduced by the first method and thus gives an independent demonstration of its validity. As mutation approaches its maximum value $(u+v=1)$, the variance of q approaches $\bar{q}(1-\bar{q})/2N$, that due to random sampling alone.

Migration

The distribution of gene frequencies in an incompletely isolated subgroup of a large population can be obtained immediately from the preceding results. The change in gene frequency per generation under migration $\Delta q = -m(q-q_m)$ can be written $-m(1-q_m)q+mq_m(1-q)$ which is in the same form as the change of q under mutation, $\Delta q = -uq+v(1-q)$. We may write at once for the distribution under negligible mutation rates:

$$\phi(q) = \frac{\Gamma(4Nm)}{\Gamma[4Nmq_m]\Gamma[4Nm(1-q_m)]}q^{4Nmq_m-1}(1-q)^{4Nm(1-q_m)-1}.$$

The mutation terms 4Nu and 4Nv can be inserted, if mutation rates are not negligible.

Figure 6 shows how the form of the distribution changes with change in m or N. Where m is less than 1/2N there is a tendency toward chance fixation of one or the other allelomorph. Greater migration prevents such fixation. How little interchange would appear necessary to hold a large population together may be seen from the consideration that $m = 1/2N$

means an interchange of only one individual every other generation, regardless of the size of the subgroup. However, this estimate must be much qualified by the consideration that the effective N of the formula is in general much smaller than the actual size of the population or even than the breeding stock, and by the further consideration that q_m of the formula refers to the gene frequency of actual migrants and that a further factor must be included if q_m is to refer to the species as a whole. Taking both of these into account, it would appear that an interchange of the order of thousands of individuals per generation between neighboring subgroups of a widely distributed species might well be insufficient to prevent a considerable random drifting apart in their genetic compositions. Of course,

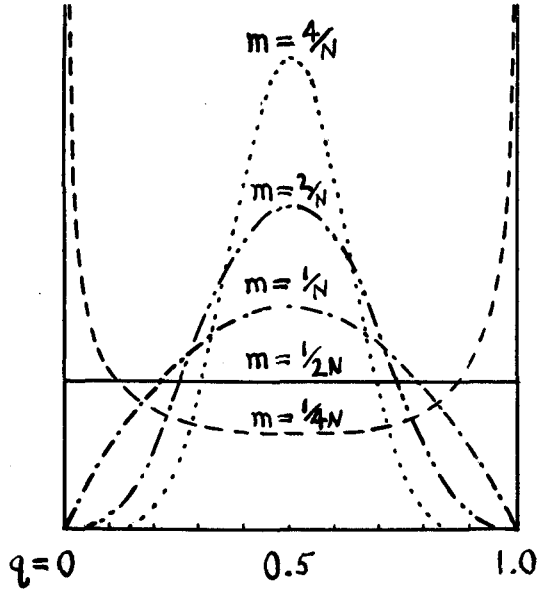

FIGURE 6.—Distribution of frequencies of a gene among subdivisions of a population in which $q_m = 1/2$ (or probability array of gene within a subdivision) under various amounts of intermigration. $y = Cq^{4Nmq_m-1}(1-q)^{4Nm(1-q_m)-1}$.

differences in the condition of selection among the subgroups may greatly increase this divergence. It appears, however, that the actual differences among natural geographical races and subspecies are to a large extent of the nonadaptive sort expected from random drifting apart. An interesting example, apparently nonadaptive, is the racial distribution of the 3 allelomorphs which determine human blood groups (BERNSTEIN 1925).

The variance of distribution of values of q among subgroups (in the ideal

case) is $\sigma_q^2 = q_m(1-q_m)/(4Nm+1)$ by substitution in the formula for the preceding case.

The zygotic distribution $[(1-q)a+qA]^2$ cannot be expected to hold in a population made up of isolated groups among which gene frequency varies. WAHLUND (1928) has shown that the proportions in each homozygous class are increased at the expense of the heterozygotes by the amount of the variance of the gene frequencies among the subgroups,[8] the proportions becoming $[(1-q)^2+\sigma_q^2]aa+[2q(1-q)-2\sigma_q^2]\ Aa+[q^2+\sigma_q^2]\ AA$. By substituting the expression for σ_q^2, given above, in WAHLUND'S formula one might determine empirically the effective value of 4Nm for the population, except that it would be difficult to rule out the possibility that some of the variance of gene frequencies might be due to differences in the selection coefficients among the subgroups instead of merely to random drifting apart.

Irreversible recurrent mutation

The solution $s=0$, $t=4Nu-1$ for the equation reached in the case of recurrent mutation satisfies the conditions for equilibrium of form under irreversible mutation ($v=0$), with decay at rate $K=u$.

$$\phi(q) = 4NuL_0e^{-uT}(1-q)^{4Nu-1}.$$

The proportional frequency of the unfixed subterminal class which is not replenished by mutation is $f_1/(L_0e^{-uT}) = 2u$, twice the rate of decay and thus approximately satisfying the necessary terminal condition.

For values of u as small as $1/(2N \log 3.6N)$ the coefficient in the expression for $\phi(q)$ must be calculated to a closer approximation $\dfrac{4NuL_0e^{-uT}}{1-\left(\dfrac{1}{2N}\right)^{4Nu}}$ which approaches $\dfrac{L}{\log 3.6N}$ as u approaches zero.

The distribution of gene frequencies under irreversible mutation is illustrated in figure 4.

This case is of most interest as representing for a long time the distribution of type genes in a small group isolated from a large one in which all type genes are close to fixation. The release of deleterious mutation pressure from equilibrium with selection will result in approximate equi-

[8] The percentage of heterozygotes is $2\int_0^1 q(1-q)\phi(q)dq$ where $\phi(q)$ is the distribution of values of q among the subgroups. As shown above this reduces to $2\bar{q}(1-\bar{q})-2\sigma_q^2$, thus demonstrating WAHLUND'S principle.

librium of the form described above. With decay at the rate u, it may be a very long time before effects of reverse mutation become appreciable and the final equilibrium $y = Cq^{-1}(1-q)^{-1}$ approached. Assuming that type genes are dominant, the dominance ratio in this case is 1/3.

Selection[9]

Using $\Delta q = sq(1-q)$ as the measure of the effect of genic selection, the class of genes with frequency $(1-q)a : qA$ is distributed after one generation according to the expression:

$$\{(1 - q)(1 - sq)a + q[1 + s(1 - q)]A\}^{2N}.$$

The distribution of gene frequencies which is in equilibrium may be obtained from the following equation which represents the total contribution to class q_1 after one generation, as equal to its previous frequency.

$$\frac{\phi(q_1)}{2N} = \frac{\lfloor 2N}{\lfloor 2Nq_1 \ \lfloor 2N(1 - q_1)} \int_0^1 q^{2Nq_1}(1 - q)^{2N(1-q_1)}(1 + s(1 - q))^{2Nq_1}(1 - sq)^{2N(1-q_1)}\phi(q)dq$$

To a first approximation, the selection terms approach the value $e^{2Ns(q_1 - q)}$. The introduction of a factor e^{2Nsq} into the previously reached formula for $\phi(q)$ gives a solution of the equation (for very small values of s) since it cancels the new term e^{-2Nsq} in the integral, and leaves e^{2Nsq_1} as a factor in $\phi(q_1)$. This was the basis for the formula published (WRIGHT 1929a) as $\phi(q) = Ce^{2Nsq}q^{4Nv-1}(1-q)^{4Nu-1}$ intended to exhibit in combination the effects of selection, mutation in both directions and size of population. Further consideration reveals that this solution is the correct one only for the case of irreversible mutation and then only when the selection coefficient is exceedingly small, less than 1/2N in fact. FISHER (1930) in his recently published revision of the results of his method of attack on this problem has given a formula for a special case of selection, equilibrium of flux from an inexhaustible supply of mutating genes. This is given as accurate as long as Ns^2 is small. Assuming one mutation per generation, he writes:

$$y = \frac{2dp(1 - e^{-4anq})}{pq(1 - e^{-4an})}.$$

[9] This and the following section have been rewritten since submission of the manuscript in order to take account of the correction of my formula, suggested by FISHER'S results in *The genetical theory of natural selection*, 1930 as noted herein.

In this formula, $a(=-s)$ is the selection coefficient, $p(=1-q)$ is frequency of mutant genes and dp may be taken as $1/2N$ numerically. This agrees with my previous formula for irreversible mutation, $y=Ce^{2Nsq}(1-q)^{-1}$ only when s is less than $1/2N$, above which value my formula rapidly leads to impossible results. On reexamination of my method, however, I find that the same degree of approximation can be reached by it. The expansion of $[1+s(1-q)]^{2Nq_1}[1-sq]^{2N(1-q_1)}$ yields series of terms which condense into the expression $e^{2Ns(q_1-q)}\{1-Ns^2[q_1(1-q_1)+(q_1-q)^2]\}$ taking into account terms in Ns^2, N^2s^3, N^3s^4, N^4s^5 as well as those in which N and s have the same exponent. Since the random deviations of q have a variance of $q_1(1-q_1)/2N$ the term (q_1-q) is of the order $\sqrt{1/2N}$. A second order approximation should be obtainable by retaining the term $Ns^2q_1(1-q_1)$ while that in $Ns^2(q_1-q)^2$ may be dropped. The equation to be solved can now be written.

$$\phi(q_1) = \frac{2N\,\underline{|2N}}{\underline{|2Nq_1}\;\;\underline{|2N(1-q_1)}}e^{2Nsq_1}[1 - Ns^2q_1(1 - q_1)] \int_0^1 q^{2Nq_1}(1 - q)^{2N(1-q_1)}e^{-2Nsq}\phi(q)dq.$$

Let $\phi(q)=e^{2Nsq}q^{-1}(1-q)^{-1}(a+bq+cq^2+dq^3\cdots)$.

The exponential term in the integral being cancelled, it becomes possible to carry out the integration by means of the approximate formula already used in the case of mutation (page 122).

$$\frac{2N\,\underline{|2N}}{\underline{|2Nq_1}\;\;\underline{|2N(1-q_1)}}\int_0^1 q^{2Nq1+z-1}(1 - q)^{2N(1-q_1)-1}dq = \frac{4N + z(z - 1)q_1^{-1}}{4N + z(z - 1)}q_1^{z-1}(1 - q_1)^{-1}.$$

The resulting coefficients of the powers of q_1 on the right side of the equation may now be equated separately to those of $\phi(q_1)$. To a sufficient approximation it turns out that $c = \frac{(2Ns)^2}{\underline{|2}}a$, $d = \frac{(2Ns)^2}{\underline{|3}}b$, $e = \frac{(2Ns)^4}{\underline{|4}}a$, $f = \frac{(2Ns)^4}{\underline{|5}}b$, $g = \frac{(2Ns)^6}{\underline{|6}}a$, etc.

Letting $C_1 = a/2$ and $C_2 = \frac{b}{4Ns}$

$$\phi(q) = 2e^{2Nsq}q^{-1}(1 - q)^{-1}[C_1 \cosh 2Nsq + C_2 \sinh 2Nsq].$$

From considerations of symmetry, it is obvious that another solution may be obtained by replacing q by $(1-q)$ and s by $-s$. The full solution may be written in the form

$$\phi(q) = q^{-1}(1-q)^{-1}[C_1(e^{4Nsq}+1) + C_2(e^{4Nsq}-1) + C_3(1+e^{-4Ns(1-q)}) + C_4(1-e^{-4Ns(1-q)})].$$

The relative values of the coefficients in the case of equilibrium can be obtained by setting up the equation for the absence of flux. Each group of genes, $f=\phi(q)dq$ tends to be shifted by the amount $\Delta q = sq(1-q)$ in a generation. There is thus a total flux measured by $\int_0^1 \phi(q)\Delta q dq$ unless there is counterbalancing mutation. The amount of mutation in each direction (assuming the rates of recurrence to be very small compared with 1/4N) is approximately half the respective subterminal classes, as demonstrated in the preceding cases.

$$f_1 = 2C_1 + 2sC_2 + (1+e^{-4Ns})C_3 + (1-e^{-4Ns})C_4$$
$$f_{2N-1} = (e^{4Ns}+1)C_1 + (e^{4Ns}-1)C_2 + 2C_3 + 2sC_4.$$

Since mutation moves genes from the fixed classes to the subterminal classes with gene frequencies of 1/2N and $\left(1-\frac{1}{2N}\right)$ respectively, it creates a net flux of $\frac{f_{2N-1}}{4N} - \frac{f_1}{4N}$ which at equilibrium should balance that due to selection

$$\int_0^1 \phi(q)\Delta q dq - \frac{f_{2N-1}}{4N} + \frac{f_1}{4N} = 0.$$

Substitution of the values given above leads to the condition $C_1-C_2+C_3+C_4=0$. Under this condition the formula simplifies greatly, becoming for all values of s $\left(\text{of lower order than } \frac{1}{\sqrt{N}}\right)$

$$\phi(q) = Ce^{4Nsq}q^{-1}(1-q)^{-1}.$$

The effect of selection in this case is perhaps best exhibited in the ratio of the classes of alternative fixed genes in the highly artificial case of equality in the rates of mutation in opposite directions. This ratio is e^{4Ns}. More generally, $f_0 = \frac{C}{4Nv}$ and $f_{2N} = \frac{Ce^{4Ns}}{4Nu}$ where u and v, both assumed to

be very small compared with 1/4N, are the opposing mutation rates. The number of unfixed loci (pairs of allelomorphs) takes the form

$$L = \frac{2N\mu}{f_1 + f_{2N-1}} = \frac{2N\mu}{C(e^{4Ns} + 1)}$$

where μ is the mutation rate per individual and C is chosen so that $\int_0^1 \phi(q)dq = 1$. The effect of selection on the variance of cumulative characters (pairs of allelomorphs) may be seen by comparing the formula

$$\sigma^2 = 2\mu a^2\left(\frac{e^{4Ns} - 1}{2s(e^{4Ns} + 1)}\right)$$

with the previously given form $2N\mu a^2$ which it approaches as s approaches 0.

In the case treated by FISHER, there is assumed to be irreversible mutation at the rate of one per generation from an inexhaustible supply. As each new gene becomes fixed, it may be considered as transferred to the type class, ready to mutate to new allelomorphs in its series. Thus in place of a return flux of $\frac{f_1}{4N}$, due to reversible mutation, we must write $\frac{f_1}{2}$ (if v = 0)

$$\int_0^1 \phi(q)\Delta q dq - \frac{f_{2N-1}}{4N} + \frac{f_1}{2} = 0.$$

This is solved if $C_1 = C_3 = C_4 = 0$ and

$$\phi(q) = C_2(e^{4Nsq} - 1)q^{-1}(1 - q)^{-1}.$$

In case the direction of mutation coincides with that of selection (u = 0), the mutational terms must be written $\frac{f_{2N-1}}{2} - \frac{f_1}{4N}$ giving the solution

$$\phi(q) = C_4(1 - e^{-4Ns(1-q)})q^{-1}(1 - q)^{-1}.$$

These are identical with FISHER's results on proper choice of the coefficient.

An interesting question which FISHER has discussed, is the chance of fixation of a single mutation. This is given by the ratio of the subterminal classes in the formulae just considered. Where selection opposes

mutation, $\frac{f_1}{f_{2N-1}} = \frac{2s}{e^{4Ns} - 1}$, always less than 1/2N. In the case of favorable mutations, $\frac{f_{2N-1}}{f_1} = \frac{2s}{1 - e^{-4Ns}}$, or approximately 2s. FISHER also gives an independent derivation of the last figure.

General formula

It is of especial importance to assemble the effects of all evolutionary factors into a single formula. Unfortunately, the equation of equilibrium of class frequencies becomes rather complicated and has not yet been worked through. Presumably the form is given at least approximately by a formula of the type $Ce^{aq}q^{4Nv-1}(1-q)^{4Nu-1}$ in the case of reversible mutation. In order that there may be no flux, $\int_0^1 \phi(q)\Delta q dq = 0$. It is not necessary to consider the terminal classes in this case. Thus

$$C\int_0^1 e^{aq}q^{4Nv-1}(1-q)^{4Nu-1}[-uq + v(1-q) + sq(1-q)]dq = 0.$$

Integration of the first term (that in $-uq$) by parts gives an expression which is immediately solved by letting $a = 4N$. Thus the selection term appears to be e^{4Nsq} regardless of the rates of mutation provided there is reversibility. It is approximately of this value in the case of irreversible mutation, discussed above, provided that s is considerably larger than 1/4N. The conclusions based on the previously presented value e^{2Nsq} still hold,[10] except that they should be applied to selection intensities just half as great.

