At the beginning of each sampling period, we recorded band membership in order to track any changes in female movements and foal survival. If females changed bands during the study, their new band was recorded and behavioral observations were taken with the new band. Mares were classified as band changers only if they left their band for more than 1 day and stayed with a new band. If females came back to their original band after leaving for less than one day, they were considered stable members of the band. The time of band change was also recorded in order to determine if the mare left the band while pregnant or lactating. We determined foal survival up to weaning age and a foal was determined to be dead if it disappeared before age one, since they rarely disperse so young (Linklater 2000).

During the behavioral sampling period, we focal sampled mares and stallions to determine changes in maternal and paternal behavior (Altmann 1974). In order to measure maternal protectiveness, every approach and leave by mares and their foals within a distance of two adult body lengths was recorded. A two adult body length distance is considered close contact and is similar to the criterion used in other studies

that have measured mother-infant spatial relationships and protectiveness (e.g., Linklater et al. 1999, Cameron et al. 2003, Heitor and Vicente 2008). The percentage of approaches and leaves was then transformed into a contact maintenance score as a measure of protective behavior (Hinde and Atkinson 1970). This score was calculated from the percentage of approaches towards the foal due to the mare minus the percentage of leaves from the foal due to the mare:

$$\%A_M\text{-}\%L_M = [A_M/(A_M+A_F] - [L_M/(L_M+L_F)]$$

where A_M is the number of approaches by the mare, A_F is the number of approaches of the foal, L_M is the number of leaves by the mare and L_F is the number of leaves by the foal (Hinde and Atkinson 1970). The resultant score varies from +1 to -1, with a score closer to +1 indicating more effort by the mare to in maintain contact with her foal. In order to determine changes in nutritional investment, we recorded all nursing episodes as well as the individual who ended the episode (Cameron and Linklater 2000). For changes in stallion behavior, we measured all aggression directed towards the foal by the stallion. These behaviors included kicks, kick threats, head threats, bites, charges, and bite threats (see McDonnell and Haviland 1995 for ethogram). These data are presented as average aggressive interactions per hour.

Fecal Sample Collection and DNA Extraction Procedure

Fecal samples were collected on an opportunistic basis from known individuals during behavioral sampling. To avoid cross contamination all fecal samples were collected while wearing gloves and individual sterile swabs were used to collect the mucus on the exterior of each fecal bolus. The mucus has been shown to contain the

highest number of cells that have been shed from the intestinal lining during defecation (Wehausen et al. 2004). We placed swabs in collection tubes filled with Buffer ASL (lysis buffer, Qiagen QIAamp DNA Stool Mini Kit). Additional fecal samples that were not swabbed in the field were frozen, and genomic DNA was extracted at a later time by removing and placing a small amount (approximately 2 mg) of the surface of the pellet into the ASL buffer. DNA extraction was carried out following the QIAamp DNA Stool Mini Kit manufacturer's protocol with minor modifications as per Wehausen et al. (2004) as follows: 1) after the addition of ethanol, the samples were left for 1 hour to maximize precipitation of DNA and 2) the elution buffer (AE) was heated to 70ºC and incubated in the spin columns for three minutes.

DNA from blood samples taken during the round-up was extracted using Qiagen Tissue and Blood kit according to the manufacturer's specifications. After extraction, all samples were stored at -20ºC until further processing. DNA from blood samples was isolated and analyzed separately from that of the fecal samples. Consistency of genotype scoring for DNA from fecal samples was assessed for multiple individuals for whom both blood and fecal samples were available.

PCR Conditions

Twelve horse-specific nuclear polymorphic microsatellite loci were chosen from the literature (Marklund et al. 1994, Tallmadge et al. 1999, Tozaki et al. 2000a, 2000b, 2001; Table 1). We chose loci that could be combined in multiplex PCR reactions and that produced a small amplicon, which are more reliably amplified from fecal DNA (Marklund et al. 1994, Tallmadge et al. 1999, Tozaki et al. 2000a, 2000b, 2001; Table 1).

We ordered all forward microsatellite primers with M13 tail extension to the 5'end to allow for an economic method to label the PCR product with a corresponding fluorescent dye, as suggested by Schuelke (2000). This protocol uses 4 different M13 tails, each 5' end labeled with a different dye: NED (taaaacgacggccagtgc), PET (ggaaacagctatgacca), VIC (gcggataacaatttcacacagg), or FAM (tttcccagtcacgacgttg) to allow for multiplex reactions. All of the reverse primers were pigtailed by adding (gtttcttt) to the 5' end. We chose all primers to have an optimal annealing temperature from 60-63 °C. A touch down annealing temperature was used in the PCR parameters starting at 65°C and ending at 55 °C. In the early cycles of the PCR (65-58°C), the horse specific primers anneal, and in the later cycles (55 °C), the fluorescently labeled M13 primers anneal to label the products. We optimized PCR reactions to include 4 loci per reaction. Optimal PCR conditions were slightly different for blood samples than for fecal samples as detailed.

For the blood samples, we prepared a multiplex primer cocktail to give a final primer concentration of 0.05 µM for each tailed forward primer, 0.5 µM for each reverse primer, and 0.1 µM for each labeled M13 primer in a 16 µl reaction. PCRs consisted of 8 µl Qiagen Multiplex PCR kit master mix and 50 ng of genomic DNA where possible. PCR cycle parameters included a 15 minute hot start at 95°C, followed by 41 cycles of 95°C for 30 seconds, a touch-down annealing temperature for 90 seconds, and 72 °C for 30 seconds. The annealing temperature had 7 cycles with an annealing temperature of 65 °C, 7 cycles at 61 °C, 7 cycles at 58 °C, and 20 cycles at 55 °C in which the first 21 cycles were amplifying the horse DNA template and the final 20 cycles were amplifying the labeled M13 tail.

We carried out PCRs for the fecal samples in a separate laboratory in order to avoid cross contamination from blood samples. To increase the signal received from the fecal DNA, we modified the tailed protocol to include 2 PCR reactions per sample, such that the amplification of the template DNA was done to completion and then a second PCR reaction was carried out to fluorescently label the product. Four µl of fecal DNA extract, 7.5 µl Qiagen Multiplex PCR kit master mix, and 0.125 µM for each tailed forward and 1.25 µM for each reverse primer were used in the first reactions with a final reaction volume of 10 µl with addition of molecular grade water. PCR cycle parameters included a 15 minute hot start at 94°C followed by 35 cycles of 95°C for 30 seconds, a touch down annealing temperature for 90 seconds, 72°C for 30 seconds followed by a final extension of 62°C for 30 minutes. Annealing temperature started at 65°C and was reduced by 0.2°C each cycle for 35 cycles, ending at 58°C. One µL of this PCR product was used as a template for a second reaction with 0.53 µM for each fluorescently labeled M13 primers as a forward primer, 1.33 µM for each equine specific reverse primer, 7.5 µl Qiagen Multiplex PCR kit master mix with a final reaction volume of 15 µl by addition of molecular grade water. PCR cycle parameters for the second reaction included a 15 minute hot start at 94°C followed by 25 cycles of 94°C for 30 sec, 55°C for 90 sec, 72°C for 30 sec , followed by a final extension of 62°C for 30 minutes.

We diluted all PCR products 1:100 to 1:400, depending on the intensity of allele peaks during test runs. One µl of diluted product was added to 19 µl of HiDye Formamide with Liz (500) size standard. Fragment analysis was carried out on an ABI Prism 3730 DNA analyzer by the University of Nevada, Reno Genomics Center. We used ABI GeneMapper 3.7 software to score and bin all alleles per locus.

To ensure accurate paternity assignment, we collected at least three different fecal samples per foal, mare and stallion. This has been shown to reduce problems of low DNA quantity and poor extract quality found in fecal samples and increase the probability of reliably genotyping each individual (Frantzen et al. 1998, Taberlet et al. 1999, Goossens et al. 2000). At least 2 of the 3 fecal samples had to match in order for an allele call to be made (Taberlet et al. 1999). If samples did not match, we extracted another sample and rerun for the same individual. The two most common alleles were considered the true alleles. Individuals that did not consistently genotype were excluded from the data set.

Paternity Analysis

We used program CERVUS 2.0 to perform a parentage likelihood analysis for each foal (Marshall et al. 1998). In addition to paternity assignment, the program calculates deviations from Hardy-Weinberg equilibrium, observed and expected heterozygosities, and null allele frequencies (Table 1). To determine paternity, CERVUS 2.0 uses maximum likelihood analysis and calculates the log-likelihood of each candidate parent against random individuals. This method assigns a LOD score, with the highest LOD score representing the most likely father. The LOD score is obtained by taking the natural log of the overall likelihood ratio. The difference between the LOD score of the putative father and that of the next likely candidate is called as delta (Δ). The significance of delta values was assessed using paternity simulation of 10,000 cycles at an estimated 1% genotyping error rate and paternity was assigned with strict (95%) confidence levels (Marshall et al. 1998). Each foal had a known mother and was tested against all candidate males sampled for this study. We used the software GIMLET version 1.3.3

(Valière 2002) to compute the probability of identity (P_{ID}), which is the probability that two individuals randomly selected from a population contain the same genotype at multiple loci (Waits et al. 2001).

Statistical Analyses

To test differences in maternal behavior, we used a multivariate analysis of variance with paternity status (sired vs. not sired by band stallion), group size, sex of foal, and age of mother as predictor variables of contact maintenance between mares and foals and nutritional investment. For females that had foals in both paternity categories (sired and not sired by the band stallion), we used a paired t-test to examine differences in protective behavior. We used a Mann-Whitney test to examine differences in stallion aggression toward related and nonrelated offspring. The difference in survival to weaning based on paternity status was analyzed with a chi-squared. We considered $P<0.05$ as statistically significant and $0.05<P<1.10$ as a nonsignificant trend.

Results

Genetic Characteristics

A total of 51 foals, 33 mares, and 26 stallions from 23 bands were successfully genotyped and had sufficient alleles to make accurate paternity assessment. An additional 48 stallions from other bands and bachelors were also included. The average observed heterozygosity for the entire population was 0.673 based on all loci. The average allelic richness for each locus was 6.17 (Table 1). The genetic characteristics are summarized for each band in Table 2. There were no significant deviations from Hardy-Weinberg

equilibrium and no issues with null alleles (Table 1, 2). The probability of identity value for this subpopulation was 2.72E-10.

Band Composition

Most of the bands in the study had one adult stallion (19/23). One band had two stallions and three had three stallions. The average group size of all bands was 3.50 adults (range 2-6) and 2.19 adult females (range 1-5). Most mares (23/33, 70%) were found in the same band at the beginning and end of the study.

Mating Strategies

Females followed three different reproductive strategies: (1) females mated with the band stallion and stayed in the band while they raised their foal (N=31); (2) mares immigrated to a new band during pregnancy or during offspring dependency (N=12); and (3) females mated with males other than their band stallion (N=4) (Table 3). Four additional mares had an unknown band status at the beginning of the study, so could not be classified into any of the reproductive strategies. However, they were most likely band changers since three of these mares had foals sired by another band stallion. Most females mated with the band stallion and stayed in the band while they raised their foal (31/51 foals), resulting in stallions siring 61% of the foals in their bands (Table 3).

While most females remained in their same band, the next most common pattern was band changing. Seven of the12 mares that changed bands did so as a result of the roundup in 2005, so the cause of band changing may have been artificially induced. However, five of these seven mares stayed in the same band they changed into after the

roundup suggesting that stability in bands occurs even after a disturbance. The remaining five mares changed bands without human disturbance. Three of these were young, but the sample size was too low to detect any consistent reasons for females changing bands. Of the other two mares, one was old, but left a band with 2 stallions for a band with one stallion, and the other mare left her band for a group of 5 males, but later returned to her original band. Of the four females who engaged in extra-band copulation, the fathers were not identified among the sampled band or bachelor stallions.

In multi-stallion bands, mares followed the same strategies as described above. In the Fire band, two mares had two foals and neither was sired by any of the band stallions. In the O band, the female had two foals, one of which was sired by the dominant stallion and the other by none of the stallions. In the Y band, two females had a total of three foals. The first female had two foals both sired by the dominant stallion. The other female had a foal sired by the second ranked male, but changed to another multi-stallion band (Y/2 band) while she was pregnant and was young at the time of dispersal.

Maternal Behavior and Foal Survival

The only significant predictor of maternal protectiveness was paternity status of foals, as mothers were more protective of foals not sired by the band stallion, and maintained contact with their foals more often than those mares with offspring whose father was the dominant stallion ($F_{1,18}=6.323$, $P=0.022$, Figure 1). In order to control for the age of the foal, we looked at the contact maintenance scores of foals less than 200 days old, and the trend was the same with paternity status as the only significant predictor of protectiveness ($F_{1,14}=7.485$, $P=0.016$). For females that had foals sired and not sired by

the band stallion (N=3), the same trend of protectiveness was seen (paired t-test, t =7.83, $P=0.016$). For foals not sired by the band stallion, there was no difference in level of protectiveness based on whether they were born in the band or changed with their mothers ($F_{1,5}=0.113$, $P=0.750$). There was no difference in nursing episodes ended by the mother regardless of paternity status ($F_{1,23}=0.812$, $P=0.377$), suggesting that nutritional investment did not vary but protectiveness did.

The paternity status of foals had a significant impact on survival to weaning as foals born in the band with their sire had a higher chance of survival to weaning than foals born in bands without their sire ($\chi^2_1=4.006$, $P=0.045$, Figure 2). In addition, foals not sired by the band stallion had different survival rates depending on the timing of the band change. Foals that changed bands with their mothers had higher survival (6/8 foals survived) than foals born in a band without their sire as a result of mothers that changed bands while pregnant or had engaged in extra-band copulations (2/11 foals survived) ($\chi^2_1=6.134$, $P=0.013$). There was a nonsignificant trend for stallions to be more aggressive towards foals sired by another male (Mann Whitney test: $W=430.5$, $N_1=21$, $N_2=15$, $P=0.091$; Figure 3).

Discussion

Female Strategies

Our results are similar to blood-typing studies that showed that band stallions sire 85% of offspring in stable bands (Feh 1990, Kaseda and Khalil 1996). The majority of mares remained stable in one band and had a foal sired by the band stallion. However, we also found some bands have even lower rates of paternity and supported that up to 40%

of all foals in a band are not sired by the band stallion (Ashley 2000). Extra-band paternity could be due to either temporary band changes or to sneak copulations. We found that the majority of extra-band paternity was attributable to females who immigrated to new bands. Since this behavior persists, it is fundamental to understand under what circumstances females will change bands. Most of these females were young and most likely their band changes can be attributed to the dispersal process. Young mares disperse from their natal bands when they become reproductively mature (Monard et al.1996). However, during the dispersal process, mares commonly have low band fidelity and change bands up to the age of five until they eventually stay in a single band (Linklater and Cameron *in press*). This instability or lack of fidelity of young females is likely the cause of our results. Older mares that changed bands were changing into bands with fewer stallions, but since few older females engaged in this behavior; it is difficult to make conclusions about this behavior.

Most females do not seem to regularly seek extra-band copulations, but immigrate during pregnancy or during offspring dependency. The low rate of active extra-band copulations suggests that this behavior may be too costly for females as we predicted. The main cost would be losing their foal to infanticide, which has been shown to occur in feral horses, and is related to paternity (Gray 2009). In addition, females that solicit extra band copulations risk increased harassment by stallions. Male harassment is costly to mares, and has been shown to decrease body condition scores and reproductive success in females (Linklater et al. 1999). However, since some females engage in this mating behavior, there might be some benefits. Inbreeding avoidance is a possible benefit, but given that mares disperse from their natal bands we did not expect females to seek extra-

band matings in order to reduce inbreeding. Furthermore, there is evidence that both fathers and step fathers will not copulate with young females in their bands, suggesting active inbreeding avoidance (Berger 1986, Berger and Cunningham 1987). Another possible explanation for why females seek these copulations is to mate with males of higher quality, as seen in other species (reviewed in Jennions and Petrie 2000). However, a previous study suggested that extra-band paternity could be attributed to either other harem stallions or bachelors, which questions the importance of male quality (Ashley 2000). Unfortunately, we could not identify the males in the few documented cases of extra-band copulations. This behavior warrants further investigation.

Maternal behavior

Since infanticide occurs in equids and an attempt has been documented in feral horses (Gray 2009), females that adopt counter strategies including increased protectiveness have an advantage (Agrell et al. 1998). Protective behavior by mothers increases in the presence of non-paternal males in many species and these behaviors can decrease attacks (lions: Packer and Pusey 1983; rodents: Wolff 1985, vom Saal et al. 1995, Ebensperger 1998; primates: Collins et al. 1984, Fairbanks and McGuire 1987, Maestripieri 1995). Female feral horses are known to increase their level of protectiveness of their foals in situations in which paternity is uncertain (e.g., multistallion bands, after a band change; Cameron et al. 2003). However, it was not known if females changed their protectiveness in response to actual paternity or just the uncertainty of paternity. We found that these mares, regardless of the breeding strategy, were more protective of foals not sired by the band stallion. Furthermore, females that

changed bands with their foal or while pregnant but had a foal the subsequent year sired by the band stallion all showed the same pattern, becoming less protective toward the foals sired in the band. While the sample size was small (N=3), these data suggest that females are responding to paternity and not just general stallion aggressiveness, especially since stallions were not more aggressive towards these mares. In bands where paternity is uncertain due to presence of other males (e.g., multistallion bands), females were more protective of their offspring, even when the sire was present. This may be due to higher rates of harassment (Cameron et al. 2003, Linklater et al. 1999), but perhaps also due to an increased risk of infanticide (Cameron et al. 2003). Mares may use cues such as band changing, lack of mating, or lack of consortship with the band stallion to determine the paternity of their foals, but this behavior warrants further investigation. While maternal protectiveness changed in response to paternity, survival also varied with these different strategies, suggesting that males may also assess paternity.

Stallion Behavior and Foal Survival

Paternity is relatively predictable and, with the exception of band changes, foals are almost always sired by the band stallion. While most band stallions are successful at securing paternity of the foals in their band, there are some circumstances in which paternity is less certain. Infanticide occurs in equids and is usually attributed to stallions that did not father an offspring (Duncan 1982, Penzhorn 1984, Ryder and Massena 1988, Pluháček and Bartoš 2000, Feh and Munkhtuya 2008, Gray 2009). While there was only one witnessed infanticide attempt in this population (Gray 2009), this does not indicate that these attacks do not exist, only that they are rarely documented (as in other species;

Pusey and Packer 1994). Infanticidal males can increase their reproductive success by decreasing the time needed for females to come into estrus again (van Schaik 2000). Mares that lose foals have higher foaling rates in the subsequent year (Cameron et al. 2003), thus infanticidal males would be advantaged to attack when a foal is young in order to return a mare to estrus. We found that the strategies of mares dramatically changed the risk of foal death. Almost all foals died that were born in a band without their sire, but most foals survived that immigrated with their mothers to a new band, suggesting that being born in band without their sire increases their risk of infanticide. Our data lend support to the importance of the timing of the infanticidal attack and the potential benefits of it. Most documented attacks occur early in the foal's life, usually before 2 months of age (Pluháček and Bartoš 2005), and the benefit to return the mare to estrus and increase her subsequent reproductive success would only occur early in the foal's dependency. Here we provide more evidence that infanticidal attacks may not be advantageous when foals are older, and this is demonstrated in their higher survival rates.

Stallions may assess paternity through phenotypic matching, but it is more likely they use simple cues, similar to females, such as consort time or presence during the breeding season. Regardless, there was a trend for stallions to be more aggressive toward these foals and for these foals to have lower survival. The results suggest that stallions may also be assessing paternity and changing their behaviors accordingly.

Conclusions

Infanticide and male harassment may be more important determinants of social structure than resource acquisition (Kappeler 1997, van Schaik and Kappeler 1997,

Linklater et al. 1999). In horses, band stability has been shown to benefit mares in a variety of ways including lower parasite levels, higher reproductive success and lower harassment rates (Kaseda et al. 1995, Linklater et al. 1999). We have further demonstrated that staying in a band and raising a foal sired by the band stallion has additional benefits. First, these foals have higher rates of survival to weaning and suffer lower rates of stallion aggression. Second, mares expend less effort in maintaining contact with their foals. Protective behavior is costly and has been correlated with both lower body condition scores and reproductive success (Cameron et al. 2003). Therefore, raising a foal in the band with its sire is good for both current and future reproductive success. Furthermore, the majority of mares that were forced to change bands due to the round-up were stable afterwards and never changed bands suggesting that band stability occurs even after a disturbance. We provide further evidence for the benefits of having long tenure in a band and it appears most mares are engaged in this strategy, rather than band changing or seeking extra-band copulations.

Acknowlegements

This research was funded by grants from the Nevada Arid Rangeland Initiative NOA15353CG, 110615253BS, 140115253BS, 140215253BS, Hatch Grant 13215353BS and a research grant from the American Society of Mammalogists. We thank the Veronica Kirchoff and Nevada Genomics Center for help with the genetic analyses.

Table 1. Summary of 12 microsatellite loci used for genetic paternity analysis in feral horses, including the number of alleles per locus (A), the number of genotyped individuals (N), observed (H_O) and expected (H_E) heterozygosities, null allele frequencies (NA), and estimates of exclusion probability for paternity assignment. Values derived from CERVUS 2.0 (Marshall et al. 1998). Primers were multiplexed into 3 different panels, with loci TKY 223, TKY276, TKY 284, TKY 286 in the first panel, COR 61, COR 72, HTG 7, TKY 312 in the second panel and COR 68, COR 71, HTG 15, TKY 282 in the third panel.

Locus	A	N	H_O	H_E	NA	Exclusion Probability	Reference
TKY223	6	167	0.665	0.627	-0.037	0.362	Tozaki et al. 2000a

Table 2. Summary of genetic characteristics based on each individual band including the number of alleles per locus (A), the number of genotyped individuals in each band (N), observed (H_O) and expected (H_E) heterozygosities. Each band is displayed vertically and each locus is displayed horizontally. Bachelors and other band stallions are listed in the "unk" column.

Table 3. Genetic data from all successfully genotyped foals. LOD scored and delta values were derived from CERVUS 2.0. The most likely father was the band stallion, another band stallion, bachelor, or unidentified male. Band stallion indicates the foal was born in the band with its true sire and other band stallion indicates the foal was sired by a different band stallion. Unidentified males were males whose DNA was taken during the round-up but they could not be identified in the field as bachelors or band stallions. All of these males were old age category. Confidence levels were set at 95% in order to determine the most likely father.

CHAPTER 2

An infanticide attempt by a free-roaming feral stallion (*Equus caballus*)

"You cannot love a thing without wanting to fight for it."
Gilbert K. Chesterton

Author's note: Chapter 2 is published in the journal Biology Letters and is presented in the style of this journal.

Abstract: Infanticide by adult males occurs in a variety of species. While infanticidal attacks have been documented in several equid species in captivity, it has never been witnessed in free-roaming feral horses. I report an infanticide attempt by a free-living feral stallion on a recently born female foal. The stallion picked up the foal by the shoulders, tossed it around twice and bit in on the neck several times. The dam of the foal charged the stallion and successfully protected her foal from additional attacks. The foal survived the attack and later weaned successfully. The stallion recently took over the band and was excluded as the sire through genetic analysis. While this type of attack is rare, this case lends support to the sexual selection hypothesis and further demonstrates that equids have evolved with the risk of infanticide. Furthermore, it shows that maternal protectiveness can be successful against attacks by infanticidal males.

Introduction

Infanticide, while rare, is a widely documented phenomenon in several mammal species including primates (Hrdy 1977; Crockett & Janson 2000; Watts *et al.* 2002), carnivores (Packer & Pusey 1983; Swenson *et al.* 1997), and rodents (Coulon *et al.* 1995; Vom Saal *et al.* 1995; Blumstein 2000). Male infanticide is generally considered to be an adaptive strategy whereby the interbirth interval is reduced, and the male can sire the subsequent offspring (van Schaik 2000). Sexual selection implies a benefit to the reproduction of infanticidal males provided that only unrelated infants are killed, since infanticide is costly to males if related offspring are killed (van Schaik 2000). Thus, recognition of paternity plays a key role in the evolution of this strategy.

With the exception of red deer (*Cervus elephus*) (Bartoš & Madlefousek 1994) and the hippopotamus (*Hippopotamus amphibus*) (Lewison 1998), the majority of cases of infanticide involving ungulates are reported in equids, including the horse (*Equus caballus*) (Duncan 1982), Przewalski horse (*Equus przewalskii*) (Ryder & Massena 1988; Feh & Munkhtuya 2008), mountain zebra (*Equus zebra*) (Penzhorn 1984), and Burchell's zebra (*Equus burchelli*) (Pluháček & Bartoš 2000). Feral horses are unusual among ungulates in that they form stable harem-type groups year-round consisting of one or more mares and usually one but sometimes several stallions (Linklater 2000). Band stallions are known to obtain high paternity within their band (Bowling & Touchberry 1990), but sneak copulations occur and mares change bands, which can result in paternity differences between foals (Miller 1981). In feral horses, infanticide has never been documented in the wild, but feticide may occur (Berger 1983). Feral mares have been shown to increase maternal protectiveness in response to paternity uncertainty (Cameron

et al. 2003), which suggests that females have evolved to protect their foals from attacks by males. Here, I document a case of a resident band stallion attacking a young foal shortly after birth in a free-roaming situation.

Methods

A feral horse population in the Virginia Range outside Reno, Nevada was observed intensively from 2004-2008 for the purposes of another study. The total population fluctuated from over 1200 horses down to 1000 horses over the course of those years. The Nevada Department of Agriculture is responsible for managing the horses and the population size was and is still controlled by removals and contraception. The study included approximately 300 known individuals. Horses were habituated to human observers. The band in which the attack occurred was seen on a weekly basis to determine band membership and fidelity. At the time of the attack, the band consisted of 2 adult stallions, 2 adult mares, one juvenile male, and one male foal. The band was being observed due to a recent birth of a foal and from that time, ad libitum observations were recorded until the end of the incident. All aggressive behaviours were documented and a description of these behaviours can be found in an equid ethogram (McDonnell & Haviland 1995).Genetic data were taken from fecal samples from the foal, dam, and band stallion. Paternity was assessed using 12 polymorphic horse-specific microsatellites.

Results

During routine behavioural observations on April 12, 2005, an infanticide attempt was witnessed. The band was passed at 15:40, while observing another band. At that

time, the foal was not born. At 16:14, while passing the band again, the mare had recently given birth. A new female foal was covered with mucous and lying on the ground next to her dam. The foal was estimated to be no more than 1 hour old when the attack occurred and had not attempted to stand up. The rest of the band, including the dominant band stallion (stallion A), were all resting near the mare and newborn foal. At 16:20, a stallion (stallion B) from a nearby band called out and approached the mare. She immediately gave a head threat towards stallion B. The foal attempted unsuccessfully to stand up. The band stallion (stallion A) lunged towards the mare and foal and immediately bit the foal on the neck several times. Stallion A subsequently picked the foal up by the shoulders twice and shook it around several times. The foal was dropped to the ground and subsequently bitten and kicked by the front legs of stallion A several times. The attack lasted approximately 1 minute. During the attack, the mare defended her foal by charging, biting, and kicking stallion A, which led to the end of the attack. After the attack, stallion A had several aggressive interactions with stallion B and continued to try to herd the mare away from the area. The mare continued to charge and head threat stallion A when he came near her and she remained in her position over the foal. Stallion B called out again, which led to another aggressive interaction between stallion A and the mare. While the foal appeared to be in shock, there was no visible major damage, but she suffered minor superficial wounds. The foal stood up at 17:39 and nursed at 17:47, and at that time the observations ended. The band was observed over the course of the next year and the foal successfully weaned.