The position of the mode of the I-shaped distribution curve given when u and s are greater than 1/4N can be found by equating the differential coefficient of the logarithm of the formula to zero.

$$4Ns + \frac{4Nv - 1}{q} - \frac{4Nu - 1}{1 - q} = 0.$$

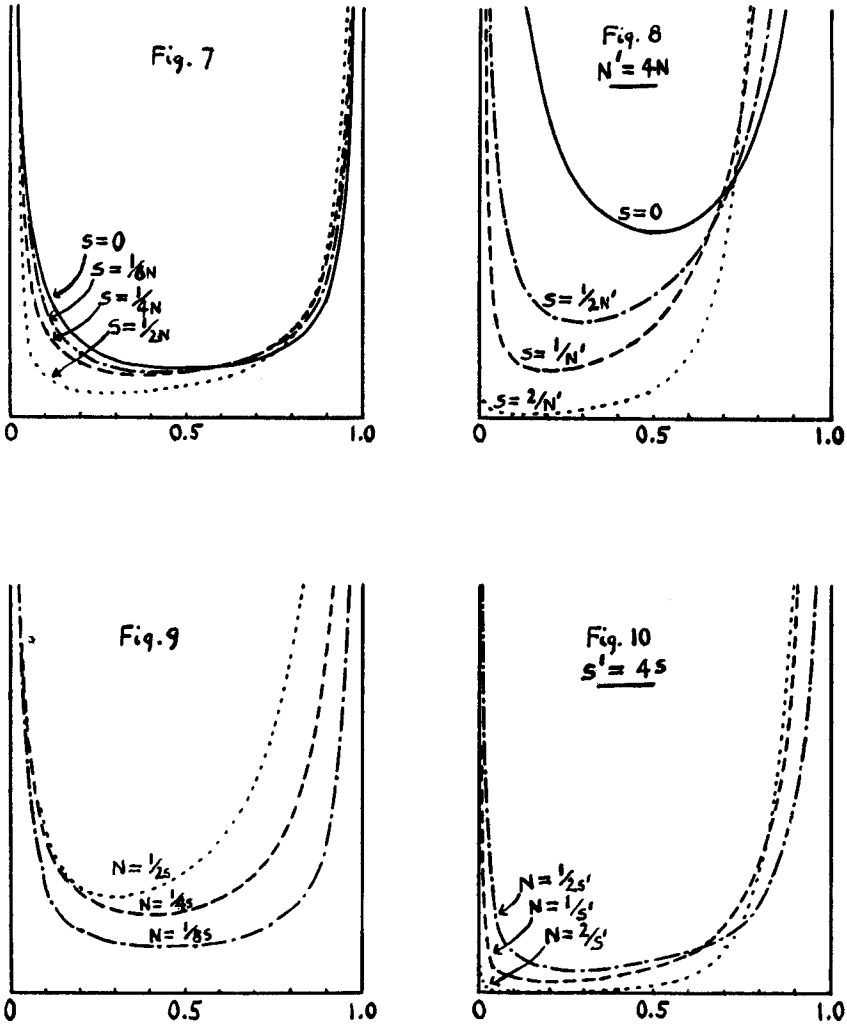
When v is small but u and s are both large, q approaches the value $1 - \frac{u}{s}$ already given as the equilibrium point. The mean would be somewhat below this point, as expected from the curvilinear relation of selection

[10] These conclusions were presented at the meeting of the AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE for 1929 and were summarized in the abstracts (WRIGHT 1929b).

pressure to gene frequency and in contrast with the case of equilibrium between opposing mutation pressures (but no selection) in which the mean is always the equilibrium point $\frac{v}{u+v}$ and the mode is more extreme than this figure, $\frac{4Nv-1}{4N(u+v)-2}$.

Migration pressure introduces no other complications. Combining all factors:

$$\phi(q) = Ce^{4Nsq}q^{4N(mq_m+v)-1}(1-q)^{4N[m(1-q_m)+u]-1}.$$

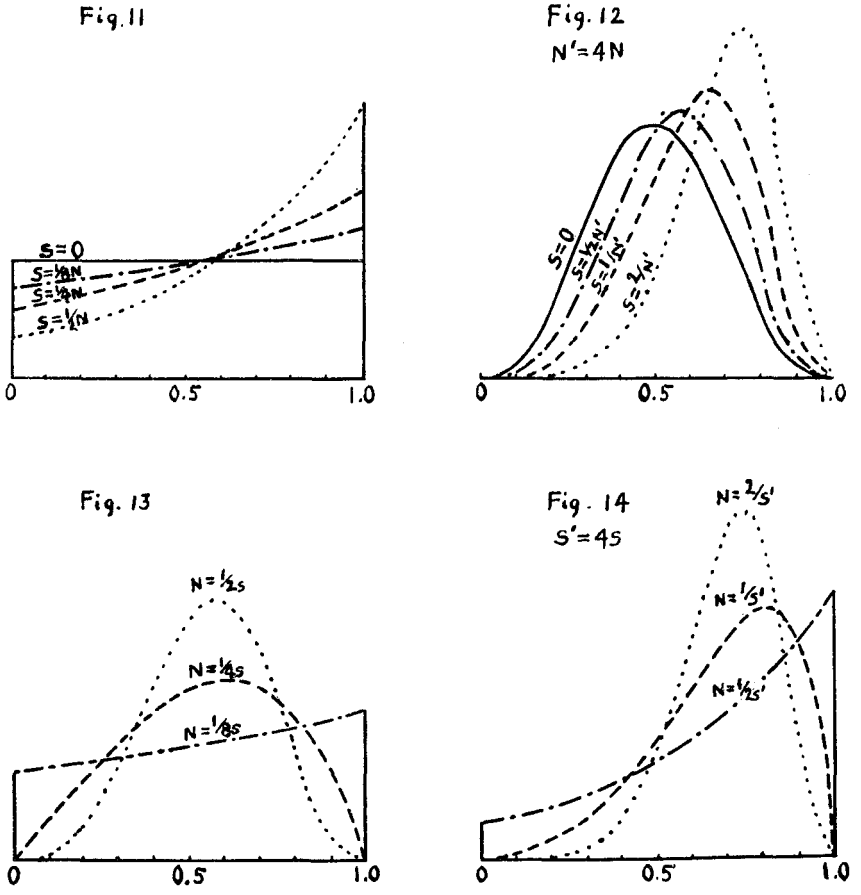


The selection coefficient refers here to the difference between the selection in the group under consideration and that in the species as a whole, the effect of the latter being taken account of in the mean gene frequency of the species q_m.

The distribution curves

Some of the forms taken by the probability array of gene frequencies, in cases involving selection, are illustrated in figures 7 to 14. Figures 7 to 10 deal with the case in which the rates of mutation are negligibly small compared with 1/4N. The curves are thus all variants of the form $y = Ce^{4Nsq}q^{-1}(1-q)^{-1}$. Figure 7 illustrates the relatively slight effect of selection below a certain relation to size of population. All conditions are the same in figure 8 except that the populations are four times as large as in figure 7. Thus while the absolute intensities of the selection coefficients are the same, the relations to size of population are altered.[11] The curves bring out the great effect of selection beyond the critical point, $s = \frac{1}{2N}$ (where mutation rates are low). Figures 9 and 10 are intended to show the effects of change in size of population where the intensity of selection remains constant (low in figure 9, four times as severe in figure 10). Up to a certain point $\left(N = \frac{1}{2s}, \text{ figure } 9\right)$ increase in population raises the middle portion of the curve. Above this point (figure 10) increase in population depresses the middle portion. In the former case, the increase in unfixed factors brings increased variability of cumulative characters, in the latter there is little change of variability in relation to population size, the depression among middle frequencies being balanced by the accumulation of nearly but not quite fixed factors. All of these fig-

[11] The probability that increase in the number of unfixed genes would react on the individual gene selection coefficients, reducing them, is here ignored.



ures (7 to 10) may be taken as representative of conditions in small inbred populations which have been isolated sufficiently long to reach equilibrium in relation to mutation. It will be recalled that figures 3 and 4 represent successive stages preceding the attainment of such equilibrium.

FIGURES 7, 8, 9, and 10.—Distribution of gene frequencies in relation to size of population and intensity of selection where rates of mutation and migration are small compared with 1/4N. Formulae all of type $y = Cy^{4Nsq}q^{-1}(1-q)^{-1}$.

Figure 7. Small population, four degrees of selection. Figure 8. Population four times as large as in figure 7 under the same four (absolute) degrees of selection. Figure 9. Three sizes of population under given weak selection. Figure 10. Same three sizes of population as in figure 9, under selection four times as severe.

Figures 11 to 14 present exactly the same series of comparisons as figures 7 to 10, for small populations that are not completely isolated from the main body of a species.[12] In all cases the gene frequency (q_m) of the

FIGURES 11 to 14.—Distribution of gene frequencies in subgroups of large population (mean frequency $q_m = 1/2$) in relation to size of population and intensity of selection. Formulae all of the type $y = Ce^{4Nsq}q^{4Nmq_m-1}(1-q)^{4Nm(1-q_m)-1}$ Same comparisons as in figures 7 to 10.

Figure 11. Small subgroups ($2Nm = 1$), four degrees of selection. Figure 12. Subgroups four times as large as in figure 11, under same four (absolute) degrees of selection. Figure 13. Subgroups of three sizes under given weak selection. Figure 14. Same three sizes as in figure 13 under selection four times as severe.

The figures may also be used to illustrate cases of equal mutation to and from a gene ($u = v$). $y = Ce^{4Nsq}q^{4Nv-1}(1-q)^{4Nu-1}$

[12] These figures also represent the distribution of gene frequencies in population in which mutation and reverse mutation are equally frequent, but this seems to be so exceptional a case especially under multiple allelomorphism, as to be of little importance.

whole species is assumed to be 1/2. The relations of migration to size of population are such that there is very little complete fixation of genes. In figure 11, $m = 1/2N$ and the purely exponential curves show how increasing intensity of genic selection shifts a uniform distribution in the direction favored by the selection. The fourfold greater population of figure 12 brings about concentration, in curves approaching the normal in form. Figure 13 brings out the concentrating effect of increase in population in the case of weak selection while figure 14 does the same for the case of selection four times as severe.

The important case in which mutation is balanced by selection in a moderately large population (both s and u large compared with 1/4N) is illustrated in figure 19. The four curves represent four degrees of selection, rising by doubling of severity at each step from a case in which mutation pressure practically overwhelms the effect of selection to the reverse situation. The limiting condition in populations so large that 1/4N is very small compared with both s and u is that of concentration of factor frequency almost at a single value (figure 20, page 148).

Dominance ratio

The form of the distribution of the frequencies of the dominant genes affecting a character is of interest in connection with the dominance ratio. Since different genes have different mutation rates and selection coefficients, this distribution is a composite of curves of the types discussed. In small populations which have reached equilibrium, all of these arrays and hence their composite are of the type $Cq^{-1}(1-q)^{-1}$. The dominance ratio is 1/5 in so far as dominance is complete. FISHER gives the value as $3/13 = 0.23$ for the case "when in the absence of selection, sufficient mutation takes place to counteract the effect of random survival." The difference from the value 0.20 given above is due solely to the difference in the formula for the curve, discussed earlier.

In the case of the isolation of a small part of a large population, the dominance ratio takes the value 1/3 in so far as dependent on dominant type genes in equilibrium with recessive mutation but not with reverse mutation ($y = C/(1-q)$). Where following isolation both fixation and loss are substantially irreversible ($y = 1$) the dominance ratio is 1/4 in agreement with FISHER'S result. In both of these cases, of course, the dominance ratio falls to 1/5 when equilibrium is finally attained.

The foregoing discussion applies practically only to very small completely isolated populations. In large populations where the distribution of gene frequencies, even in partially isolated subgroups, tends to approach

the normal type, the dominance ratio comes to depend mainly on the mean gene frequency which depends on the relation of selection to mutation, or on selection against both homozygotes in favor of heterozygotes. In the extreme case in which the gene frequency is reduced to a single value, the dominance ratio is $q/(2-q)$. Values close to unity should not be uncommon, especially where gene frequency is controlled by the balance of selection and mutation. Such a dominance ratio has rather surprising effects on the correlation between relatives. The correlation between parent and offspring approaches 0 although that between brothers may remain as high as 0.25. However, the occurrence of an appreciable number of genes at lower frequencies, for example, held in equilibrium by selection favoring the heterozygote against both homozygotes would greatly lower the dominance ratio.

All of these figures are on the assumption that dominance is complete. Dominance, however, is frequently not complete. Among 22 heterozygotes in the guinea pig which have been studied with some care, at least 9 or about 40 percent are to some extent intermediate. Most of these have to do with color characters. It is not unlikely that incomplete dominance will be found to be even more frequent on careful study of size characters.

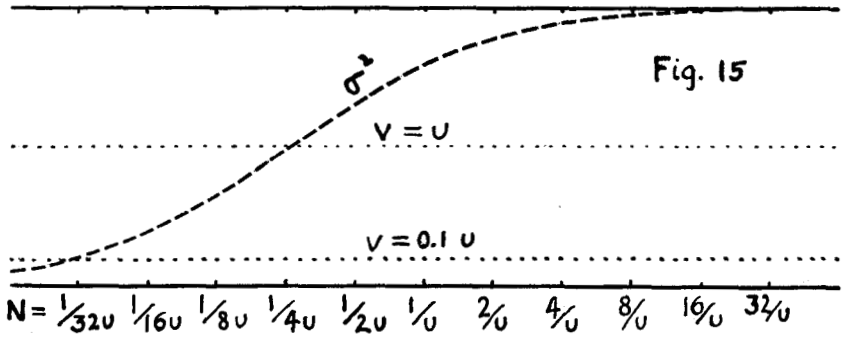
FISHER (1922) comes rather definitely to the conclusion that the dominance ratio is typically in the neighborhood of 1/3. This was based primarily on a distribution of factor frequencies which he reached for the case of selection against a recessive,[13] with which the results of the present study are not at all in agreement. He also finds, however, that the differences between fraternal and parent-offspring correlations in data which he analyzes indicate the same figure. The analysis of a large number of correlations of these sorts would undoubtedly furnish valuable information with regard to the statistical situation in populations. It is to be noted, however, that similarity in the environment of brothers as compared with parent and offspring may also contribute to a higher fraternal correlation and that in any case one cannot reason from the dominance ratio deduced from correlations to the distribution of factor frequencies without making some assumption as to the prevalence of dominance.

About all that seems justified by the present analysis, is the statement that for permanently small populations under low selection the value should

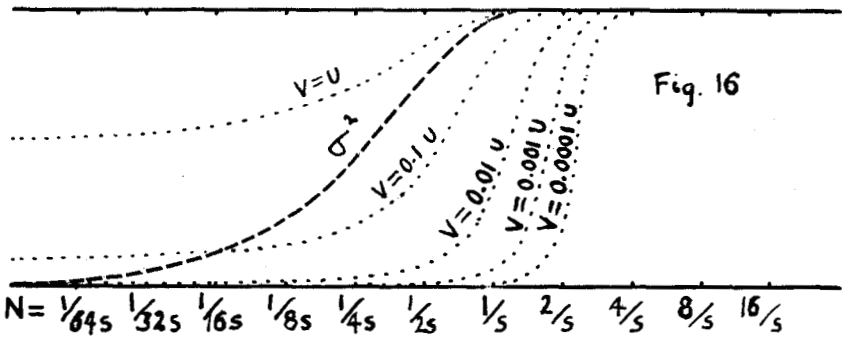
[13] This was given as $df \propto \frac{d\theta}{\sin \frac{1}{2}\theta \cos^3 \frac{1}{2}\theta}$ or $\phi(q) = Cq^{-1}(1-q)^{-2}$ on transformation of scale.

FISHER does not discuss dominance ratio in connection with his recent revision of his results in *The genetical theory of natural selection*, 1930.

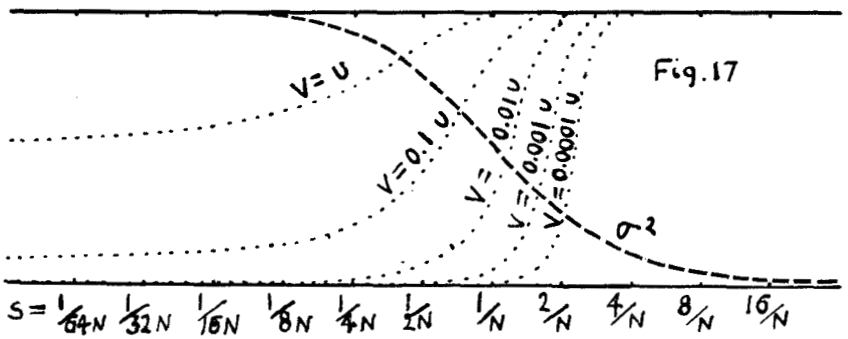
be less and probably considerably less than 0.20 but that this figure may be raised by severe selection (favoring dominants) and especially by increase in size of population. It may even approach unity in very large populations under severe selection, if complete dominance is the rule.



Mean and variability of characters



In the case of genes which are indifferent to selection (s less than u), the mean frequency $\bar{q} = v/(u+v)$ remains unchanged through all transformations from a U-shaped distribution in small populations to an I-shaped one in large populations. The variance, due to such genes, is small in small populations, rises in nearly direct proportion to size of population up to a certain critical point (about $N = 1/4u$) and then approaches a limiting value. For the case in which mutations in one direction (u) occur at a much greater rate than in the other (v), the general formula reduces to $\sigma^2 = \sigma_\infty^2\left(\frac{4Nu}{1+4Nu}\right)$, in which $\sigma_\infty^2 (= 2La^2v/u)$ is the limiting value. This case is illustrated in figure 15. The dotted lines represent mean gene frequencies and the line of dashes the variance.



Actual changes in the size of a given population are not of course accompanied by instant adjustment of the distribution of gene frequencies. A decrease in size to a point well below the critical value is followed by decrease in heterozygosis and variance at a rate between 1/4N and 1/2N per generation depending on the number of allelomorphs. This may be a fairly rapid process in terms of geologic time but the recovery of heterozygosis through growth of the population to its original size occurs more slowly, since this depends on mutation pressure. On the other hand, the intercrossing of a number of isolated strains, in each of which the reduction of variance has occurred, is followed by immediate recovery of the original statistical situation (except with respect to factor combinations in which there is some delay).

In the opposite case of genes under vigorous selection (s much greater than u) mean frequency as well as variance is affected by size of population and by severity of selection. As in the preceding case, variance is small in small populations, rises in nearly direct proportion to growth of population[14] until a critical point is approached (here about $N = 1/4s$) and then rapidly approaches a limiting value $\sigma^2 = \sigma_\infty^2\left(\frac{e^{4Ns}-1}{e^{4Ns}+1}\right)$ where

[14] As before, the probability that the increase in variance, due to growth of population, would react on the selection coefficients of the individual genes, reducing them, requires some qualification of this statement in application to actual populations.

FIGURES 15 to 17.—The variance (σ^2) and mean gene frequencies (dotted lines) at equilibrium under various conditions of mutation, selection and size of population. Figure 15. Effects of increasing population where selection is negligible relative to mutation. Figure 16. Effects of increasing population where mutation rates are small compared with 1/4N. Figure 17. Effects of increasing selection where mutation rates are small compared with 1/4N.

$\sigma_\infty^2 = \mu a^2/s$. The mean factor frequency in large populations ($\bar{q} = 1 - u/s$) is close to 1, nearly complete fixation of the favorable gene. In small populations, on the other hand, the equilibrium point approaches that of the opposing mutation pressures ($\bar{q} = v/(u+v)$) and hence practically 0, with complete loss ($v = 0$) as the inevitable ultimate fate in an extended multiple allelomorphic series. Up to the point at which mutation pressure seriously disturbs the form of the distribution curve, the mean gene frequencies are simply the ratios of the chances of fixation at each extreme, namely, $ve^{4Ns}/(u+ve^{4Ns})$.

The relations of mean frequency and variance to size of population in this case are both shown in figure 16, the former for various relative values of u and v. Inspection of figures 9 and 10 may also be of assistance in understanding this situation.

As in the other case, actual change in size of population is not accompanied by immediate attainment of the new equilibrium. Decrease in population to a number well below the critical point is followed by decrease in heterozygosis at the rate described, bringing with it at the same rate the well known inbreeding effects, loss of variance and, in general, decline in vigor toward a new level. This immediate decline in vigor is not due to change in mean gene frequency, but merely to the greater proportion of recessive phenotypes as homozygosis increases, and thus comes to an end when the degree of homozygosis has reached equilibrium. The change in mean gene frequency proceeds more slowly since it depends on mutation pressure. Long continued isolation should thus involve two distinct degeneration processes, a rapid but soon completed process of fixation and a very slow process of accumulation of injurious genes. The recovery on increase in size of population is slow in both cases, depending on mutation pressure. The intercrossing of isolated lines, on the other hand, is followed by immediate return to the original status of the population if only the immediate inbreeding effect has occurred, but must wait on favorable mutations if there has been time for the slower process.

The effects of different intensities of selection on mean gene frequency and variance (population size constant) are illustrated in figure 17, still assuming that the selection coefficient is of higher order than mutation rate. Figures 7 and 8 showing the distribution of gene frequencies in this case may also be of assistance here. Selection has little effect on variability until it reaches about the value 1/8N, about half the variance is eliminated when selection reaches 1/N and most of it at $s = 4/N$. The formula is $\sigma^2 = \sigma_0^2\left(\frac{e^{4Ns}-1}{2Ns(e^{4Ns}+1)}\right)$. Selection, of course, affects the mean gene

frequency, the formula being the same as that given above under the effect of size of population. On actual increase in the intensity of selection, the rate of change toward the new equilibrium both in mean and variance is controlled by selection pressure and may thus be fairly rapid in terms of geologic time in a large population. This is the case in which HALDANE'S formulae for progress under selection are most applicable. The increase in variance and in the proportion of unfavorable genes following relaxation of selection, on the other hand, are controlled by mutation pressure and thus approach equilibrium relatively slowly. A shift in gene frequency at rate uq may well mean no more than 0.000,001 per generation.

The type of result where the selection coefficient is of the same order of magnitude as mutation rate can be inferred, qualitatively, at least from the preceding extreme cases. Inspection of figure 19 may also be of assistance here.

THE EVOLUTION OF MENDELIAN SYSTEMS

Classification of the factors of evolution

In attempting to draw conclusions with respect to evolution one is apt, perhaps, to assume that factors which make for great variation are necessarily favorable while those which reduce variation are unfavorable. Evolution, however, is not merely change, it is a process of *cumulative* change: fixation in some respects is as important as variation in others. Live stock breeders like to compare their work to that of a modeller in clay. They speak of moulding the type toward the ideal which they have in mind. The analogy is a good one in suggesting that in both cases it is a certain intermediate degree of plasticity that is required.

The basic cumulative factor in evolution is the extraordinary persistence of gene specificity. This doubtless rests on a tendency to precise duplication of gene structure in the proper environment. The basic change factor is gene mutation, the occasional failure of precise duplication. Since the time of LAMARCK, a school of biologists have held that the primary changes in hereditary constitution must be adaptive in direction in order to account for evolutionary advance. Unfortunately, the results of experimental study have given no support to this view. Instead, the characteristics of actually observed gene mutations seem about as unfavorable as could be imagined for adaptive evolution. In the first place, is their fortuitous occurrence. No correlation has been found between external conditions and direction of mutation, and those few agents which have been found to affect the rate (X-ray, radium, and to a relatively unimportant extent, temperature) merely speed up the rate of random mutation. The great

majority of mutations are either definitely injurious to the organism or produce such small effects as to be seemingly negligible. MULLER has graphically compared the range of mutations to a spectrum in which the nonlethal conspicuous mutations form a narrow field between broad regions of individually inconspicuous mutations on the one hand and of sublethal and lethal mutations on the other. In addition, the great majority of mutations are more or less completely recessive to the type genes from which they arise. These effects are easily understood if mutation is an accidental process. Random changes in a complex organization are more likely to injure than to improve it, and with respect to the immediate products of the gene, random changes are more likely to be of the nature inactivation (and hence probably recessive) than of increased activation. Finally is to be mentioned the extreme rarity of gene mutation. Even in Drosophila, mutation rates as high as $u = 10^{-5}$ per locus seem to be exceptional and 10^{-6} or less more characteristic. This infrequency seems unfavorable to rapid evolution, yet it is a necessary corollary of the usually injurious effect, if life is to persist at all. Moreover, the more advanced the evolution, the slower must be the time rate of mutation. In one-celled organisms, dividing several times a day, a rapid time rate of mutation will not prevent the production of sufficient normal offspring to maintain the species. The same time rate in Drosophila with an interval of some two weeks between generations would mean such an accumulation of lethals in every gamete that the species would come to an abrupt end. The time rate of lethal mutation in Drosophila (7 per 1000 chromosomes per month under ordinary conditions according to MULLER (1928)) would be quite impossible in the human species. The problem is to determine how an adaptive evolutionary process may be derived from such unfavorable raw material as the infrequent, fortuitous and usually injurious gene mutations.

It will be convenient here to classify factors of evolution according as they tend toward genetic homogeneity or heterogeneity of the species. They are grouped below in more or less definitely opposing pairs.

Factors of Genetic Homogeneity	*Factors of Genetic Heterogeneity*
Gene duplication	Gene mutation (u, v)
Gene aggregation	Random division of aggregate
Mitosis	Chromosome aberration
Conjugation	Reduction (meiosis)
Linkage	Crossing over
Restriction of population size (1/2N)	Hybridization (m)
Environmental pressure (s)	Individual adaptability
Crossbreeding among subgroups (m_1)	Subdivision of group ($1/2N_1$)
Individual adaptability	Local environments of subgroups (s_1)

The first pair have been discussed above. They enter into the formulae through the mutation rates u and v. MULLER has pointed out the necessary similarity, in order of size, of genes and of filterable viruses and has suggested the possibility that the latter may consist of single genes. If so, their evolution rests wholly on a not too high rate of mutation, and selection, which seems possible enough in organisms as simple as these presumably are, especially as in this case where the gene is the organism, the mutation of the gene need not be expected to be as fortuitously related to the activities of the organism as in more complex cases.

Presumably the first step toward higher organisms is the aggregation of such genes with multiplication of the aggregate by random division. Given occasional gene mutation, this leads to a new kind of variation, that in proportional abundance of the different kinds of genic material. The larger the aggregate, the less violent the variation. Large aggregates present a labile system capable of quantitative variation in response (perhaps physiologically as well as through selection) to changing conditions. As far as observation goes, the bacteria, and blue green algae have no mechanism of division beyond a random division of the protoplasmic constituents. Such apportionment of more or less autonomous materials may also be important in the differentiating cell lineages of multicellular organisms, but, except for a few plastid characters, seems to play no important role in heredity from generation to generation, as far as has been determined by experiment. There seems here an adequate basis for an evolutionary process in organisms so simple that the handing on of a few different protoplasmic constituents can determine all of the characteristics of the species but the conditions are not favorable for an extensive cumulative process.

Mitosis provides the mechanism by which an indefinitely large number of qualitatively different elements may be maintained in the same proportions. But it provides so perfectly for the persistence of complex organization that further change is difficult. Irregularities in mitosis provide a source of variation but of so violent a nature for the most part as to be of infrequent evolutionary importance, although the differences in chromosome numbers of related species demonstrate that they play a genuine rôle. Complete duplication (tetraploidy) is important in doubling the possible number of different kinds of genes. Other aberrations, especially translocations, are probably more important in isolating types, than for the character changes which they bring. Gene mutation remains the principal factor of variation, but seems inadequate as the basis of an evolutionary process under exclusively mitotic (asexual) reproduction.

The most important factor in transcending the evolutionary difficulties

inherent in the characteristics of gene mutation is undoubtedly the attainment of biparental reproduction (EAST 1918). This involves two phases, conjugation, a factor which makes the entire interbreeding group a physiological unit in evolution, and meiosis, with its consequence, Mendelian recombination which enormously increases the amount of variability within the limits of the species. Each additional viable mutation in an asexually reproducing form merely adds one to the number of types subject to natural selection. The chance that two or more indifferent or injurious mutations may combine in one line to produce a possibly favorable change is of the second or higher order. Under biparental reproduction, each new mutation doubles the number of potential variations which may be tried out. The contrast is between $n+1$ and 2^n types from n viable mutations.

Biparental reproduction solves the evolutionary requirement of a rich field of variation. But by itself it provides rather too much plasticity. It makes a highly adaptable species, capable of producing types fitted to each of a variety of conditions, but a successful combination of characteristics is attained in individuals only to be broken up in the next generation by the mechanism of meiosis itself.

An excellent illustration of the principle that a balance between factors of homogeneity and of heterogeneity may provide a more favorable condition for evolution than iether factor by itself may be found in the effects of an alternation of a series of asexual generations with an occasional sexual generation. Evolution is restrained under exclusive asexual reproduction by the absence of sufficient variation, and under exclusive sexual reproduction by the noncumulative character of the variation, but, on alternating with each other, any variety in the wide range of combinations provided by a cross may be multiplied indefinitely by asexual reproduction. The selection of individuals is replaced by the much more effective selection of clones and leads to rapid statistical advance which, however, comes to an end with reduction to a single successful clone. On the other hand a new cross (before reduction to a single clone) may provide a new field of variation making possible a repetition of the process at a higher level. This method has been a favorite of the plant breeder and is perhaps the most successful yet devised for human control of evolution in those cases to which it can be applied at all. Under natural conditions, alternation of asexual and sexual reproduction is characteristic of many organisms and doubtless has played an important rôle in their evolution.

The demonstration of the evolutionary advantages of an alternation of the two modes of reproduction seems to prove too much. Asexual re-

production is practically absent in the most complex group of animals, the vertebrates, and is rather sporadic in its occurrence elsewhere. The purpose of the present paper has been to investigate the statistical situation in a population under exclusive sexual reproduction in order to obtain a clear idea of the conditions for a degree of plasticity in a species which may make the evolutionary process an intelligible one.

First may be mentioned briefly a modification of the meiotic mechanism which has been introduced only qualitatively into the investigation where at all. This is the aggregation of genes into more or less persistent systems, the chromosomes. Complete linkage cuts down variability by preventing recombination. Wholly random assortment gives maximum recombination but does not allow any important degree of persistence of combinations once reached. An intermediate condition permits every combination to be formed sooner or later and gives sufficient persistence of such combinations to give a little more scope to selection than in the case of random assortment. Close linkage, moreover, brings about a condition in which selection tends to favor the heterozygote against both homozygotes and so helps in maintaining a store of unfixed factors in the population.

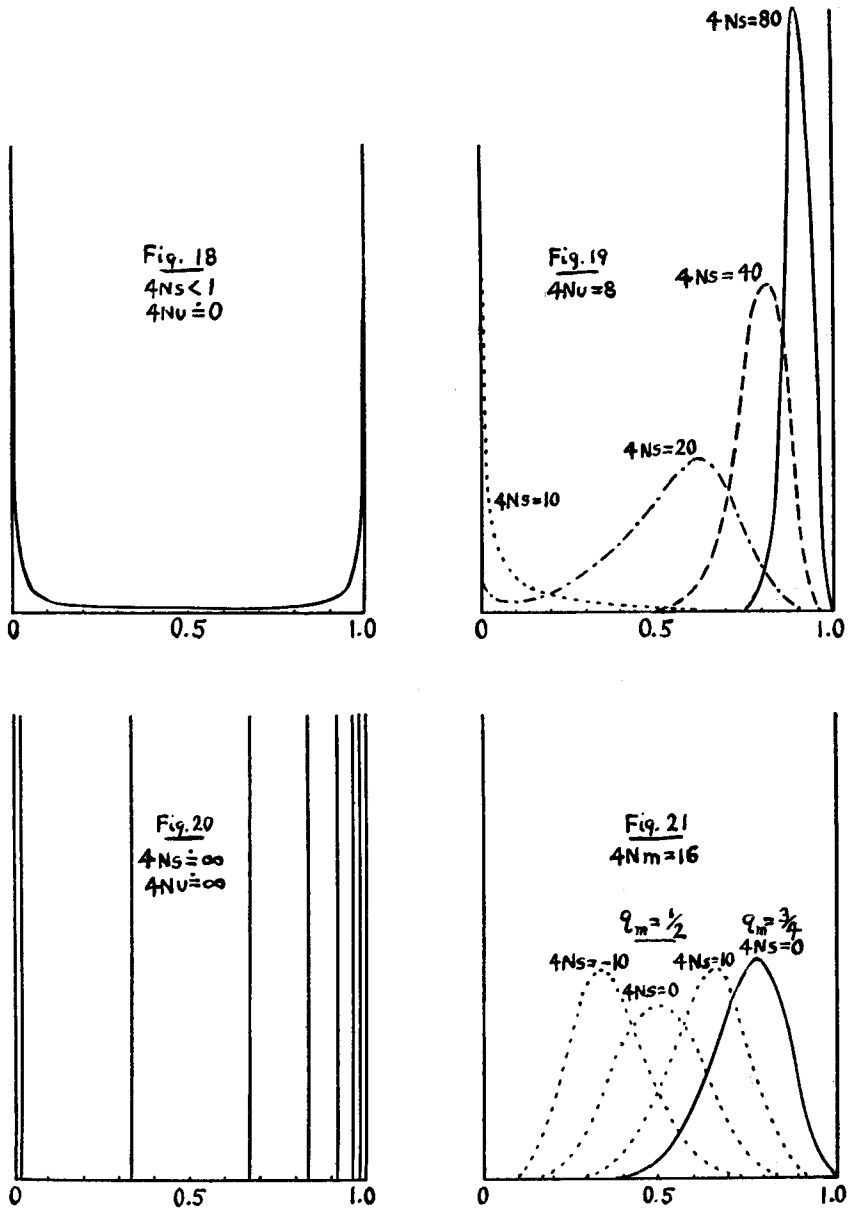
Resrtiction of size of population, measured by $1/2N$, is a factor of homogeneity and conversely with increase of size. The effects of restricted size may also be balanced by those of occasional external hybridization, measured by m.

Environmental pressure on the species as a whole is a factor of homogeneity. It has been urged by some that because natural selection is a factor which reduces variability, and most conspicuously by eliminating extreme types, it cannot be the guiding principle in adaptive evolution. From the viewpoint of evolution as a moving equilibrium, however, the guiding principle may be found on the conservative as well as on the radical side. The selection coefficient, s, depends on the balance between environmental pressure and individual adaptability. High development of the latter permits the survival of genetically diverse types in the face of severe pressure.

Subdivision of a population into almost completely isolated groups, whether by prevailing self fertilization, close inbreeding, assortative mating, by habitat or by geographic barriers is a factor of heterogeneity with effects measured by $1/2N_1$, N_1 being here the size of the subgroup. This factor may be balanced by crossbreeding between such groups, measured by m_1.

It is interesting to note that restriction of population size is a factor of homogeneity or of heterogeneity for the species, depending on whether it relates to the species as a whole or to subgroups and conversely with the crossbreeding coefficient. Similarly the selection pressures of varied environments within the range of the species (s_1) constitute factors of heterogeneity, restrained from excessive genetic effect by the same individual adaptability which appears in the opposite column in relation to the general environment of the species. Individual adaptability is, in fact, distinctly a factor of evolutionary poise. It is not only of the greatest significance as a factor of evolution in damping the effects of selection and keeping these down to an order not too great in comparison with 1/4N and u, but is itself perhaps the chief object of selection. The evolution of complex organisms rests on the attainment of gene combinations which determine a varied repertoire of adaptive cell responses in relation to external conditions. The older writers on evolution were often staggered by the seeming necessity of accounting for the evolution of fine details of an adaptive nature, for example, the fine structure of all of the bones. From the view that structure is never inherited as such, but merely types of adaptive cell behavior which lead to particular structures under particular conditions, the difficulty to a considerable extent disappears. The present difficulty is rather in tracing the inheritance of highly localized structural details to a more immediate inheritance of certain types of cell behavior.

Lability as the condition for evolution



The statistical effects of the more important of these factors in a freely interbreeding population are brought together in the formula

$$y = Ce^{4Nsq}q^{-1}(1 - q)^{4Nu-1}.$$

The term 4Nv in the exponent of q is here assumed to be negligible and the terms applicable in case of external hybridization are also omitted.

Consider first the situation in a small population in which 1/4N is much greater than u and than s (figure 18). Nearly all genes are fixed in one phase or another. Even rather severe selection is without effect. There is no equilibrium for individual genes. They drift from one state of fixation to another in time regardless of selection, but the rate of transfer is extremely slow. Such evolution as there is, is random in direction and tends toward extinction of the group.

Consider next the opposite extreme, a very large undivided population under severe selection. Assume that s is in general much greater than u and that the latter is much greater than 1/4N. There is almost complete

FIGURES 18 to 21.—Distributions of gene frequencies in relation to size of population, selection, mutation and state of subdivision. Figure 18. Small population, random fixation or loss of genes ($y = Cq^{-1}(1-q)^{-1}$. Figure 19. Intermediate size of population, random variaton of gene frequencies about modal values due to opposing mutation and selection ($y = Ce^{4Nsqq-1}(1-q)^{4Nu-1}$. Figure 20. Large population, gene frequencies in equilibrium between mutation and selection ($q = 1-u/s$, etc.). Figure 21. Subdivisions of large population, random variation of gene frequencies about modal values due to immigration and selection. ($y = Ce^{4Nsqq_4Nmq_m-1}(1-q)^{4Nm(1-q_m)-1}$.

fixation of the favored gene for each locus. Here also there is little possibility of evolution. There would be complete equilibrium under uniform conditions if the number of allelomorphs at each locus were limited. With an unlimited chain of possible gene transformations, new favorable mutations should arise from time to time and gradually displace the hitherto more favored genes but with the most extreme slowness even in terms of geologic time.[15]

Even if selection is relaxed to such a point that the selection coefficients of many of the genes are not much greater than mutation rates, the conditions are not favorable for a rapid evolution (figure 20). The amount of variability in the population may be great, maximum in fact, but if the distributions of gene frequencies are closely concentrated about single values, the situation approaches one of complete equilibrium and hence of complete cessation of evolution. At best an extremely slow, adaptive, and hence probably orthogenetic advance is to be expected from new mutations and from the effects of shifting conditions.