The attacker (stallion A) was excluded as the father of the foal through microsatellite DNA analysis.

Discussion

The attack was unmistakably an infanticide attempt as it was similar to other reported attacks in equids (Duncan 1982; Feh & Munkhtuya 2008). Most infanticidal attacks by stallions occur before the foal reaches one month (Pluháček & Bartoš 2000) and in this case, the foal was recently born. Infanticide imposes direct fitness consequences on the parents of the offspring, especially the mother. Such costs include decreased inclusive fitness, energy expenditure, and the loss of investment (Ebensperger 1998). Females should adopt counterstrategies against infanticide in order to maximize their lifetime fitness (Ebensperger 1998). These counterstrategies include fighting back, having close associations with males for infant protection, prolonged receptivity, territoriality, avoidance, and termination of infant care (Ebensperger 1998). In horses, mares will defend against infanticidal attacks (Feist & McCullough 1975; Ryder & Massena 1988) by generally positioning themselves between their foal and another approaching horse, even if no direct threat is apparent (Crowell-Davis & Houpt 1986). This protective behaviour was witnessed during the attack, as the mare defended her foal by charging and biting the stallion. She also tried to position herself between the stallion and foal and stood over the foal after the incident. All of these actions appeared to stop the attack and prevent further assaults.

There were several factors that possibly led to this attack. First, genetic analysis confirmed the band stallion was not the sire. Second, the band stallion had recently taken over the band and shared the band with another adult stallion. Because of these factors, there was a high level of paternity uncertainty which may have influenced the decision to attack. Little is known about how males detect paternity, but evidence in primates

suggests that males detect paternity by consort time, phenotypic matching, or the amount of time spent within the troop during the mating season (Buchan *et al.* 2003). In this case, the male did not have a consortship with the female, nor did he spend any time with this female during the previous mating season. The uncertainty of paternity has been postulated as a proximate cause of an infanticide attempt (Borries at al. 1999), and is believed to be the major cause in this particular case.

Recently, infanticide in equids was suggested to be in response to human intervention (human disturbance hypothesis), as most cases have been associated with unnatural environments and introductions of foreign males (Feh & Munkhtuya 2008). While humans may influence infanticide attempts, most documented cases have also been associated with foreign males. For example, in equids, attacks end after males and females have been housed together for longer periods of time (Ryder & Massena 1988), suggesting that the unnatural conditions do not explain infanticide. In addition, many infanticidal events in the wild are associated with contact with foreign males, and attacks are generally attributed to these males. In this case, the male was relatively foreign in the band and several factors increased the level of uncertainty of paternity (i.e. multi-stallion band, recent takeover, no consortship before foal was born). In addition, the similarity of attacks between equid species, maternal protectiveness, and genetic data all suggest that equids have evolved with and respond to infanticide risk. Furthermore, infanticide has been postulated as a main explanation for primate social structure and the evolution of year-round male-female associations (Kappeler 1997; van Schaik & Kappeler 1997). Feral horses have similar social structure to primates and male harassment plays a primary role in social structure (Linklater *et al.* 1999).

This was the only attack witnessed during 3 years of behavioural observations. Several studies suggest that feticide may be more adaptive in horses (Berger 1983), and there are some suggestions that infanticide is low risk in equids (Feh & Munkhtuya 2008). However, several foals disappear and are found dead every year in all populations, even when no predators are present. While these deaths could be due to numerous factors, infanticide is a possible cause of some deaths. Furthermore, foals not sired by the band stallion have lower survival rates to weaning (*unpublished data*). All of this makes a witnessed event and possible causes that much more important to document. To my knowledge, this is the first documentation of this type of attack in feral horses in a free-living situation and lends support to the role of infanticide in social structure.

CHAPTER 3

Multi-year fertility reduction by two contraceptive formulations in free-roaming feral horses: Is body condition important when evaluating efficacy?

“Contraceptives should be used on all conceivable occasions.”
Spike Milligan

Photo caption: Antarctica band: Mare (3/7) right before birth of 2007 foal

Abstract: Feral horses (*Equus caballus*) continue to increase in numbers in the western United States. Past management techniques have used the round-up and adopt-out method, but contraception is becoming increasingly tested and used to reduce fertility in wildlife populations. To date, multi-year fertility reduction with one vaccination has not been demonstrated in free-roaming feral horses. We tested two contraceptive formulations, a porcine zona pellucida (PZP) formulation SpayVac®, and a gonadotropin releasing hormone (GnRH) formulation GonaCon-B™, to determine efficacy in a population of free-roaming feral horses near of Reno, Nevada. Females were treated in June 2005 and monitored year round until the summer of 2008. For mares treated with GonaCon-B™, the average reproductive success from 2006-2008 was 39%, 42% and 31% respectively. SpayVac® treated mares showed average reproductive success of 36%, 56%, and 44% respectively. During the same seasons, 61%, 67% and 76% of control females foaled. Linear mixed model analysis revealed that both contraceptive treatments significantly reduced fertility in the combined 3 years. However, several treated females in both treatment groups had foals and our fertility rates were much higher than reported in other studies. Our lower efficacy rates may have been due to our intensive sampling efforts that increased our ability to observe foals more often than researchers in other studies who only surveyed a few times per year. However, when the treatments worked on individuals, they worked for several years. Most of the treated females were never fertile or fertile one year compared with control females were fertile every year or 2 of 3 years, suggesting that contraceptive treatments worked better on certain individuals. We found that body condition at time of treatment had a significant impact on reducing fertility as females in good condition showed reduced fertility

compared to controls, but females in poor condition did not. We found no significant effects from contraceptive treatment on the sex ratio of foals, birthing season or foal survival. The results of this study demonstrate that both vaccines are capable of significantly reducing fertility for several years without boosters and may aid in population control of feral horses, but body condition at time of treatment may be an important, yet overlooked factor when evaluating efficacy.

Introduction

Anthropogenic disturbance of natural ecosystems by removal of predators and introduction of invasive species, has led to the overabundance of many species to the detriment of both the environment and other wildlife species (e.g., white tailed deer; Warren 1997, feral horses; Wagner 1983, Canadian geese; Conover and Chasko 1985). Traditionally, populations of overabundant wildlife were controlled by manipulating mortality by removing individuals permanently from the population by lethal control or permanent removals. However, mortality manipulation can cause increased population growth (Garrott and Taylor 1990, Kirkpatrick and Turner 1991), changes to animal movements (Henderson et al. 2001) and public objections (Jonker et al. 2006, Stout et al. 1997, Lauber et al. 2007). Consequently, non-lethal methods of control are becoming increasingly advocated when traditional culling methods are impractical or undesirable (Kirkpatrick 2007). Non-lethal population management usually involves manipulating fertility rather than mortality.

Contraception has become a widely used nonlethal technique to reduce fertility in managed species and is usually considered a more humane long-term approach to population control because of its reversibility (Oogjes 1997, Kirkpatrick 2007). In particular, immunocontraception, which uses an animal's own immune system to inhibit fertility, has been tested extensively in many wildlife species to inhibit pregnancy by blocking fertilization or estrous cycling with the use of GnRH immunizations [e.g., elk (*Cervus elaphus*): Baker et al. 2002, Conner et al. 2007; feral swine (*Sus scrofa*): Killian et al. 2006; white-tailed deer (*Odocoileus virginianus*): Miller et al. 2000a], porcine zona pellucida [PZP, e.g., black bears (*Ursus americanus*): Lane et al. 2007; burros (*Equus*

asinus): Turner et al. 1996; elephants (*Loxodonta africana*): Fayrer-Hosken et al. 2000, Delsink et al. 2002; elk (*Cervus elaphus*): Kirkpatrick et al. 1996; feral horses (*Equus caballus*): Kirkpatrick et al. 1992, Turner et al. 1997, 2001, 2007; white-tailed deer (*Odocoileus virginianus*): Miller et al. 2000b, Naugle et al. 2002, Walter et al. 2002, Rutberg et al. 2004], or progesterone implants [e.g., gray kangaroos (*Macropus giganteus*): Nave et al. 2002, Herbert et al. 2005; tammar wallabies (*Macropus eugenii*): Hynes et al. 2007]. While biologically effective, contraceptive formulations also need to be practical for management, using a single dose and having minimal side effects.

Feral horses (*Equus caballus*), federally managed under the Free-Roaming Wild Horse and Burro Protection Act of 1971, continue to overpopulate rangelands in the western United States where they can negatively impact grasslands, soils and other wildlife species (Rogers 1990, Beever and Brussard 2000, Levin et al. 2002, Beever and Brussard 2004, Zalba and Cozzani 2004, Beever and Herrick 2006). Despite this trend, lethal control is illegal and largely unacceptable to the public. The Bureau of Land Management (BLM) is responsible for maintaining sufficient numbers of horses in order to preserve genetic diversity while balancing rangeland capacity. Past management techniques have focused on the "round-up and adopt-out" method, but there have been concerns about the efficacy of these programs and their impact on animal welfare (Kirkpatrick 2007). While these management techniques have initially reduced numbers, feral horse populations continue to grow, and adoption rates are declining, resulting in a surplus in holding facilities. Consequently, new ways to manage free-living horses effectively and humanely are increasingly urgent. Contraceptive formulations have been extensively researched in free-roaming horses (PZP; Kirkpatrick et al. 1990, 1996, Turner

et al. 1997, 2001, 2002, 2007 and GnRH; Killian et al. 2008) and show promise for population control that may be more cost effective than removals over the long term (Bartholow 2007). However to date, there is no formulation that lasts for several years without the need for boosters, and there is limited data on the behavioral and physiological consequences of contraceptive treatment in feral horses.

Concerns have been raised over the potential side effects of contraceptive treatments (see Nettles 1997), yet there has been little research conducted that addresses side effects in comparison to efficacy studies in many species (see Gray and Cameron *in review*). The manipulation of fertility will most likely impact the physiology and behavior of treated individuals, which can in turn impact other individuals in the population (Gray and Cameron *in review*). Most research on side effects has focused on breeding behavior and body condition of treated females. For example, several studies have shown that contraceptives alter breeding behavior of females resulting in a lengthened breeding season and later offspring birth dates (McShea et al. 1997; Heilmann et al. 1998; Miller et al. 2000b). Several studies have also reported increased body condition of treated females in wild species (McShea et al. 1997, Turner and Kirkpatrick 2002). While increases in body condition can be desirable, this could impact offspring sex ratios as females that experience increased condition tend to have more sons (see Cameron 2004). Another potential side-effect that has yet to be tested is the unintended selection of immunocompromised individuals. Because immunocontraception relies upon a competent immune system, animals with more expansive immune systems would have greater reductions in fertility than those with poor immune systems (Nettles 1997, Cooper and Herbert 2001, Cooper and Larsen 2006). Over time, this could lead to the selection of

non-responders, eventually making the treatment ineffective (Nettles 1997, Cooper and Herbert 2001, Cooper and Larsen 2006). While there is a potential for this to occur over a long time, it is not known if the variation in response to contraception is related to immune system function (Cooper and Larsen 2006). Regardless of treatment, side effects should be studied on managed species in order to minimize impacts on behavior, physiology and population health.

We simultaneously tested efficacy of alternative contraceptive formulations in free-roaming feral horses in the Virginia Range in Nevada. We used two different formulations which were developed to reduce fertility for multiple years from one injection and without the need for revaccination. The first formulation, SpayVac®, is a liposome encapsulated porcine zona pellucida (PZP) that allows for continued cycling and acts to prevent pregnancy by blocking fertilization, with a single dose lasting for several years (Brown et al. 1997). This contrasts with other PZP formulations that require multiple doses to achieve several years of infertility (Turner et al. 2001, 2002). It has been successfully used in fallow deer (Fraker et al. 2002), white-tailed deer (Hernandez et al. 2006), hooded seals (Brown et al. 1997), and captive feral horses (Killian et al. 2008). The second formulation, GonaCon-B™, is a gonadotropin-releasing hormone (GnRH) vaccine that combines GnRH with a mollusk protein. The antibodies resulting from this vaccine bind with endogenous GnRH (Miller et al. 2008). The resultant product is too large to diffuse through the hypothalamo-hypophyseal portal system into the anterior pituitary, and prevents GnRH from binding to pituitary receptors (Miller et al. 2008). Therefore, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are not produced in high quantities and do not act on the gonads, thereby preventing

ovulation (Talwar 1985). This product takes GnRH out of circulation, but does not alter the hormone itself (Miller et al. 2008) and does not impact other hypothalamic hormones (Awoniyi et al. 1993). This formulation has been proven to work in several ungulates including white-tailed deer (Miller et al. 2000a), bison (Miller et al. 2004), feral swine (Killian et al. 2006), wild boar (Massei et al. 2008), and captive feral horses (Killian et al. 2008). Each formulation alone would not elicit a large or long-term response, thus AdjuVac™, an oil based adjuvant, was used to increase the immune response. Here we present efficacy data for 3 foaling seasons (2006-2008) for contraceptive formulations that have never been field tested in free-roaming feral horses, using intensive observations of individuals supplemented by hormonal analysis of pregnancy.

In addition to efficacy, we looked at potential side effects of contraceptive treatment. We tested if contraception impacted foal survival, birth sex ratio, and birthing season. We also tested if body condition at time of treatment had an impact on the reduction in fertility to determine if immunocontraceptive efficacy is dependent on individual quality as a potential indicator of immune system health.

Methods

Study site and animals

The study was conducted in the Virginia Range centered at 39°26'N and 119°30'W, located southwest of Reno, Nevada. The range is approximately 145,000 hectares and is mostly private land, with a small percentage developed for houses and industry. The mountain range consists of sagebrush communities (*Artemesia tridentata*) with groups of pine (*Pinus jeffreyi, Pinus monophylla*) and juniper (*Juniperus*

osteosperma) in higher elevations. The range has several other common plant species including bluegrass (*Poa secunda*), rabbitbrush (*Chrysothamnus nauseosus*), bitterbrush (*Purshia tridentata*), and cheatgrass (*Bromus tectorum*). There are several natural and artificial water sources, including a spring that runs year-round and is used by the study population. Other than feral horses, other ungulates in the range included mule deer (*Odocoileus hemionus*) and pronghorn (*Antilocapra americana*). The only predators in the range were mountain lions (*Puma concolor*), bobcats (*Lynx rufus*) and coyotes (*Canis latrans*).

The feral horses in this population are classified as estray horses since they range on private property and are therefore not protected under the Wild Horse and Burro Protection Act. Consequently, they are legally defined as feral animals, and the Nevada Department of Agriculture is responsible for the management of the population. The population size has fluctuated from over 1200 in 2004 to around 1400 in 2009, and is currently being managed with the use of both removals and contraception. The long term management goal is to continue to decrease and stabilize population growth.

Formulation types and treatment protocol

We selected a treatment site for both ease of capture, the large number of horses present in the valley, and permission from private land owners. Horses were rounded up with a helicopter on June 15th and 16th 2005. Horses were held in purpose-built yards and restrained in a hydraulic squeeze chute for treatment. We treated every female over one year of age with 1 cc intramuscular dose in the neck of 1 of 4 treatments: a) GonaCon-B™, a GnRH immunization (N=20), b) SpayVac®, a PZP formulation (N=20), c) control

consisting of adjuvant only (ADJ) (N=19), or d) control consisting of no treatment (N=18), but every other capture aspect was equivalent. After testing for differences in efficacy rates between adjuvant treated mares and those that received no injection, we grouped these together as the control group. All of the treatments contained the same adjuvant. Treatments were provided by the National Wildlife Research Council. Finally, the treatment group to which each mare belonged was kept blind from the field observer.

Mares ranged in age from 1 to 20 years. All females were aged by tooth eruption and wear patterns (after Tutt 1968), examined for overall health, had a blood sample taken and were freeze branded with unique brands on the left side of the rump. We used body condition scores on the date of treatment to visually estimate fat deposits around the neck, ribs and rump using an 11 point scale from 0-5, with 0.5 gradations (Carroll and Huntingdon 1988, Rudman and Keiper 1990). We used these scores as a measurement of energy reserves, which are correlated with fat percentage in horses (Henneke et al. 1983). We classified females into 3 categories of either good condition (score of 3 or greater), average condition (score of 2.5) and poor condition (score of 2 and below). A total of 77 females were treated over the two day period. All horses were immediately released after treatment. A small group of females (N=9) were treated in May of 2005. These horses were captured by a feed trap and processed using the same protocol. All females were monitored for pregnancy until summer 2008. All handling and treatment procedures were done by and under the supervision of veterinarians from the Nevada Department of Agriculture and were approved by the University of Nevada, Reno Animal Care and Use Committee.

Data Collection

We monitored mares on at least weekly basis from the ground to determine fertility rates until August 2007 and during the spring and summer of 2008. Efficacy of treatment was determined if a foal was born at any time during the year or if a female was noticeably pregnant, judged conservatively by an enlarged belly and swollen teats. If females were not seen until after the foaling season and no foal was present, they were recorded as unknown and excluded from the analysis.

Fecal Sampling and Steroid Hormone Assay

To supplement visual observations, we collected fecal samples opportunistically from October to May to determine pregnancy of mares that may have lost a foal before any visual observations took place. Fecal samples were stored in -20°C freezers until extraction. We used the extraction protocol of Asa et al. (2001). Samples were thawed and approximately 0.5 g of wet fecal material was placed in a vial with 5 ml of modified phosphate-saline buffer (Shideler et al. 1993) and shaken overnight at room temperature. Samples were centrifuged for one hour and the supernatant was stored at -80°C until the assay was conducted. The remaining fecal material was dried in a 100°C oven overnight and weighed the next day. Hormone values are based on the dry weight of the fecal samples and are presented as ng/g of dried feces.

Fecal progesterone assays were run at the Saint Louis Zoo and have been used to verify reproductive status of females in many species (Asa et al. 1996, Asa et al. 2001, Munson et al. 2001). We analyzed extracted fecal samples for progesterone with commercially available radioimmunoassay kits (Progesterone Coat-a-Count, Siemens

Medical Solutions Diagnostics, Los Angeles, CA, USA). We used stripped calf serum to prepare all standards and to dilute all fecal sample extracts. Fecal samples were run against a calibration curve of progesterone from stripped calf serum. Extraction buffer was added to tubes containing standards and calf serum was added to fecal extracts to equalize the matrices of the samples and standards. All samples, standards and quality controls were run in duplicate.

Statistical Analysis

We determined the effectiveness of contraceptive treatment by comparing the proportion of fertile females in each treatment group to control females across the combined foaling seasons. Therefore, efficacy rates are presented as fertility rates of each treatment group. We classified females into three categories of reproductive status. The first group consisted of mares that were seen with a foal or visibly pregnant and the second group consisted of females that tested pregnant through fecal progesterone. Both of these groups were considered contraceptive failures and combined for analyses. The third group comprised females in which contraception was considered successful, i.e., mares that did not foal and did not test positive for pregnancy. If any female did not meet these criteria (e.g., not seen on a regular basis or no fecal samples) they were excluded from the analysis. Therefore, fertility rates include females that were observed with a foal, pregnant, or tested pregnant with fecal progesterone. We used a linear mixed model analysis with restricted maximum likelihood estimation to determine treatment effects on fertility rates. We used subjects as a random variable repeated across three foaling seasons. A chi-squared test was used to test differences between foal sex ratios,

seasonality of births and foal survival. We defined the foaling season to include April, May and June (Kirkpatrick and Turner 2003). Results are shown as means ± standard errors where appropriate.

Results

Efficacy

There was no difference in foaling rates between control mares and adjuvant only mares across the 3 years (2006: t =-0.138, P=0.891, 2007: t=0.244, P=0.809, 2008: t=1.185, P=0.246; Table 1), thus they were combined for all further analyses. Treatment with contraception significantly reduced fertility for all combined foaling seasons ($F_{2,72}$=6.489, P=0.003). Post hoc comparisons revealed that both contraceptive treatments significantly differed from control mares (GonaCon-B™: t_{75}=-3.452, P=0.001, SpayVac®: t_{68}=-2.135, P=0.036). Overall, treated mares foaled less often in the 3 years, but the biggest difference was found in 2008. For individual females with known reproductive status for all three foaling seasons, most treated females were never fertile over the three years, or fertile for one year, whereas the majority of control females was fertile every year or two out of the three years (Figure 1).

We supplemented fertility data with four additional mares that were not seen on a regular basis, but had fecal samples tested for progesterone levels. We found two females that were not pregnant (both <50 ng/g progesterone) and two females that were pregnant (>1000 ng/g progesterone) (Asa et al. 2001). Pregnant mares had mean fecal progesterone of 2242 ± 258 ng/g and non-pregnant females averaged 109 ± 11.5 ng/g. Fecal progesterone was biologically verified correctly on 17/19 mares, but revealed that two

treated mares were pregnant in the first year, but lost their foal. Neither of these mares looked visibly pregnant and would have been counted as not pregnant. One mare (GonaCon-B™ treated) lost her foal in October and the other mare (SpayVac® treated) lost her foal sometime between March and April. The GonaCon-B™ treated mare may have already been pregnant when she was treated, but these data indicate that intensive visual and fecal sampling is necessary to get an accurate picture of mare fertility.

Body Condition

The average body condition score of all females at treatment was 2.38 ± 0.048. There was no difference in the mean body condition between treated (GonaCon-B™, 2.40 ± 0.09 and SpayVac®, 2.32 ± 0.10) and control females (2.40 ± 0.07) ($F_{1,71}$=0.28, P=0.754). However, body condition at the time of treatment significantly impacted efficacy in the 2007 and 2008 foaling seasons. While mares in good condition treated with either formulation had the expected reduction in fertility rates (41% fertile) compared to control females (75% fertile; χ^2_1=4.432, P=0.035), there was no reduction in fertility between contraception treated (60% fertile) and control females (55% fertile) in poor condition (χ^2_1=0.064, P=0.801). The same trend was seen in 2008 as good condition treated females had lower fertility rates (21%) than controls in good condition (76%) (χ^2_1=11.056, P=0.001), but there was no difference for poor condition females (55% fertile treated and 75% fertile control females, χ^2_1=0.786, P=0.375). In addition, there was a trend in the last two foaling seasons for treated females in good condition at time of treatment to have lower fertility rates than treated females in poor condition at time of

treatment ($F_{1,32}$=3.123, P=0.087). There was no difference in control mares based on condition at time of treatment during those same seasons ($F_{1,30}$=0.934, P=0.342).

Side effects of Treatment

In order to examine impacts of contraception on foals, we compared fertile treated mares (contraceptive failures) to control mares. There was no difference in the seasonality of births across the first two years between these treated mares and controls (χ^2_1 = 0.406, P=0.524), with the majority of all foals being born in April (40%) and May (52%) (Figure 2). Among treated mares, 88% foaled during April, May, and June and for control mares, 94% foaled during this time period. There was no treatment effect on foal survival (χ^2_3=0.002, P=0.969). There was also no difference in the foal sex ratio between treatments across three foaling seasons (χ^2_3=0.939, P=0.816), as 48% of foals were males from treated mares and 50% from control mares.

Discussion

Free-living horse populations continue to present a management problem in the western United States, and past management methods are increasingly unfeasible or ineffective. Consequently, contraceptive treatments have become more widely used to reduce herd numbers and population growth, especially with the development of a contraceptive agent which provides multi-year contraception after a single dose (Killian et al. 2008). We show that free-living horse fertility rates were decreased by contraceptive formulations with the use of a single vaccination. Females treated with either GonaCon-B™ or SpayVac® had lower fertility rates every foaling season than

control females. Furthermore, both treatments consistently reduced fertility within individual females throughout the three years.

While we found a reduction in fertility, we did not have as high efficacy rates as other free-living horse studies that have shown efficacy >90% during the first year (Kirkpatrick et al. 1990, Turner et al. 2002, Turner et al. 2007). Although there may have been problems with the treatment method, this seems unlikely since all mares received the full dose while in the squeeze chute. Alternatively, we monitored our horses more intensively than other studies by locating horses on a weekly to monthly basis, and used conservative estimates of pregnancy and foal production since horses may abort fetuses throughout the year or may lose foals shortly after birth (Keiper and Houpt 1984, Lucas et al. 1991). If individuals are not closely monitored, these events would be missed and would increase the appearance of contraceptive efficacy. In our study, mares that were only seen late in the foaling season without a foal were excluded from the analysis since it was not possible to determine if they had lost their foal or had not foaled at all. In addition, intensive monitoring and fecal hormone evaluation enabled us to identify treated females that were pregnant and lost their foal, which would have been recorded as effective contraception in a less intensive study. These techniques contrast with these of other researchers who only sample a few times per year, but use absence of offspring as an indicator that the contraceptive worked (Kirkpatrick et al. 1990, Rutberg et al. 2004, Turner et al. 1997, 2007). Furthermore, some of these studies have shown a similar trend with fecal hormone sampling and foaling data providing different results (e.g., mares pregnant from fecal hormone analysis, but show no visible signs) (Turner et al. 1997,

2007). This suggests that visual estimations a few times per year do not give an accurate representation of contraceptive efficacy.

Body condition

We found significant variation in contraceptive efficacy, explaining some of the inter-individual variation in responsiveness to immunocontraception. Fertility rates were lower in females that were in good condition at treatment, while mares in poor condition foaled at the same rate as control mares. Furthermore, Killian et al. 2008 showed high efficacy in captive feral horses using the same treatments on the same species from the same population we studied. The captive mares had a much better response to the treatment and showed higher levels of fertility reduction for the first 2 years post treatment [e.g.,100% and 83% for SpayVac® treated mares and 94% and 60% for GonaCon treated mares (Killian et al. 2008)]. All of these captive mares were in good condition (3 or better) at the time of treatment (Thain, personal communication). Captive populations are typically in better condition and have access to better-quality nutrition and could therefore respond better to contraceptive treatment. Furthermore, studies have demonstrated variation in response to different contraceptive formulations and adjuvants both among and within species (Garrott et al. 1998, Fayrer-Hosken et al. 2002, Frank et al. 2005). However, there have been no studies that investigated differences in individual phenotypes as a possible explanation for this variation. One such explanation could be body condition.

Individuals in better body condition, or with more energy reserves, generally have better immune systems and are able to respond better to foreign bodies (Chandra 1996,

Alonso-Alvarez and Tella 2001, Demas et al. 2003, Ujvari and Madsen 2006, Houston et al. 2007, Vicente et al. 2007, Corbin et al. 2008). Both contraceptive treatments we tested use the individual's own immune system to elicit a response that blocks critical aspects of reproduction. Theoretical concerns have been raised over the idea that over time, immunocontraception treatment leads to the removal of individuals with good immune systems from the population; essentially selecting for immunocompromised individuals that do not respond to immunocontraception and potentially have lower disease resistance (Nettles 1997, Cooper and Herbert 2001, Cooper and Larsen 2006). While our study is too short to evaluate the long-term impacts of contraception on immunocompetence, we did find consistent variation in relation to body condition at treatment, which may be an indicator for immune health. Our results therefore suggest that further research is required on inter-individual variation in responsiveness, particularly in relation to body condition and health at treatment, and indicate that long-term impacts of population health, particularly immunocompetence, could occur.