It should be added that a relatively rapid shift of gene frequencies can be brought about in this case by vigorous increase in the intensity of selection. The effects of unopposed selection of various sorts and in various relations of the genes has been studied exhaustively by HALDANE, with regard to the time required to bring about a shift of gene frequency of any required amount. The end result, however, is the situation previously discussed. The rapid advance has been at the expense of the store of variability of the species and ultimately puts the latter in a condition in which any further change must be exceedingly slow. Moreover, the advance is of an essentially reversible type. There has been a parallel movement of all of the equilibria affected and on cessation of the drastic selection, mutation pressure should (with extreme slowness) carry all equilibria back to their original positions. Practically, complete reversibility is not to be expected, and especially under changes in selection which are more complicated than can be described as alternately severe and relaxed. Nevertheless, the situation is distinctly unfavorable for a continuing evolutionary process.

Thus conditions are unfavorable for evolution both in very small and in very large, freely interbreeding, populations, and largely irrespective of severity of selection. We have next to consider the intermediate situa-

[15] This, nevertheless, seems to be the case which FISHER (1930) considers most favorable to evolution. The greatest difference between our conclusions seems to lie here. His theory is one of complete and direct control by natural selection while I attribute greatest immediate importance to the effects of incomplete isolation.

tion in which s is not much greater than u for many genes and the latter is not much greater than 1/4N. Such a case is illustrated in figure 19. The size of population is sufficient to prevent random fixation of genes, but insufficient to prevent random drifting of gene frequencies about their mean values, as determined by selection and mutation. It is to be supposed that the relations of the selection and mutation coefficients vary from factor to factor. The more indifferent ones drift about through a wide range of frequencies in the course of geologic time while those under more severe selection oscillate about positions close to complete fixation. In any case, all gene frequencies are continually changing even under uniform environmental conditions. But the selection coefficients themselves are in general to be considered functions of the entire array of gene frequencies and will therefore also be continually changing. The probability arrays of some genes will travel to the right and close up as their selection coefficients stiffen, while some of the genes which have been nearly fixed will come to be less severely selected and their probability arrays will shift to the left and open out or even move to the extreme left under displacement by another allelomorph. A continuous and essentially irreversible evolutionary process thus seems inevitable even under completely uniform conditions. The direction is largely random over short periods but adaptive in the long run. The less the variation of gene frequency about its mean value, the closer the approach to an adaptive orthogenesis. Complete separation of the species into large subspecies should be followed by rather slow more or less closely parallel evolutions, if the conditions are similar, or by adaptive radiation, under diverse conditions, while isolation of smaller groups would be followed by a relatively rapid but more largely nonadaptive radiation.

As to rate, since the process depends mainly on the value of 1/4N, assumed to be somewhat less than u (and s) the process cannot be as rapid as one due temporarily to either unopposed selection or unopposed mutation pressure. Hundreds of thousands of generations seem to be required at best for important nonadaptive evolutionary changes of the species as a whole; while adaptive advance, depending on the chance attainment of favorable combinations would be much slower. Even so the process is much the most rapid non-self-terminating one yet considered.

In reaching the tentative conclusion that the situation is most favorable for evolution in a population of a certain intermediate size, one important consideration has been omitted. This is the tendency toward subdivision into more or less completely isolated subgroups in widely distributed populations. Within each subgroup there is a distribution of gene fre-

quencies dependent largely on its own size (N_1), amount of crossing with the rest of the species (m_1), selection due to local conditions (s_1) and the mean gene frequency of migrants from the rest of the species (q_m). It may be assumed that $1/4N_1$ is so much larger than u that mutation pressure (and also the average selection coefficient, s, for the whole species) can be ignored.

$$y = Ce^{4N_1s_1q}q^{4N_1m_1q_m-1}(1 - q)^{4N_1m_1(1-q_m)-1}.$$

Gene frequency in each subgroup oscillates about a mean value, which is that of the whole species only if conditions of selection are uniform. Figure 21 represents various cases. The random variations of gene frequency have effects similar to those described above within each group. The result is a partly nonadaptive, partly adaptive radiation among the subgroups. Those in which the most successful types are reached presumably flourish and tend to overflow their boundaries while others decline, leading to changes in the mean gene frequency of the species as a whole. In this case, the rate of evolution should be much greater than in the previous cases. The coefficients $1/4N_1$ and s_1 may be relatively large and bring about rapid differentiation of subgroups, while the competition between subgroups will bring about rapid changes in the gene frequencies of the species as a whole. The direction of evolution of the species as a whole will be closely responsive to the prevailing conditions, orthogenetic as long as these are constant, but changing with sufficiently long continued environmental change.

A question which requires consideration is the effect of alternation of conditions, large and small size of population, severe and low selection. The effects of changes in the conditions of selection have already been touched upon. Persistence of small numbers or of severe selection for such periods of time as to bring about extensive fixation of factors compromises evolution for a long time following, there being no escape from fixation except by mutation pressure. Many thousands of generations may be required after restoration to large size and not too severe selection, before evolutionary plasticity is restored. Short time oscillations in population number or severity of selection, on the other hand, probably tend to speed up evolutionary change by causing minor changes in gene frequency.

Control of evolution

With regard to control of the process, it is evident that little is possible either within a small stock or a freely interbreeding large one. Even drastic

selection is of little effect in the former, and in the latter, while it may bring about a rapid immediate change in the particular respect selected, this must be at the expense of other characters, and in any case, soon leads to a condition in which further advance must wait on the occurrence of mutations more favorable than those fixed by the selection. The limitations in this case have been well brought out in a recent discussion by KEMP (1929). Maximum continuous progress in a homogeneous population requires an intensity of selection for each of the more indifferent genes not much greater than its mutation rate and also a certain size of population. Even so, the direction of advance is somewhat uncertain and the rate to be measured in geologic time.

If infrequency of mutation is the limiting factor here, it would seem that a considerable increase in the rate of evolution should be made possible by a speeding up of mutation, as by X-rays. There is a limit, however, imposed by the prevailingly injurious character of mutations. Even the most rigorous culling of individuals means in general, only a low selection coefficient (in absolute terms) for each of the presumably numerous unfixed genes, which are not in themselves lethal or sublethal in effect. Such culling would become insufficient to hold mutation pressure in check when the latter had increased beyond a certain point ($u > s$). Moreover, as the number of unfixed genes becomes greater under an increased mutation rate, the smaller becomes the separate gene selection coefficients, making it certain that mutation rate could not increase very much before the possibility of effective selection (in all respects at once) rather than infrequency of mutation would become the limiting factor. With respect to lethal mutations, it has already been noted that the observed natural time rate in Drosophila is such as would mean immediate extinction, if transferred to the human species. It is clear that an evolution in the direction of increased gene stability, rather than mutability, has been a necessary phase, in the evolution of the longer lived higher animals. This makes it unlikely that a general increase in mutation rate would increase the rate of evolutionary advance along adaptive lines.

The only practicable method of bringing about a rapid and non-self-terminating advance seems to be through subdivision of the population into isolated and hence differentiating small groups, among which selection may be practiced, but not to the extent of reduction to only one or two types (WRIGHT 1922a). The crossing of the superior types followed by another period of isolation, then by further crossing and so on *ad infinitum* presents a system by means of which an evolutionary advance through the field of possible combinations of the genes present in the original stock, and

arising by occasional mutation, should be relatively rapid and practically unlimited. The occasional use of means for increasing mutation rate within limited portions of the population should add further to the possibilities of this system.

Agreement with data of evolution

We come finally to the question as to how far the characteristics of evolution in nature can be accounted for on a Mendelian basis. A review of the data of evolution would go far beyond the scope of the present paper. It may be suggested, however, that the type of moving equilibrium to be expected, according to the present analysis, in a population comparable to natural species in numbers, state of subdivision, conditions of selection, individual adaptability, etc. agrees well with the apparent course of evolution in the majority of cases, even though heredity depend wholly on genes with properties like those observed in the laboratory. Adaptive orthogenetic advances for moderate periods of geologic time, a winding course in the long run, nonadaptive branching following isolation as the usual mode of origin of subspecies, species and perhaps even genera, adaptive branching giving rise occasionally to species which may originate new families, orders, etc.; apparent continuity as the rule, discontinuity the rare exception, are all in harmony with this interpretation.

The most serious difficulties are perhaps in apparent cases of nonadaptive orthogenesis on the one hand and extreme perfection of complicated adaptations on the other. In so far as extreme degeneration of organs is concerned, there is little difficulty—this is to be expected as a by-product of other evolutionary changes. Because of their multiple effects, there can be no really indifferent genes, whatever may be true of organs which have been reduced beyond a certain size. Zero as the value of a selection coefficient is merely a mathematical point between positive and negative values. It is common observation that mutations are more likely to reduce the development of an organ than to stimulate it. It follows that evolutionary change in general will have as a by product the gradual elimination of indifferent organs. Nonadaptive orthogenesis of a positive sort, increase of size of organs to a point which threatens the species, constitutes a more difficult problem, if a real phenomenon. Probably many of the cases cited are cases in which the line of evolution represents the most favorable immediately open to a species doomed by competition with a form of of radically different type or else cases in which selection based on individual advantage leads the species into a cul-de-sac. The nonadaptive differentiation of small subgroups and the great effectiveness of subsequent

selection between such groups as compared with that between individuals seem important factors in the origin of peculiar adaptations and the attainment of extreme perfection. It is recognized that there are specific cases which seem to offer great difficulty. This should not obscure the fact that the bulk of the data indicate a process of just the sort which must be occurring in any case to some extent as a statistical consequence of the known mechanism of heredity. The conclusion seems warranted that the enormous recent additions to knowledge of heredity have merely strengthened the general conception of the evolutionary process reached by DARWIN in his exhaustive analysis of the data available 70 years ago.

"Creative" and "emergent" evolution

The present discussion has dealt with the problem of evolution as one depending wholly on mechanism and chance. In recent years, there has been some tendency to revert to more or less mystical conceptions revolving about such phrases as "emergent evolution" and "creative evolution." The writer must confess to a certain sympathy with such viewpoints philosophically but feels that they can have no place in an attempt at scientific analysis of the problem. One may recognize that the only reality directly experienced is that of mind, including choice, that mechanism is merely a term for regular behavior, and that there can be no ultimate explanation in terms of mechanism—merely an analytic description. Such a description, however, is the essential task of science and because of these very considerations, objective and subjective terms cannot be used in the same description without danger of something like 100 percent duplication. Whatever incompleteness is involved in scientific analysis applies to the simplest problems of mechanics as well as to evolution. It is present in most aggravated form, perhaps, in the development and behavior of individual organisms, but even here there seems to be no necessary limit (short of quantum phenomena) to the extent to which mechanistic analysis may be carried. An organism appears to be a system, linked up in such a way, through chains of trigger mechanisms, that a high degree of freedom of behavior as a whole merely requires departures from regularity of behavior among the ultimate parts, of the order of infinitesimals raised to powers as high as the lengths of the above chains. This view implies considerable limitations in the synthetic phases of science, but in any case it seems to have reached the point of demonstration in the field of quantum physics that prediction can be expressed only in terms of probabilities, decreasing with the period of time. As to evolution, its entities, species and ecologic systems, are much less closely knit than individual organisms.

One may conceive of the process as involving freedom, most readily traceable in the factor called here individual adaptability. This, however, is a subjective interpretation and can have no place in the objective scientific analysis of the problem.

SUMMARY

The frequency of a given gene in a population may be modified by a number of conditions including recurrent mutation to and from it, migration, selection of various sorts and, far from least in importance, mere chance variation. Using q for gene frequency, v and u for mutation rates to and from the gene respectively, m for the exchange of population with neighboring groups with gene frequency q_m, s for the selective advantage of the gene over its combined allelomorphs and N for the effective number in the breeding stock (much smaller as a rule than the actual number of adult individuals) the most probable change in gene frequency per generation may be written:

$$\Delta q = v(1 - q) - uq - m(q - q_m) + sq(1 - q)$$

and the array of probabilities for the next generation as $[(1-q-\Delta q)a + (q+\Delta q)A]^{2N}$. The contribution of zygotic selection (reproductive rates of aa, Aa and AA as $1-s^1:1-hs^1:1$) is $\Delta q = s^1q(1-q)[1-q+h(2q-1)]$. In interpreting results it is necessary to recognize that the above coefficients are continually changing in value and especially that the selection coefficient of a particular gene is really a function not only of the relative frequencies and momentary selection coefficients of its different allelomorphs but also of the entire system of frequencies and selection coefficients of non-allelomorphs. Selection relates to the organism as a whole and its environment and not to genes as such. The mutation rate to a gene (v) can usually be treated as of negligible magnitude assuming the prevalence of multiple allelomorphs.

In a population so large that chance variation is negligible, gene frequency reaches equilibrium when $\Delta q = 0$. Among special cases is that of opposing mutation rates $\left(q = \frac{v}{u+v}\right)$, of selection against both homozygotes $\left(q = \frac{1-h}{1-2h}\right)$, of mutation against genic selection $\left(q = 1 - \frac{u}{s}\right)$, of mutation against zygotic selection $\left(q = 1 - \frac{u}{hs^1}\right.$ unless h approaches 0, when $\left. q = 1 - \sqrt{\frac{u}{s}}\right)$, of selection and migration $\left(q = 1 - \frac{m}{s}(1 - q_m)\right)$ or

$-\frac{mq_m}{s}$ if s is much greater than m, $q = q_m\left(1+\frac{s}{m}(1-q_m)\right)$ if s is much smaller than m, while the values $q = \sqrt{q_m}$ or $1-\sqrt{1-q_m}$ when $s = \pm m$ illustrate the intermediate case).

Gene frequency fluctuates about the equilibrium point in a distribution curve, the form of which depends on the relations between population number and the various pressures. The general formula in the case of a freely interbreeding group, assuming genic selection, is

$$y = Ce^{4Nsq}q^{4N[mq_m+v]-1}(1-q)^{4N[m(1-q_m)+u]-1}.$$

The correlation between relatives is affected by the form of the distribution of gene frequencies through FISHER's "dominance ratio." It appears that this is less than 0.20 in small populations under low selection but may even approach 1 in large populations under severe selection against recessives.

In a large population in which gene frequencies are always close to their equilibrium points, any change in conditions other than population number is followed by an approach toward the new equilibria at rates given by the Δq's. Great reduction in population number is followed by fixation and loss of genes, each at the rate 1/4N per generation, where N refers to the new population number. This applies either in a group of monoecious individuals with random fertilization or, approximately, in one equally divided between males and females (9.6 percent instead of 12.5 percent, however, under brother-sister mating, N = 2). More generally with an effective breeding stock of N_m males and N_f females, the rates of fixation and of loss are each approximately $(1/16N_m+1/16N_f)$ until mutation pressure at length brings equilibrium in a distribution approaching first the form $y = C(1-q)^{-1}$ with decay at rate u and ultimately $Cq^{-1}(1-q)^{-1}$. The converse process, great increase in the size of a long inbred population, is followed by a slow approach toward the new equilibrium at a rate dependent in the early stages on mutation pressure.

With respect to genes which are indifferent to selection, the mean frequency is always $q = v/(u+v)$. The variance of characters, dependent on such genes, is proportional (at equilibrium) to population number up to about $N = 1/4u$. Beyond this, there is approach of variance to a limiting value.

In the presence of selection (s considerably greater than 2u) the mean frequency at equilibrium varies between approximate fixation of the favored genes ($q = 1 - u/s$) in large populations and approximate, if not complete, fixation of mutant allelomorphs ($q = v/(u+v)$) in small popula-

tions, the rate of change from one state to the other being the mutation rate (u). A consequence is a slow but increasing tendency to decline in vigor in inbred stocks, to be distinguished from the relatively rapid but soon completed fixation process, described above as occurring at rate 1/2N. The variance of characters in this as in the preceding case, is approximately proportional to population number up to a certain point (N less than 1/4s) and above this rapidly approaches a limiting value. Variance is inversely proportional to the severity of selection in large populations unless the selection is very slight but in small populations is little affected by selection unless the latter is very severe (s greater than 1/4N).

Evolution as a process of cumulative change depends on a proper balance of the conditions, which, at each level of organization—gene, chromosome, cell, individual, local race—make for genetic homogeneity or genetic heterogeneity of the species. While the basic factor of change—the infrequent, fortuitous, usually more or less injurious gene mutations, in themselves, appear to furnish an inadequate basis for evolution, the mechanism of cell division, with its occasional aberrations, and of nuclear fusion (at fertilization) followed at some time by reduction make it possible for a relat vely small number of not too injurious mutations to provide an extensive field of actual variations. The type and rate of evolution in such a system depend on the balance among the evolutionary pressures considered here. In too small a population (1/4N much greater than u and s) there is nearly complete fixation, little variation, little effect of selection and thus a static condition modified occasionally by chance fixation of new mutations leading inevitably to degeneration and extinction. In too large a freely interbreeding population (1/4N much less than u and s) there is great variability but such a close approach to complete equilibrium of all gene frequencies that there is no evolution under static conditions. Change in conditions such as more severe selection, merely shifts all gene frequencies and for the most part reversibly, to new equilibrium points in which the population remains static as long as the new conditions persist. Such evolutionary change as occurs is an extremely slow adaptive process. In a population of intermediate size (1/4N of the order of u) there is continual random shifting of gene frequencies and a consequent shifting of selection coefficients which leads to a relatively rapid, continuing, irreversible, and largely fortuitous, but not degenerative series of changes, even under static conditions. The rate is rapid only in comparison with the preceding cases, however, being limited by mutation pressure and thus requiring periods of the order of 100,000 generations for important changes.