Impacts on foals

Feral horse populations differ in the birthing season, but the majority of foals are born in the spring (Feist and McCullough 1975, Keiper and Houpt 1984, Berger 1986). Foal survival is related to season of birth, as foals are more likely to survive when they are born in the spring than in the winter. Because contraception can cause out of season births, which can impact survival, we tested if treated mares foaled out of season. Previous studies have shown that PZP treatments can lead to increased estrus cycling during the nonbreeding seasons (McShea et al. 1997; Miller et al. 2000b, Curtis et al.

2002). These side effects can result in offspring born out of season leading to reduced survival (e.g., white-tailed deer, McShea et al.1997). We found no evidence to suggest that foals were born out of the normal birthing season to any treated females. A majority of the foals were born in the spring months of April and May to both treated and control females and this is consistent with other feral horse populations. Our data on foaling dates are consistent with other studies that investigated seasonality of foal births of treated individuals (see Kirkpatrick and Turner 2003). These data suggest that contraceptive treatment does not impact birthing seasons in feral horses or foal survival.

Contraceptive treatment has been shown to increase body condition of mares (Turner and Kirkpatrick 2002). These changes to body condition can impact the sex of the foal as females that experience an increase in body condition at time of conception have more males and females that experience a decrease in body condition have more females (Cameron and Linklater 2007). In our study, we found no evidence that the sex ratio of foals changed due to contraceptive treatment. Since treated females in poorer condition were more likely to foal, we expected some of these females to have more daughters, but there was no difference between treatment groups. It would be interesting to continue to monitor sex ratios in mares after the contraceptive has ceased to be effective, since mares that have not foaled for several years should be in better body condition (e.g., Turner and Kirkpatrick 2003), which could lead to an increase in male births (e.g. Monard et al. 1997, Cameron and Linklater 2000, Cameron and Linklater 2007).

Summary

Our findings demonstrate that new contraceptive formulations are able to reduce fertility in females for several years. Only one shot was necessary to deliver the contraceptive vaccine, and would be beneficial to managers because it eliminates the need for several round-ups. We conclude that these formulations would be useful for managing feral horse populations, but models are needed to determine how many females should be treated in order to reduce or stabilize the population. In addition, our results indicate that body condition may be an important but overlooked factor in efficacy of treatment and sampling methods are important when studying efficacy rates in wild populations.

Acknowledgements

This research was funded by grants from the Nevada Arid Rangeland Initiative NOA15353CG, 110615253BS, 140115253BS, 140215253BS, Hatch Grant 13215353BS and a research grant from the Animal Behavior Society. We thank the National Wildlife Research Council, especially Lowell Miller, for providing all of the contraceptive formulations. We are grateful to anonymous land owners for access to their land for both treatment and observations. We thank Joan Bauman from the St. Louis Zoo Endocrinology Lab for her valuable guidance with the fecal hormone analysis.

Table 1. Fertility rates of treated and control females for three foaling seasons. The number of females seen in each group is in parentheses. Both treatments significantly reduced fertility in the combined three foaling seasons ($P<0.01$).

Treatment	2006 (N)	2007 (N)	2008 (N)
Control (no injection)	60% (15)	69% (13)	86% (14)
Adjuvant only	63% (16)	65% (20)	67% (15)
SpayVac®	36% (14)	56% (16)	44% (16)
GonaCon-B™	39% (18)	42% (12)	31% (16)

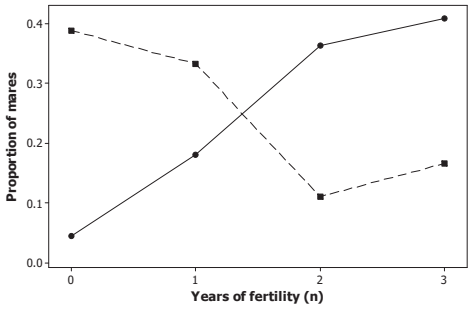

Figure 1. The proportion of females that were never fertile (0), fertile one year (1), fertile 2/3 years (2), or fertile all 3 years (3). All females had a known fertility status in all three foaling seasons within treatment and control groups. The dashed line with squares represents treated mares combined (N=18) and the solid line with circles represents control females (N=22).

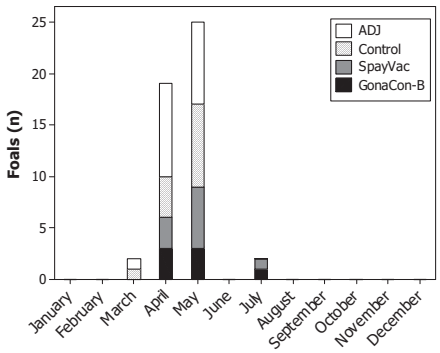

Figure 2. The number of foals born in each month of the year. Data pooled over two foaling seasons (2006 and 2007) and only from foals with known birth dates.

CHAPTER 4

Does contraceptive treatment in wildlife result in side effects? A review of quantitative and anecdotal evidence

"There is nothing like looking, if you want to find something. You certainly usually find something, if you look, but it is not always quite the something you were after."
J.R.R. Tolkien

Photo caption: Fire band in the spring of 2006

Author's note: Chapter four has been submitted to the journal Reproduction and is presented in the style of this journal.

Abstract: The efficacy of contraceptive treatments has been extensively tested, and several formulations are effective at reducing fertility in a range of species. However, these formulations should minimally impact the behaviour of individuals and populations before a contraceptive is used for population manipulation, but these effects have received less attention. Potential side effects have been identified theoretically and we reviewed published studies that have investigated side effects on behaviour, physiology or population dynamics, which provided mixed results. Physiological side effects were most prevalent. Most studies reported a lack of secondary effects, but these reports were usually based on qualitative data or anecdotes. A meta-analysis on quantitative studies of side effects showed that secondary effects consistently occur across all categories and all contraceptive types. This contrasts with the qualitative studies, suggesting that anecdotal reports are insufficient to investigate secondary impacts of contraceptive treatment. We conclude that more research is needed to address fundamental questions about secondary effects of contraceptive treatment and experiments are fundamental to conclusions. In addition, researchers are missing a vital opportunity to test the roles of reproduction, sex and fertility in wildlife species.

Introduction

Fertility control for population management of wildlife and zoo species has some advantages over other control methods, such as lethal control (Kirkpatrick 2007). For example, culling reduces population size, but also increases population growth rates, counteracting the goals of most population control operations (Garrott *et al.* 1991). Furthermore, there are ethical concerns about culling (Littin *et al.* 2004) such that public acceptance of lethal control is typically low when other management options are viable (e.g. Stout *et al.* 1997). However, for contraception to be successful for population control it must not only be safe, effective and long-acting, but also have minimal impact on the social organisation, behaviour, and ecology of populations with treated individuals (Castle & Dean 1996). Contraceptive technologies are becoming increasingly effective, safe and long-lasting (Kirkpatrick & Turner 2007), but despite several decades of contraceptive treatment, little research has considered secondary impacts, except in domestic animals. Fertility control is used to manage farm, domestic and recreational animals (D'Occhio 1993) and provides a viable and reversible alternative to de-sexing (e.g. cats, Ivanova *et al.* 1995; Gorman *et al.* 2002), but only if the animals behave similarly before and after treatment. In wildlife, the alternative is often lethal control which raises a plethora of other legal and logistical issues (e.g. Kirkpatrick 2007). Nonetheless, the side effects of contraception need to be understood for fertility control to be an effective management tool, even if alternative management practices have more extreme side effects (see Kirkpatrick 2007).

Contraceptive formulations either prevent ovulation, fertilization or implantation, or terminate pregnancy. Immunocontraception uses an animal's own immune system to

prevent reproduction. The body produces antibodies in response to the injection of a foreign body, and the antibodies then interfere with critical events in reproduction. Several different types of immunocontraceptive formulations have been developed, including those against ova (Sacco 1987), sperm (Primakoff *et al.* 1988) and gonadotropins (Moudgal *et al.* 1986). The most commonly used formulation is porcine zona pellucida (PZP), which stimulates the production of antibodies to zona pellucida (ZP) when injected into the host (Aitken *et al.* 1984). These antibodies prevent sperm binding to the ZP sperm receptors, thereby preventing fertilization (Sacco *et al.* 1984). Infertility results, but females continue to cycle. Since the structure of these receptors is conserved, PZP inhibits fertility in a range of mammalian taxa (Wood *et al.* 1981; Mahi-Brown *et al.* 1985; Sacco 1987; Kirkpatrick *et al.* 1996). Gonadotropin releasing-hormone (GnRH) formulations, both agonists and active immunizations, result in a cessation of the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH). Treated females thereby enter a variable length anestrous period (Talwar 1985). These GnRH formulations have been widely used in domesticated livestock as a practical application to improve carcass quality and to reduce aggressive behaviour (i.e. Huxsoll *et al.* 1998; Kiyma *et al.* 2000). To a lesser extent they have been used for fertility control in both males and females of wildlife species (e.g. Miller *et al.* 2000a). Other common types of contraceptive agents include (1) melengestrol acetate (MGA), a progesterone-like drug that suppresses LH, preventing ovulation, but allowing development of large follicles and endogenous estradiol, and (2) progesterone analogs that inhibit ovulation and prevent implantation, both of which have been used successfully in several zoo species (reviewed in Patton *et al.* 2007). Surgical sterilization is also an option in some species, but presents

some practical issues associated with surgery (i.e. catching, anesthesia, irreversibility, morbidity, mortality) that make it unsuitable for most wildlife species.

The potential side effects of these contraceptive treatments have been considered theoretically, but few have been tested empirically. Nettles (1997) reviewed potential side effects, which included physiological effects, behavioural effects, population impacts and evolutionary impacts, and more recently suggested side effects include evolutionary effects (Magiafoglou *et al.* 2003; Cooper & Larsen 2006) and impacts on disease transmission rates (Tuyttens & MacDonald 1998; Caley & Ramsey 2001; Miller *et al.* 2004). The diversity of contraceptive agents means that there is potential for a variety of secondary impacts. Here we review the literature to determine 1) potential impacts on individuals and populations, 2) which impacts have been documented and 3) which impacts have been empirically tested. Finally, we consider the implications of the side effects of contraception for addressing fundamental theoretical questions, particularly in behavioural ecology.

Materials and Methods

We searched ISI Web of Science (1975-2007) for 'immunocontraception' and 'contraception'. Additional searches were made to narrow the papers to those with the terms 'side effects' and 'secondary effects', and we further searched the literature cited section of each paper to find more studies that were not identified in the initial search. Only papers that included applications to mammalian wildlife, zoo, or livestock species were used in the review, and humans were excluded. We use the terms secondary effects and side effects interchangeably throughout the paper and define these terms as any

effects resulting from contraceptive treatment but are not related to the actual contraceptive action, and could be either positive or negative.

Initially we reviewed the theoretically suggested side effects. We then compiled all the studies that had addressed secondary effects either directly or during the course of a study on efficacy. Papers that only researched efficacy or impacts of contraception on fertility directly were not included. A total of 212 papers were found that investigated secondary effects or reported side effects noticed during research on efficacy (the full list is presented as Appendix 1). The papers fell into three categories; 1) physiological effects, 2) behavioural effects on the individuals, and 3) population-level effects, and we use these three categories hereafter. From these papers, we considered sex, species, sample size, length of study, type of effect investigated and if that effect had an impact on the animals. We then compared the theoretical effects with the empirical evidence to determine which effects seemed to be supported, or not supported, and in which areas more research is required.

Meta-analysis

From the reviewed papers, we analyzed studies that empirically tested if side-effects were found in treated wildlife populations through a meta-analysis in order to estimate the magnitude of the experimental effect (effect size). We only included wildlife populations and excluded wildlife in zoos if the contraceptive treatment was used intentionally to change behaviour (i.e. decreasing aggressions or sexual activity), so as to not skew the analysis towards side-effects. In addition, in an effort to be conservative, livestock papers were excluded since 87% of these studies reported side-effects and most

of these papers used the contraception to make a change. A criticism of every meta-analysis is the possibility of publication bias (file-drawer problem), in which only statistically significantly papers are published (see Gurevitch and Hedges 1999). Therefore, we made every attempt to remove publishing bias by the previously described methods. In addition, since our original search included papers that did not experimentally test for secondary effects but reported that they found none, we included those papers if a test statistic could be computed to help reduce this bias. For the meta-analysis we used p-values and sample size reported in each study in order to obtain a combined effect size (r). Effect sizes were weighted for sample size and indicate the strength of associations across the selected studies. The corresponding $Z_{weighted}$ value provides the significance of the difference between treated (contracepted) and control groups. In addition, we calculated a χ^2 statistic to test for heterogeneity of results across the selected studies. A random effect model was used in order to account for differences in both effects size and sampling error (Gurevitch and Hedges 1999). A total of 54 papers were included that empirically tested secondary effects from contraceptive treatment. From those papers, all measures were treated as separate statistics. If there was not sufficient evidence to determine p-values and sample sizes, the papers (or statistics) were excluded from the analysis. An overall analysis was done, in which all experimental studies were included, regardless of treatment type and study classification. The separate analyses were done to test for differences within each study category (physiology, behaviour and population-level effects) and contraceptive type (GnRH, progesterone, PZP, and surgery). The meta-analysis was conducted using META, v 5.3 (Schwarzer 1989).

Results

Trends in publications

The reviewed studies emphasized pest animals and agriculturally important species. Several orders have been investigated, but studies concentrated on Artiodactyla (particularly deer and domestic cows), Perissodactyla (mainly horses), and Carnivora (particularly felids) (Appendix Table 1). There was an increase in published papers from 1975-2002 (Fig. 1). These publication trends indicate increasing interest in side effects with a peak in 2002 when a special issue of Reproduction Supplement was published. After this supplement, the rate of publication returned to a consistent pre-2001 level.

Most studies investigated the impacts of female contraceptives (Table 1), which is consistent with efficacy studies in wildlife which usually target females. Physiological responses were addressed in a high percentage of the papers (85%) for both males and females. While physiological impacts are important, behavioural and population-level effects may be more relevant to the management of wild populations. Approximately 35% of the papers addressed individual behaviour and 11% addressed population-level effects. Roughly 30% of the papers addressed more than one category. There was a sex bias with 90% of the papers on males considering physiological side effects (particularly carcass quality), compared to 83% in females (usually impacts on reproductive organs). Behavioural measures were also investigated more in males (Table 1). Only one paper investigated population-level effects in males, most likely because females are treated more often than males in wildlife populations (Table 1).

Documented secondary effects

Several secondary effects are theoretically possible, and these are summarized in Table 2. Only a few hypothesized impacts have not been investigated, with most being studied at least once. However, few studies produced consistent results, even among studies using the same formulations. The main impacts are summarized below.

Physiology

How does contraception impact internal organs?

The impact of contraception on internal organs has received the most attention, with a total of 135 studies published. Changes in ovarian structure and function were found in most studies (83%, Table 2), which is not surprising since contraceptive formulations act directly on reproductive functioning, and so changes in reproductive organ histology and function are more likely than other impacts. For example, intrauterine devices (IUD's) increase inflammation of the uterus (Daels & Hughes 1995), while ovarian function is altered by both GnRH treatment (McNeilly & Fraser 1987; Gong *et al.* 1995; D'Occhio & Kinder 1995; Maclellan *et al.* 1997) and PZP treatment (Dunbar *et al.* 1989; Kirkpatrick *et al.* 1992; Kitchener *et al.* 2002; Curtis *et al.* 2007). In addition to alterations in ovarian functions, MGA implants can increase mineralization and cystic hyperplasia in captive felids (Munson *et al.* 2002). Consequently, changes to the ovaries or female reproductive tract were consistently found for all contraceptive treatments.

In domesticated livestock, GnRH treatment has been used to improve carcass characteristics by increasing lean meat (Huxsoll *et al.* 1998), feeding efficiency (Cook *et*

al. 2001) and live weight (Bonneau *et al.* 1994; Zeng *et al.* 2002), and treatment usually resulted in positive or no effects on carcass traits. Milk production did not seem to be influenced by contraception in the few studies in which it has been investigated (Mattos *et al.* 2001; Nave *et al.* 2000), although there was some evidence of mammary hyperplasia in cats treated with progesterone (Loretti *et al.* 2005)

In addition to effects on internal organs, several studies (64%, Table 2) found inflammation or abscesses at the injection site. These usually healed quickly with no long-term health effects. Overall, most of the treatments showed little to no impacts on internal organs other than the ovaries (or testes) and some of the effects were considered positive.

Does contraception alter body condition?

Without the costs of lactation and gestation, females should hypothetically have improved condition and health, possibly leading to increased longevity and lifespan (Williams 1966). The impacts could extend beyond treated females. For example, untreated males may lose condition in the presence of contracepted females due to prolonged breeding activities (Ji *et al.* 2000). Some studies have confirmed that treated females are in better condition than untreated conspecifics (26% of reviewed studies), but the majority found no difference, or that differences did not last (Table 2). For example, PZP treatment increased female condition in both feral horses (*Equus caballus*) and white-tailed deer (*Odocoileus virginianus*) in some studies (McShea *et al.* 1997; Turner and Kirkpatrick 2002), but not in others (Walter *et al.* 2003). Generally, females treated with GnRH show no changes in weight or condition (Miller *et al.* 1997; D'Occhio *et al.*

2002; Herbert *et al.* 2005; Herbert *et al.* 2006; Rubion *et al.* 2006). Finally, both longevity and offspring survival could be influenced by contraceptive treatment (Table 2). Furthermore, untreated females may have more successful reproduction due to reduced competition for resources. The impacts of these factors on population dynamics can counteract the desired impact of the contraceptive treatment in reducing population size (see Williams *et al.* 2007). Such population-level effects are discussed later.

Are some contraceptive agents reversible?

For contraceptive treatment to be an effective management tool, it usually needs to be reversible (Kirkpatrick & Turner 1991). A long term study of feral horses (*Equus caballus*) showed that PZP was reversible even when females were treated for several years (Kirkpatrick & Turner 2002). However some females appeared not to return to full fertility after long-term PZP treatment and similar side effects were shown with progesterone implants in marsupials (*Macropus giganteus*) (Nave *et al.* 2000) and GnRH treatments in deer (*Odocoileus virginianus*) (e.g. Miller *et al.* 2000a). Consequently, most wildlife contraceptives are reversible, or have minimal impact after prolonged use.

Individual Behaviour

Do activity patterns change in treated individuals?

Most studies suggest that activity patterns were unchanged after contraceptive treatment (80%, Table 2). With PZP treatment, no changes were detected in activity budgets of elk (*Cervus elaphus*), horses (*Equus caballus*), elephants (*Loxodonta africana*), and white-tailed deer (*Odocoileus virginianus*) females (McShea *et al.* 1997;

Heilmann *et al.* 1998; Powell 1999; Delsink *et al.* 2002), although the increased number of estrus cycles resulted in PZP treated white-tailed does (*Odocoileus virginianus*) being more active than control females (McShea *et al.* 1997). GnRH did not change activity budgets in treated kangaroo females (*Macropus giganteus*) (Woodward *et al.* 2006), nor did progesterone implants in kangaroos (*Macropus giganteus*) (Poiani *et al.* 2002), or fruit bats (*Pteropus rodricensis*) (Hayes *et al.* 1996). However, MGA treatment caused baboons (*Papio hamadryas*) to decrease their time foraging (Portugal & Asa 1995). Overall, few studies report changes in activity patterns after contraceptive treatment.

Does rank and dominance change in treated females?

Rank and dominance are important in social mammals (Ellis 1995). By changing the levels of hormones or cycling patterns, females could become more or less aggressive, which could have implications for behaviour, social structure and welfare. Such side effects have been used by captive managers (e.g. GnRH to control aggressive behaviour, Patton *et al.* 2001), but the few studies on wildlife have produced mixed results (50% showed changes Table 2). In captive felids, females treated with PZP had increased levels of irritability, masculine behaviour, and aggression (Harrenstien *et al.* 2004), and in white-tailed deer (*Odocoileus virginianus*), treated females associated less frequently with conspecifics (Bertrand *et al.* 1996). MGA treatment in tamarins (*Leontopithecus chrysomelas*) caused a decrease in affiliative and sexual interactions, with a subsequent increase in aggression toward other females (De Vleeschouwer *et al.* 2000; De Vleeschouwer *et al.* 2003). Pioani *et al.* (2002) found that progesterone treatment altered the amount of time males spent with females, as males preferred to be in

groups with untreated females. In elephants (*Loxondonta africana*), the matriarch remained in place after treatment with PZP (Delsink *et al.* 2002), but was affected by hormonal treatments (Fayrer-Hosken *et al.* 2000). PZP treatment did not change the spatial relationship between females and males in horse harem bands (*Equus caballus*) (Powell 1999), although all females had been treated with PZP at some point, confounding the conclusions. Finally, surgical sterilization had little impact on coyote (*Canis latrans*) pair bond maintenance or territorial behaviour (Bromley & Gese 2001), and no changes in social hierarchy were observed in brushtail possums (*Trichosurus vulpecula*) with GnRH treatment (Jolly *et al.* 1996).

Unfortunately, many of the studies reporting no change in social structure have either used opportunistic observations of social groups, rather than quantitative techniques, or have been of short duration. Consequently, the results are inconclusive, and studies that specifically and intensively investigate behavioural changes at a fine level over a long time period are urgently needed.

Are home ranges and movement patterns altered?

If sexual behaviour is altered in treated females, movement patterns could also change. PZP treatment resulted in no difference in space use or home range size in elephants (*Loxodonta africana*) and white-tailed deer (*Odocoileus virginianus*) (Delsink *et al.* 2002; Hernandez *et al.* 2006), similar to surgically sterilized foxes (*Vulpes vulpes*) (Saunders *et al.* 2002). In contrast, surgically sterilized female rats (*Rattus argentiventer*) had larger ranges than both control and hormonally sterilized females (Jacob & Matulessy 2004). In addition, hormonally sterilized female rats abandoned burrows more

often, suggesting a change in dominance or social status, although overall habitat use was not changed (Jacob & Matulessy 2004). Male home range size may also be impacted, as found in brushtail possums (*Trichosurus vulpecula*) (Ramsey 2007). Sterilization resulted in no difference in territory size, overlap or territorial behaviour between controls and treated coyote packs (*Canis latrans*) (Bromley & Gese 2001). Consequently, most studies suggest that contraception had minimal impact on home range size and movement patterns, but there was some evidence that males alter their movement patterns to be in groups of untreated females, or with treated females during the nonbreeding season (Poiani *et al.* 2002).

Do sexual interactions and breeding behaviour change?

Changing the fertility of individual females could impact sexual interactions, especially in PZP-treated individuals because the number of estrous cycles is increased (i.e. McShea *et al.* 1997; Heilmann *et al.* 1998; Miller *et al.* 2000b; Miller *et al.* 2000c; Curtis *et al.* 2002). There was some evidence that breeding behaviour changed in treated females (Table 2), and this varied with contraceptive type. Does (*Odocoileus virginianus*) treated with GnRH immunizations had fewer estrus events (Miller *et al.* 2000a), but female wapiti (*Cervus elaphus*) showed no difference in copulatory behaviours (Baker *et al.* 2004). Treatment with progesterone analogs showed similar results to GnRH, but more males were seen in groups of control females (Poiani *et al.* 2002). Ji *et al.* (2000) suggested that males were attracted to areas with sterilized females, potentially increasing male mortality due to decreased body condition. In contrast, with PZP treatment, females remained sexually active after the end of the breeding season and showed an increase in

estrus events (McShea *et al.* 1997; Heilmann *et al.* 1998; Miller *et al.* 2000b; Miller *et al.* 2000c). Although changes in breeding behaviour appeared to be related to contraceptive formulations, 64% of the studies found changes in estrus and breeding behaviour (Table 2), suggesting that these changes should be expected.

Does contraception impact the overall welfare of individuals?

The reviewed impacts on physiology and behaviour suggest that contraception had little impact on overall welfare of individuals, particularly compared to the alternative options (see Kirkpatrick 2007). While most studies found some changes in physiology or behaviour, these changes may not impact the individual enough to affect its welfare, as most studies found no changes to activity, movements or rank of treated females. However, these conclusions are based largely on qualitative and anecdotal studies. In addition, some studies showed that changes could occur to non-treated animals in the population (e.g. males), which needs to be considered in future research.

POPULATION-LEVEL EFFECTS

Do survival, abundance, and age class distribution change in treated populations?

Contraception reduces the costs of reproduction, and could therefore result in increased body condition and longer lifespan, thereby altering population dynamics. Furthermore, the offspring of untreated females may have less competition for resources, enhancing their survival and working against the goals of the management operation. Few studies had the longitudinal data required to investigate increased survival, but 75% found an increase in longevity or survival in individuals. For example, PZP treated feral

horse mares (*Equus caballus*) lived longer, resulting in a new age class (>25 years) not present before treatment (Turner & Kirkpatrick 2002). Therefore, while contraception may limit offspring production, these benefits may be offset by decreased mortality in older individuals, negating the population effects of contraceptive treatment. In addition, both adults and juveniles had increased survival in surgically sterilized rabbits (*Oryctolagus cuniculus*) (Williams *et al.* 2007), which meant that the majority of females must be sterilized to reduce population size (Williams *et al.* 2007). Furthermore, non-treated females show improved breeding success (Chambers *et al.* 1999), which also counteracted the effects of contraception for reducing population growth rates. Finally, while the sex ratio of offspring could change due to increased maternal condition (e.g. Cameron 2004), this has yet to be investigated, although Ji *et al.* (2000) recorded a change in population sex ratios, probably as a result of male dispersal. Overall, contraceptive treatment appears to increase longevity in treated females and, in some cases, non-treated individuals.

Is the mating season extended?

Mating behaviour can demand high levels of energy for both sexes. In species with a discrete breeding season, the lengthening of the season could impact the survival and welfare of treated females and nontreated males. Most studies showed a change in the annual breeding season where it was investigated (78%, Table 2). Treatment with PZP increased breeding behaviour, caused later fawning dates, and increased sexual activity outside the normal breeding season in several studies (McShea *et al.* 1997; Heilmann *et al.* 1998; Miller *et al.* 2000b). However, no differences were reported in

populations with females treated with GnRH (Miller *et al.* 2000a; Baker *et al.* 2002; Baker *et al.* 2004; Woodward *et al.* 2006; Conner *et al.* 2007), or progesterone (Poiani *et al.* 2002). Differences in the actions of these formulations and their contrasting effects on cycling probably account for the differences in the impacts on the breeding season. Consequently, the type of contraceptive treatment should be considered for species with a discrete breeding and birthing season.

Does contraception decrease disease transmission?

If contraception decreases sexual interactions, there may be a decrease in overall social interactions which could decrease the level of disease transmission of certain diseases. This decrease would be advantageous in certain pest species, such as the brushtail possum (*Trichosurus vulpecula*), which have a high population size, and are carriers of economically or ecologically important diseases, such as bovine tuberculosis (Caley & Ramsey 2001; Ramsey 2007). A potential decrease of brucellosis transmission is predicted in bison (*Bison bison*) with GnRH treatment (Miller *et al.* 2004), as anestrous females would be unable to spread the disease. However, PZP treatment, in which females continue to cycle, could have the opposite effect as there could be an increase in sexual interactions. While there has been little research, most studies concur that disease transmission rates remain unchanged with contraceptive treatment (Kerr *et al.* 1998; Williams *et al.* 2007). However, the potential to reduce disease transmission exists (Ramsey 2007) and studies on rabbits (*Oryctolagus cuniculus*) showed a decrease in flea abundance (Twigg *et al.* 2000; Williams *et al.* 2007); possibly indicating a decrease in overall interactions between individuals. More research is clearly required.

Meta-Analysis

Of the 212 reviewed papers, 54 (25%) experimentally tested the secondary effects of contraception and reported their results in sufficient detail to be included in the meta-analysis. From our qualitative review, most papers concluded no significant secondary effects were found. However, the quantitative studies produced contrasting results. From the 339 test statistics from 54 papers, 52% found side effects from contraception and an additional 8% showed a non-significant trend suggesting side effects. The support varied between contraceptive types and between secondary effect types, with progesterone treatments and physiological studies having the most side effects (Fig. 2). Despite this variation, an overall meta-analysis confirmed that side effects consistently occurred where investigated as there was a significant relationship for secondary effects, with high predictive power and relatively large effect size, and no significant heterogeneity of data (Table 3). Therefore, contraceptive treatment resulted in changes to the physiology and behaviour of individuals, and impacted populations with treated individuals.

An interesting contrast thereby arises in that quantitative studies showed that side effects were consistently found, whereas qualitative studies and anecdotal reports suggest that side effects were generally absent. While a publication bias is possible, most studies were predominantly publishing results on efficacy, such that data on side effects would not influence publication potential. Consequently, more studies specifically investigating secondary effects are required to quantify the impacts of contraceptive treatment on physiology, behaviour and population dynamics.

Discussion

Future Directions

While there have been an increasing number of studies of side effects, much is still unknown. Unfortunately, many studies were not designed to investigate the side effects and many conclusions were based on small sample sizes, anecdotal reports, or lacked a true control. In this review, sample sizes, when reported, ranged from 1-353 for treated individuals and 0-230 for control individuals, with an average sample size of 31.7 ± 49.0 (median 17) treated individuals and 18.2 ± 30.0 (median 9) for controls, indicating high variability among studies. Most studies were of relatively short duration, with an average duration of 1.8 ± 2.4 years; although data collection was often conducted in short field periods of a few days or weeks over the course of the entire study, probably resulting in an overestimate of average study length. Most studies failed to address changes over a long period of time.

Conclusions based on data from studies designed to investigate efficacy may not be methodologically suitable for testing for behavioural or ecological effects. Many studies were designed to test efficacy, and the side effects reported were based only on short-term observations. Many studies on efficacy concluded “no change” for side effects based on anecdotal observations, but these studies did not directly investigate the physiology, behaviour or ecology during the study, limiting the conclusions. This contrasts with the meta-analysis further questioning the validity of qualitative studies reporting “no change”. While the meta-analysis does not account for the severity of the effect, all of the major contraceptive treatments resulted in side effects (Table 3). Thus, these qualitative studies represent an interesting foundation, but future research requires

more detailed behavioural and ecological protocols, larger sample sizes, and longer study durations.

Evolutionary level

No evolutionary level questions have been investigated, but are most relevant for future impacts (Table 2). Two main impacts of immunocontraception have been proposed; 1) genetic resistance could evolve, similar to the response seen to other biological control agents (Magiafloglou *et al*. 2003), and 2) immunocontraceptives could be selecting for immuno-compromised individuals since those treated females that do breed have a lower immune response to the contraceptive (Nettles 1997; Cooper & Herbert 2001). These aspects require long-term research which has not been possible to date. Nonetheless, given the potential implications of either of these changes, research is urgently required in this field.

Conclusions

While physiological effects have been well-documented, there is less consistency in studies investigating behavioural or ecological side effects, compounded by the tendency for studies to be designed to investigate efficacy specifically and side effects only opportunistically. Such studies often lack appropriate controls, sampling methodology or time scales. Those studies that have specifically investigated side effects consistently find them. While contraception is supported as a humane treatment, research has not extended much beyond the scope of management concerns.

Both physiological and behavioural effects can impact population dynamics. The goal of contraceptive treatment is to manipulate population dynamics, and consequently it is imperative to understand population-level effects, some of which compromise the effectiveness of contraceptive treatment (such as through increased breeding in untreated females or increased survival of offspring), while others could enhance effectiveness (such as a male biased sex ratio). To be an effective tool, we need to understand these impacts. Furthermore, most research examined short term effects and research is needed that addresses questions beyond one estrous cycle or breeding season. For example, no studies looked at how genetic diversity or immunity could change over time.

Finally, contraception provides a powerful tool to address fundamental questions in biology but such applications have not been realized to date. By manipulating fertility we can address questions regarding, for example, the costs of reproduction, importance of copulation in maintaining social structure and parental investment strategies. This would enable us to simultaneously address management questions, questions about contraceptive actions and secondary effects, and questions in basic biology, thereby maximizing the utility of contraception research.

Table 1. A comparison of the 212 reviewed papers (%) based on sex and category.

	Total Papers	Behaviour	Physiology	Population
Female (N=145)	68	30	83	14
Male (N=50)	24	46	90	2
Both (N=17)	8	41	88	12

Table 2. Theoretical side effects of contraceptives, and the number of studies investigating these side effects. References are in Appendix Table 2.

Side-effect	Theoretical	Effect	No effect
Physiological			
Harmful effects on pregnant animals	*Nettles 1997*		
Stillbirth		8	1
Abnormal offspring		2	1
Inhibition of parturition or dystocia	*Nettles 1997*	2	0
Changes in ovarian structure or function	*Nettles 1997*	52	11
Changes in lactation or mammary glands	*Nettles 1997*	1	4
Changes in secondary sex characteristics	*Seal 1991, Nettles 1997*	0	0
Changes in bodyweight or condition	*Nettles 1997*		
Increased in treated females		9	26
Decreased in males		1	0
Toxicity	*Nettles 1997*	0	0
Interference with diagnostic tests	*Nettles 1997*	1	0
Abscesses or inflammatory reactions	*Nettles 1997*	14	8
Individual behaviour			
Changes in behaviour	*Nettles 1997*		
Sexual activity		9	5
Increased movement		2	1
Activity patterns		2	8
Increased irritability or aggression		3	0
Social disruption, change in status, territory loss		5	5
Population-level			
Changes in sex ratio	*Nettles 1997*		
Due to immigration		1	0
Offspring sex ratios		0	0
Changes in annual breeding season	*Nettles 1997*	7	2
Ecological alterations	*Nettles 1997*		
Home range or territory size		3	4
Increased immigration or emigration		0	1
Change in habitat use		1	1
Increased longevity or survival		6	2
Increased survival of offspring		3	2
Impact on fertility of young	*Nettles 1997*	0	1
Improved breeding of non-treated females		1	0
Disease transmission rates	*Tuyttens & MacDonald 1998; Caley & Ramsey 2001; Miller et al. 2004*	1	2
Evolutionary level			
Genetic resistance	*Magiafoglou et al. 2003*	0	0
Genetic changes influencing disease resistance or immune function	*Nettles 1997; Cooper & Larsen 2006*	0	0

Table 3. Meta-analysis of reviewed papers on wildlife species when contraceptive treatment was investigated for secondary effects.

Measure	$n_{studies}$	$n_{statistics}$	$n_{datapoints}$	$Z_{weighted}$	effect size (r)	Heterogeneity (x^2)	p value
All studies	54	339	9471	19.4002[a]	0.1993	338.1099	0.4881

Zumpe D & Michael RP 1988 Effects of medroxyprogesterone acetate on plasma testosterone and sexual behavior in male cynomolgus monkeys *Macaca fascicularis*. *Physiology and Behavior* **42** 343-349.

Zumpe D, Bonsall RW, Kutner MH & Michael RP 1991 Medroxyprogesterone acetate, aggression, and sexual behavior in male cynomolgus monkeys *Macaca fascicularis*. *Hormones and Behavior* **25** 394-409.

Zumpe D, Bonsall RW & Michael RP 1992 Some contrasting effects of surgical and chemical castration on the behavior of male cynomolgus monkeys (*Macaca fascicularis*). *American Journal of Primatology* **26** 11-22.

Appendix Table 1. The entire set of papers that published results on secondary effects, based on the species researched. GnRH = either immunization or agonists, IUD's = intrauterine devices, LH = luteinizing hormone agonists, MGA = melengestrol acetate, Progesterone = hormone treatments that contain progesterone, PZP = porcine zona pellucida.

Order	Common Name	Scientific Name	Contraceptive Type	References
Artiodactyla	Addax	*Addax nasomaculatus*	MGA	*Hall-Woods et al. 2007*
Artiodactyla	Antelope	*Antilopa cervicapra*	MGA	*Raphael et al. 2003*
Artiodactyla	Axis Deer	*Cervus axis*	MGA, PZP	*Kirkpatrick et al. 1996; Raphael et al. 2003*
Artiodactyla	Banteng	*Bos javanicus*	PZP	*Kirkpatrick et al. 1995*

CHAPTER 5

The role of sex in social life: lack of behavioral consequences of contraceptive treatment in feral horses

“The common thread that binds nearly all animal species seems to be that males are willing to abandon all sense and decorum, even to risk their lives, in the frantic quest for sex.”
Randy Thornhill & Craig T. Palmer

Photo caption: Unknown band; mare and foal allogrooming

Abstract: Both sex and reproduction play important roles in the life of social mammals and are often associated with social bonding and cohesion. Consortships are long lasting bonds between males and females and sex functions to maintain these bonds. Females mating within social groups can increase social relationships, decrease harassment, and potentially increase offspring survival suggesting that copulation has important implications for female fitness. The manipulation of sexual behavior may have undesirable consequences for females that live in social groups. Feral horses live in stable year-round harem bands with one to several stallions and adult females with offspring. They are polygynous breeders, but females often stay in bands for long periods of time or for most of their lives. Long tenure in bands by females is correlated with an increase in body condition and reproductive fitness. We manipulated fertility in feral horse mares by using two contraceptive formulations, SpayVac® and GonaCon-B™, that have opposite effects on cycling (increase in estrous cycling vs. reduced cycling) but similar effects on fertility (both prevent pregnancy). We analyzed several behavior measures using linear mixed models to determine if contraceptive treatments affect female behavior. Sexual interactions did not vary among treatment groups and we found few changes in behavior of treated mares related to the mare-stallion relationship. Treated mares did not change bands more often than controls. However, mares that changed bands, regardless of treatment, suffered more aggression, spent more time traveling, and avoided the harem stallion more than females in single stallion bands. While we found few changes in behavior of treated mares, we caution that these results may not reflect all contraceptive formulations and other horse populations. In addition, we saw no breakdown in the consortships between stallions and treated mares and it is likely that sexual interactions,

rather than foal production, are sufficient to maintain these social bonds in feral horse systems on a short time scale.

Introduction

Stable group living is found in many mammalian species (Krause and Ruxton 2002). Traditionally, the driving force behind sociality was related to resource distribution and predation risk (Alexander 1974, Bertram 1978, Wrangham 1980, Clark and Mangel 1986, Chapman et al. 1995, Janson and Goldsmith 1995, Hill and Dunbar 1998, Hass and Valenzuela 2002, Krause and Ruxton 2002). However, social explanations have also been proposed (e.g., sexual coercion, male harassment, infanticide risk) as strong factors that drive the evolution of these mating systems (Clutton-Brock et al. 1992, Smuts and Smuts 1993, Clutton-Brock and Parker 1995, Kappeler 1997). A growing body of literature has demonstrated costs to females associated with male harassment (e.g., infanticide, injuries, mortality, constraints on mating preferences) and how that harassment influences social structure of many mammals [chimpanzees (*Pan troglodytes*) (Williams et al. 2004), New Zealand sea lions (*Phocarctos hookeri*) (Chilvers et al. 2005), American sea lions (*Otaria flavescens*) (Cassini and Fernández-Juricic 2003, Cappozzo et al. 2008), feral horses (*Equus caballus*) (Linklater et al. 1999, Cameron et al. 2003) feral sheep (*Ovis aries*) (Reale et al. 1996) orangutans (*Pongo pygmaeus*) (Fox 2002), quail (*Cortunix japonica*) (Persaud and Galef 2003)]. Moreover, stable group membership has been shown to increase reproductive success of females, lower risk of infanticide, and increase male reproductive success, suggesting that group living has additional benefits beyond lowering predation risk and increasing availability of resources [primates (Kappeler 1997, van Schaik and Kappeler 1997), equids (Kaseda et al. 1995, Linklater et al. 1999, Cameron et al. 2003)].

Within groups, males and females may form bonds known as consortships that can vary from temporary associations to long term bonds (Carpenter 1942, Dixson 1998). Consortships are maintained through social interactions, particularly affiliative behaviors like grooming, remaining in close proximity, and sexual interactions (Bercovitch 1995). They require mutual effort in maintaining close proximity and communication between males and females (Bercovitch 1995). While the overall function of these associations is debated, both sexes appear to benefit. Males benefit by potentially increasing paternity through mate guarding or monopolization (Szykman et al. 2001, Engelhardt et al. 2006, Brauch et al. 2008). Females can benefit from these associations by decreased harassment from other males and increasing their offspring survival, both of which can increase reproductive success (Smuts and Smuts 1993, Dixson 1998, Linklater et al. 1999, Fox 2002). Therefore, the function of these bonds is associated with the production of offspring, and their maintenance is associated with sexual interactions, suggesting that both reproduction and fertility play key roles in the cohesion of these social bonds.

Feral horses are unusual among ungulates in that they live in stable year-round harem bands with one to several stallions and adult females with offspring (Linklater 2000). Females often stay in bands for long periods of time or for most of their lives after natal dispersal (Klingel 1979, Berger 1986, Linklater 2000). These long term relationships between stallions and mares have been previously described as consortships (Kaseda et al. 1995). There is evidence of strong selection for mate fidelity and band loyalty so as to decrease harassment by other males (Linklater et al. 1999). Females that change bands have higher parasite loads, lower body condition, higher harassment rates and lower reproductive success, suggesting that band stability is adaptive for females

(Linklater et al. 1999). In addition, the longevity of band fidelity, or long term consortships, is correlated with an increase in body condition and reproductive fitness in mares (Kaseda et al. 1995). Females that maintain long term bonds with the same male avoid aggression associated with changing bands and increase their reproductive success (Kaseda et al. 1995).

The unusual social structure of long term harem bands is thought to be supported by the socio-sexual behavior of mares (Asa 1986). Female horses are unlike most mammals because they display sexual behavior throughout the year, even during pregnancy, the anovulatory period and after an ovariectomy (Asa 1986, Crowell-Davis 2007). These sexual behaviors have been proposed to maintain interest and stimulate loyalty with stallions and to be a possible explanation for the unusual ungulate mating system (Asa 1986, Linklater et al. 1999). Thus, sexual behavior, regardless of the whether mares become pregnant, is important to the social behavior of mares and the maintenance of band stability. As a result, the manipulation of fertility of females may have important behavioral and social consequences.

Female contraception has been extensively used in many wildlife species to reduce fertility (see Chapter 3). While it is used as an important management tool, the manipulation of fertility in females can also offer insights into sexual and social behavior. Several studies have examined efficacy of contraception, but in comparison, little research has been conducted on the behavioral side effects (reviewed in Chapter 4). While most of the literature shows mixed support for secondary effects of treatment, several contraceptive formulations have been shown to impact behavior (Chapter 4). We studied how contraceptive treatment could impact fertility and mating behavior of mares.

We used two different formulations that have significantly different ways of decreasing fertility. First, SpayVac® is a porcine zona pellucida (PZP) formulation that acts to block fertilization and allows for continued, and sometimes an increase in cycling (Brown et al. 1997, Fraker et al. 2002, Killian et al. 2008). In contrast, GonaCon-B™ is a gonadotropin-releasing hormone (GnRH) immunization that acts to block cycling altogether by significantly reducing the production of LH and FSH (Miller et al. 2000a, Killian et al. 2006, 2008). Both formulations work to reduce pregnancy, but do so in ways that allow us to predict how sexual interactions, or lack thereof, can impact female behavior and social life and if absence of foaling can also cause breakdown in social structure.

Several factors suggest that changes in behavior and band stability would occur in mares treated with contraceptives. First, the socio-sexual behavior of mares implies an important function of social structure and altering fertility could impact consort relationships and band stability. Second, several studies have found changes in behavior with both contraceptive formulations in other species. For example, PZP is a widely used contraceptive in wildlife species and has been shown to prolong breeding behavior and breeding seasons and delay birthing dates in ungulates (McShea et al. 1997, Heilmann et al. 1998, Miller et al. 2000b, 2000c, Curtis et al. 2002). In addition, increased aggression and irritability have been reported with PZP treatment in captive female felids (Harrenstien et al. 2004). Studies that investigated GnRH contraceptive formulations found decreased sexual behavior in females (Miller et al. 2000a), while others have found no changes in sexual behavior (Baker et al. 2002, 2004, Conner et al. 2007). One study showed that male kangaroos preferred to be closer to groups of control kangaroo females

rather than GnRH-treated females, suggesting that sexual interactions may have a function in group formation and fidelity (Poiani et al. 2002). Third, while there is a lack of research that has investigated changes in behavior of feral horses, the few studies that have been conducted have resulted in mixed outcomes, with one study showing no difference in female behavior within an estrous cycle (Powell 1999) and a recent study showing significant changes in female behavior and group fidelity during the nonbreeding season (Nuñez et al. 2009). In addition, both of these studies only used PZP formulations, and a GnRH formulation has not been investigated in feral horses to date. Lastly, since group maintenance and function have been linked to the production of offspring, it is possible that when females do not produce offspring, groups may eventually start to break down.

The current study was initiated in June 2005 when females were treated with two different contraceptive formulations and then followed until August 2007 to look for differences in mare-stallion relationships. By manipulating fertility, we tested the importance of sexual behavior to social behavior in mares, the importance of offspring production and how both could impact band loyalty over time. We looked for differences in behavior in both the breeding and nonbreeding season. First, we tested if foal production was necessary for band cohesion. Then, we investigated how sexual interactions influenced female behavior and impacted consortships. We predicted that SpayVac® (PZP) would increase harassment due to increased sexual activity, which would lead to more band changes, especially in the nonbreeding season. Conversely, since GnRH formulations mimic a more natural cycling pattern (e.g., most mares are pregnant year round and do not cycle), we expected less harassment in the nonbreeding

season, but increased harassment in the breeding season since we expected there would be few sexual interactions with the stallion. While we initially expected an absence of sexual behavior in GonaCon-B™ treated mates, there is some evidence that GonaCon-B™ does not impact FSH, therefore females produce small amounts of estrogen that can stimulate estrus behavior (Killian et al. 2008). Thus, we predicted a significant reduction, rather than absence, of breeding behavior in these females. We tested whether contraception impacted individual behavior of mares, and whether contraceptive treatment impacted consort relationships with the band stallion. We specifically looked at aggressive interactions, sexual interactions, affiliations, spatial distancing, and contact maintenance with the band stallion. We then tested if alterations to sexual behavior and lack of offspring production would impact band fidelity of treated females.

Methods

Study Subjects

The feral horse study population lives in the Virginia Range, east of Reno, Nevada. The mountain range is approximately 145,000 hectares. While the total population is currently around 1400 individuals, the study population consisted of 300 individuals including stallions, mares, juveniles and foals. Feral horses were gathered in June 2005 and females were treated with contraceptive formulations; 1) SpayVac®, a PZP formulation, 2) GonaCon-B™, a GnRH immunization. Control mares consisted of females that received only the adjuvant or no injection. We aged females by tooth eruption patterns (Tutt 1968) and classified into the following age categories: 1-5 (young), 6-8 (middle age), and >9 years (old). We branded all treated females with

individual brands on their left hindquarter, and followed for the next 2 years. Details of treatment protocols can be found in Chapter 3. All treatment procedures were carried out under the supervision of veterinarians from the Nevada Department of Agriculture.

Sampling Regime

Behavioral observations were carried out by one person who was unaware of the treatment status of each female. Behavioral observations began in July 2005 and ended in August 2007. We located bands randomly and observations were evenly distributed during daytime hours. A total of 44 bands were located on a weekly-monthly basis, with 36 having a single stallion and 8 having more than one stallion. Once a band was located, we recorded the GPS location and behavioral observations took place for 30-60 minutes or until the focal animals moved out of view. Samples shorter than 30 minutes were not used in analysis. Observations took place on foot near habituated bands or in a truck from farther distances with the aid of binoculars. Horses were identified by brands or unique coat color and white markings on the face and legs. Branded mares were considered focal individuals and no more than two focal mares were sampled during the observation period (Altmann 1974).

Activity, Aggression and Social Behavior

In order to determine changes in activity, we recorded the focal mare's activity every four minutes. The four minute time interval is similar to that used in other horse studies (Duncan et al. 1984, Crowell-Davis 1986, Cameron and Linklater 2000, Linklater et al. 1999) and enhances the independence of data (Rollinson et al. 1956). Most

activities could be classified into grazing, resting (standing or lying), alert, travel (walk, trot, canter), social (play, affiliative behaviors, sexual behaviors), and not seen (individual out of view or activity could not be determined).

To determine changes in the spatial relationship with the band stallion, we recorded the distance from the focal mare to the stallion in adult body lengths at four minute intervals. Only samples in which at least one member of the dyad was active were included in the analysis. Distances that were less than one body length were recorded as 0.5 body lengths. Spatial distances were transformed into average distance to stallion. In addition, we recorded the nearest neighbors within a two adult body length distance from each focal mare every four minutes. These data were transformed into the percentage of time a female was within two body lengths of the stallion. A two body length distance is considered a close distance and a measure of association (Linklater et al. 1999). We recorded all approaches and leaves within a two body length boundary of the focal mare and stallion on an all-occurrence basis (Altmann 1974). These data were transformed into an index that measures contact maintenance as described by Hinde and Atkinson 1970. Briefly, this score is calculated from the percentage of approaches by the mare towards the stallion minus the percentage of leaves from the stallion by the mare. The resultant score varies from +1 to -1, with a score closer to -1 indicating that the mare was avoiding the stallion (Hinde and Atkinson 1970). Therefore, the spatial relationship between focal mares and stallions was measured as the average body length distance, the percentage of time they were within two body lengths of each other, the percentage of approaches by mares and the contact maintenance scores between focal mares and stallions.

We recorded all social interactions between the focal mare and stallion on an all-occurrence basis. The initiator of the interaction was recorded as well as whether the interaction was aggressive or affiliative. Aggressive interactions include head threats, bites, bite threats, kicks, and kick threats (McDonnell and Haviland 1995). Only aggressive interactions between adult horses were included in the analysis. Sexual interactions included naso (nose to nose sniffing), general sniffing, stallion calls directed towards the focal mare, rubbing by the stallion, genital sniffing, tail lifting from the mare, mounting, and copulation. Both affiliative behaviors and aggression were transformed into average rates of interaction per hour of observation.

Estimating Band Changes

At the beginning of each sampling period, we recorded band membership, which included observations on births, deaths and dispersals. We classified a band change as immigration into a new band that lasted for more than a day. The amount of band changing was calculated as the number of band changes divided by the total days the mare was observed in each season. The mares that changed bands more than once during the course of the study were classified as maverick mares or band changers (Linklater et al. 1999).

Seasonal Designations

Previous studies have shown that behavioral effects of contraceptive treatment differ between breeding and nonbreeding seasons (McShea et al. 1997, Nunez et al. 2009). Because we expected that these effects could occur, all behavioral data were

subdivided into breeding and nonbreeding seasons. We defined the breeding seasons to encompass 30 days before the first foal was born to 30 days after the last foal was born in the foaling season in order to include the peak of sexual activity. This designation resulted in March-July being the breeding season and the nonbreeding season encompassed the rest of the year. During the course of the study, two breeding seasons and two nonbreeding seasons were studied.

Statistical Analyses

A nested analysis to examine differences among bands could not be conducted due to low sample size. Therefore, we tested for behavioral differences based on contraceptive treatment with linear mixed models with restricted maximum likelihood estimation (Bolker et al. 2009). Mares were treated as individual replicates, but their band was treated as a random effect to account for variation among bands. The fixed predictor variables were treatment (control, GonaCon-B™, SpayVac®), band type (single stallion, multistallion, maverick) and age (young, medium, old age). Band type was classified by the number of stallions in the band and if females were habitual band changers (maverick) as these different strategies impact female behavior and reproductive success (Linklater et al. 1999). We combined behavioral data from both breeding seasons and both nonbreeding seasons and females were considered individual samples for each season. A female must have been sampled more than once to be included in the analyses and those females only sampled once were excluded from the analyses. Treated mares that foaled or were pregnant (e.g., contraceptive failures) were excluded from the analysis. We ran all models in SPSS 14.0 (SPSS 2005).

We analyzed band changing data with an analysis of variance using treatment type and age category as predictor variables. Data were normalized by log transformation. All band changes during the first nonbreeding season were excluded because these changes may have been due to the effects of the 2005 roundup. The rest of the seasons (breeding seasons 1 and 2, nonbreeding season 2) were analyzed separately. Data are shown as mean ± standard error. We considered statistical significance as $P<0.05$ and trends as $0.05<P<0.10$.

Results

Behavioral Data Characteristics

A total of 716.38 hours of observation took place during both nonbreeding seasons combined and 558.70 hours for both breeding seasons combined for the mares included in the analysis. A total of 44 bands and 64 mares were used in these analyses. There were no differences in the average hours observed among treatment groups, age classes, and band types within the combined nonbreeding and combined breeding seasons (Table 1). There was no difference in observation hours among treatment groups within each age class for both the nonbreeding (χ^2_4=4.743, P=0.315) and the breeding season (χ^2_4=5.124, P=0.275).

Activity

There was no difference among treatment groups in time spent grazing, resting or traveling during the breeding (graze: $F_{2,58}$=0.063, P=0.939; rest: $F_{2,57}$=0.117, P=0.890; travel: $F_{2,49}$=0.234, P=0.793) and nonbreeding season (graze: $F_{2,80}$=0.444, P=0.643; rest:

$F_{2,78}$=1.094, P=0.340; travel: $F_{2,74}$=0.694, P=0.503). There was a trend for band type to interact with activity as maverick mares traveled more than mares in single stallion bands in the breeding season ($F_{2,29}$=2.804, P=0.077) and mares in multistallion bands traveled more than mares in single stallion bands ($F_{2,35}$=3.403, P=0.045; Figure 1).

Sexual Interactions

There were no differences in sexual interactions among the treatment groups both within the breeding season ($F_{2,45}$=0.538, P=0.588) and outside the breeding season ($F_{2,79}$=0.746, P=0.478) (Figure 2). A total of 25 copulations were witnessed during the course of the study with 13 control mares, 11 SpayVac® mares, and 1 GonaCon-B™ mare. Most of the copulations were seen during the breeding season (N=20). During the nonbreeding season, there was no evidence that SpayVac® mares cycled more and had more sexual interactions than the control mares. The one copulation observed with the GonaCon-B™ mare was seen in the nonbreeding season.

Stallion-Mare Relationships

In both the breeding and nonbreeding seasons, there was no overall treatment effect on the distance of the mare to the stallion (breeding: $F_{2,58}$=0.502, P=0.608; nonbreeding: $F_{2,76}$=0.213, P=0.809), the percentage of time within two body lengths of the stallion (breeding: $F_{2,51}$=0.085, P=0.918; nonbreeding: $F_{2,74}$=1.723, P=0.186), the percentage of approaches by the mare (breeding: $F_{2,56}$=0.237, P=0.790; nonbreeding: $F_{2,67}$=0.344, P=0.710) and the contact maintenance score with the stallion (breeding: $F_{2,56}$=0.537, P=0.587; nonbreeding: $F_{2,67}$=1.597, P=0.210). However, post hoc

comparisons suggested that SpayVac® mares spent less time within two body lengths of the band stallions than control mares in the nonbreeding season (t_{74}=1.675, P=0.098, Figure 3).