Finally in a large population, divided and subdivided into partially isolated local races of small size, there is a continually shifting differentiation among the latter (intensified by local differences in selection but occurring under uniform and static conditions) which inevitably brings about an indefinitely continuing, irreversible, adaptive, and much more rapid evolution of the species. Complete isolation in this case, and more slowly in the preceding, originates new species differing for the most part in nonadaptive respects but is capable of initiating an adaptive radiation as well as of parallel orthogenetic lines, in accordance with the conditions. It is suggested, in conclusion, that the differing statistical situations to be expected among natural species are adequate to account for the different sorts of evolutionary processes which have been described, and that, in particular, conditions in nature are often such as to bring about the state of poise among opposing tendencies on which an indefinitely continuing evolutionary process depends.

Reproductive function

ABSTRACT

To investigate the effect of gonadotropin-releasing hormone 2-multiple antigen peptide (GnRH2-MAP) on reproductive function. In our study, 20-day-old male rats (n = 90) were randomly allocated to one of three treatment groups: GnRH2-MAP immunization, GnRH2 immunization, and non-immunized control groups. The immunized animals were administered three doses of GnRH2-MAP or GnRH2 vaccines from 0 to 6 weeks at 2-week intervals. The control group only received oil adjuvant. Blood and right testis samples were collected, and the left testis was weighed and its volume was measured at 0, 2, 4, 6, 8, 10 and 12 weeks after the first immunization. The serum antibody titer and testosterone concentration were determined by ELISA, and the right testis samples were collected for histological analysis. The results revealed that the serum of vaccinated rats elicited a significantly higher antibody titer and a lower T concentration compared with the control group two weeks after the first immunization ($P < 0.05$), but the highest antibody titer and lowest T concentration were found in animals treated with GnRH2-MAP ($P < 0.05$). The second immunization resulted in a significant decrease in testicular weight and volume ($P < 0.05$) in both immunized groups compared to the control, but these values were significantly lower in the GnRH2-MAP group than in the GnRH2 group. Furthermore, seminiferous tubules revealed more significant atrophy in the GnRH2-MAP group than in the GnRH2 group, and no sperm were observed in rats of the GnRH2-MAP group. Thus, GnRH2-MAP may be an effective antigen and a potential immunocastration vaccine with higher effectiveness.

1. Introduction

Immunocastration is an alternative method to traditional surgical castration and has been successfully implemented for fertility control in animals [1]. The gonadotropin-releasing hormone 2 (GnRH) vaccine increases the serum level of anti-GnRH antibody to neutralize endogenous GnRH, a decapeptide that is synthesized from hypothalamic neurons and then acts on the anterior pituitary via the portal circulation. Exogenous GnRH can be produced as an immunological castration vaccine, because it can block testicular function by disturbing the hypothalamic-pituitary-gonadal (HPG) axis. Thus, most studies focus on developing vaccines to overcome the shortcomings of existing vaccines, such as low efficiency and safety and high cost [2,3].

There are two ways to enhance the immunogenicity of GnRH: coupling macromolecules to GnRH or changing the structure of GnRH. Existing GnRH vaccines can be divided into three categories [1,3,4], all of which have unavoidable shortcomings. Due to the weak immunogenicity of the GnRH monomer, recent studies have coupled various carrier substances or albumin fractions such as ovalbumin (OVA), keyhole limpet hemocyanin, and bovine serum albumin (BSA) [5–7], to GnRH and GnRH analogues in order to enhance the immunogenicity of the vaccine. Han et al. [8,9] found that linking the GnRH tandem dimer with OVA prior to immunizing male rats and rams can induce testicular atrophy, inhibit spermatogenesis, and reduce the level of testosterone (T), inhibin A, LH,

and FSH. However, the low rate of GnRH-carrier protein linking inhibits its commercial application. Moreover, chemical conjugation did not result in consistent homogeneity across different batches [1]. Consequently, genetically engineered and nucleic acid vaccines have emerged as potential low-cost vaccines. Stewart et al. [10] used live recombinant vectors and for the first time attempted to produce Tra T-GnRH fusion protein and achieved good results. However, as it was a live carrier, its safety was questioned. Han et al. [11] used the human *GnRH* gene and hepatitis B surface antigen S (HBsAg-S) gene to build a recombinant plasmid in mice, pVAx-HbsAg-S-2GnRH, which was used to encode the target protein vaccine. This vaccine was found to significantly inhibit testicular function; however, the cellular uptake rate of DNA vaccines is low, and consequently protein expression is also low. However, as the effect of the recombinant vaccine on other animals has not yet been verified, it can only be used as a potential new type of attenuated vaccine. Zhang et al. [12] inserted the *OVA-GnRH* gene into a prokaryotic expression vector system to obtain recombinant OVA-GnRH protein; however, it required a high number of *OVA-GnRH* genes in t he inserted plasmid. In brief, genetically engineered vaccines are limited at present due to the low protein expression, high genetic requirements, and complex purification process. To simplify the purification procedure and to stabilize plasmid expression, foreign genes encoding the antigen of interest are cloned into an expression plasmid, as a result of which the foreign gene can directly express antigen in the host cells, in this case, the nucleic acid vaccine [13]. Studies have found that the transfection rate of eukaryotic plasmids is low, and is at a potential risk of being integrated into the host genome. Recent research has proved that chemically synthesized peptide vaccines are associated with high safety and ease of synthesis and purification and are therefore preferred over other type of vaccines [14]. However, the effects of immunization among vaccines were not uniform, and immunocastration could only be achieved after the conjugation of carrier protein. Therefore, developing a low-cost, safe, and efficient vaccine is the main solution for fertility control in commercially raised animals.

The multiple antigen peptide (MAP) was proposed by James et al., in 1988 [15]. Studies show that there are two types of MAPs. The first type has a branched structure formed by multiple antigen peptides linked by lysine; it usually consists of three or seven Lys residues that form the core of four-branched or eight-branched peptides [16]. The second has a linear skeleton of Gly-Lys [17], within which Lys is linked to multiple antigenic peptides to form branched peptides perpendicular to the linear backbone. At present, more studies focus on the first type of MAP, as the Lys residues in its core can randomly connect to other amino acids by forming peptide bonds to increase the molecular weight of the antigen. The advantage of this structure is that its radial form not only enhances the immunogenicity of the synthetic peptide but also prolongs its half-life in vivo without causing the body to produce antibodies against the Lys core structure. Huang et al. [18] used antigenic peptides derived from *Schistosoma mansoni* glutathione-*S*-transferase (Sm28GST) to synthesize a four-branched peptide with an MAP structure by solid-phase peptide synthesis. Immunization of mice with this vaccine effectively induced antibody responses without the need for any adjuvant. After the schistosome infection, the number of worms and eggs in the liver of the mice dropped significantly compared with the control group, and the results showed that the protective effect of MAP was much better than that of the single peptide. Feng et al. [19] found that epitope tetrameric peptide (MAP) had a purity of >95% when the 9-fluorenylmethoxycarbonyl (FMOC) was used to synthesize the lipopolysaccharide-binding protein by solid-phase synthesis. Thus, the MAP system can make up for the low connection rate defect of the carrier protein vaccine. Therefore, we speculated that synthetic GnRH2 with straight chains could connect to Lys due to its binding capacity to produce the GnRH2-MAP vaccine. Due to its radial structure and molecular weight, GnRH2-MAP can act as a better antigen with high immunogenicity. In particular, it can make up for the shortcomings of protein vaccines with high connection and purity rates.

The current study aimed to test the feasibility and reliability of the novel GnRH vaccine (GnRH2-MAP) in achieving immunocastration in male Sprague-Dawley (SD) rats. It is hoped that the proposed method will resolve these issues in immunocastration vaccines.

2. Materials and methods

2.1. Vaccine formulation

GnRH2 peptide [20] and GnRH2-MAP were synthesized (Shanghai Shanjing Ltd., China). GnRH2 was modified to the eight-branched peptide system of MAP to produce GnRH2-MAP [21]. The purity of GnRH2 and GnRH2-MAP was found to be 95% by high-performance liquid chromatography. Oil adjuvant (30 ml, MONTANIDE™; Franch SEPPIC Company) and saline (30 ml) were combined using a stirring rod, beakers, for autoclaving. After low speed centrifugation, GnRH2-MAP and GnRH2 lyophilized powders (100 μg each) were dissolved in 7.5 ml saline, and then mixed with 7.5 ml oil adjuvant with the magnetic stirrer (X85-2S, Shanghai Chijiiu Company) at 800 rpm for 5 min.

2.2. Animals

Ninety healthy male SD rats (20 days of age) were used in this experiment. The animals were reared in a controlled temperature (22 °C) and light (12:12 h light:dark cycle) environment. Food and tap water were provided ad libitum. The study was approved by the Animal Care and Use Committee of Anhui Agricultural University. All experimental procedures involving rats were performed according to the Regulations for the Administration of Affairs Concerning Experimental Animals (Ministry of Science and Technology, China; revised in June 2004).

2.3. Experimental design and immunization

The rats were randomly allocated into one of the following three groups with 30 rats per group: GnRH2-MAP, GnRH2, and control groups. The immunized animals in the GnRH2-MAP and GnRH2 groups were treated with the novel GnRH2-MAP vaccine (100 μg/dose) or GnRH2 (100 μg/dose), respectively. The control group was injected with 0.5 mL oil adjuvant alone. The primary immunization was carried out at 0 weeks followed by two booster doses at 2-week intervals. All rats were administered 0.5 mL of the vaccine by subcutaneous injections on the back.

2.4. Collection and processing of samples

The rats were decapitated at 9:00–11:00 h and the blood samples (1.5–2.0 mL) were obtained without anticoagulant. The samples were incubated at 4 °C for 3 h, and centrifuged for 15 min at 2000 rpm to collect the serum, which was used to determine the T concentration and antibody titer by enzyme-linked immunosorbent assay (ELISA). After each blood collection, the rats ($n = 5$) were sacrificed by decapitation under intraperitoneal injection of 2% pentobarbital sodium. Paired testes were removed, their weights and axis lengths were measured, and data were recorded immediately. Then, the right testes were directly immersed into 4% v/v

paraformaldehyde at 4 °C for 12–24 h for subsequent histological analysis.

2.5. Histological analysis of the testes

The right testis sample was removed from paraformaldehyde, and the tissue was cut into flakes (thickness, about 5 μm) into the embedding box to water for the night. Testicular tissue was dehydrated using an ascending ethanol series (80%, 95%, and 100%), cleaned in xylene, embeded in paraffin wax, and stored at 4 °C. Then, 5-μm sections were obtained using a microtome (Shenyang Longshou Electronic Instrument limited computer, LS-2055+), and stained with hematoxylin and eosin (H-E). All sections were photographed with a microscope (Motic, Hong Kong, China).

2.6. Detection of antibody titer and T concentration

The serum antibody titer and T concentration in serum were determined by ELISA 2 weeks after sampling. The ELISA kit for antibody detection (Lianshuo, Shanghai, China) had a sensitivity of 1.0 mIU/ml, and the T kit (Yuanye, Shanghai, China) had a sensitivity of 0.1 nmol/L. Both kits were allowed to equilibrate for 20 min at room temperature. Then, 50 μl of standard substance was added to standard wells, and 50 μL of serum (1:50 dilution) was added to each of the sample wells almost simultaneously. Then, 100 μL of horseradish peroxidase (HRP)-conjugated anti-mouse IgG (IgG) solution was added to the standard and sample wells, and the plate was incubated for 1 h at 37 °C. After successive washing with PBS, 3,3,5,5-tetra-methyl-benzidene (TMB, A and B, 50 μL each) was added to react with the enzyme-antigen conjugate, and the mixture was incubated at 37 °C for 15 min. Finally, the reaction was terminated by adding 50 μL of H_2SO_4. The optical density was determined by measuring the absorbance at 450 nm using a microplate reader (BioTek, USA).

2.7. Measurements of the testicular volume, weight, and body weight

At each sampling timepoint, the animals (n = 5) were weighed immediately prior to death. After the rats were sacrificed, the abdominal skin was quickly cut to remove and weigh the left testis. The testicular volume was calculated after measuring the largest width (a) and length (b) of the testis according to formula $V = [4\pi (a/2)^2 (b/2)] /4$ [8].

2.8. Statistical analysis

Data were expressed as means ± standard error of the mean, and processed and analyzed using SPSS version 17.0. Data were analyzed by one-way analysis of variance. A p value of <0.05 was considered statistically significant.

3. Results

3.1. Individual reaction differences

The comprehensive antibody titer, T concentration, testis and body weights, and histological analysis of the rat tissue samples revealed no significant differences (non-effective individuals) in these two immunized groups compared with the control group (Table 1). Only one of five rats in weeks 6 and 10 in the GnRH2-MAP group, respectively. In the GnRH2 group, invalid immune rats did not appear two weeks after the second immunization, but this number increased after the third immunization.

Table 1
Non-effective individuals in the GnRH2-MAP- and GnRH2-immunized groups.

Time (wks)	GnRH2-MAP (n = 5)	GnRH2 (n = 5)
2W	0	1
4W	0	0
6W	1	2
8W	0	1
10W	1	1
12W	0	2

The time of the first vaccination was set to 0 weeks. Rats were immunized three times from 0 to 6 weeks with 2-week intervals. There were no significant differences ($P > 0.05$) in the GnRH antibody titer, T concentration, testis volume and histological features in the non-responsive immunization group between these three groups at this time point.

3.2. Serum antibody titer

Fig. 1 shows the serum antibody titer in the immunized, control, and non-effective male rats for 12 weeks after the first immunization. In the immunized groups, the antibody titer began to significantly increase two weeks after the first immunization ($P < 0.05$). It appeared to decrease slightly after the third immunization, after which it peaked at four weeks after the third injection. After the eighth week, the antibody titer in the GnRH2-MAP group first declined then showed a second increase at 12 weeks, but the antibody titer in the GnRH2 group maintained a downward trend.

Overall, the antibody titer was higher in the GnRH2-MAP group than in the GnRH2 group, and the difference was significant ($P < 0.05$) at 2, 4, 8, and 12 weeks after the first immunization. Moreover, there was no significant difference ($P > 0.05$) between the non-effective and control rats, except at the second immunization.

3.3. Serum T concentration

The serum T concentration in the immunized, control, and non-effective rats were determined for 12 weeks after the first immunization (Fig. 2). There were significant differences ($P < 0.05$) from the second immunization onwards between the immunized and control groups, and the GnRH2-MAP group had an obviously lower T concentration than the GnRH2 group. Both immunized groups exhibited the lowest T concentration at week 12. In the GnRH2 group, T concentration was maintained at a low level but showed

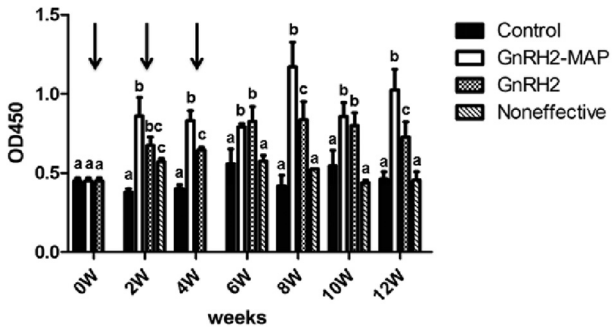

Fig. 1. High antibody titers in the serum of male rats immunized with GnRH2-MAP or GnRH from 0 to 12 weeks with 2-week intervals. Compared with the control group (n = 30), the GnRH vaccinated group (n = 30) showed a significantly high titer ($P < 0.05$) at two weeks after the first immunization, and the antibody titer was higher in the GnRH2-MAP group than in the GnRH2 group. Values are presented as mean ± standard deviation and show the absorbance at 450 nm for 1:500 dilution of sera. Arrows indicate the times of immunization. Significantly different from control * $P < 0.05$; ** $P < 0.01$.

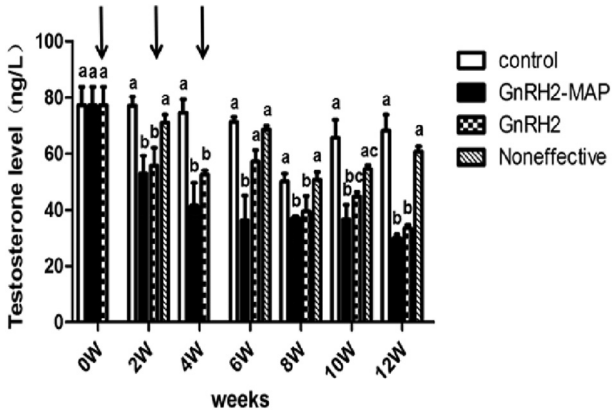

Fig. 2. Observation of the serum testosterone concentration in male SD rats immunized with GnRH2-MAP or GnRH at 2-week time intervals. In comparison with control group, the GnRH2-MAP (n = 30) and GnRH2 (n = 30) groups presented significantly lower testosterone concentrations ($P < 0.05$) from the second week after the first immunization. Values are presented as means ± standard deviation and show the absorbance at 450 nm for 1:500 dilution of sera. Arrows indicated the time of immunization. Significantly different from control * $P < 0.05$; ** $P < 0.01$.

increases at 2 and 6 weeks after the third immunization. At the same time, the T concentration between the immunized groups showed a significant difference ($P < 0.05$). Moreover, there was a slight but not obvious decrease in the non-effective group relative to the control group.

3.4. Body weight

After the first immunization, no significant difference was found in body weight between the GnRH2-MAP group, the GnRH2 group, the non-effective group and the control group ($P > 0.05$) (Table 2), which means that the vaccine does not affect the growth of rats.

3.5. Testicular weight and volume

Testicular weight was determined for 12 weeks from the first immunization (Table 3). The testis weight was significantly lower ($P < 0.05$) in the GnRH2-MAP group than in the control group, and this difference was significant at 4 and 8 weeks. Significant differences between the immunized groups only appeared at 6 and 10 weeks (Table 4). After the first immunization, the significant difference in testicular volume between groups was also reflected by the significant difference in testis weights, which can be seen in Fig. 3.