There was trend for band type to affect the percentage of approaches by mares (breeding: $F_{2,39}$=2.911, P=0.066, nonbreeding: $F_{2,67}$=2.390, P=0.099), as maverick mares significantly approached stallions less than mares in single stallion bands (breeding: t=2.386, df=48, P=0.021; nonbreeding: t_{67}=2.134, P=0.036, Figure 4). In the breeding season, maverick mares had lower contact maintenance scores compared to mares in single stallion bands (t_{47}=2.132, P=0.038) and mares in multistallion bands (t_{43}=1.804, P=0.078), indicating that maverick mares avoided stallions (Figure 5).

Aggression

There was no overall treatment effect on the amount of aggression a mare received from the rest of the group (breeding: $F_{2,44}$=1.527, P=0.229, nonbreeding: $F_{2,68}$=0.194, P=0.824) or the amount of aggression given by a mare towards other adults in the band (breeding: $F_{2,61}$=0.341, P=0.713, nonbreeding: $F_{2,74}$=0.507, P=0.604). However, the GonaCon-B™ mares tended to receive more aggression than SpayVac® mares during the breeding season (t_{46}=1.735, P=0.089) (Figure 6).

There was an overall band type effect on aggression received in the breeding season ($F_{2,27}$=5.047, P=0.014) as maverick mares received more aggressive behaviors than mares in single stallion bands (t_{30}=2.589, P=0.015) and multistallion bands (t_{31}=2.589, P=0.004).

Band Changing

There was no difference in band changing based on treatment status in any season (first breeding season: $F_{2,32}$=1.40, P=0.262, second nonbreeding season: $F_{2,35}$=1.40, P=0.262, second breeding season: $F_{2,36}$=0.05, P=0.948) (Figure 7).

Discussion

The Role of Sex

Sexual interactions have been associated with social bonding and cohesion, and are thought to maintain male-female bonds, suggesting the importance of sexual interactions in the social life of many group living mammals. The socio-sexual behavior of mares has been hypothesized to play a major role in the social life of feral horses and potentially maintains the stability of bands throughout the year and over long periods of time (Asa 1986). The control of feral horse populations with contraception presents the unique opportunity to manipulate fertility and test predictions about sex, reproduction and group living. Contrary to most of our predictions, contraceptive treatment had minimal impact on female social behavior with regards to the relationship with the band stallion. However, most of our predictions were based on expected changes in sexual behavior. Previous studies on PZP treatment demonstrated changes in sexual behaviors in other species as treated females showed an increase in sexual activity (McShea et al. 1997, Heilmann et al. 1998, Miller et al. 2000b, 2000c, Curtis et al. 2002). We found no difference in the amount of sexual behavior or actual copulations between SpayVac® mares and controls. It is possible that since horses can display sexual behavior year round (Asa 1986), an increase in estrous cycling in SpayVac® mares may not be observed.

Recently a study showed that PZP treated mares showed an increase in sexual behavior compared to controls and had lower band fidelity (Nuñez et al. 2009). We found no evidence that SpayVac® mares had increased cycling during the nonbreeding season or changed bands more frequently. The difference between these results may be due to a difference in PZP formulations, as our formulation SpayVac® may not increase estrous cycling (Killian et al. 2008). Therefore, treatment with PZP that does not increase estrous cycling may not have harmful side effects suggesting that the cycling, not the PZP, causes changes in behavior and band fidelity. The discrepancy in results may also be due to a difference in methods. It was not clear whether the investigators took band variation into account, and all controls from their study would be considered old aged females by our methodology, all of which can confound results (see Nunez et al. 2009).

In contrast, we expected a significant reduction of all breeding behavior in GonaCon-B™ mares (Miller et al. 2000a, Killian et al. 2006, 2008). Again, we detected no difference in sexual behavior between GonaCon-B™ mares and controls. Our results are similar to those of other studies that investigated GnRH treatment in other species in which females showed no difference in sexual behavior compared to controls (Baker et al. 2002, 2004, Conner et al. 2007). GonaCon-B™ did not suppress reproductive behaviors of mares and it is unknown why these females still seem to be receptive to stallions. In a captive study, GonaCon-B™ mares had plasma estrodial concentrations similar to control mares, contrary to what we expected because GonaCon-B™ works to reduce hormone levels that control estrous cycling (see Killian et al. 2008). However, there is evidence that follicle-stimulating hormone-releasing hormone (FSHRH) is secreted by the anterior pituitary and would cause some follicular development (McCann

et al. 1993, Yu et al. 1997, Padmanabhan and McNeilly 2001). GonaCon-B™ works to inhibit the LH surge needed for ovulation, but would not inhibit FSHRH, thus some estrodial would be produced from follicular development. This suggests that these mares may have enough circulating estrodial to exhibit estrous-like behavior, but do not completely cycle and therefore do not become pregnant. While these results are still inconclusive, it would appear that these mares continue to act like untreated mares and engage in sexual interactions. Since sexual interactions did not change in treated individuals, it is possible that other social behaviors will not change enough to disrupt consortships and band fidelity on a short time scale. The development of a FSHRH agonist and its use in conjunction with a GnRH agonist may help elucidate the role of sex in social life.

The Role of Foals

While sex maintains consortships, the function of these social bonds is linked to reproduction as consorting with a male has been shown to decrease male harassment (Linklater et al. 1999) and decrease the chance of infanticide (Kaseda et al. 1995, Gray 2009). Sexual interactions occurred in all treatment groups, even without reproduction, suggesting that consortships can be maintained even without the production of offspring. We found that treated females without foals did not change bands more often than control mares. This indicates that sex alone, and not necessarily reproduction is important to maintaining these social bonds. These results do not imply that reproduction is irrelevant to consortships or group living in horses, only that these relationships are maintained in

the short term without foals. It is possible that an absence of foaling for several years would cause the social units to break down, but this requires a longer study.

Mare-Stallion Relationships

Based on our behavioral measurements, contraceptive treatment had little impact on mare-stallion relationships. Most treated females maintained a similar spatial relationship with the band stallion, except for SpayVac® mares that spent less time within two body lengths of the stallion in the nonbreeding season (Figure 3).While this may indicate some avoidance by these mares, none of the other behavioral measurements showed any trends. Over time, if SpayVac® mares start to avoid stallions, they may begin to change bands more often than controls, but these effects would take time to elucidate.

The only difference found in GonaCon-B™ treated mares was aggressive interactions in the breeding season compared to SpayVac® mares. Since this formulation works at the hormone level, it is likely that changes to hormone levels (e.g., estrogen, progesterone) could impact aggressive and submissive behavior. The influence of sex hormones on aggressive behavior in females has largely been ignored compared to research on males and research shows mixed results depending on species (Floody 1983, Debold and Miczek 1984, Kapusta 1998, Woodley and Moore 1999, Kohlert and Meisel 2001). However, research on horses has shown that mares during diestrous are more aggressive towards stallions when circulating progesterone is high (Crowell-Davis 2007), suggesting that lower progesterone levels might decrease aggressive behavior. In addition, observations of captive GonaCon-B™ mares showed that these mares were

more submissive and easier to work with, thus we expected these mares in the wild to receive more aggression. We only found this trend when they were compared to SpayVac® mares. There is some evidence that GonaCon-B™ may decrease aggressiveness in females and over time, these females may suffer higher rates of harassment, which could influence band changing. Ultimately, we expected behavioral changes to the mare-stallion relationship would lead to changes in band fidelity. Again, we found no evidence that band changing was impacted by contraceptive treatment.

Behavioral Consequences of Band Changing

Stallion harassment has been shown to decrease the health and reproductive success of mares (Linklater et al. 1999). Our results confirmed that band loyalty and the presence of more than one stallion had a greater influence on female behavior, than contraceptive treatment. Regardless of treatment, mares that changed bands suffered higher rates of aggression and spent more time traveling than mares that were loyal to bands. We also found that maverick mares approached stallions less often and had lower contact maintenance scores with stallions, which would indicate that these mares avoid stallions during the breeding season (Figure 4, 5), most likely due to increased harassment rates. These data support the importance of long term band fidelity in mares.

Management Implications

Both of these contraceptive formulations offer the benefit of a single shot for multi-year infertility, which contrasts to other formulations currently being used to treat wildlife species. Few studies have investigated behavioral side effects of contraceptive

treatment, and most of those studies focused on short term effects in captive or semi-captive species (McShea et al. 1997, Heilmann et al. 1998, Miller et al. 2000b, 2000c, Baker et al. 2002, 2004, Massei et al. 2008). While we found no major behavioral changes, we caution that these results were based on observations for only 2 years post treatment and sample sizes for treatment groups were low in the analysis of the data. The low efficacy rates were not expected (see Chapter 3); therefore many of our treated females were excluded due to an ineffective treatment. This lowered our sample size only in our treatment groups which resulted in an unbalanced design and possibly not enough power to detect changes. It is also possible that major changes take more time to occur.

There is potential that these particular formulations may have minimal impacts on horses. Our results suggests that at least initially, treated females have little change in behavior and do not have lower band fidelity because sexual behaviors appear to be the same in treated and control mares. These contraceptive formulations could be used for management application with little behavioral consequences in the short term. However, more long term longitudinal studies are required on other formulations in order to determine the effects of contraceptive treatment over a long time period.

Conclusions

While consortships are thought to be maintained by sexual interactions, band formation has also been linked to male harassment and infanticide avoidance. Thus, mares in single stallion bands have better reproductive success and overall health than mares in multistallion bands or mares that continually change bands. Fertility manipulation was hypothesized to impact mare-stallion relationships since sex is deemed

important to band stability and group maintenance is associated with offspring. These manipulations allow for separation of impacts of sexual interactions and reproduction. We found no evidence that behavioral changes occurred and this is likely because sexual behaviors did not change. We showed that without changes to sexual behavior, changes to social behavior or structure should not be expected in feral horses. We confirmed that the mating strategy of mares (band type) is an important determinant of female social behavior and mare-stallion relationships. There was no breakdown in the consortships between stallions and mares and it is likely that sexual interactions, rather than foal production, are sufficient to maintain these social bonds in feral horse systems on a short time scale.

Table 1. The mean hours observed for mares in each treatment group, age category and band type in both the breeding and nonbreeding season.

Breeding Season Treatment	N	Mean	SE	F	*P*
Control	27	12.33	2.29	$F_{2,47} = 0.44$	0.645
GonaCon-B™(GnRH)	9	9.07	1.42		
SpayVac® (PZP)	14	10.31	2.03		
Age					
Young (<5 yrs)	21	9.11	1.20	$F_{2,47} = 2.47$	0.095
Medium (6-8 yrs)	9	17.39	4.01		
Old (>9yrs)	20	10.54	2.55		
Band Type					
Single Stallion	41	12.21	1.63	$F_{2,47} = 1.29$	0.284
Multistallion	5	6.67	1.55		
Maverick	4	6.22	1.49		

Nonbreeding Season Treatment	N	Mean	SE	F	*P*
Control	32	12.66	2.07	$F_{2,57} = 0.48$	0.662
GonaCon-B™(GnRH)	13	13.08	4.10		
SpayVac® (PZP)	15	9.42	1.90		
Age					
Young (<5 yrs)	23	8.86	1.61	$F_{2,56} = 1.07$	0.349
Medium (6-8 yrs)	9	13.61	1.95		
Old (>9yrs)	27	12.93	2.68		
Band Type					
Single Stallion	49	12.53	1.71	$F_{2,57} = 0.55$	0.580
Multistallion	7	7.64	1.67		
Maverick	4	12.20	7.00		

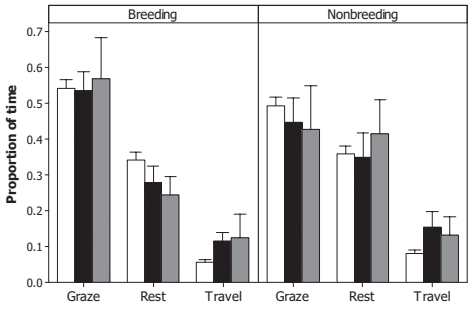

Figure 1. The proportion of time devoted by mares in single stallion bands (□), mares in multistallion bands (■), and band changers (mavericks) (▨) to grazing, resting and traveling. Time spent traveling differed between maverick mares and mares in single stallion bands in the breeding season ($P<0.10$) and between mares in multistallion bands and mares in single stallion bands ($P<0.05$).

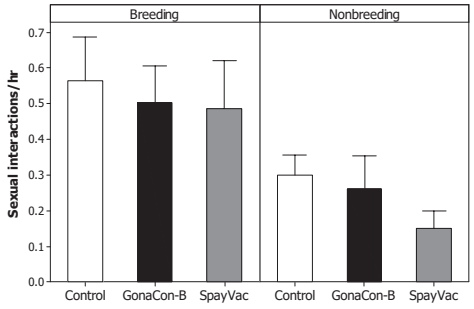

Figure 2. The total number of sexual interactions in the breeding and nonbreeding seasons for each treatment group. There was no difference among treatment groups in either season ($P>0.05$).

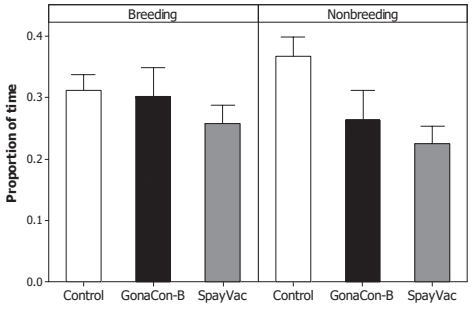

Figure 3. The proportion of time a mare was within two body lengths of the harem stallion based on treatment category. SpayVac® mares spent less time within two body lengths of the band stallions than control mares in the nonbreeding season ($P<0.10$).

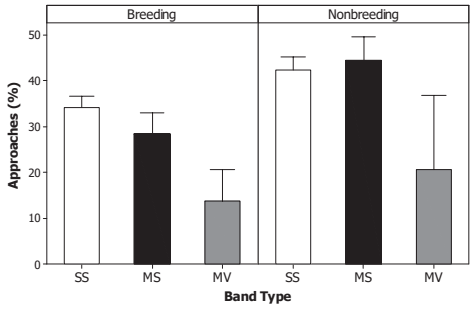

Figure 4. The percentage of approaches between the mare and stallion done by the mares in single stallion bands (SS) (□), mares in multistallion bands (MS) (■), and mavericks (band changers) (MV) (▩). Maverick mares significantly approached stallions less than mares in single stallion bands in both seasons (P<0.05).

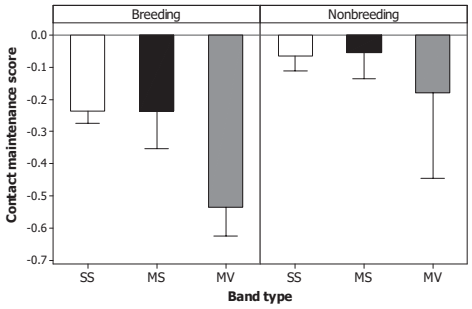

Figure 5. The contact maintenance scores between band stallions and mares in single stallion bands (SS) (□), multistallion bands (MS) (■), and mavericks (MV) (▩). Scores closer to -1 indicate avoidance by mares. Maverick mares had lower contact maintenance scores in the breeding season compared to mares in single stallion bands (P<0.05) and multistallion bands (P<0.10).

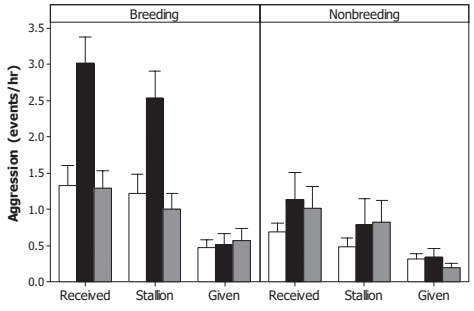

Figure 6. The rate of aggression received by other members in the band (received), received by the band stallion (stallion) and given towards other members of the band (given) for control mares (□), GonaCon-B™ mares (■), and SpayVac® mares (▩). Values differed between GonaCon-B™ mares and SpayVac® mares during the breedingseason (P<0.10).

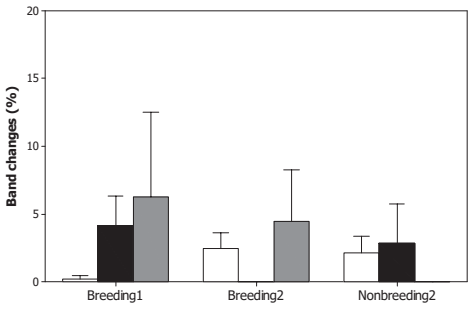

Figure 7. The percentage of band changes observed in the first breeding season, the second breeding season and the second nonbreeding season in control mares (□), GonaCon-B™ mares (■), and SpayVac® mares (▩).

DISCUSSION

"...I heard a neigh. Oh, such a brisk and melodious neigh as that was! My very heart leaped with delight at the sound."

Nathaniel Hawthorne

DISCUSSION

Feral horses are ideal for testing hypotheses on group living, mating strategies and social behavior. Unlike other social mammals, feral horses require some management, often in the form of contraception, which sets up experimental manipulations that allow testing of the roles of sex and reproduction in the social behavior of females and band fidelity.

Male harassment and infanticide have been proposed as major influences on mating systems and male-female associations (Kappeler 1997, van Schaik and Kappeler 1997). There is increasing evidence that females join groups to avoid harassment from other males and potentially increase the protection of their offspring (e.g., Williams et al. 2004, Muller et al. 2007, Cappozzo et al. 2008). This is especially true in feral horses, where females that join and remain loyal in bands have higher reproductive success than mares with lower fidelity (Kaseda et al. 1995, Linklater et al. 1999). In my first chapter, I explored these influences in the context of paternity of offspring. Females may choose to seek extra-group copulations, but can suffer severe consequences, such as infanticide (van Schaik 2000). I found that in feral horses extra-band copulations were rare and most females were loyal to their band stallion. Most of the foals not sired by the band stallion were the result of band changing. Females that remained stable in their bands had higher offspring survival than those that had foals sired by an extra-band stallion, further supporting the idea of band stability as an adaptive strategy. In addition, almost all foals died that were born in a band without their sire, but most foals survived that immigrated with their mothers to a new band, suggesting that being born in band without their sire increases the risk of infanticide. Females were also more protective of foals not sired by

the band stallion, suggesting that females assess paternity and alter their behavior accordingly. Furthermore, I documented the first infanticide attack in free-roaming feral horses and showed that the attacker was not the genetic sire, but also that the mother was successful at ending the attack by protecting her foal. Given these results, I demonstrated that infanticide is a risk that females assess and attempt to minimize by increasing their protectiveness. However, most females are loyal to their band stallion, suggesting that infanticide risk is high. Furthermore, mares that changed bands remained loyal thereafter, further supporting strong selection for long term stable associations. I showed that infanticide risk may be an important determinant of this mating system and confirmed the majority of females engage in the strategy of band loyalty, rather than band changing or seeking extra-band copulations.

Most horse populations require some form of management. The increasing use of contraceptives provides potential experiments for testing the importance of reproduction and fertility in consortships. I worked with two contraceptive formulations, initially looking at efficacy. Neither of these formulations had been tested in free-roaming horses previously. I demonstrated that these contraceptive formulations can reduce fertility for multiple years with the use of one injection. I expected the efficacy rates to be as high as 90-100%, but instead they were 60-70%. Several factors could explain some of this lowered level of efficacy. First, the horses in the study were monitored on a weekly basis, which is much more intensive than other studies that use a few surveys per year, which allowed me to observe early foal loss. I also tested all mares for pregnancy using fecal progesterone levels and found that 2/19 mares that showed no visible signs of pregnancy were actually pregnant, further demonstrating the importance of constant monitoring of

wild populations for accurate reporting of efficacy. Second, I looked at body condition at time of treatment and found that there were more contraceptive failures in females that were in poor condition at time of treatment. My results indicate that body condition may be an important but overlooked factor in efficacy of treatment, but this requires further investigation. I found no evidence that the contraceptives impacted foal sex, foal survival or timing of birth in females that were contraceptive failures, which supports previous research on other feral horse populations (Kirkpatrick and Turner 2003). I also investigated whether side effects occurred in other species treated with contraceptives. A meta-analysis confirmed that side effects are found when they are investigated, including changes to behavior. This result was contrary to conclusions made from papers that suggested that there were no side effects, but did not quantitatively investigate their claims and often lacked appropriate controls and sampling methodology. Most of the side effects were minor, including some physiological changes to the reproductive system, but some were more serious, including changes to breeding behavior, activity, and the mating season (McShea et al. 1997, Heilmann et al. 1998, Curtis et al. 2002). If species are going to be managed by contraception, then continued research is necessary to understand population-level effects of wildlife species. Contraception provides a powerful tool to address fundamental questions in biology, such as the costs of reproduction, importance of copulation in maintaining social structure and parental investment strategies. I then investigated if contraception would impact the behavior of the females due to lack of reproduction and the alteration of sexual activity and if these factors ultimately lead to changes in band fidelity.

Contrary to most of my predictions, contraceptive treatment did not impact interactions between mares and stallions or band fidelity. Sexual interactions were the same among treatment groups, thus consortships were maintained even without the production of offspring. There was no difference in the mare-stallion relationship in treated mares and these females did not change bands more often than controls. However, these changes may take time to occur, and my study did not extend past two years post-treatment. I did find that mating strategy and band type had a greater impact on female behavior. Females that changed bands suffered from more aggression, spent more time traveling, and avoided the stallion, all of which confirms previous research suggesting the importance of band stability for female reproductive success and the costs of male harassment (Linklater et al. 1999).

Managers should consider both contraceptive type and the species before they begin treatment of individuals in order to minimize changes to behavior and social structure. While I found no change in social behavior and consortships, it is possible that these changes take time to occur. It is also possible that the formulations that I used had little impact on behavior. Numerous studies that investigated changes to behavior have found them, thus it is important to monitor treated individuals for changes in behavior and welfare.

In conclusion, I conducted a study on social behavior in feral horses, with an emphasis on the influence of paternity and fertility manipulation. I found that most females remain stable in a band and have a foal sired by the band stallion. For females that did not have a foal sired by the band stallion, they were more protective, but their foals had a lower survival rate. I also found that contraception may not be as efficacious

as some report, and intensive monitoring should be done to get more accurate measurements of efficacy. In addition, consortships can be maintained for the short term without the requirement of foal production as long as sexual activity remains unchanged.

The authors wish to alert readers to the following error.

We mistakenly used the term SpayVac® to describe the PZP preparation tested in our manuscript. SpayVac® is a trade name that refers to a PZP formulation made by Immunovaccine Technologies (IVT) with an IVT DepoVax® liposome technology. SpayVac® does not include the adjuvant AdjuVac™. The PZP tested in our study was prepared by IVT without the liposomes and sent to the USDA/APHIS National Wildlife Research Center (NWRC), where the final formulation was made as a water-in-oil emulsion of the PZP with NWRC's AdjuVac™. The formulation we evaluated was not a conjugate, as stated in the manuscript.

In our article we reported that 'Killian *et al.* (2008) showed higher efficacy rates in captive feral horses by using the same treatments on the same species from the same population as we studied,' and hypothesised that this might have been due to differences in condition between captive and wild mares. However, we now acknowledge that the difference in PZP preparations may have contributed to the difference in efficacy rate between these studies.

We accept responsibility for this mistake and apologise to readers and Immunovaccine Technologies.

Abstract

Context. Contraception is increasingly used as a management technique to reduce fertility in wildlife populations; however, the feasibility of contraceptive formulations has been limited until recently because they have required multiple treatments to achieve prolonged infertility.

Aims. We tested the efficacy and evaluated potential side effects of two contraceptive formulations, a porcine zona pellucida (PZP) formulation, SpayVac® and a gonadotrophin-releasing hormone (GnRH) formulation GonaCon-B™, in a population of free-roaming feral horses (*Equus caballus*). Both formulations were developed to provide several years of infertility with one injection.

Methods. Females were treated in June 2005 with either GonaCon-B ($n = 24$), SpayVac ($n = 20$), adjuvant only ($n = 22$), or received no injection ($n = 18$). Females were monitored for fertility status year round for 3 years after treatment.

Key results. Both contraceptive treatments significantly reduced fertility for 3 years. Fertility rates for GonaCon-B mares were 39%, 42% and 31%, respectively, and 37%, 50% and 44% for SpayVac mares. During the same seasons, 61%, 67% and 76% of control females were fertile. We found no significant effects from contraceptive treatment on the sex ratio of foals, birthing season or foal survival.

Conclusions. These results demonstrated that both vaccines are capable of significantly reducing fertility for several years without boosters.

Implications. Contraceptive vaccines examined in the present study represent a useful tool for the management of feral horses, because of their being efficacious for 3 years in the absence of booster immunisations.

Introduction

The overabundance of wildlife is an ongoing problem, with many pest species increasing to numbers that become detrimental to both the environment and other wildlife species (e.g. elephants (*Loxodonta africana*): Whyte *et al*. 1998; white-tailed deer (*Odocoileus virginianus*): Warren 1997; feral horses (*Equus caballus*): Wagner 1983; Canadian geese (*Branta canadensis*): Conover and Chasko 1985). Traditionally, populations of overabundant wildlife were controlled by lethal control or permanent removals. However, mortality manipulation can cause increased population growth as a result of compensatory growth (Garrott and Taylor 1990; Kirkpatrick and Turner 1991), changes to animal movements (Henderson *et al*. 2000) and public objections (Stout *et al*. 1997; Lauber *et al*. 2007). Consequently, non-lethal methods of control, usually involving fertility manipulations, are becoming increasingly advocated when traditional culling methods are impractical or undesirable (Kirkpatrick 2007).

Contraception has become a relatively widely used non-lethal technique to manage overabundant wildlife populations and is usually considered a more humane and politically acceptable long-term approach to population control because animals remain in the wild and most treatments are reversible (Oogjes 1997; Kirkpatrick 2007). In particular, immunocontraception, which uses an animal's own immune system to inhibit fertility, has been tested extensively in many wildlife species to prevent pregnancy, particularly formulations that block oestrous cycling or fertilisation through GnRH immunisation (Miller *et al*. 2000*a*; Baker *et al*. 2002; Killian *et al*. 2006; Conner *et al*. 2007) or treatment with porcine zona pellucida (PZP) (Kirkpatrick *et al*. 1992, 1996; Turner *et al*. 1996, 1997, 2001, 2007; Fayrer-Hosken *et al*. 2000; Miller *et al*. 2000*b*; Delsink *et al*. 2002; Naugle *et al*.

2002; Walter *et al*. 2002; Rutberg *et al*. 2004; Lane *et al*. 2007). While biologically effective, contraceptive formulations also need to be practical and cost-effective for management, preferably using only a single dose.