3.6. Histological observation of the testes

Fig. 4 shows the results of the histological analysis of the right

Table 2
Body weight (g) of male rats immunized with GnRH2-MAP and GnRH2 vaccine compared with the control group.

Fig. 3. Testicular size in the GnRH2-MAP, GnRH2, and control groups. Testicular photographs of the immunized and control groups. Compared to the control group, the testes of rats in the GnRH2-MAP and GnRH2 groups were sharply atrophied, and the degree of atrophy was more significant in the GnRH2-MAP group ($P < 0.05$).

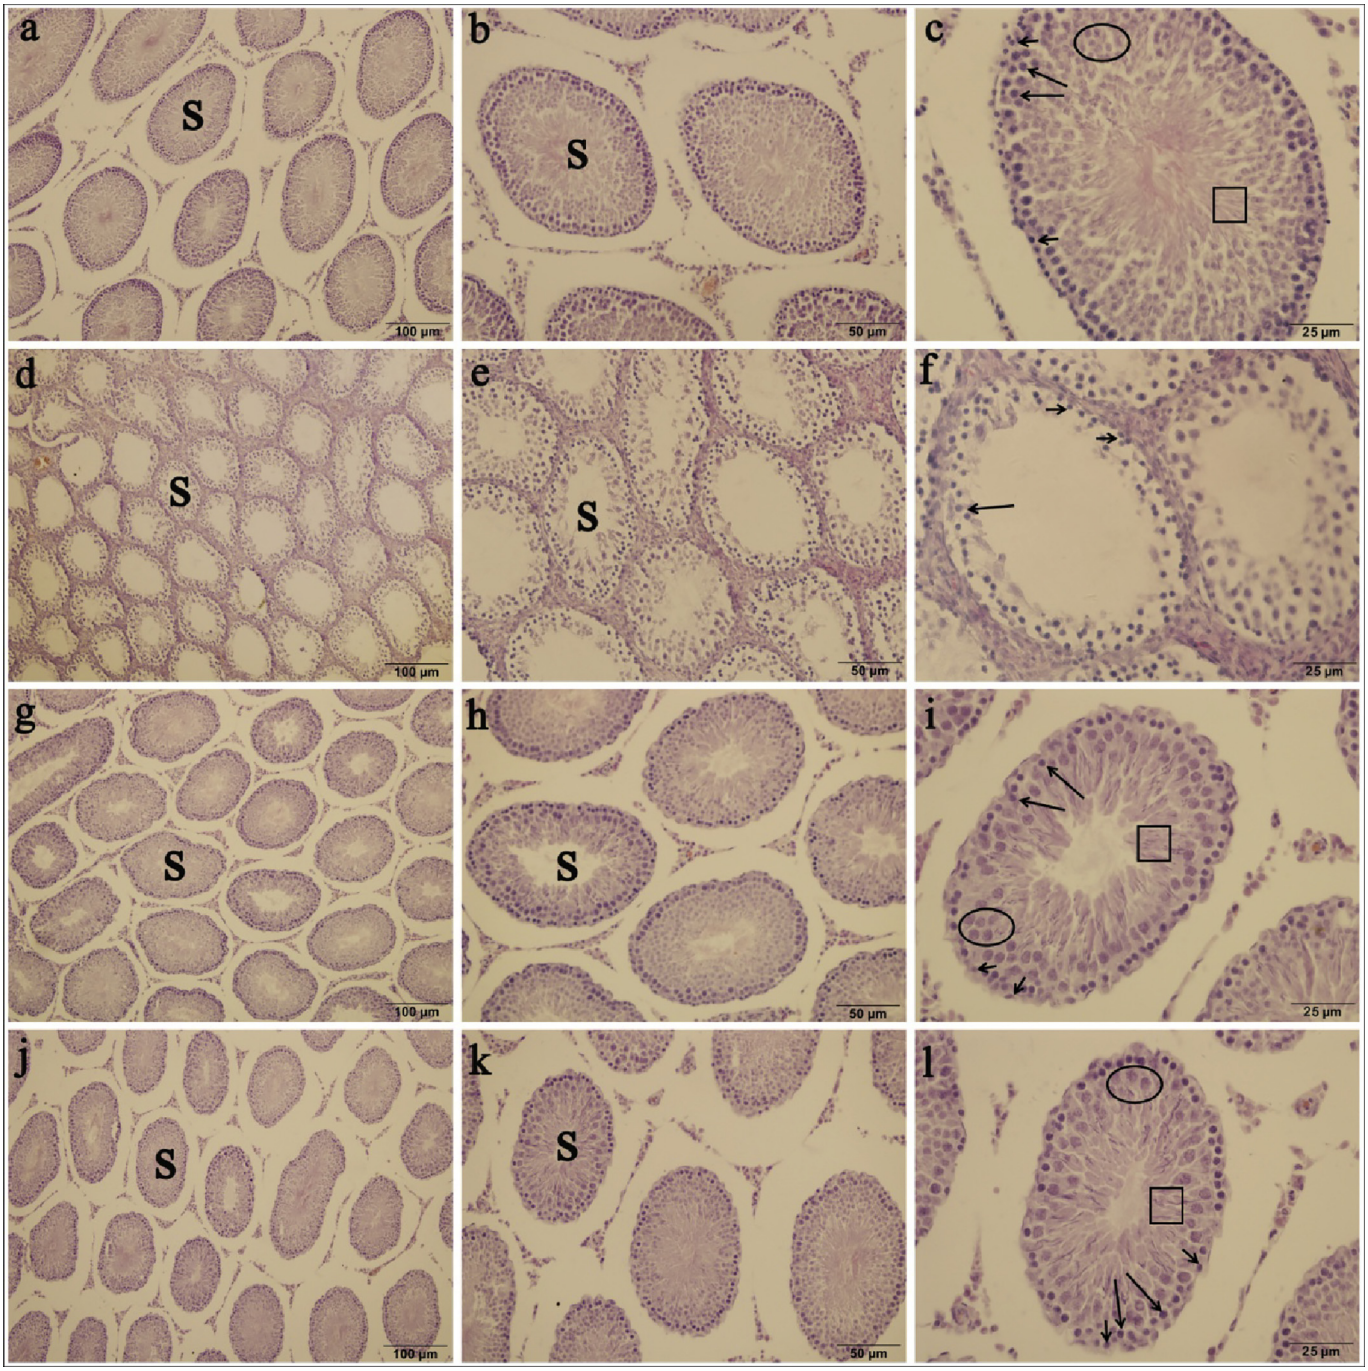

Fig. 4. Microscopic observation of tissue sections in the GnRH2-MAP, GnRH2, and control groups. Testicular tissue of rats in the control group (a, b, c), GnRH2-MAP group (d, e, f), GnRH2 group (g, h, i), and non-effective group (j, k, l). Seminiferous tubules (S) contain spermatogonia (short arrows), primary spermatocytes (long arrows), spermatid (ellipses), and spermatozoa (squares). Note: (a, d, g, and j) scale bar = 100 μm; (b, e, h and k) scale bar = 50 μm; (c, f, I, and l) scale bar = 25 μm. Testicular tissues were stained by hematoxylin and eosin.

testes. The seminiferous tubules in the control group (Fig. 4a, b, and c) were normal and exhibited a large number of spermatozoa in the lumen, with a close arrangement of spermatogonial cells, spermatocytes, and sperm cells. The number of spermatogonia, spermatocytes, and sperm cells in the germinal epithelium was significantly reduced in the GnRH2-MAP group, and there were almost no sperm in the lumen (Fig. 4d, e, and f). In the GnRH2 group, the seminiferous tubules of the testes were normal, with closely arranged spermatogonial cells, spermatocytes, and sperm cells. However, there were relatively fewer spermatozoa in the lumen (Fig. 4g, h, and i). There were no differences in testicular morphology between the non-effective (Fig. 4j, k, and l) and control (Fig. 4a, b, and c) groups; moreover, in the non-effective group, the seminiferous tubules were normal, with closely arranged spermatogonia, spermatocytes, and sperm cells and a large number of sperm in the lumen. Ten seminiferous tubules were randomly selected from each group to analyze the number of spermatogonia, primary spermatocytes, and spermatozoa. We found that the spermatogonia, primary spermatocytes, and sperm cells were significantly lower in the GnRH2-MAP and GnRH2 groups than in

Table 5
Number of spermatogonia, primary spermatocytes, sperm cells and spermatozoa in testicular seminiferous tubules in the GnRH2-MAP, GnRH, and control groups.

Group	GnRH2-MAP (n = 5)	GnRH2 (n = 5)	Non-effective (n = 5)	Control (n = 5)
Spermatogonia	54.30 ± 6.077^{a}	41.444 ± 6.333^{a}	88.80 ± 3.841^{b}	79.70 ± 2.951^{b}
Primary spermatocytes	57.90 ± 3.737^{a}	63.888 ± 6.886^{a}	88.10 ± 1.251^{b}	84.00 ± 2.304^{b}
Sperm cells	86.70 ± 3.422^{a}	88.90 ± 5.20^{a}	223.70 ± 15.56^{b}	207.70 ± 11.65^{b}
Sperm	0.00^{a}	31.698 ± 5.075^{b}	137.50 ± 5.335^{c}	122.00 ± 4.784^{c}

Rats were treated thrice from 0 to 6 weeks with 2-week intervals. All data are presented as the means ± standard deviation. Different superscript letters in the row indicate significant differences between the two groups ($P < 0.05$).

the control group ($P < 0.05$). No spermatozoa were present in the seminiferous tubules of GnRH2-MAP group, and there were significantly fewer spermatozoa in the GnRH2 group than in the control group ($P < 0.05$). There were no significant differences in the numbers of spermatozoa between the non-effective and control groups ($P > 0.05$; Table 5)

4. Discussion

The most commonly used immunocastration vaccine is the GnRH vaccine, which contains synthetic peptides. However, the restrictions on the commercial promotion of this vaccine could be attributed to its low binding rate, low purity, and the differences in quality between batches, which could not ensure a consistent castration effect [22]. Moreover, while some current vaccines are effective in some animals, the higher cost associated with these vaccines is one of the biggest factors limiting vaccine development [8]. Here, we aimed to overcome some of these shortcomings using GnRH2 linked to MAP, i.e., GnRH2-MAP. Three aspects of this novel vaccine enhance immunogencity. One, GnRH2 is synthesized by two GnRH monomers whose structure is modified by replacing the sixth position of Gly with D-type Lys [20]. Second, the amino terminal of one GnRH monomer is linked to the carboxyl terminal of another monomer, which has been reported to be an effective method to enhance vaccine immunogenicity [6]. Third, MAP has eight branches with a Lys core and four Lys terminals. Based on the special structure of MAP, peptides or proteins can be randomly linked to it to increase the molecular weight of the antigen. Increasing the molecular weight of the antigen is well known to induce a higher immunogencity. In our study, we found that the binding rate and the novel antigen purity were higher than those of the former vaccine; this could be attributed to the homology of MAP and endogenous GnRH [18]. Comprehensive analysis of antibody concentration, testosterone concentration, testicular parameters, and histological features revealed that the GnRH2-MAP vaccine may be an effective alternative vaccine for use in immunocastration. Individual differences following administration of the immunocastration vaccine is observed in most studies. Although we ensured consistency in breed, age, weight, genetic background, and health status; immunization program; and feeding environment, some experimental differences were shown significantly in some of these animals [23]. In our study, the testes of two rats in the GnRH2-MAP group developed normally, and their serum antibody and T levels did not differ from those in the control group; similarly, 9 such cases appeared in the GnRH2 group. After GnRH active immunization, the immune “escape” phenomenon was observed in rats [39], pigs [40] and some other animals. The testosterone concentration and testicle size decreased only slightly after immunization with GnRH, but the values were not significantly different from those of the control group. Some studies suggest that the weaker antibody response after GnRH immunization is responsible for the “escape reaction” in animals. Because of the effective antibody response after active GnRH immunization, the anti-GnRH antibodies produced are the key to successful castration. In the present study, testosterone decline occurred after active immunization in the GnRH2-MAP group, while the testosterone level in non-responsive rats was not significantly changed. Robbins et al. [41] immunized cats with a recombinant fusion protein of GnRH and found that the testosterone level in immunized cats was maintained at the same level as in the surgically castrated group when the serum GnRH antibody titers reached the threshold of 30% of the binding rate. This suggests that the serum anti-GnRH antibody level after GnRH active immunization needs to reach a certain threshold to inhibit reproductive function in animals. It is also possible that a small amount of gonadal hormones still exist in GnRH2-MAP rats. In addition, it may also be related to individual differences between rats with regard to the absorption and distribution of the vaccine. Thus, further studies are required to explore the cause of these individual differences.

In our study, GnRH2-MAP induced high anti-GnRH antibody titers in male rats from the first immunization to week 12, and most related studies have consistent results about antibody titer. Our study showed that the antibody peak appeared four weeks after the third immunization, but Balet et al. [24] found that the peak appeared two weeks after the second immunization in dairy cattle, which is consistent with the result of Janett et al. in bulls [25]. This difference may be because antigen sensitivity differs in different species or animals [26,27]. Moreover, different type of antigens are used in experiments, and there is a natural difference in the degree and effect of the immune antibody response [28,29]. The antibody concentration was maintained at a high concentration after the second dose of immunization until the end of the 12-week experiment. Similarly, the GnRH2 group also exhibited similar results, but the antibody titer of the novel vaccine was lower than that of the GnRH2 vaccine, causing its weak immunogenicity. Moreover, factors underlying the maintenance of a high antibody response time also need further study.

The reduction in the serum T concentration of immunized male SD rats reflects inhibition of testicular function. This result is also discussed in previous papers [1,30]. In this experiment, we found that the serum T concentration decreased again at 12 weeks after maintaining a low level after the third immunization, which was consistent with the secondary increase in the antibody concentrations at 12 weeks. We speculated that antigen was released slowly, causing enfolded by the oil adjuvant, which increased the amount of antigen release after three immunizations. When the antigen enters body several times, the corresponding antigen levels in the body will rise, resulting in the simultaneous production of a large number of memory cells. Furthermore, the serum T concentration decreased significantly after the first immunization, and maintained a low stable level after the third injection. This may be due to the decrease in the LH and FSH levels in the pituitary. Without stimulation from LH and FSH, testicular degradation occurs due to the low concentrations of T secreted by Leydig cells, and it may partly disrupt testicular secretion [25,31]. According to a recent study, in bulls immunized with Improvac W at two weeks

after the second immunization, the serum T concentration reached a low level at 22 weeks, which was maintained [25]. This result was further demonstrated in the same year, when Bopriva-immunized bulls also produced a T minimum peak two weeks after the second immunization [32]. In contrast, our T peak appeared in the last week, which may be due to species differences [23,33].

Active immunization using a GnRH vaccine causes the testes to shrink, indicating the castration effect of this antigen. Studies have indicated that the thickness of the spermatogenic epithelium, the cytoplasmic content of testicular stromal cells, and testicular weight were significantly related [34]. Previous studies have found a close association between testis weight and serum T concentration [35]. Contrary to these reports, we found that the T concentration decreased at 12 weeks after the first immunization, but testicular weight increased. Therefore, the relationship between serum T concentration and testicular weight seems to be unclear, and the differences between studies may be attributable to differences in species, immunogenicity of the vaccine, or other reasons. Our study suggested that testicular weight and volume changes are consistent, which was in accordance with previous study findings [36]. Our result showed that GnRH2-MAP caused testicular atrophy. The volume reduction is natural, and is based on the temporary reduction or disappearance of testicular materials. The phenomenon of testicular function returning to normal was detected in previous studies [34,35,37].

Histological observation of the testis revealed that sperm production was significantly affected. In the later period following immunization, no sperm could be detected in the lumens of seminiferous tubules. Although spermatogonial cells could be detected, they presented an irregular arrangement. Moreover, spermatids and sperms present in the lumen of seminiferous tubules were almost undetectable. This finding was consistent with the testis weight, as the reduced volume of the testis may be the primary reason for this observed decline in the number of sperm cells and spermatozoa. Similarly, a previous study in dogs administered GnRH-I also reported that spermatogenesis was inhibited, with no sperm detected in the epididymis [38].

In this study, we administered our novel vaccine GnRH2-MAP to male SD rats and studied its effects. However, due to several volatile factors such as species, vaccine dose, time intervals between vaccine doses, and types and doses of adjuvants used, further studies are required to determine the actual castration effect of this vaccine in rats.

5. Conclusion

In conclusion, active immunization usingGnRH2-MAP elicited a significantly high antibody titer, which interfered with the HPG axis, thereby inhibiting testicular function. This finding suggested that GnRH2-MAP can induce a significant castration effect. Therefore, GnRH2-MAP may be an alternative and commercial castration vaccine in animals. However, future experiments are warranted to identify the best dose, procedure of immunization, and the adjuvant types.

Declaration of interest

The authors declare that there is no conflict of interest.

The time of the first dose of vaccination was set to 0 weeks. Rats were immunized three times from 0 to 6 weeks with 2-week intervals. All data are presented as the mean ± standard deviation values. No significant differences were found between the groups ($P > 0.05$). - indicated no data available (because the number of non-effective rats was 0).

WILDLIFE FERTILITY CONTROL: FACT & FANCY

A Publication of the Science and Conservation Center at ZooMontana

INTRODUCTION

One of the major efforts of the Science and Conservation Center at ZooMontana involves the humane control of wildlife populations by means of fertility control. To that end, the Science and Conservation Center was created in 1998, an independent non-profit organization that is the world's only dedicated facility for the development of wildlife contraceptives and methods of application. This Center produces and carries out quality control for a wildlife contraceptive vaccine, distributes the vaccine and is the repository for all records and data required by the Food and Drug Administration and Environmental Protection Agency. Additionally, the Center and its staff coordinate and in some cases carry out field-based application of contraception to wildlife populations.