In the USA, feral horses are federally managed and protected on public lands under the *Wild Free-Roaming Horse and Burro Act of 1971* and continue to overpopulate rangelands where they can have a negative impact on grasslands, riparian areas, soils and other wildlife species (Rogers 1990; Beever and Brussard 2000, 2004; Levin *et al*. 2002; Zalba and Cozzani 2004; Beever and Herrick 2006). Despite this trend, lethal control is largely unacceptable to the public. Past-management techniques have focused on the 'round-up and adopt-out' method, although there have been concerns about the efficacy of these programs and their impact on animal welfare (Kirkpatrick 2007). Contraceptive formulations have been extensively researched in feral horses (PZP; Kirkpatrick *et al*. 1990, 1996; Turner *et al*. 1997, 2001, 2002, 2007) and show promise for population control that may be more cost effective than removals over the long-term (Bartholow 2007). However, there is a need for a formulation that lasts for more than 1 year without the need for boosters or multiple injections so as to decrease the costs and stress associated with multiple gathers.

Concerns have been raised over the potential side effects of contraceptive treatments (see Nettles 1997), yet there has been little research conducted that addresses side effects in comparison to efficacy studies (Gray and Cameron 2010). Most research on side effects has focused on breeding behaviour and body condition of treated females. For example, several studies have shown that contraceptives alter breeding behaviour of females, which results in a lengthened breeding season and later offspring birth dates (McShea *et al*. 1997; Heilmann *et al*. 1998; Miller *et al*. 2000*b*). However, a study on PZP showed no difference in the month that foals were born to females where contraception was waning (Kirkpatrick and Turner 2003). Several studies have also reported increased body condition of treated females in wild species (McShea *et al*. 1997, Turner and Kirkpatrick 2002). Although increases to body condition can be desirable, they could have an impact on offspring sex ratios because females that experience increased condition tend to have more sons (Cameron 2004). Regardless of treatment, side effects should be studied on managed species to minimise impacts to behaviour, physiology and population health.

We tested efficacy of contraceptive formulations in free-roaming feral horses in the Virginia Range in Nevada. We used two different formulations that were developed to reduce fertility over multiple years following one vaccination. The first formulation, SpayVac®, is a liposome-encapsulated porcine zona pellucida (PZP) that acts to prevent pregnancy by blocking fertilisation by targeting the zona pellucida of the ovum. A single dose can last for several years (Brown *et al*. 1997). This contrasts with other PZP formulations that require multiple doses to achieve multiple years of infertility (Turner *et al*. 2001, 2002), although a vaccination that lasts between 2 and 3 years has been developed recently (Turner *et al*. 2007). SpayVac has been successfully used as a single-dose, multi-year contraceptive in fallow deer (*Dama dama*) (Fraker *et al*. 2002), white-tailed deer (Hernandez *et al*. 2006), grey seals (*Halichoerus grypus*) (Brown *et al*. 1997) and captive feral horses (Killian *et al*. 2008). The second formulation, GonaCon-B™, is a gonadotrophin-releasing hormone (GnRH) vaccine that consists of synthetic GnRH conjugated with a blue mollusk protein. Once injected, antibodies are produced and bind to endogenous GnRH. The antibody–GnRH complex is too large to diffuse from the blood into the anterior pituitary, resulting in a significant reduction in the production of follicle-stimulating hormone (FSH) and luteinising hormone (LH), thereby preventing ovulation (Miller *et al*. 2008). This formulation has been effective in white-tailed deer (Miller *et al*. 2000*a*), bison (*Bison bison*) (Miller *et al*. 2004), feral swine (*Sus scrofa*) (Killian *et al*. 2006; Massei *et al*. 2008) and captive feral horses (Killian *et al*. 2008). Both formulations alone would not elicit a large or long-term response, thus AdjuVac™, an oil-based adjuvant (a non-specific immune stimulant), was used to increase the immune response. Our main objectives were to test two contraceptive formulations in free-roaming horses to determine (1) the effectiveness of these contraceptives to induce infertility up to 3 years after administration of a single dose and (2) potential side effects on foal survival, birth sex ratio and birthing season.

Materials and methods

Study site and animals

The study was conducted in the Virginia Range, south-west of Reno, Nevada, USA. The range is ~145 000 ha of private land, with a small percentage developed for houses and industry. The mountain range consists of sagebrush (*Artemesia tridentata*) communities, with groups of pine (*Pinus jeffreyi*, *Pinus monophylla*) and juniper (*Juniperus osteosperma*) at higher elevations. Other common plant species include bluegrass (*Poa secunda*), rabbitbrush (*Chrysothamnus nauseosus*), bitterbrush (*Purshia tridentata*) and cheatgrass (*Bromus tectorum*). In addition to feral horses, other ungulates in the range included mule deer (*Odocoileus hemionus*) and pronghorn (*Antilocapra americana*). The predators in the range were mountain lions (*Puma concolor*), bobcats (*Lynx rufus*) and coyotes (*Canis latrans*).

The population of feral horses is classified as estray by the Nevada Department of Agriculture because they range on private property and are therefore not protected under the *Wild Free-Roaming Horse and Burro Act of 1971*. Consequently, they are legally defined as feral livestock, and the Nevada Department of Agriculture is responsible for the management of the population. The population size has fluctuated from >1200 in 2004 to ~1400 in 2009, and is currently being managed with the use of both removals and contraception. The long-term management goal is to decrease population size and stabilise population growth.

Vaccine types and treatment protocol

We selected a treatment site for both ease of capture, the large number of horses present in the valley and permission from private land owners. Horses were rounded up with a helicopter on 15 and 16 June 2005. Horses were held in purpose-built yards and restrained in a hydraulic squeeze chute for treatment. We treated every female >1 year of age with 1-mL intramuscular dose in the left side of the neck in the serratus ventralis muscle with one of the following four treatments: (1) GonaCon-B (NWRC, Fort Collins, CO, USA) ($n = 20$), (2) SpayVac (ImmunoVaccine

Technologies (IVT), Halifax, Nova Scotia, Canada) ($n = 20$), (3) control, consisting of adjuvant only (AdjuVac) (NWRC) ($n = 19$) or (4) control, consisting of no injection ($n = 18$), with every other capture aspect being equivalent. Both GonaCon-B (1000 μg of conjugate) and SpayVac (400 μg of conjugate) were prepared as a water-in-oil emulsion in AdjuVac.

All females were aged by tooth eruption and wear patterns (after Tutt 1968), examined for overall health status and freeze-branded for permanent identification on the left side of the rump. In total, 77 females ranging in age from 1 to 20 years were treated systematically over the 2-day period, allowing for random distribution of treatment across all age categories. All horses were immediately released after treatment. In addition to the 77 mares, a small group of females ($n = 7$) were treated with GonaCon-B ($n = 4$) or adjuvant only ($n = 3$) in May of 2005 in a different part of the range. These horses were captured by a feed trap and processed by using the same protocol. They were grouped with the rest of the mares in all of the analyses. All handling and treatment procedures were carried out by and under the supervision of veterinarians from the Nevada Department of Agriculture and were approved by the University of Nevada, Reno Animal Care and Use Committee (Protocol #A06/07-47).

Field observations

We monitored mares from the ground at least weekly to determine fertility rates until December 2008. The treatment group to which each mare belonged was not known to the field observer. Mares were judged fertile if a foal was born at any time during the year or if a female was noticeably pregnant, judged conservatively by an enlarged belly and swollen teats. If females were not seen until after the foaling season and no foal was present, they were recorded as unknown and excluded from the analysis. To examine impacts of contraception on foals, we compared fertile treated mares (contraceptive failures) to control mares. During field observations, we would record the birth of any foal, the sex of the foal and foal survival to weaning.

Faecal sampling and steroid hormone assay

To supplement visual observations, we collected faecal samples opportunistically from August to May yearly to determine pregnancy of mares that may have lost a foal before being visibly pregnant. The behaviour of the horses was monitored throughout the year and when a horse defecated during the observation period, the time and horse identity were recorded. The faecal sample was collected once collection would not disturb the horses. Only samples with 100% certainty of which horse they came from were collected to be as conservative as possible. The number of faecal samples collected from an individual ranged from 1 to 32.

Faecal samples were stored in –20°C freezers until extraction. We used the extraction protocol of Asa *et al*. (2001). Samples were thawed and ~0.5 g of wet faecal material was placed in a vial with 5 mL of modified phosphate–saline buffer (Shideler *et al*. 1993) and shaken overnight at room temperature. Samples were centrifuged for 1 h and the supernatant was stored at −80°C until the assay was conducted. The remaining faecal material was dried in a 100°C oven overnight and weighed the next day. Hormone values are based on the dry weight of the faecal samples and are presented as ng g^{-1} of dried faeces.

Faecal progesterone assays were run at the Saint Louis Zoo and have been used to verify reproductive status of females in many species (Asa *et al*. 1996, 2001; Munson *et al*. 2001). We analysed extracted faecal samples for progesterone metabolites with a commercially available radioimmunoassay kit (Progesterone Coat-a-Count, Siemens Medical Solutions Diagnostics, Los Angeles, CA, USA). The progesterone antibody in this kit cross-reacted with multiple progesterone metabolites: progesterone (100%), 17α-hydroxyprogesterone (3.4%), 5α-pregnan-3,20-dione (9.0%) and 5β-pregnan-3,20-dione (3.2%). We used stripped calf serum to prepare all standards and to dilute all faecal-sample extracts. Faecal samples were run against a calibration curve of progesterone from stripped calf serum. Extraction buffer was added to tubes containing standards and calf serum was added to faecal extracts to equalise the matrices of the samples and standards. All samples, standards and quality controls were run in duplicate.

The inter-assay coefficients of variation were 19%, 23%, 28.5% for low-, medium- and high-quality control standards for seven different assays. The assays were validated for faecal extracts by demonstrating parallelism between serial dilutions of faecal samples (from 1 : 2 to 1 : 16) to the standard curve. The displacement curves were parallel to the standard curve, with correlation coefficients $r^2 > 0.99$. Recovery of known amounts of hormone added to faecal supernatants (diluted in calf serum) at several different concentrations was 92.3 ± 3%. We biologically verified faecal progesterone samples from 19 mares by comparing their progesterone levels to our observations of their pregnancy and foaling status.

Statistical analysis

We determined the efficacy of contraceptive treatment by comparing the proportion of fertile females in each treatment group with control females across the combined foaling seasons. Females were classified as being either fertile or infertile on the basis of visual monitoring of reproductive status or faecal progesterone levels. If any female was not seen on a regular basis or had no faecal samples collected, they were excluded from the analysis. We used a linear mixed-model analysis with restricted maximum likelihood estimation to determine treatment effects on fertility rates. We used individual identification as a random variable repeated across three foaling seasons. A chi-square test was used to test for differences between foal sex ratios, seasonality of births and foal survival. We defined the foaling season to include April, May and June (Kirkpatrick and Turner 2003). Results are shown as means ± standard errors where appropriate.

Results

Efficacy

At the time of treatment, there were no differences in the age among all treatment groups ($F_{3,79} = 0.48$, $P = 0.694$). There was no difference in fertility rates between control mares and adjuvant only mares across the three years ($F_{1,30} = 0.737$, $P = 0.397$; Table 1), and so they were combined for all further analyses. Treatment with contraception significantly reduced fertility

Table 1. Fertility rates (%) of treated and control females for three foaling seasons

Both treatments significantly ($P < 0.01$) reduced fertility for the combined three foaling seasons. The number of mares observed in each season is given in parentheses

Treatment	Percentage fertile mares		
	2006	2007	2008
Control (no injection)	60 (15)	69 (13)	86 (14)
Adjuvant only	63 (16)	65 (20)	67 (15)
SpayVac®	37 (14)	50 (16)	44 (16)
GonaCon-B™	39 (18)	42 (12)	31 (16)

for all combined foaling seasons ($F_{2,72} = 5.811$, $P = 0.005$). Post hoc comparisons revealed that both contraceptive treatments significantly differed from control mares for all foaling seasons combined (GonaCon-B: $t_{75} = -3.138$, $P = 0.002$, SpayVac: $t_{68} = -2.314$, $P = 0.024$).

We supplemented fertility data with those from four additional mares that were not seen on a regular basis, but had faecal samples tested for progesterone metabolite levels from October through March. We found two females that were probably not pregnant (both <50 ng g^{-1} progesterone) and two females that were probably pregnant (both >1800 ng g^{-1} progesterone) (Asa *et al*. 2001). We confirmed our visual observations of fertility status with faecal progesterone levels in 17 out of 19 mares (control: $n = 10$; treated: $n = 7$) from faecal samples that ranged from 8 to 24 samples per female. Pregnant mares had mean faecal progesterone of 2426 ± 228 ng g^{-1} and non-pregnant females averaged 105 ± 10 ng g^{-1}. The other two mares, neither of which looked visibly pregnant although they had faecal progesterone levels that indicated pregnancy, were one SpayVac-treated mare that lost her foal between March and April 2006 (likely post partum), and one GonaCon-B-treated mare who lost her foetus in October 2005. The cause of these losses is unknown.

Side effects of treatment

During our monitoring efforts, we found no abscesses or inflammation at the injection sites in the mares observed after treatment. There was no difference in the seasonality of births across the 3 years between these treated mares and controls ($\chi^2_1 = 0.630$, $P = 0.427$), with the majority of all foals being born in April (46%) and May (46%) (Fig. 1). There was no treatment effect on foal survival ($\chi^2_3 = 0.002$, $P = 0.969$). There was also no difference in the foal sex ratio between treatments across three foaling seasons ($\chi^2_3 = 0.939$, $P = 0.816$), with 48% and 50% of the foals being male in the treated and control mares, respectively.

Discussion

As with many wildlife species, free-living horse populations continue to present a management problem, and past management methods are increasingly unfeasible or ineffective. Consequently, contraceptive treatments have become more widely tested to reduce herd numbers and population growth, especially with the development of a contraceptive agent that provides multi-year contraception

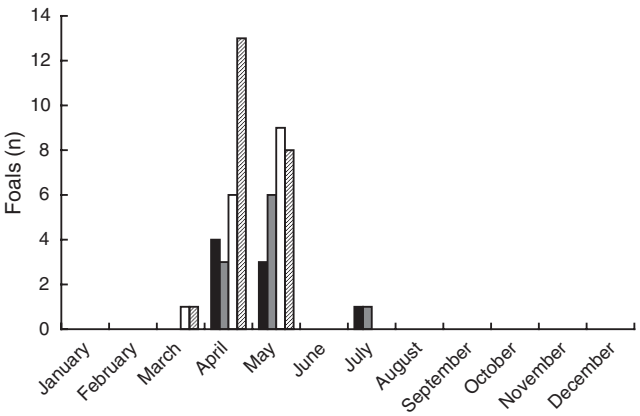

Fig. 1. The number of foals born in each month of the year from control mares (open), adjuvant only mares (striped), SpayVac® mares (grey) and GonaCon-B™ mares (black). Data pooled over three foaling seasons and only from foals with known birth dates.

after a single dose (Turner *et al*. 2007; Killian *et al*. 2008). We show that free-living horse fertility rates were decreased by contraceptive formulations, with the use of single-injection vaccinations. Both GonaCon-B and SpayVac reduced fertility rates in every foaling season, suggesting that both formulations were successful at preventing pregnancy for multiple years. In addition, both treatments consistently reduced fertility within individual females throughout the 3 years. Our results indicated that long-term contraception of free-roaming horses is possible with both GonaCon-B and SpayVac, providing viable alternatives for long-term population control in feral horses. Furthermore, both GonaCon-B and SpayVac have been shown to be effective in several other wildlife species (Brown *et al*. 1997; Miller *et al*. 2000*a*, 2004; Fraker *et al*. 2002; Hernandez *et al*. 2006; Killian *et al*. 2006; Massei *et al*. 2008). Although we report fertility rates for only 3 years after treatment, we expect, on the basis of our captive trials (Killian *et al*. 2008), that treated mares will continue to be effectively contracepted for the following 2 years and we are continuing to monitor these females for the duration of that time.

Although we found a reduction in fertility, our efficacy was lower than in most previous studies of contraception in free-living horses (Kirkpatrick *et al*. 1990; Turner *et al*. 2002, 2007). Although this may have been due to the treatment method, this seems unlikely because all mares received the full dose while in the squeeze chute. It is likely that in the first foaling season (2006) some mares were already pregnant when we treated them in 2005, thus reducing the appearance of efficacy for the first season because they were already pregnant and these formulations are not supposed to interfere with pregnancy. This would not explain our lower efficacy rates in the second and third season. It is possible that our lower efficacy rates are due to our sampling techniques. We monitored our horses more intensively than in other studies by locating horses at least weekly and used highly conservative estimates of pregnancy and foal production because horses may abort foetuses throughout the year or may lose foals shortly after birth (Keiper and Houpt 1984; Lucas *et al*. 1991). If individuals are not closely monitored, these events would be missed and would increase the appearance of contraceptive

efficacy and also fertility in control females. In our study, mares that were only seen late in the foaling season without a foal were excluded from the analysis because it was not possible to determine whether they had lost their foal or had not foaled at all. The inclusion of these mares would significantly boost our efficacy rates. This suggests that constant monitoring of individuals may give a more accurate representation of fertility rates.

Our lower efficacy rates may have resulted from inter-individual differences in responsiveness to the treatment. We noticed that certain mares consistently responded to the treatment, whereas others did not (e.g. they were pregnant or foaled). Variation in response to different contraceptive formulations and adjuvants has been demonstrated (Garrott *et al*. 1998; Fayrer-Hosken *et al*. 2002; Frank *et al*. 2005), although the cause of that variation has not been investigated. Killian *et al*. (2008) showed higher efficacy rates in captive feral horses by using the same treatments on the same species from the same population as we studied. The captive mares had a much better response to the treatment and showed higher levels of fertility reduction for the first 2 years after treatment (e.g. 100% and 83% for SpayVac-treated mares and 94% and 60% for GonaCon-treated mares (Killian *et al*. 2008)). We hypothesise that this may be due to differences in condition between captive and wild mares because captive mares are all in good body condition and have access to better-quality nutrition, which may increase immune functioning compared with animals in poor condition (Houston *et al*. 2007).

Impacts on foals

Another limitation of contraceptive treatment is the potential for side effects (Nettles 1997). We investigated how contraceptive treatment could affect foals born to females in which the contraception failed. Feral-horse populations differ in the timing of their birthing season, although the majority of foals are born in the spring (Feist and McCullough 1975; Keiper and Houpt 1984; Berger 1986). Foal survival is related to the season of birth, with foals being more likely to survive when they are born in the spring than in the winter. Previous studies have shown that PZP treatments can lead to increased oestrous cycling during the non-breeding seasons (McShea *et al*. 1997; Miller *et al*. 2000*b*; Curtis *et al*. 2002). These side effects can result in offspring born out of season leading to reduced survival (e.g. white-tailed deer, McShea *et al*. 1997). Although we found two foals born in July, most foals were born in the spring months of April and May to both treated and control females and this is consistent with other feral-horse populations (Kirkpatrick and Turner 2003). These data suggest that contraceptive treatment does not significantly affect the timing of foal births or foal survival in feral horses.

Contraceptive treatment has been shown to increase the body condition of mares (Turner and Kirkpatrick 2002). These changes to body condition can have an impact on the sex of the foal because females that experience an increase in body condition at the time of conception have more males (Cameron and Linklater 2007). In our study, we found no evidence that the sex ratio of foals changed as a result of a failure of contraceptive treatment. It would be interesting to continue to monitor sex ratios in mares after the contraceptive has ceased to be effective, because mares that have not foaled for several years should be in better body condition (e.g. Turner and Kirkpatrick 2002), which could lead to an increase in male births (e.g. Monard *et al*. 1997; Cameron and Linklater 2000, 2007).

Summary

A current drawback of most contraceptive vaccines is the need for annual inoculations and, therefore, the need for multiple gathers. For many wildlife managers, this issue alone makes contraception an impractical option. Fertility control of pest or invasive species has become increasingly important for management, especially when lethal control is unacceptable or impractical. Our findings demonstrate that new contraceptive formulations are able to reduce fertility in females for several years without the need for boosters. We conclude that these formulations would be useful for managing feral-horse populations, and also other species that require long-term population control because they reduce the costs and stress associated with multiple treatments. We also emphasise the importance of sampling methods when studying efficacy rates in wild populations to get an accurate representation of fertility rates in treated and control individuals.

Acknowledgements

This research was funded by grants (NOA15353CG, 110615253BS, 140115253BS, 140215253BS) from the Nevada Arid Rangeland Initiative, Hatch Grant 13215353BS and a research grant from the Animal Behaviour Society. We thank the National Wildlife Research Center and ImmunoVaccine Technologies for providing all of the contraceptive formulations. We are grateful to anonymous land owners for access to their land for both treatment and observations. We thank Mike Holmes for managing the population and assisting with the research. We thank Joan Bauman from the St Louis Zoo Endocrinology Laboratory for her valuable guidance with the faecal hormone analysis.

REVIEW

Does contraceptive treatment in wildlife result in side effects? A review of quantitative and anecdotal evidence

Abstract

The efficacy of contraceptive treatments has been extensively tested, and several formulations are effective at reducing fertility in a range of species. However, these formulations should minimally impact the behavior of individuals and populations before a contraceptive is used for population manipulation, but these effects have received less attention. Potential side effects have been identified theoretically and we reviewed published studies that have investigated side effects on behavior and physiology of individuals or population-level effects, which provided mixed results. Physiological side effects were most prevalent. Most studies reported a lack of secondary effects, but were usually based on qualitative data or anecdotes. A meta-analysis on quantitative studies of side effects showed that secondary effects consistently occur across all categories and all contraceptive types. This contrasts with the qualitative studies, suggesting that anecdotal reports are insufficient to investigate secondary impacts of contraceptive treatment. We conclude that more research is needed to address fundamental questions about secondary effects of contraceptive treatment and experiments are fundamental to conclusions. In addition, researchers are missing a vital opportunity to use contraceptives as an experimental tool to test the influence of reproduction, sex and fertility on the behavior of wildlife species.

Reproduction (2010) **139** 45–55

Introduction

Fertility control for population management of wildlife and zoo species has some advantages over other control methods, such as lethal control (Kirkpatrick 2007). For example, culling reduces population size, but also increases population growth rates, counteracting the goals of most population control operations (Garrott *et al*. 1991). Furthermore, there are ethical concerns about culling (Littin *et al*. 2004) such that public acceptance of lethal control is typically low when other management options are viable (e.g. Stout *et al*. 1997). However, for contraception to be successful for population control it must not only be safe, effective and long-acting, but also have minimal impact on the social organization, behavior, and ecology of populations with treated individuals (Castle & Dean 1996). Contraceptive technologies are becoming increasingly effective, safe and long-lasting (Kirkpatrick & Turner 2007), but despite several decades of contraceptive treatment, little research has considered secondary impacts, except in domestic animals. Fertility control is used to manage farm, domestic and recreational animals (D'Occhio 1993) and provides a viable and reversible alternative to de-sexing (e.g. cats, Ivanova *et al*. 1995, Gorman *et al*. 2002), but only if the animals behave similarly before and after treatment. In wildlife, the alternative is often lethal control which raises a plethora of other legal and logistical issues (e.g. Kirkpatrick 2007). Nonetheless, the side effects of contraception need to be understood for fertility control to be an effective management tool, even if alternative management practices have more extreme side effects (see Kirkpatrick 2007).

Contraceptive formulations either prevent ovulation, fertilization or implantation, or terminate pregnancy. Immunocontraception uses an animal's own immune system to prevent reproduction. The body produces antibodies in response to the injection of a foreign body, and the antibodies then interfere with critical events in reproduction. Several different types of immunocontraceptive formulations have been developed, including those against ova (Sacco 1987), sperm (Primakoff *et al*. 1988), and gonadotropins (Moudgal *et al*. 1986). The most commonly used formulation is porcine zona pellucida (PZP), which stimulates the production of antibodies to zona pellucida (ZP) when injected into the host (Aitken *et al*. 1984). These antibodies prevent sperm binding to the ZP sperm receptors, thereby preventing fertilization (Sacco *et al*. 1984). Infertility results, but females continue to cycle. Since the structure of these

receptors is conserved, PZP inhibits fertility in a range of mammalian taxa (Wood *et al*. 1981, Mahi-Brown *et al*. 1985, Sacco 1987, Kirkpatrick *et al*. 1996). GNRH formulations, both agonists and active immunizations, result in a reduction of the release of FSH and LH. Treated females thereby enter a variable length anestrous period (Talwar 1985). These GNRH formulations have been widely used in domesticated livestock as a practical application to improve carcass quality and to reduce aggressive behavior (i.e. Huxsoll *et al*. 1998, Kiyma *et al*. 2000). To a lesser extent they have been used for fertility control in both males and females of wildlife species (e.g. Miller *et al*. 2000*a*). Other common types of contraceptive agents include 1) melengestrol acetate (MGA), a progesterone-like drug that suppresses LH, preventing ovulation, but allowing development of large follicles and endogenous estradiol, and 2) progesterone analogs that inhibit ovulation and/or prevent implantation, both of which have been used successfully in several zoo species (reviewed in Patton *et al*. (2007)). Surgical sterilization is also an option in some species, but presents some practical issues associated with surgery (i.e. catching, anesthesia, irreversibility, morbidity, and mortality) that make it unsuitable for most wildlife species.

The potential side effects of these contraceptive treatments have been considered theoretically, but few have been tested empirically. Nettles (1997) reviewed potential side effects, which included physiological effects, behavioral effects, population impacts and evolutionary impacts, and more recently suggested side effects include evolutionary effects (Magiafoglou *et al*. 2003, Cooper & Larsen 2006) and impacts on disease transmission rates (Tuyttens & MacDonald 1998, Caley & Ramsey 2001, Miller *et al*. 2004). The diversity of contraceptive agents means that there is potential for a variety of secondary impacts. Here we review the literature to determine: 1) potential impacts on individuals and populations, 2) which impacts have been documented, and 3) which impacts have been empirically tested. Finally, we consider the implications of the side effects of contraception for addressing fundamental theoretical questions, particularly in behavioral ecology.

Results

Trends in publications

The reviewed studies emphasized pest animals and agriculturally important species. Several orders have been investigated, but studies concentrated on Artiodactyla (particularly deer and domestic cows), Perissodactyla (mainly horses), and Carnivora (particularly felids) (Supplementary Table 1, see section on supplementary data given at the end of this article). There was an overall increase in published papers from 1975 to 2002 (Fig. 1). These publication trends indicate

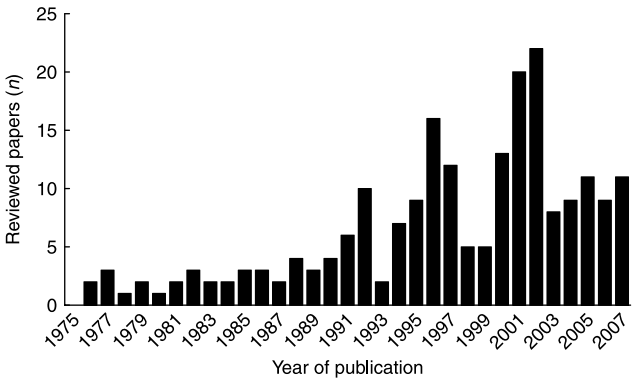

Figure 1 Publication trends of papers ($n=212$) that investigated or reported on secondary effects of contraceptive agents from 1975 to 2007.

increasing interest in side effects with a peak in 2002 when a special issue of *Reproduction Supplement* (vol 60) was published. After this supplement, the rate of publication returned to a consistent pre-2001 level.

Most studies investigated the impacts of female contraceptives (Table 1), which is consistent with efficacy studies in wildlife which usually target females. Physiological responses were addressed in a high percentage of the papers (85%) for both males and females. While physiological impacts are important, behavioral and population-level effects may be more relevant to the management of wild populations. Approximately 35% of the papers addressed individual behavior and 11% addressed population-level effects. Roughly 1/3 of the papers (30%) addressed more than one category. Only one paper investigated population-level effects in males, most likely because females are treated more often than males in wildlife populations (Table 1). Most of the research in the reviewed papers was done in captivity (84%) and the majority of studies that investigated changes in behavior of contracepted individuals were conducted in captivity (76%).

In this review, sample sizes, when reported, ranged from 1 to 353 for treated individuals and 0–230 for control individuals, with an average sample size of 31.7 ± 49.0 (median 17) treated individuals and 18.2 ± 30.0 (median 9) for controls, indicating high variability among studies. Most studies were of relatively

Table 1 A comparison of the 212 reviewed papers (%) based on sex and category that were included in the review. Total papers refers to the combined set of papers only based on sex, while the rest of the categories are specific to each sex.

	Total papers	Behavior	Physiology	Population
Female ($n=145$)	68	30	83	14
Male ($n=50$)	24	46	90	2
Both ($n=17$)	8	41	88	12

short duration, with an average duration of 1.8±2.4 years; although data collection was often conducted in short field periods of a few days or weeks over the course of the entire study, probably resulting in an overestimate of average study length.

Documented secondary effects

Several secondary effects are theoretically possible, and these are summarized in Table 2. Only a few hypothesized impacts have not been investigated, with most being studied at least once. However, few studies produced consistent results, even among studies using the same formulations. The main impacts are summarized below.

Physiology

How does contraception impact internal organs?

The impact of contraception on internal organs has received the most attention, with a total of 134 studies published. Changes in ovarian structure and function were found in most studies (82%, Table 2), which is not surprising since contraceptive formulations act directly on reproductive functioning, and so changes in reproductive organ histology and function are more likely than other impacts. Most changes that occurred to the reproductive tract were changes to follicle number, weight and size with the use of GNRH formulations (McNeilly & Fraser 1987, D'Occhio & Kinder 1995, Gong *et al.* 1995, Maclellan *et al.* 1997) and PZP

Table 2 Theoretical side effects of contraceptives and the number of studies that investigated these side effects. Both experimental and anecdotal papers are included in this table.

Side-effect	Theoretical	*Effect (*n*)	No effect (*n*)
Physiological			
Harmful effects on pregnant animals	Nettles (1997)		
Stillbirth		8	1
Abnormal offspring		2	1
Inhibition of parturition or dystocia	Nettles (1997)	2	0
Changes in ovarian structure or function	Nettles (1997)		
Associated with contraceptive mechanism		17	11
Associated with pathological changes		34	
Changes in lactation or mammary glands	Nettles (1997)	1	4
Changes in secondary sex characteristics	Seal (1991) and Nettles (1997)	0	0
Changes in bodyweight or condition	Nettles (1997)		
Increased in treated females		9	26
Decreased in males		1	0
Toxicity	Nettles (1997)	0	0
Interference with diagnostic tests	Nettles (1997)	1	0
Abscesses or inflammatory reactions	Nettles (1997)	14	8
Individual behavior			
Changes in behavior	Nettles (1997)		
Sexual activity		9	5
Increased movement		2	1
Activity patterns		2	8
Increased irritability or aggression		3	0
Social disruption, change in status, territory loss		5	5
Population-level			
Changes in sex ratio	Nettles (1997)		
Due to immigration		1	0
Offspring sex ratios		0	0
Changes in annual breeding season	Nettles (1997)	7	2
Ecological alterations	Nettles (1997)		
Home range or territory size		3	4
Increased immigration or emigration		0	1
Change in habitat use		1	1
Increased longevity or survival		6	2
Increased survival of offspring		3	2
Impact on fertility of young	Nettles (1997)	0	1
Improved breeding of non-treated females		1	0

Evolutionary level			
Genetic resistance	Magiafoglou *et al.* (2003)	0	0
Genetic changes influencing disease resistance or immune function	Nettles (1997) and Cooper & Larsen (2006)	0	0

*References are in Supplementary Table 2, see section on supplementary data given at the end of this article.

treatment (Dunbar *et al*. 1989, Kirkpatrick *et al*. 1992, Kitchener *et al*. 2002, Curtis *et al*. 2007). However, more serious side effects have been reported including increased inflammation of the uterus by intrauterine devices (Daels & Hughes 1995) and alterations to ovarian function, oophoritis and cyst formation with PZP treatment (Mahi-Brown *et al*. 1988, Sehgal *et al*. 1989, Rhim *et al*. 1992, Stoops *et al*. 2006, Curtis *et al*. 2007). In addition, MGA implants can increase mineralization and cystic hyperplasia in felids (Munson *et al*. 2002) and cause endometrial hyperplasia (Sokolowski & VanRavenswaay 1976). Consequently, changes to the ovaries or female reproductive tract were consistently found for all contraceptive treatments.

In domesticated livestock, GNRH immunization has been used to improve carcass characteristics by increasing lean meat (Huxsoll *et al*. 1998), feeding efficiency (Cook *et al*. 2001) and live weight (Bonneau *et al*. 1994, Zeng *et al*. 2002), and treatment usually resulted in positive effects on carcass traits, or no effect. Milk production did not seem to be influenced by contraception in the few studies in which it has been investigated (GNRH agonist: Mattos *et al*. 2001; progesterone: Nave *et al*. 2000), although there was some evidence of mammary hyperplasia in cats treated with progesterone (progestin: Loretti *et al*. 2005).

In addition to effects on internal organs, several studies (64%, Table 2) found inflammation or abscesses at the injection site. The majority of these papers examined inflammations due to injectable contraceptive formulations ($n=18$) and most found some inflammation at the injection site (67%). Most of these papers ($n=14$) investigated the impacts of PZP treatment and the majority found injection site reactions (71%). However, the injection site reactions were often associated with the type of adjuvant (e.g. Freund's Complete Adjuvant) used in association with contraceptive treatment, and these effects have been reduced with the use of modified adjuvants (Deigert *et al*. 2003). These injection site reactions usually healed quickly with no long-term health effects. Overall, most of the treatments showed little to no impacts on internal organs other than the ovaries (or testes) and some of the effects were considered positive.

Does contraception alter body condition?

Without the costs of lactation and gestation, females should hypothetically have improved condition and health, possibly leading to increased longevity and lifespan (Williams 1966). These impacts could extend beyond treated females. For example, untreated males may lose condition in the presence of contracepted females due to prolonged breeding activities (Ji *et al*. 2000). Some studies have confirmed that treated females are in better condition than untreated conspecifics (26% of reviewed studies), but the majority found no difference, or that differences did not last (Table 2). For example, PZP treatment increased female condition in both feral horses and white-tailed deer in some studies (McShea *et al*. 1997, Turner & Kirkpatrick 2002), but not in others (Walter *et al*. 2003). Generally, females treated with GNRH show no changes in weight or condition (Miller *et al*. 1997, D'Occhio *et al*. 2002, Herbert *et al*. 2005, 2006, Rubion *et al*. 2006). Finally, both longevity and offspring survival could theoretically be influenced by contraceptive treatment because untreated females may have more successful reproduction due to reduced competition for resources. The impacts of these factors on population dynamics can counteract the desired impact of the contraceptive treatment in reducing population size (see Williams *et al*. 2007) and such population-level effects are discussed later.

Are some contraceptive agents reversible?

For contraceptive treatment to be an effective management tool, it usually needs to be reversible (Kirkpatrick & Turner 1991). A long term study of feral horses showed that PZP was reversible even when females were treated for several years (Kirkpatrick & Turner 2002). However some females appeared not to return to full fertility after long-term PZP treatment and similar side effects were seen with GNRH treatments in deer (e.g. Miller *et al*. 2000*a*). Consequently, most wildlife contraceptives are reversible, or have minimal impact after prolonged use.

Individual behavior

Do activity patterns change in treated individuals?

Most studies suggest that activity patterns were unchanged after contraceptive treatment (80%, Table 2). With PZP treatment, no changes were detected in activity budgets of elk, horses, elephants, and white-tailed deer females (McShea *et al*. 1997, Heilmann *et al*. 1998, Powell 1999, Delsink *et al*. 2002), although the increased number of estrous cycles resulted in PZP treated white-tailed does being more active than control females (McShea *et al*. 1997). GNRH did not change activity budgets in treated kangaroo females (Woodward *et al*. 2006), nor did progesterone implants in kangaroos (Poiani *et al*. 2002), or fruit bats (Hayes *et al*. 1996). However, MGA treatment caused baboons to decrease their time foraging (Portugal & Asa 1995). Overall, few studies reported changes in activity patterns after contraceptive treatment.

Does rank and dominance change in treated females?

Rank and dominance are important in social mammals (Ellis 1995). By changing the levels of hormones or cycling patterns, females could become more or less

aggressive, which could have implications for behavior, social structure and welfare. Such side effects have been used by captive managers (e.g. GNRH to control aggressive behavior, Patton *et al*. 2001), but the few studies on wildlife have produced mixed results (50% showed changes Table 2). In captive felids, females treated with PZP had increased levels of irritability, masculine behavior, and aggression (Harrenstien *et al*. 2004), and in white-tailed deer, treated females associated less frequently with conspecifics (Bertrand *et al*. 1996). MGA treatment in tamarins caused a decrease in affiliative and sexual interactions, with a subsequent increase in aggression towards other females (De Vleeschouwer *et al*. 2000, 2003). Poiani *et al*. (2002) found that progesterone treatment altered the amount of time males spent with females, as males preferred to be in groups with untreated females. In elephants, the matriarch remained in place after treatment with PZP (Delsink *et al*. 2002), but changes occurred with hormonal treatments (unpublished study described in Fayrer-Hosken *et al*. (2000)). PZP treatment did not change the spatial relationship between females and males in horse harem bands (Powell 1999), although all females had been treated with PZP at some point, confounding the conclusions. Finally, surgical sterilization had little impact on coyote pair bond maintenance or territorial behavior (Bromley & Gese 2001), and no changes in social hierarchy were observed in brushtail possums with GNRH treatment (Jolly *et al*. 1996).

Unfortunately, many of the studies reporting no change in social structure have either used opportunistic observations of social groups, rather than quantitative techniques, or have been of short duration. Consequently, the results are inconclusive, and studies that specifically and intensively investigate behavioral changes at a fine level over a long time period are urgently needed.

Are home ranges and movement patterns altered?

If sexual behavior is altered in treated females, movement patterns could also change. PZP treatment resulted in no difference in space use or home range size in elephants and white-tailed deer (Delsink *et al*. 2002, Hernandez *et al*. 2006), similar to surgically sterilized foxes (Saunders *et al*. 2002). In contrast, surgically sterilized female rats had larger ranges than both control and hormonally sterilized females (Jacob & Matulessy 2004). In addition, hormonally sterilized female rats abandoned burrows more often, suggesting a change in dominance or social status, although overall habitat use was not changed (Jacob & Matulessy 2004). Male home range size may also be impacted, as found in brushtail possums (Ramsey 2007). Sterilization resulted in no difference in territory size, overlap or territorial behavior between controls and treated coyote packs (Bromley & Gese 2001). Consequently, most studies suggest that contraception had minimal impact on home range size and movement patterns, but there was some evidence that male kangaroos alter their movement patterns to be in groups of untreated females, or with treated females during the nonbreeding season (Poiani *et al*. 2002).

Do sexual interactions and breeding behavior change?

Changing the fertility of individual females could impact sexual interactions, especially in PZP-treated individuals because the number of estrous cycles is increased (i.e. McShea *et al*. 1997, Heilmann *et al*. 1998, Miller *et al*. 2000*b*, 2000*c*, Curtis *et al*. 2002). There was some evidence that breeding behavior changed in treated females (Table 2), and this varied with contraceptive type. Does treated with GNRH agonists had fewer estrus events (Miller *et al*. 2000*a*), but female wapiti showed no difference in copulatory behaviors (Baker *et al*. 2004). Treatment with progesterone analogs showed similar results to GNRH, but more males were seen in groups of control females (Poiani *et al*. 2002). Ji *et al*. (2000) suggested that males were attracted to areas with sterilized females, potentially increasing male mortality. In contrast, with PZP treatment, females remained sexually active after the end of the breeding season and showed an increase in estrus events (McShea *et al*. 1997, Heilmann *et al*. 1998, Miller *et al*. 2000*b*, 2000*c*). Although changes in breeding behavior appeared to be related to contraceptive formulations, 64% of the studies found changes in estrus and breeding behavior (Table 2), suggesting that these changes should be expected.

Does contraception impact the overall welfare of individuals?

Animal welfare refers to the systematic concern for the well-being of animals. The assessment of welfare involves the examination of both emotional and physical states (Fraser 1995). The reviewed impacts on physiology and behavior suggest that contraception had little impact on overall welfare of individuals, particularly compared to the alternative options (see Kirkpatrick (2007)). While most studies found some changes in physiology or behavior, these changes may not impact the individual enough to affect their well-being, as most studies found no changes to activity, movements or rank of treated females. However, these conclusions are based largely on qualitative and anecdotal studies and there were no studies that specifically set out to address welfare of individuals. While welfare can be difficult to measure, there are many ways to objectively evaluate welfare (Dawkins 2001, Scott *et al*. 2003). For example, measuring stress levels in both treated and control individuals could give an assessment of overall well-being, yet none of the reviewed studies took a systematic approach to address this issue. In addition, some studies

indicated that changes could occur to non-treated animals in the population (e.g. males), which needs to be considered in future research. Furthermore, since most of these studies were conducted in captivity, the applicability to free-ranging populations may be limited since conditions in captivity do not necessarily mimic natural conditions. Given all of these issues, the assessment of welfare implications of contraceptive treatment is a research priority.

Population-level effects

Do survival, abundance, and age class distribution change in treated populations?

Contraception reduces the costs of reproduction, and could therefore result in increased body condition and longer lifespan, thereby altering population dynamics. Furthermore, the offspring of untreated females may have less competition for resources, enhancing their survival and working against the goals of the management operation. Few studies had the longitudinal data required to investigate increased survival, but 75% found an increase in longevity or survival in individuals. For example, PZP treated feral horse mares lived longer, resulting in a new age class (>25 years) not present before treatment (Turner & Kirkpatrick 2002). Therefore, while contraception may limit offspring production, these benefits may be offset by decreased mortality in older individuals, negating the population level effects of contraceptive treatment. In addition, both adults and juveniles had increased survival in surgically sterilized rabbits (Williams *et al*. 2007), which meant that the majority of females must be sterilized to reduce population size (Williams *et al*. 2007). Furthermore, non-treated females showed improved breeding success (Chambers *et al*. 1999), which also counteracted the reduction of population growth rates by contraception. Finally, while the sex ratio of offspring could change due to increased maternal condition (e.g. Cameron 2004), this has yet to be investigated, although Ji *et al*. (2000) recorded a change in population sex ratios in brushtail possums, probably as a result of male dispersal. Overall, contraceptive treatment appears to increase longevity in treated females and, in some cases, non-treated individuals.

Does contraception decrease disease transmission?

If contraception decreases sexual interactions, there may be a decrease in overall social interactions which could decrease the level of disease transmission. Diseases could also be decreased in a treated population simply from lower densities of animals and healthier conditions (see body condition section). This decrease would be advantageous in certain pest species, such as the brushtail possum, which have a high population size, and are carriers of economically or ecologically important diseases, such as bovine tuberculosis (Caley & Ramsey 2001, Ramsey 2007). In addition, a potential decrease of brucellosis transmission is predicted in bison with GNRH treatment (Miller *et al*. 2004), as anestrous females would be unable to spread the disease due to lack of offspring production. Both of these circumstances would result in a positive side effect of contraceptive treatment. Alternatively, if sexual interactions increase, such as in the case of PZP treatment, there could be a potential increase in the transmission of certain diseases. While there has been little research that addresses these effects, most studies concur that disease transmission rates remain unchanged with contraceptive treatment (Kerr *et al*. 1998, Williams *et al*. 2007). However, the potential to reduce disease transmission exists (Ramsey 2007) and studies on rabbits showed a decrease in flea abundance (Twigg *et al*. 2000, Williams *et al*. 2007); possibly indicating a decrease in overall interactions between individuals. More research is clearly required.

Is the mating season extended?

Mating behavior can demand high levels of energy for both sexes. In species with a discrete breeding season, the lengthening of the season could impact the survival and welfare of treated females and nontreated males. Most studies showed a change in the annual breeding season where it was investigated (78%, Table 2). Treatment with PZP increased breeding behavior, caused later fawning dates, and increased sexual activity outside the normal breeding season in several studies (McShea *et al*. 1997, Heilmann *et al*. 1998, Miller *et al*. 2000*b*). However, no differences were reported in populations with females treated with GNRH (Miller *et al*. 2000*a*, Baker *et al*. 2002, 2004, Woodward *et al*. 2006, Conner *et al*. 2007), or progesterone (Poiani *et al*. 2002). Differences in the actions of these formulations and their contrasting effects on cycling probably account for the differences in the impacts on the breeding season. Consequently, the type of contraceptive treatment should be considered for species with a discrete breeding and birthing season. These side effects could have animal welfare implications as these changes could lead to a reduction in the survival of treated females, untreated males and offspring.

Meta-analysis

Of the 212 reviewed papers, 54 (25%) experimentally tested the secondary effects of contraception and reported their results in sufficient detail to be included in the meta-analysis. Studies were classified as experimental if the authors described an experiment with controls, and used statistical analysis of their results. We did not attempt to judge the robustness of their experimental design since we could not always judge

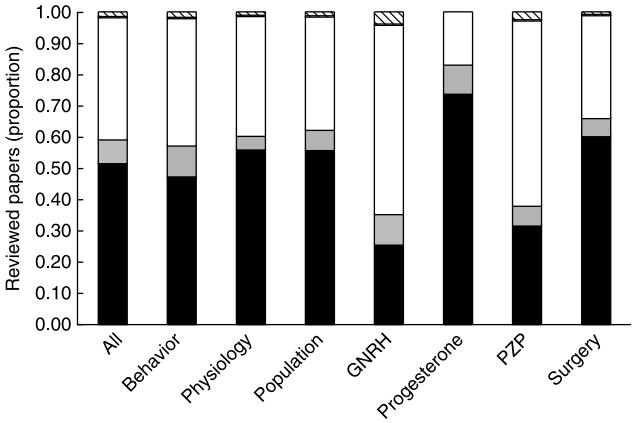

Figure 2 Wildlife studies that empirically tested ($n=54$) if contraceptive treatment produced side effects that either showed significant support (■) or non-significant trend to support (▣), or no significant variation (□), or significant support in the opposite direction to that predicted (▧).

from methodological descriptions whether these represented true experiments with randomized subjects and appropriate controls. Although the quality of experiments may vary, they provide results suitable for meta-analysis, and enable the detection of general trends. From our qualitative review, most papers concluded no significant secondary effects were found. However, the quantitative studies produced contrasting results. From the 339 test statistics from the 54 papers, 52% found side effects from contraception and an additional 8% showed a non-significant trend suggesting side effects. The support varied between contraceptive types and between secondary effect types, with progesterone treatments and physiological studies reporting the most side effects (Fig. 2). Despite this variation, all meta-analyses yielded highly significant z values for the difference between treated and control groups and confirmed that side effects consistently occurred where investigated regardless of study category or treatment type (Table 3). The magnitude of the overall effect size was medium, as r ranged from 0.17 to 0.39. Furthermore, there was no significant heterogeneity of effect sizes within analyses, suggesting that studies were measuring the same thing and coming to the conclusion that side effects occur when investigated. Therefore, contraceptive treatment resulted in changes to the physiology and behavior of individuals, and impacted populations with treated individuals.

An interesting contrast thereby arises in which quantitative studies showed that side effects were consistently found, whereas qualitative studies and anecdotal reports suggest that side effects were generally absent. While a publication bias is possible, most studies were predominantly publishing results on efficacy, such that data on side effects would not influence publication potential. Consequently, more studies specifically investigating secondary effects are required to quantify the impacts of contraceptive treatment on physiology, behavior and population dynamics.

Discussion

Future directions

While there have been an increasing number of studies on side effects, much is still unknown. Unfortunately, many of the reviewed studies were not designed to investigate the side effects and many conclusions were based on small sample sizes, anecdotal reports, or lacked true controls. Conclusions based on data from studies designed to investigate efficacy may not be methodologically suitable for testing for behavioral or ecological effects. Many studies were designed to test efficacy, and the side effects reported were based only on short-term observations. Many studies on efficacy concluded 'no change' for side effects based on anecdotal observations, but these studies did not directly investigate the physiology, behavior or ecology during the study, limiting the conclusions. This contrasts with the meta-analysis further questioning the validity of qualitative studies reporting 'no change'. While the meta-analysis does not account for the severity of the effect, all of the major contraceptive treatments resulted in side effects (Table 3). Thus, these qualitative studies represent an interesting foundation, but future research

Table 3 Meta-analysis of reviewed papers on wildlife species when contraceptive treatment was investigated for secondary effects ($n=54$). All data are generated from Meta 5.3 including effect size (difference between treated and control groups among all studies), $Z_{weighted}$ (the significance of the effect size), heterogeneity (difference of measurements among studies) and the P value of the heterogeneity.

requires more detailed behavioral and ecological protocols, larger sample sizes, and longer study durations.

Evolutionary level

No evolutionary level questions have been investigated, but are most relevant for future impacts (Table 2). Two main impacts of immunocontraception have been proposed; 1) genetic resistance could evolve, similar to the response seen to other biological control agents (Magiafoglou *et al*. 2003), and 2) immunocontraceptives could be selecting for immuno-compromised individuals since those treated females that do breed have a lower immune response to the contraceptive (Nettles 1997, Cooper & Herbert 2001). These aspects require long-term research which has not been possible to date. Nonetheless, given the potential implications of either of these changes, research is urgently required in this field.

Conclusions

While physiological effects have been well-documented, there is less consistency in studies investigating behavioral or ecological side effects, compounded by the tendency for studies to be designed to investigate efficacy specifically and side effects only opportunistically. Such studies often lack appropriate controls, sampling methodology or time scales. Those studies that have specifically investigated side effects consistently find them. While contraception is currently supported as a humane treatment by many managers, researchers and advocacy groups, research in this field has not extended much beyond the scope of management concerns.

Both physiological and behavioral effects can impact population dynamics. The goal of contraceptive treatment is to manipulate population dynamics, and consequently it is imperative to understand population-level effects, some of which compromise the effectiveness of contraceptive treatment (such as through increased breeding in untreated females or increased survival of offspring), while others could enhance effectiveness (such as a male biased sex ratio). To be an effective tool, we need to understand these impacts. Furthermore, most research examined short term effects and research is needed that addresses questions beyond one estrous cycle or breeding season. For example, no study investigated how genetic diversity or immunity could change over time. In addition, most studies, including behavioral studies, were done in captivity, which often limits the application to wildlife species, further suggesting the need for long term experimental studies on wildlife populations.

Finally, contraception provides a powerful tool to address fundamental questions in biology but such applications have not been realized to date. By manipulating fertility we can address questions regarding, for example, the costs of reproduction, importance of copulation in maintaining social structure and parental investment strategies. This would enable us to simultaneously address management questions, questions about contraceptive actions and secondary effects, and questions in basic biology, thereby maximizing the utility of contraception research.

Materials and Methods

We searched ISI Web of Science (1975–2007) for 'immunocontraception' and 'contraception'. Additional searches were made to narrow the papers to those with the terms 'side effects' and 'secondary effects', and we further searched the literature from the cited section of each paper to find more studies that were not identified in the initial search. Only papers that included applications to mammalian wildlife, zoo, or livestock species were used in the review, and humans were excluded. Papers that only researched efficacy or impacts of contraception on fertility directly were not included.

Initially we reviewed the theoretically suggested side effects. We then compiled all the studies that had addressed secondary effects either directly or during the course of a study on efficacy. We defined a side effect as an unintended or unwanted secondary effect and use the terms side effect and secondary effect interchangeably. Both of these terms refer to unintended side effects, but could be positive, neutral or negative. We considered changes to ovarian structure as side effects as both changes induced by pathology or association with the mechanism of contraceptive action. Pathological changes would include cyst formation, hyperplasia, abnormal tissue formation, as well as changes that occurred from a contraceptive treatment where the intended purpose was not associated with ovarian function (e.g. block fertilization). This resulted in the classification of most papers that researched GNRH formulations as changes associated with the mechanism of contraceptive action since GNRH formulations directly act on hormones that regulate cycling and oocyte development. This definition also resulted in papers that investigated PZP being classified under pathological changes. In some of these cases the side effects are absolutely expected, but nonetheless they are secondary to the main contraceptive action and therefore considered side effects.

A total of 212 papers were found that investigated secondary effects or reported side effects noticed during research on efficacy (the full list is presented as Supplementary Appendix 1, see section on supplementary data given at end of this article). The papers fell into three categories; 1) physiological effects, 2) behavioral effects on the individuals, and 3) population-level effects, which we use hereafter. From those papers, we considered sex, species, sample sizes, length of study, type of effect investigated and if that effect had an impact on the animals. We then compared the theoretical effects with the empirical evidence to determine which effects seemed to be supported, or not supported, and in which areas more research is required.

Meta-analysis

From the reviewed papers, we analyzed studies that empirically tested if side effects were found in treated wildlife populations through a meta-analysis in order to estimate the magnitude of the experimental effect (effect size). We only included wildlife populations and excluded wildlife in zoos if the contraceptive treatment was used intentionally to change behavior (i.e. decreasing aggression or sexual activity), so as not to skew the analysis towards side effects. In addition, in an effort to be conservative, livestock papers were excluded since 87% of these studies reported side effects and most of these papers used the contraception to make a change. Every meta-analysis suffers from the possibility of publication bias; therefore every attempt was made to remove publishing bias by the previously described methods. In addition, our search results included papers that primarily investigated efficacy but reported on side effects in order to reduce this bias.

For the meta-analysis we used the *P* values and sample size reported in each study in order to obtain a combined effect size (*r*). Effect sizes were weighted for sample size and indicate the strength of association across the selected studies. The corresponding $Z_{weighted}$ value provides the significance of the difference between treated (contracepted) and control groups. In addition, we calculated a χ^2 statistic to test for heterogeneity of results across the selected studies. A random effect model was used in order to account for differences in both effect size and sampling error (Gurevitch & Hedges 1999). A total of 54 papers were included that empirically tested secondary effects from contraceptive treatment. From those papers, all measures were treated as separate statistics. If there was not sufficient evidence to determine *P* values and sample sizes, the papers (or statistics) were excluded from the analysis. An overall analysis was done, in which all experimental studies were included, regardless of treatment type and study classification. We then conducted separate analyses to test for differences within each side effect category (physiology, behavior and population-level effects) and contraceptive type (GNRH, progesterone, PZP, and surgery). The meta-analysis was conducted using META, v 5.3 (Schwarzer 1989).