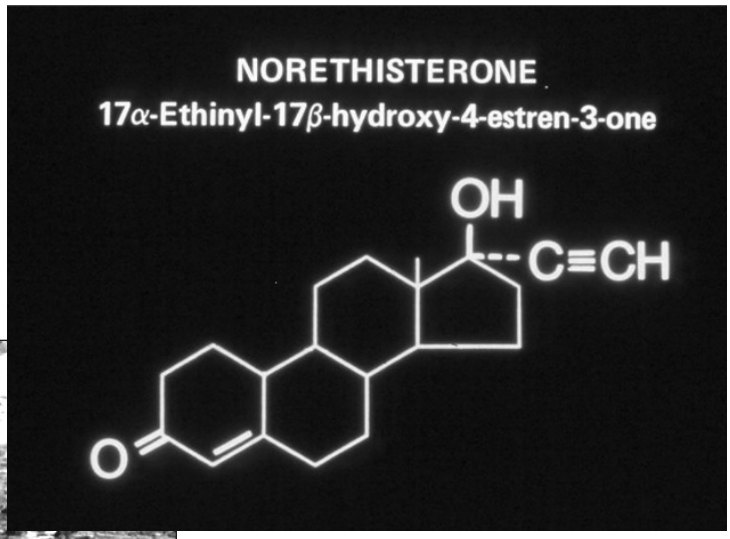
The Center receives many inquiries from around the world regarding wildlife contraception, an arcane subject that can be complicated and confusing. These inquiries center about many different species, diverse challenges, and a variety of settings, and those inquiring have a wide breadth of understanding about the subject - from very little to quite a lot. To complicate matters, there is a great deal of controversy regarding this subject, some based in misunderstanding of facts and some based in social, cultural, political or economic objections to this approach to wildlife management. To facilitate the educational process, The Science and Conservation Center, has published this overview, with the intent of providing a realistic picture of the state of the art of wildlife fertility control. To be sure, the complexity of the subject greatly exceeds the possibility of a comprehensive discussion here, but this publication can acquaint the reader with the basics necessary to develop a realistic picture, and the bibliography can lead the interested reader to a wealth of more detailed information.

The Science and Conservation Center at ZooMontana is where contraceptive vaccine is produced.

WHY FERTILITY CONTROL?

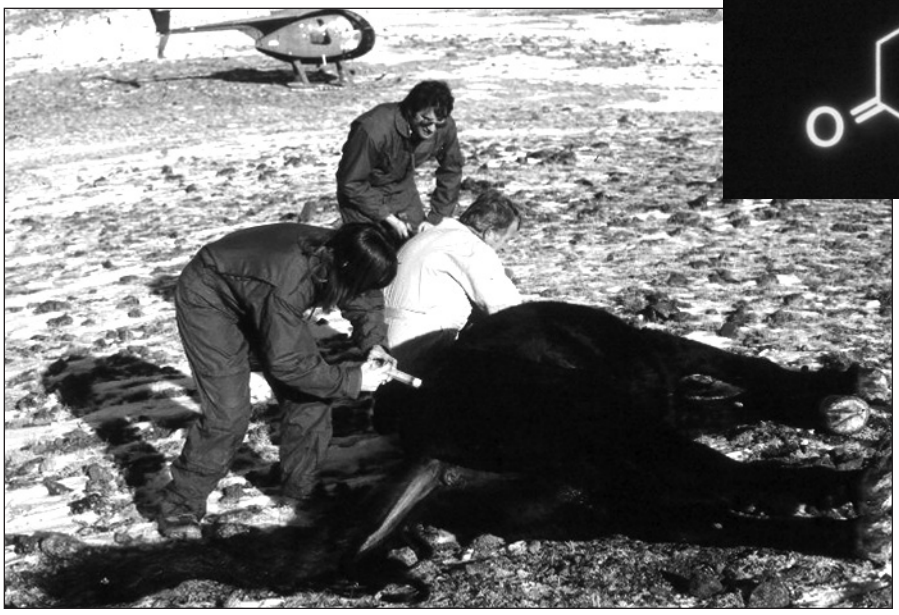
At earlier times in history wildlife populations were controlled by two natural processes. These included mortality control and fertility control. When animal populations exceed the carrying capacity of their environment, animals die from starvation and disease as well as predation. At the same time, high densities among wildlife populations lead to a decrease in reproductive success; animals delay the age at which they will first breed, they produce fewer offspring, and juvenile mortality rates increase.

Urbanization and modern agricultural development led to the reduction of predators, and regulated hunting and trapping soon replaced predators as population control devices. Dwindling wildlife resources and loss of habitat led to the creation of reserves, parks, and special legislation that protect certain species from traditional lethal controls. Examples might include wild horses protected by the Wild Free-Roaming Horse and Burro Act or elk, or elephants living in national parks where large predators no longer exist, or even zoological gardens, where unregulated reproduction can lead to "surplus" animals and massive ethical problems associated with the disposition of these excess animals.



Humans have chosen to impose artificial human-induced mortality control on wild populations, through regulated hunting, trapping, and poisoning, and this is accepted as "normal" human activity. In many areas of the world, and with many species, traditional human-induced mortality control will continue to be the primary management tool. In recent history, however, increasing urbanization, the withdrawal of private lands from the public hunting domain, regulatory prohibitions on the use of poisons, legislation against trapping, low fur prices and, most important, changing public attitudes about lethal wildlife control methods have reduced the effectiveness of human-induced mortality control as a management tool for many species. Thus, we now face exploding populations of some adaptable or highly protected species but without adequate management tools with which to protect environment and animals alike.

The use of human-imposed fertility control however, is still often viewed as "bizarre" or "unnatural", and the reasons for this view are not understood. It may have something to do with the simplicity or relatively lower cost of mortality control, or something as simple as a cultural mindset. Regardless of the answer to this question, we are rapidly facing a point in time when safe, humane and publicly acceptable wildlife management paradigms are beginning to replace lethal methods. The public demands it and the animals we have displaced deserve it.



The scientific community is also responding to this need, and thus far, six international conferences on wildlife fertility control have been held around the world, and public acceptance has followed suit.

A BRIEF HISTORY OF WILDLIFE FERTILITY CONTROL

The concept of wildlife fertility control is not new and research has been carried out for many years. Most of this work was based on the fruits of human contraceptive research and therefore mirrored human contraceptive technologies. This in turn meant that until recently, the most common approach to wildlife contraception was through the use of steroid hormones, and particularly natural and synthetic estrogens, progestins, and androgens, similar to those found or used in human contraception. Zoos really led the way, administering these compounds to captive animals, where delivery was not an issue, but their use in free-roaming wildlife was another matter. These compounds often worked in a pharmacological sense but they fell far short of the standards that permit them to be used with free-roaming wildlife. Basically, they failed because (1) they had to be given in extremely large quantities, ruling out remote delivery, (2) they had to be administered too often, (3) they caused a variety of pathologies in treated animals, (4) the cost was relatively high, (5) they often had profound effects upon social behaviors, (6) they were often unsafe to administer to pregnant animals, and (7) they passed through the food chain to predators - human and otherwise - and scavengers. Because of these shortcomings, there was little hope that they would ever be publicly acceptable for use in free-roaming wildlife by regulatory agencies. For more extensive reading on the history of wildlife contraception we suggest Kirkpatrick and Turner 1991, (referenced in the Bibliography).

Steroids, similar to Northisterone, often change behaviors and they can pass through the food chain.

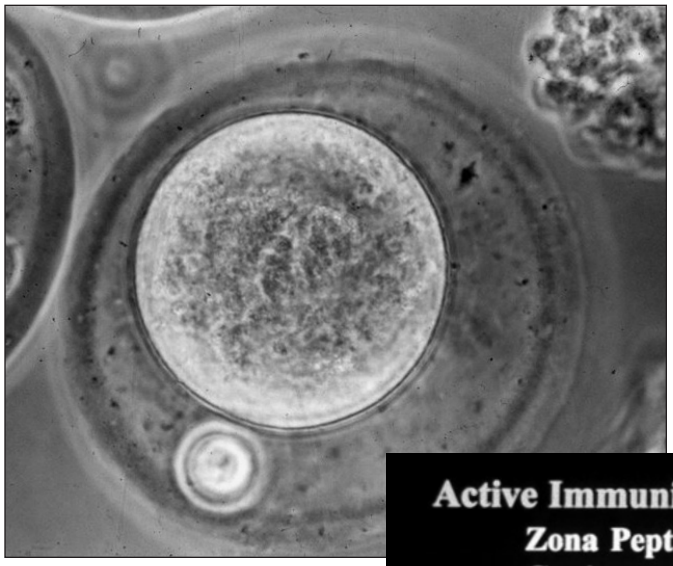
Steroid hormones have to be given in such large amounts that the animals hae to undergo stressful capture procedures, such as this wild stallion receiving a hormone injection.

CHARACTERISTICS OF THE IDEAL WILDLIFE CONTRACEPTIVE

The failure to achieve practical results with steroid hormones led to a re-examination of the problem. It became apparent by the early 1990s that research was proceeding without a "gold standard" by which to evaluate each new approach. Without such a standard evaluation of potential wildlife fertility control methods could be likened to a discussion of law without a constitution. Thus, a theoretical "standard" was created and included:

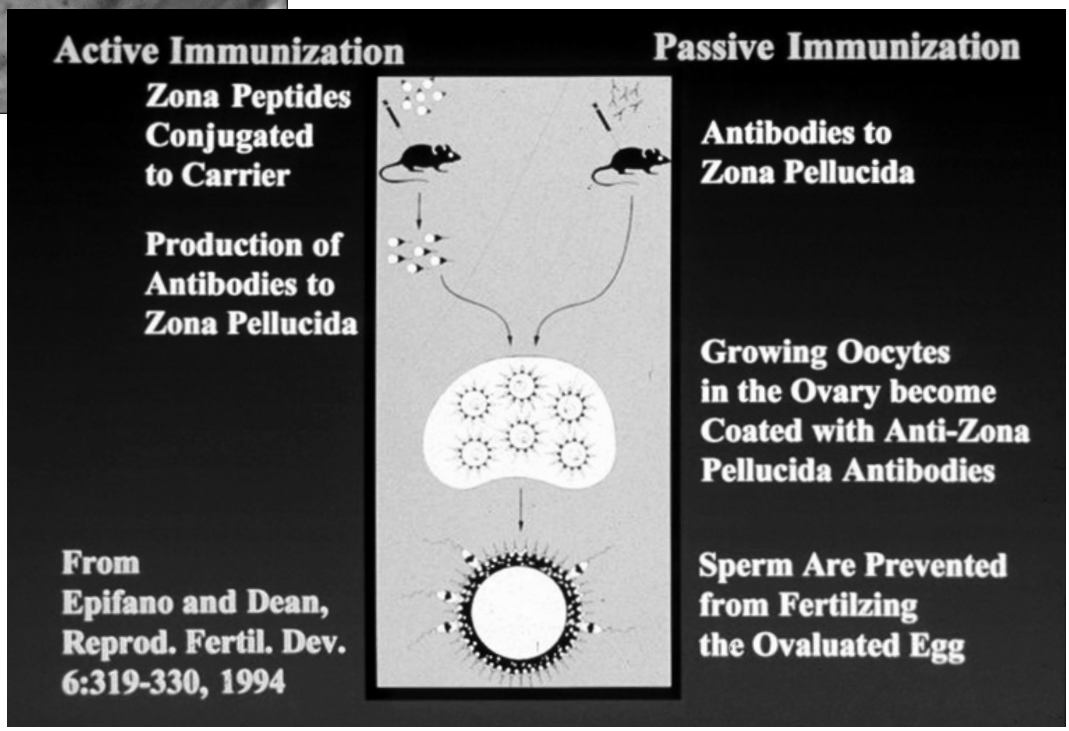
1. Contraceptive effectiveness of at least 90%.
2. The ability for remote delivery, with no handling of animals.
3. Reversibility of contraceptive effects (more important for some species than others).
4. Safety for use in pregnant animals.
5. Absence of significant health side effects, short- or long-term.
6. No passage of the contraceptive agent through the food chain.
7. Minimal effects upon individual and social behaviors.
8. Low cost.

While some of these standards are more or less arbitrary, they at least provided reasonable guidelines and any future discussions of new wildlife contraceptive agents or discussions of current agents should attend to these characteristics (see Kirkpatrick and Turner 1991).



IMMUNOCONTRACEPTION

In 1988, a new approach to wildlife contraception was launched. Immunocontraception is based on the same principles as disease prevention, through vaccination. We vaccinate ourselves and other animals against diseases by injecting dead or attenuated (weakened) disease bacteria or viruses, or with molecules that are harmless but similar to the toxins that these disease organisms produce. Our immune systems produce antibodies that attack the material we injected and any similar organism or their toxins in our systems. An immunocontraceptive vaccine works in much the same way, only it causes the production of antibodies against some essential event or structure in the reproductive process. There are a variety of immunocontraceptive vaccines under development or already registered, including vaccines against brain reproductive hormones such as gonadotropin-releasing hormone (GnRH) and vaccines against the sperm and the egg, which in turn prevent fertilization. The advantages of vaccines are that they can be delivered remotely in very small doses, and because they are primarily protein, they are readily destroyed in digestion and cannot pass through the food chain. The vaccine which thus far has had the largest application to wildlife is the Porcine Zona Pellucida, or PZP vaccine.



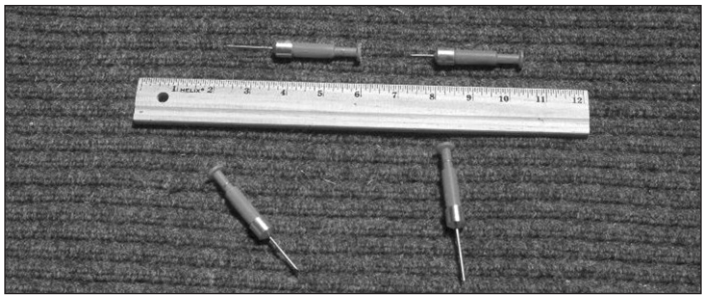
PORCINE ZONA PELLUCIDA VACCINE

What is PZP and How Does It Work?: A non-cellular membrane known as the zona pellucida (ZP) surrounds all mammalian eggs. The ZP consists of several glycoproteins (proteins with some carbohydrate attached), one of which, ZP3, is thought to be the sperm receptor (the molecule which permits attachment of the sperm to the egg during the process of fertilization). The PZP vaccine is derived from the ZP protein from pig eggs. When this vaccine is injected into the muscle of the target female animal, it stimulates her immune system to produce antibodies against the vaccine. These antibodies also attach to the sperm receptors on the ZP of the female's own eggs and distort their shape, thereby blocking fertilization (see Paterson and Aitkin 1990).

Thus far PZP has been a successful form of contraception in wildlife because (1) it has prevented pregnancy an average of 90% or greater of the time in treated animals, (2) it can be delivered remotely by small darts, (3) the contraceptive effects are reversible, (4) it is effective across many species, (5) there are no debilitating health side-effects even after long-term use, (6) it has almost no effects on social behaviors, (7) the vaccine cannot pass through the food chain, and (8) it is safe to give to pregnant animals (see Kirkpatrick et al. 2009).

A mammalian egg showing the dark non-cellular zona pelucida membrane, which is the site of sperm attachment.

The mechanism of action of the PSP contraceptive vaccine. The mechanism on the left-active immunization is the precise mechanism used in wildlife contraception.



How is the Vaccine Delivered?: The PZP vaccine must be injected into the muscle of the target animal. This can be done by hand if the animal is restrained, or by dart, for remote delivery. There are many commercial dart systems available but the thick viscosity of the vaccine requires a large needle and a quick injection. Thus far, Pneu-Dart® systems (Williamsport, PA) work the best. The Pneu-Dart® 1.0 cc barbless darts can be fired from Pneu-Dart® capture guns or from several other commercial dart guns (Dan-Inject®, for example). The darts are disposable, and after hitting the animal in the rump or hip (the only acceptable location for darting) they inject by means of a small powder charge and pop out. Because of their bright colors the darts are usually retrieved in the field. Unrecovered darts cannot be discharged by stepping on them nor by any other kind of casual contact. Over a 20 year period on Fire Island, Assateague Island, and Cape Lookout National Seashores, and more than 2,000 treatments of deer and horses, 98% of darts have been recovered.

Normally, each animal is darted twice the first year, with the first injection being given up to a year before a booster, just preceding the breeding season (March for wild horses or September for deer). Thereafter, a single annual booster inoculation will maintain contraception (Kirkpatrick et al. 1991). The second inoculation of the first year requires (1) that you are able to recognize the individual animals, or (2) that you do the first inoculation with a special "marker dart" which leaves a dye mark on the animal at the same time it injects the vaccine, or (3) that animals are treated opportunistically and randomly, with the hope of eventually treating a large proportion of the total population over the course of several years.

An alternative strategy is to give only a single inoculation the first year, from which there will be little contraception, and then a single annual inoculation thereafter, from which there will be significant contraception (see McShea et al. 1997).

Different dart delivery systems for the PZP contraceptive vaccine. From top to bottom: Pneu-Dart® X-Caliber CO_2 Rifle, Dan-Inject CO_2 Rifle, Pneu-Dart® Cartridge Rifle, Dan-Inject® Pistol Grip Blowgun.

Pneu-Dart® disposable self-injecting darts of the type used for delivering the PZP vaccine.

APPLICATION OF PZP TO WILDLIFE

Wild Horses: The vaccine has been used successfully to manage the wild horse population of Assateague Island National Seashore under the authority of the National Park Service (NPS). This population has been treated since 1988 without health problems, and the population has decreased more than 30% since management-level application began in 1995. Wild horses are also being treated on Cape Lookout National Seashore for the NPS, on Carrot Island, for the Rachel Carson National Estuarine Reserve, and on Corolla Island, both in NC, the Pryor Mountain and Little Book Cliff National Wild Horse Ranges, MT and CO, respectively, the McCullough Peaks wild horse range in WY, on many areas of Nevada, Utah, Oregon for the Bureau of Land Management (BLM), on the Carson National Forest, for the National Forest Service, on several wild horse sanctuaries, and on the Navaho and Pima/Maricopa Indian Reservations in NM and AZ. In addition to controlling the horse population on Assateague Island, treatment has extended the lives and improved the health condition of older mares, by removing the stresses of pregnancy and lactation (see Kirkpatrick and Turner 2002; Kirkpatrick et al. 1990, 1991; Liu et al. 1989; Turner and Kirkpatrick 2002; 2003, 2007, 2008).

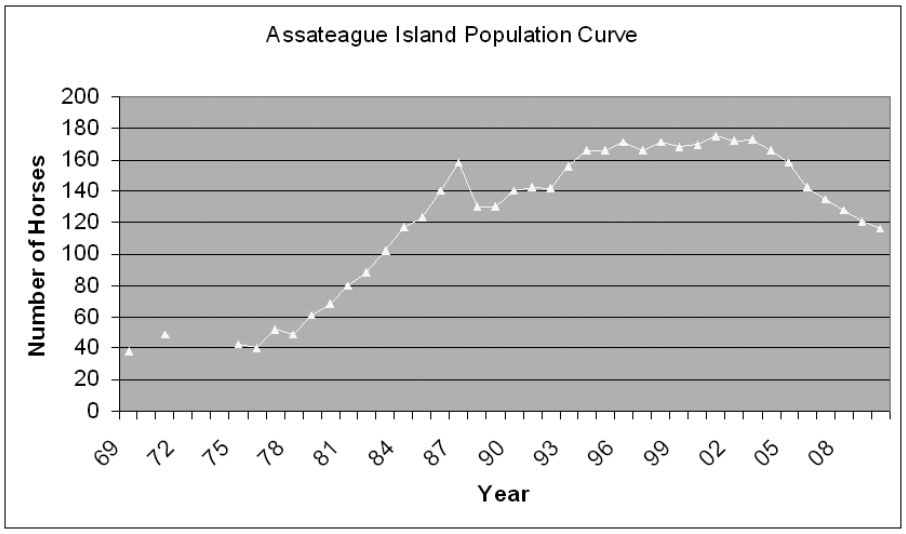
Zoo Animals: In order to prevent the production of "surplus" animals, zoo animals in more than 120 zoos have been successfully treated with PZP. Thus far PZP has shown contraceptive effects in more than 80 species. In all probability, PZP will prove to be a successful contraceptive for all ungulates (hoofed animals), but it also works in bears, pinnipeds (seals and sea lions) and elephants. We do note differences between species in the timing of the booster inoculations. Porcine Zona Pellucida vaccine is now a standard recommendation for many species by the Contraceptive Advisory Group of the Association of Zoos and Aquariums (AZA). The obvious advantage of the PZP vaccine for zoo animals is that it can be administered without the stresses of restraint (see Kirkpatrick et al. 1992b, 1995b; Deigert et al. 2003; Frank et al. 2005; Asa and Porton 2005).

Deer: The PZP vaccine was shown to block pregnancies in captive white-tailed deer as early as 1990. Since that time, numerous projects have been mounted with free-roaming deer in MD, NJ, NY, CT, WA, VA and OH. The two largest projects are on Fire Island National Seashore (FINS), NY, where approximately 215 deer are treated annually since 1993, and on the campus of the National Institute of Standards and Technology (NIST), in MD, where more than 150 deer have been treated since 1996. In both these programs the deer population has been decreased significantly. The studies and projects thus far have shown that contraception with PZP will often extend the breeding season of the female by one to two months, but that the energy cost is far less than that of getting pregnant and nursing. Although they will often follow the treated female deer, males do not carry on fights or expend additional energy beyond the normal breeding season (see McShea et al. 1997; Naugle et al. 2002; Turner et al. 1992, 1995; Rutberg and Naugle 2008).

African Elephants: In order to eliminate the need to legally kill elephants in African national parks to prevent rapid population increases, the PZP vaccine has been tested in African elephants in The Kruger National Park in South Africa. The vaccine was very successful and the results paralleled those of horse contraception. One of the most important findings was that the vaccine caused no changes in the social behaviors of family groups or harassment of cycling females by bulls. As a result of the Kruger Park studies, at least eleven game parks throughout South Africa are now using PZP to control elephant populations, rather than culling them. Growth rates have been reduced to almost zero. Demand for vaccine for elephant contraception grew so rapidly, that in 2003 the SCC trained an African team to make the vaccine in South Africa (Fayrer-Hosken et al. 2001; Delsink 2006, 2007).

Other Species: The PZP vaccine has also been used successfully in feral water buffalo inhabiting the U.S. Naval Base in Guam, feral burros in Virgin Islands National Park (Turner et al. 1996), Elk on Point Reyes National Seashore (CA) (Shideler et al. 2002), and more recently, bison on Catalina Island (CA).

Training: The SCC conducts training programs for personnel from NGOs and government agencies, for the proper use of PZP in wildlife. Examples of agencies participating in these training programs include the Bureau of Land Management, Biological Resources Division of USGA, US Fish and Wildlife Service, U.S. Navy, and the National Park Service.



An African Elephant being darted with PZP Vaccine

REGULATORY ISSUES

One of the most poorly understood dimensions of wildlife contraception is the regulatory process. Depending upon the species in question, one or more agencies, local, state and federal may be involved, and the agencies involved have changed over time. A brief description of the process and regulations follows:

Federal Regulation. Since the mid-1990's, all SCC projects in which the vaccine crossed state lines have been reported to the U. S. Food and Drug Administration (FDA). These projects have been carried out under the authority of two separate Investigational New Animal Drug documents (INADs) issued by the FDA to The Humane Society of the United States (HSUS). One of these INAD's covers wild horses, the other covers deer and zoo animals. For each project, the SCC files a form with the FDA specifying how much vaccine is being shipped and what species are to be treated. The INAD also requires that a detailed research protocol be filed for each project, data from each project be gathered in a systematic way and filed, and data made available to the FDA when the need arises. These files are maintained at the Center.

In about 2005, however, FDA began to transfer authority over most applications of wildlife contraceptives (other than zoo animals, which remain with FDA) to the Environmental Protection Agency (EPA) under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). This includes wild horses, deer, geese, and other wildlife that is "capable of doing environmental damage." The EPA approval process follows that agency's registration requirements for pesticides. (The language of "environmental damage" and

Changes in Assateague Island wild horse population as a result of immunocontraception. (Management begins in 1995.)

"pesticide" is in many ways regrettable, but is forced by the language of FIFRA.) At this writing, EPA has registered two wildlife contraceptives, OvoControl® (a nicarbazine-based oral contraceptive for geese and pigeons) and GonaCon® (a GnRH-based injectable immunocontraceptive for deer). HSUS has also applied to EPA for registration of PZP for use on wild horses.

Under EPA regulations, users of registered contraceptives must follow the directions on the label, which may include requirements for certification of applicators, target species, and methods, times, and place of application. Unlike FDA-approved drugs, which may be prescribed by physicians or veterinarians for purposes other than those described on the label, there is no such thing as "off-label use" for EPA-registered contraceptives. In addition, an EPA-registered contraceptive must generally be registered in the states in which it is being applied.

Aside from meeting FDA requirements, the Animal Care Committee of each zoo must also provide permission to treat zoo animals. The federal Animal Welfare Act also requires that experimental applications of PZP to free-ranging wildlife be reviewed and authorized by the Institutional Animal Care and Use Committee of a university or responsible agency.

Wild Horses. Contraceptives can only be applied with the permission of and/or under the supervision of the legal owners or managers of the horses (including government agencies such as the NPS, BLM, or USFS, or sanctuary owners). As each new project is identified, The HSUS reviews the need for the project in the context of scientific and ethical issues and, if approved, issues permission to proceed. Applications of PZP to wild horses by federal agencies also require compliance with the National Environmental Policy Act (NEPA), which generally entails preparation of an Environmental Assessment (EA).

Deer. The first step in deer contraception is for the affected landowners and local legal authority (city, township, county, park board or some combination thereof) to agree to carry out a deer project. The second step is a review by The HSUS, to determine the scientific and ethical dimensions of the project (do these deer really need more management?). The third step is the preparation of a proposal to the state fish and wildlife agency, regardless of whether the deer in question reside on public or private property. The principal exception to state authority is wildlife residing on federal lands, which are not subject to state authority. However, federal managers generally try to be responsive to the concerns of state wildlife agencies.

If the contraceptive is already registered with the EPA and the state, no further permissions are needed. If not, the project should be carried out under an FDA INAD or under an EPA experimental use permit. Like the INAD, the EPA's experimental use permit is granted for use at specific sites under specific conditions.

An Assateague mare being targeted for a PZP inoculation. Effective ranges are up to 50 meters.

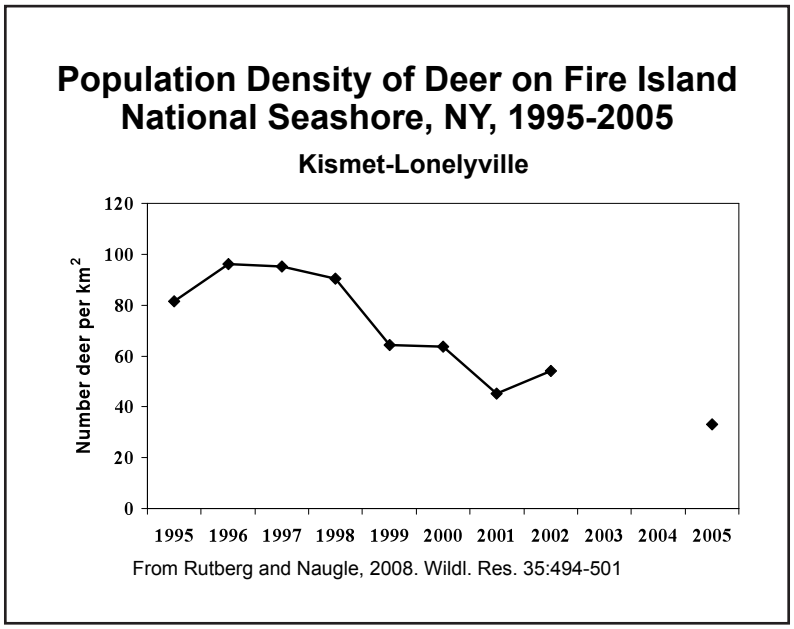
In addition to the regulations regarding the vaccine, the use of delivery equipment such as capture guns often requires additional state and local authorization and/or training. For example, the use of capture gun equipment within an NPS unit, even to deliver contraceptive drugs, requires special NPS certification. This includes documentation of prior experience with the delivery equipment, a certificate of completion of an NPS sponsored wildlife immobilization course or its equivalent, current CPR certification, passage of a qualifying test on the range, and a letter of certification from a superintendent of an NPS unit. Those contemplating projects with deer should also be sensitive to state laws and local ordinances regarding the discharge of firearms, which may apply to delivery equipment in some jurisdictions.

HOW MANY ANIMALS HAVE TO BE TREATED?

This is a very important and often-asked question, but usually it is asked without much understanding. The number of animals or percent of an animal population that needs to be treated is dependent upon many factors and there is no simple answer. For example, what is the goal? Is it the absence of all animals (impossible with contraception), or a 20% reduction or a 50% slowing of the growth rate or zero population growth? Even after the goal has been identified, data required to answer this question include at very least the reproductive rate, sex ratio, mortality rate, and immigration and emigration rate of the population. Equally important, these data on reproduction and mortality must be site-specific to the particular herd in question and not generalized data or data derived from other locations and populations. One of the most serious deficiencies noted at discussions of new projects is the lack of sound biological data and vague or no goals (Kirkpatrick and Turner 2008; Ballou et al. 2008).

Another consideration is the length of time necessary to achieve population goals. Contraception is not a good way to reduce population numbers rapidly. It takes time for animals to die off and, as seen earlier, one of the results of wildlife contraception may be increased longevity among treated animals. Wildlife contraception must be viewed as a long-term commitment. Also, humans should consider that most wildlife overpopulation problems were created over many years and that quick solutions are not the result of rational thought or fair to the wildlife.

A dart with a cut-away needle showing the small pellets containing PZP. This approach can deliver a year's worth of contraception with a single inoculation.



DIRECTIONS FOR FUTURE RESEARCH

Several areas of active research are underway by the PZP Wildlife Contraceptive Group, and these areas of research reflect current shortcomings of the PZP vaccine. These current research endeavors include the following:

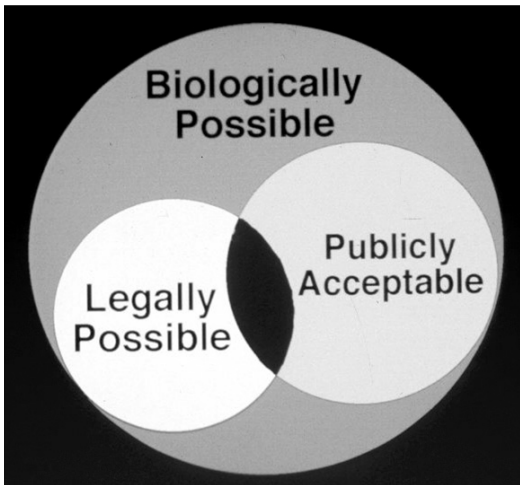
A One-Inoculation Vaccine: Because of the need to inoculate animals twice the first year, and the difficulty of doing this with wild species, research is proceeding toward a "one-inoculation" vaccine. Such a vaccine would permit a single darting to cause one or more years of contraception. The approach under study incorporates the PZP into a non-toxic, biodegradable material, which can be formed into small pellets. The pellets can be designed to release the vaccine at predetermined times after injection (at one, three and nine months currently) much the way time-release cold pills work. Trials thus far have been encouraging and continued trials are underway (Turner et al.2001, 2008). Additional research is being conducted with a biodegradable polymer gel, in collaboration with the U. of Tennessee.

Pellet-delivery Darts: There is a need for darts that can deliver the long-acting pellets remotely. Current collaborative research with at least two proprietary companies are directed at developing a reliable dart for remote pellet delivery.

A Genetically Engineered or A Synthetic ZP Vaccine: The ability to produce large quantities of the PZP vaccine at low cost will permit the increased use of this vaccine in wildlife. Currently collaborative work with the Indian National Institute of Immunology is testing a recombinant form of PZP that might be useful as a booster inoculation. Native PZP will remain the only useful "primer" inoculation.

The decline in deer population on Fire Island National Seashore brought about by PZP contraception over several years.

Oral Contraceptives: It is intuitive that the ability to deliver contraceptives to wildlife in baits would be easier and more cost effective. However, for safety and ethical reasons, both the public and regulatory agencies are likely to demand that any oral contraceptives must be species-specific (that is, it must work in only one species for which it was intended). This will be very difficult with the PZP vaccine because of its protein nature.



Biologically Modified-Vectored Contraceptives: Researchers working with the Australian government have sought to engineer the genes for PZP and similar contraceptive molecules into non-pathogenic viruses. These viruses could then be transmitted from animal to animal in wild populations. While there are some attractive features to this approach, the safety, environmental, and ethical issues associated with this technology has raised strong objections from the public and regulatory agencies in the U.S. and abroad, and it probably will never be used here.

Abortifacients: Research into compounds which will cause abortion in the recipient animals has largely been abandoned. This has already been shown to be feasible in deer, but most researchers are not pursuing this approach because of the social objections that attend this method of wildlife control.

ETHICAL AND SOCIAL ISSUES

The entire subject of wildlife contraception is attended by a variety of strongly held attitudes both favoring and objecting to this approach. Public discussions are seldom rational. For example, despite the obvious limitations to the available technology some advocates will make loud and unrealistic claims that wildlife contraception can one day completely replace public hunting. On the other side, and despite evidence to the contrary, opponents will express fears of harm after eating treated animals, or will object on the basis of high cost, or will insist that a problem that took 20 years to develop be solved in one year. Anyone seriously considering involving themselves or their community in wildlife contraception should first read Kirkpatrick and Turner 1995, 1997. At very least, do not expect unemotional and dispassionate discussions to occur when this topic is broached.

The most serious ethical considerations are when to manage and why, and the nature of the alternatives. Should wildlife populations be reduced by any method because they inconvenience humans? Should contraception be applied to seals because they are suspected of harming the economy of a fishing village? Should contraception be applied to wolves because they are eating caribou that sport hunters spend large amounts of money to shoot? Should contraception be applied to an endangered species? If contraception is not used, what will be the alternative management strategy? Who makes the decisions, and on what basis? These are serious questions involving the ethics of both science and wildlife management and they must be considered before application of this technology is applied to our wildlife resources (Kirkpatrick 2007).

The ability to control wildlife populations depends upon approaches that are collectively scientifically possible, legal and publicly acceptable.

WHO IS THE PZP CONTRACEPTIVE RESEARCH TEAM?

The entire PZP contraceptive effort involves many people, several institutions, and numerous funding agencies. At last count there were at least 12 individuals on this team, representing the Science and Conservation Center, the University of California - Davis, the Toledo University Medical College, University of Iowa, and The Humane Society of the U.S., as well as others. This team works together, bringing many disparate disciplines and talents together to solve the problems at hand.

WHO FUNDS PZP CONTRACEPTIVE RESEARCH AND APPLICATIONS?

Funding for applications of the vaccine to wildlife has been provided by many individual communities, agencies, and organizations, including but not limited to: The Humane Society of the U.S., Park Foundation, ASPCA, the Elinor Patterson Baker Trust, THAW Charitable Trust, Burket-Plack Foundation, the Bernice Barbour Foundation, Delta-Sonics, the PNC Corporation, the U. S. Navy, the National Park Service, the Bureau of Land Management, the Rachel Carson National Estuarine Reserve, the National Forest Service, the U. S. Department of Commerce, the National Institutes of Health, the Fire Island Community Association, >100 different zoos in North America, Europe and Australia, the South African National Parks Board, several Indian tribes, and several anonymous donors. This list is not all-inclusive but provides a picture of the breadth of support for this approach to wildlife management.

HOW IS THE PZP VACCINE OBTAINED?

Once all necessary authorizations and approvals have been obtained for the use of the vaccine, it is ordered from The Science and Conservation Center, 2100 South Shiloh Road, Billings, MT 59106; phone 406-652-9718; fax 406-652-9733; e-mail Kim Frank at sccpzp@hotmail.com. The vaccine is not commercially available and it is provided at 60% of the cost of production, or about $24/dose.