A dynamic simulation model for evaluating effects of removal and contraception on genetic variation and demography of Pryor Mountain wild horses

John E. Gross *

Natural Resource Ecology Laboratory, Colorado State University, Fort Collins, CO 80523-1499, USA

Received 6 January 2000; received in revised form 1 May 2000; accepted 5 May 2000

Abstract

I used an individual-based model to simulate population dynamics and changes in genetic variation of horses in the Pryor Mountain Wild Horse Range under a range of management strategies. Management strategies included population objectives of 90 to 180 horses and removal and/or contraception of animals of random, young, or old ages. Populations controlled only by removals fluctuated widely in size and generally exceeded objectives by >20%. Populations controlled by contraceptives remained within 3% of objective. Over a 200-year period, populations were very likely to lose alleles with an initial frequency of <3%, which included nearly 30% of alleles in the population. Allelic diversity was lost faster than population-level heterozygosity. Removal or contraceptive treatment of older animals hastened the loss of genetic variation compared to treatment of random-aged or young animals. Rate of loss of genetic variation was directly related to generation interval, and differences in loss of genetic variation were greater between treatments of old and young animals than between populations that differed in size by a factor of 2. These results apply to management of many long-lived species in harvested populations and they illustrate the importance of actions that modify age structure and generation interval. © 2000 Elsevier Science Ltd. Keywords: Contraception; Genetic variation; Infertility; Population control; Simulation model

1. Introduction

About 150 horses inhabited the Pryor Mountain Wild Horse Range (PMWHR) in 1998, close to the estimated range carrying capacity (BLM, 1997). The small size of this population concerned those mandated to sustain a viable and healthy population, because genetic diversity rapidly disappears in small populations (Wright, 1931). The Pryor horse population has the reproductive potential to double in size every 4–5 years and attain a size that poses risks to habitats and to populations of mountain sheep and deer that also inhabit the PMWHR (Garrott and Taylor, 1990). Management of the Pryor horse population is illustrative of the general predicament faced by agencies with a mandate to control an isolated population characterized by high reproductive potential, long life span, and limited area of available habitat. In these situations, management plans must balance measures to minimize risk of long-term habitat degradation while maximizing long-term retention of genetic variation and the likelihood of population persistence. There are thus conflicting needs to minimize population size to control habitat degradation while maximizing population size to conserve genetic resources.

Feral horses in the United States are protected by the Wild Free-roaming Horse and Burro Act of 1971 and management of most feral horse populations falls under the jurisdiction of the Bureau of Land Management (BLM, 1997). Wild horse populations in the western United States have exhibited growth rates that frequently exceed 15% per year (Garrott et al., 1991a) and they can rapidly achieve population sizes that raise concerns about long-term habitat damage. A total of about 35,000 horses inhabit ranges on public lands in the western United States, but only 25% of the 186 wild

horse populations under active management have a population objective of greater than 150 horses (BLM, 1997). The small size of these populations raised concerns about long-term maintenance of genetic variation and emphasized the need to identify methods to control population size while retaining genetic variation.

Wild horse populations have been controlled primarily through periodic gathers and removals. Programs were developed to place wild horses in private ownership, but this has proven to be exceedingly expensive (> $16 million in 1995; BLM, 1997) and it has become impossible to place all horses acquired by removal programs. As a result, there is great interest in the potential use of contraceptives to reduce fertility of horses and other overabundant species (Sturtevant, 1970; Hoffman and Wright, 1990; Garrott et al., 1991b; Holden, 1992; Eagle et al., 1992; Fayrer-Hosken et al., 1997). Use of contraceptives could provide opportunities for a variety of new management scenarios, including permanent infertility, delayed reproduction, or permitting mares to reproduce once and then preventing further breeding. Simulations of horses population dynamics have shown that a relatively high level of infertility would likely be needed to maintain a low growth rate in horse populations (Garrott, 1991), but no analyses have specifically considered the consequences of alternative management actions on long-term persistence of genetic variation in horses or similar mammals.

Management strategies to control growth rates of abundant populations by removal or contraception must focus on three decisions: How many animals should there be? What sex and age of animals are to be removed or made infertile? How often are animals removed or treated? The model described below was developed to address these questions by simulating removals only, contraceptives only, or a combination of removal and contraception. The model was specifically applied to the Pryor wild horse population to evaluate a set of realistic management alternatives. Results from the simulations lend insight to the consequences of management actions used or considered for control of overabundant species including bison, deer, elk, elephants, mountain goats, and some carnivores (Hoffman and Wright, 1990; Bradley, 1994; Fayrer-Hosken et al., 1997; Kirkpatrick et al., 1997). To preserve genetic variation, guidelines for managers almost always emphasize actions that increase overall population size or reduce reproductive variance. I offer analyses that clearly demonstrate the importance of age-related management actions and show that actions that increase (or decrease) generation time of long-lived species can have an effect equal to doubling population size. These results are important because it is frequently much easier to modify age structure than increase population size.

2. Method

I developed an individual-based population model to simulate the dynamics of the PMWHR horse population. The model operated on a yearly time step and it simulated the processes of breeding, recruitment, removal, contraception, natural mortality, and aging. Each individual in the population was explicitly represented and the sex, age, genetic constitution, number of mates, and reproductive status of all animals was followed from birth to death. Model outputs included sex and age of each individual in the population, number of mates (by age) of males and females, and the frequency of all alleles.

2.1. Model processes and parameter estimates

Wild horses on the PMWHR have high rates of survival and reproduction (Garrott and Taylor, 1990; Singer et al., 1998), consistent with observations of wild horse populations throughout the western United States (Berger, 1986; Garrott et al., 1991a). Estimates of fecundity and survival were derived from observations of the Pryor population, emphasizing data subsequent to management changes that occurred about 1990 (Garrott and Taylor, 1990; Singer et al., 1998). Horses in the PMWHR have been intensively studied since the 1980s and about 95% of all horses are individually known and repeatedly observed each year. Age-specific survival rates are thus known with a high degree of confidence up to about 15 years of age. Relatively few horses have lived longer than 15 years and these older horses make up a small proportion of the population. No density dependent regulation of survival or reproduction was included in the model because the horse population has been maintained at a size well below estimates of range carrying capacity and evidence for density dependence is lacking. Recent analyses found a significant correlation between growth rate and population size, but neither recruitment nor survival varied significantly with population size ($P > 0.10$; Singer et al., 1998).

Breeding was simulated by comparing a uniform random deviate to the probability of recruitment for each mare, and then selecting a mate. Age-specific breeding success of wild stallions was used to simulate paternity (Berger, 1986, p. 200). It is difficult to determine mating success in the field and tenuous to extrapolate results to another site. However, sensitivity analysis showed that model results were insensitive to age-specific breeding success, but were more sensitive to the probability that a male bred during its lifetime. Estimates of breeding success (Berger, 1986; Singer et al., 1998) show that that virtually all prime-aged stallions breed. The likelihood that a particular stallion mated with a female was determined by the number of breeding-age males in the

population and the age-specific probability of breeding. Every male in the population was assigned the appropriate age-specific probability of breeding (Table 1) and the cumulative breeding probabilities were placed in a vector with a length equal to the total number of breeding-age stallions. For each female that bred, a uniform random deviate between 0 and the sum of breeding probabilities was generated and compared to values in the vector. The male that corresponded to the value of the deviate was chosen as the mate for that female. All matings were independent. Factors that determined harem formation, size, and retention were too poorly known to include in the model, but harem interchange rates in the Pryor horse population are so high (Singer et al., 1998) that the age-specific algorithm was probably sufficient for this situation. If only harem-holding stallions mated, simulation results reported here will have overestimated retention of genetic variation.

After the parents of an offspring where determined, Mendelian inheritance was simulated by randomly selecting one allele from each parent at 10 independent loci. At the beginning of each set of simulations, individuals were assigned alleles in the frequency in which they occurred in the Pryor population (G. Cothran, pers. comm.). Each simulation began with a total of 41 alleles distributed over 10 loci; two to 13 different alleles occurred at each locus with an initial frequency of 0.0035 to 0.844.

2.2. Population objective, removal and contraception treatments

The current management plan for the PMWHR includes a population objective of 95 horses, excluding foals (BLM, 1992). A population objective, or appropriate management level (AML), is the optimum number of horses that remain after a removal event in order to maintain a "thriving ecological balance". Foals are usually excluded in determining the AML, and in this paper foals were always excluded from counts used to determine compliance with a population objective or to categorize a population size. Simulations included an AML of 90 horses, and increases in AML to 120, 150, and 180 horses. These objectives might be accommodated by supplemental feeding, acquisition of additional habitat, or other strategies. No specific means to attain a particular objective is implied.

Removals and/or contraceptive treatments of wild horses were simulated by applying rules based on current population size, post-treatment population objective, sex and age of animals to be treated, the minimum number of horses in each sex/age class that were to be unaffected by the treatment, and for removals, the length of time since a previous removal. To determine the annual control treatment, the population was first compared to size thresholds used to categorize the population as small, normal, or large. If the population size was less than or equal to the lower threshold, it was categorized as small. If the population size was greater than the lower threshold and less than or equal to the higher threshold, it was categorized as normal. If greater than the upper threshold it was considered large.

Population size could alter both the timing and magnitude of treatment. It is expensive to gather and remove wild horses and managers seek to minimize the frequency of these events (Boyles, 1986; BLM, 1997). The model therefore simulated a removal event only when the population size had grown to a sufficient size. Removals or contraceptive treatments always occurred when the population size was categorized as large, regardless of how long it had been since a previous treatment. Removals also occurred when the population size was categorized as normal and a threshold number of years had passed since the previous removal. This time threshold was set at 3 years for removal-only treatments and 5 years for removal-and-contraceptive treatments. For removal-only treatments, the threshold between a small and normal population size was set at 150% of the population objective and the threshold between a normal and large population size was set at 200% of the population objective. A removal never occurred when the population size was categorized as small.

Several variables determined which animals were removed from the population. The first variable was the

Table 1
Demographic parameters used to simulate wild horse dynamics

Males			Females		
Age	Survival	Probability of mating	Age	Survival	Probability of recruiting
1–4	0.98	0.00	1–2	0.98	0.00
5–6	0.98	0.10	3–4	0.98	0.50
7–8	0.98	0.26	5–16	0.98	0.60
9–16	0.98	0.64	17–22	0.75	0.47
17–19	0.75	0.50	23–24	0.50	0.47
20–22	0.62	0.25	25	0.00	0.00
23–24	0.50	0.25			
25	0.00	0.00			

population objective, which was the number of horses (excluding foals) remaining after a removal was completed. Removal treatments were categorized as young, old, or random for the age of horses emphasized in the treatment. Random animal treatments selected horses randomly with regard to sex or age until the population objective was reached. For old animal treatments, the oldest horses in the population were selected first, leaving a few males and females in each multi-year age class. Similarly, young treatments first removed the youngest animals, again leaving a few males and females in each multi-year age class. Males and females were removed to leave a slightly female-biased sex ratio, consistent with observations of other wild horse populations and prior BLM removals (Berger, 1986, p. 91).

The proportion of mares treated with contraceptives varied with population size. For each contraception-only treatment, the level of contraception was initially calibrated to achieve a stable population size. However, demographic stochasticity often resulted in populations that either grew or declined. In these situations, the rate of application of contraceptives was increased or reduced until the population declined or increased to a size that fell within the normal range. For populations regulated by contraceptives, populations were categorized as normal when they were 85 to 110% of the population objective. Contraceptive treatments were administered every year and treated mares remained infertile for one year. As with removals, females were selected for contraceptive treatments based on age, using rules that selected breeding-age females randomly, or that resulted in treatment of the oldest or youngest mares first.

Simulations that used both infertility and removal employed a constant rate of application of contraceptives and a threshold population size for determining the frequency of harvest. The rate of contraception was initially calibrated to result in removal of about 50 horses every 5 years.

2.3. Genetic analyses

Observed heterozygosity [H_o; Eq. (1)], expected heterozygosity [H_e; Eq. (2)], and the inbreeding coefficient [F_{is}; Eq. (3)] were calculated following Hartl and Clark (1997), where N is the number of loci.

$$H_o = \frac{\sum_{n=1}^{N} \frac{\text{heterozygotes at locus}_n}{\text{number of individuals}}}{N} \quad (1)$$

$$H_e = \frac{\sum_{n=1}^{N} \left(1 - \sum_{k=1}^{\infty} (\text{freq. of allele k})^2\right)}{N} \quad (2)$$

$$F_{is} = 1 - \frac{H_o}{H_e} \quad (3)$$

In the absence of agency-mandated objectives for conserving genetic diversity, changes in genetic variation were evaluated relative to a goal to achieve a 90% probability of conserving 90% of selectively neutral genetic variation for 200 years. This is a slightly less ambitious objective than suggested by Soule et al. (1986). The frequency of each allele at each locus was recorded and used to evaluate rate of loss of alleles.

2.4. Initial conditions, simulation procedures, and evaluation of results

All simulations started with an initial population of 147 horses that matched the sex and age structure of the PMWHR horse population in fall 1998. The initial population consisted of 65 males aged 1 to 22 years and 82 females aged 1 to 17 years. Treatments were evaluated from results of 500 simulations that each lasted 200 years.

A variety of output files were written to permit evaluation of the causes of differences between treatments. Each year, the age structure of the population, the age and sex of individuals removed, and the age of females treated with contraceptives was recorded. Summary files included data on age-specific fecundity and lifetime reproductive success of males and females. These outputs were used to construct life tables of simulated populations, from which standard demographic statistics such as growth rate and generation time were calculated (Carey, 1993). Annual growth rates for removal treatments accommodated removals by adding the number of horses removed back to the population, such that

$$\lambda_t = \frac{N_t}{N_{t-1} + R_{t-1}} \quad (4)$$

where λ_t is the apparent annual growth rate at year t, N is the total number of animals in the given year, and R_{t-1} is the number of animals removed from the population between year $t-1$ and t. The initial age structure led to instability for the first 10–25 years in simulations of populations regulated by contraceptives, and analyses of rates of contraception and average population processes excluded data from the first 30 years of each simulation.

3. Results

3.1. Treatment levels and demographic responses

Removal and contraceptive treatments resulted in population dynamics that were fundamentally different. Populations controlled by removals increased rapidly and declined precipitously when a removal occurred. In

contrast, populations controlled by contraceptives remained relatively stable. As a result of these dynamics, the average size of populations controlled by removals was 18–27% greater than the AML, whereas populations controlled by contraception remained within 3% of the AML (Fig. 1; dark bars referring to horses 1 year and older). Populations controlled by a combination of contraception and removal were on average 18–5% greater than the AML for population objectives of 90–180, respectively. The coefficient of variation of population size for populations controlled by removal averaged 17%, compared to 8% for populations controlled by contraceptives alone and 11% for populations controlled by contraceptives and removals.

Average annual growth rate (λ) of populations controlled by removals was 1.15 when young horses were removed, 1.16 when old horses were removed, and 1.17 for removal of random-aged horses. Population objective had no influence on average growth rate and the maximum difference in growth rate within a removal treatment (old, young, or random) was 0.004. For populations controlled by contraception and removal of younger horses, λ varied with population objective and ranged from 1.05 to 1.09 for simulated populations with objectives from 180 to 90, respectively. For these treatments, differences in λ were driven by differences in the application rate of contraceptives (Table 2), which were adjusted to achieve a removal of about 50 horses every 5 years.

To achieve a stable population with contraceptive-only treatments, an average of 78, 73, or 74% of all mares 2 years or older were rendered infertile for treatments of young, old, or random-aged mares (Table 2). Depending on population objective, this resulted in

Table 2
Percent and number of horses 1 year or older affected by simulated contraception treatments of the Pryor wild horse population, and the average number of foals in the population

	Population objective	Percent treated	Number treated (mean±1 S.D.)	Average number of foals
Contraception-only treatments				
Young age	90	78	32±7.6	5.7
	120	78	44±8.9	7.7
	150	78	54±10.1	9.6
	180	78	65±11.2	11.5
Old age	90	73	31±6.4	5.8

	120	58	37±5.2	18.3
	150	61	46±6.0	20.1
	180	64	57±6.6	21.5

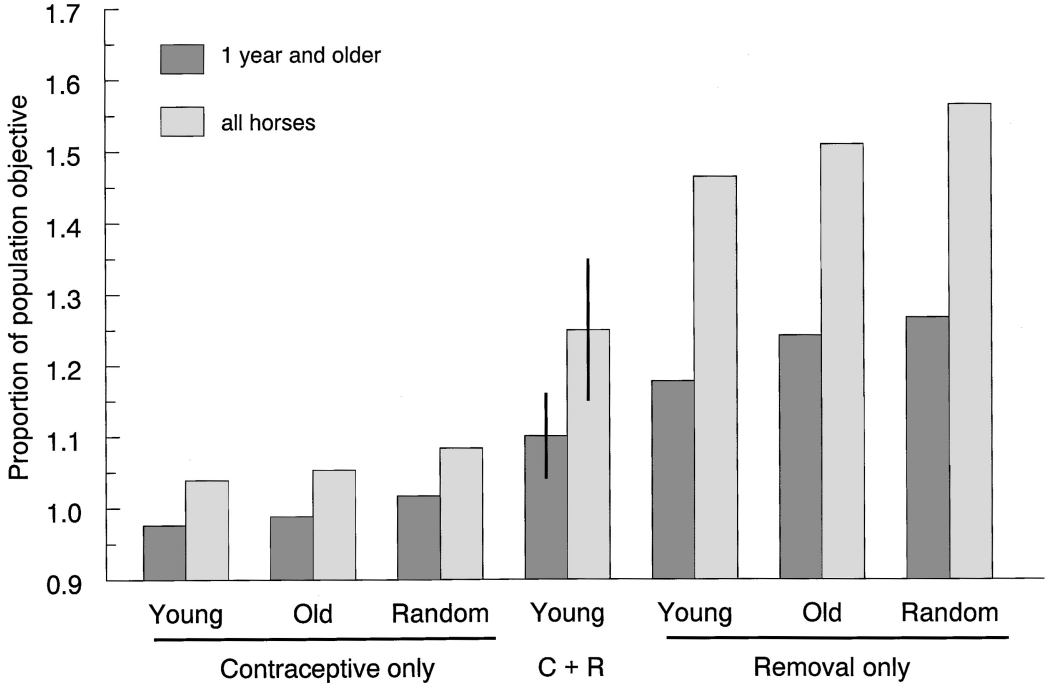

Fig. 1. Average size of populations with (dark bars) and without foals (light bars) as a proportion of population objective; C + R = control using both contraceptives and removals. Population size as a proportion of the population objective varied with the size of the population objective for only C + R treatments; vertical lines show the largest values (for an objective of 90) and smallest value (for an objective of 180).

treatment of an average of 32 to 65 mares per year. For treatments that combined both contraceptives and periodic removals, an average of 50, 58, 61 or 64% of breeding-age mares were rendered infertile each year for population objectives of 90, 120, 150, and 180 horses, respectively. These levels of infertility required treating, on average, 25 to 57 mares each year. When simulated populations were controlled by a combination of removals and contraception, more than 90% of all removals took place at a 5 or 6 year interval regardless of population objective. About 55 horses (range of means = 53–58) were culled from the population each time a removal occurred (Table 3).

For removal-only treatments, more than 90% of removals occurred at three year intervals regardless of population objective or the age of horses removed. Each time a removal occurred, an average about 35% of all horses were removed (range of means = 33 to 37%; Table 3). The number of animals removed was directly related to growth rates; the lowest rate of removal was for treatments of younger horses and the greatest was for random removals (Table 3). Removal of a random selection of horses required harvesting about 20% more horses than when younger horses were removed.

Removals and infertility treatments resulted in populations that had drastically different age structures, but differences in age structure were due entirely to the removal or contraceptive treatment and not to population objective. Within a removal or contraceptive treatment, the proportion of the population in a particular age class remained constant across all population objectives simulated. All simulated removal treatments resulted in age structures characteristic of growing populations, while contraception resulted in the flat age structure characteristic of a stable population (Fig. 2). The average number of foals in the population at the time of a removal varied from 20 to 67 depending on AML and treatment (Table 3). Because foals were not counted towards the AML, populations with a large number of foals in the year of a removal far exceeded the AML in the subsequent year. This occurred because survival rates were high for both foals and adults, and thus the number of foals was far in excess of the number of animals dying from natural causes.

Contraception of older mares or removal of older horses resulted in much shorter generation times than treatments that removed younger females or that delayed reproduction. Average generation time of mares varied by more than a factor of 3, from an average of 4.7 years (contraception of older mares) to a maximum of 16.8 years (contraception of younger mares; Fig. 3). Differences in generation time for males varied far less than that of females, from a minimum of 10.4 years to a maximum of 12.6 years (Fig. 3). Generation time for males was the same for all treatments except for removals of random or old horses; these treatments resulted in shorter generation intervals. For both sexes, differences related to population objectives were small compared to those between treatments that affected different-aged segments of the population.

Table 3
Simulated removal treatments for the Pryor horse population[a]

Age treated	Population objective	Number removed per event (mean±S.D.)	Number removed per year	Proportion removed per event	Harvest interval (years)	Foals at time of harvest
Contraception and removal treatments						
Young age	90	58±10.7	12	0.35	5	20.1
	120	54±9.7	11	0.28	5	20.8
	150	54±10.0	11	0.24	5	22.5
	180	53±9.8	11	0.21	5	23.8
Removal-only treatments

	180	144±11.4	48	0.37	3	67.1

[a] Mean percent and number of horses 1 year and older removed, and the average number of foals at the time of a removal.

3.2. Effects of treatments on heterozygosity

Initial H_o averaged 0.433 (range of means = 0.432–0.434; range of individual simulations = 0.388–0.479). After 200 years, mean H_o varied from a low of 0.301 (70% of initial H_o), for control by removal of old animals with a population objective of 90, to a high of 0.413 (95% of initial H_o) for populations controlled by contraception and removal of younger mares with a population objective of 180 (Fig. 4). The method of control and age of animal treated or removed had a greater effect on retention or loss of H_o than did population size over the ranges simulated. Treatments that affected older individuals uniformly resulted in more rapid declines in H_o than treatments of young animals. More than 10% of all simulated combinations of population objective and control strategy failed to retain 90% of initial H_o. Using H_o as a measure of genetic diversity, these simulated control strategies thus failed to meet the objective to achieve a 90% probability of retaining 90% of neutrally selective diversity for 200 years.

Inbreeding coefficients (F_{is}) after 200 years of simulation averaged 0.092 (range of means = 0.086–0.096) across all treatments and population objectives. F_{is} tended to be lower for small population sizes, a trend especially pronounced for populations with objectives of 90 and 120 horses. This counterintuitive trend probably resulted from the greater loss of rare alleles in smaller populations, which also reduced H_e in these scenarios (see below).

The use of allele frequencies from the Pryor population resulted in populations in which 34% of all alleles had an initial frequency of 0.05 or less and in which 12% of all alleles occurred at a frequency of 0.02 or less. With an AML of 90, all simulated control strategies resulted in an average loss of more than 25% of alleles (Fig. 5). Almost half (48%) of all alleles failed to persist

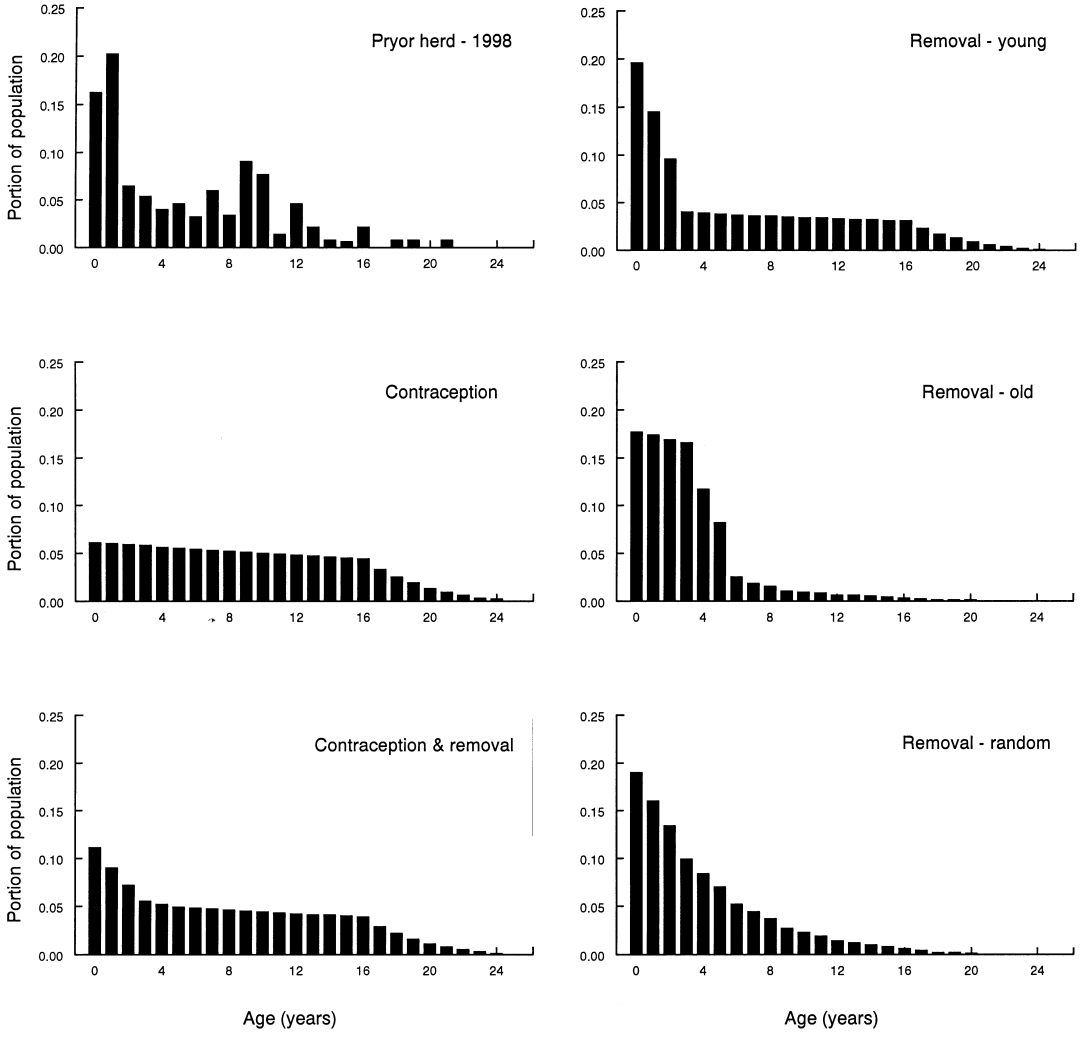

Fig. 2. Age structure of the initial population and simulated populations controlled by contraception, removal, or a combination of both. Age structure of the population was the same regardless of population objective or ages of mares rendered infertile.

for 200 years when old animals were removed from herds with a population objective of 90. Among treatments simulated, contraception of young animals or a combination of contraception and removal of young animals resulted in the greatest persistence of alleles, and an average of 83% of alleles persisted for 200 years under these treatments. These treatments had a 90% chance of retaining 76% of the initial alleles for 200 years. The lower 10th percentile of observations for other treatments included retention of as few as 47% of the initial alleles.

Rates of loss of alleles were highly and non-linearly related to allele frequency. Alleles with an initial frequency of less than about 0.025 tended to be lost very rapid during the first 50 years of simulations. The absolute rate of loss of alleles with initial frequencies greater than about 0.025 tended remain constant throughout the 200 year simulations (Fig. 6).

4. Discussion

4.1. Population control

Simulation results clearly identified contrasting effects of population control by contraception or removals. Compared to removals, infertility treatments reduced variance in population size and resulted in lower standing populations. Because the average sizes of populations managed by infertility were about 25% smaller than those managed by removals, objectives for populations controlled by infertility could be increased to reflect these differences in average size, further enhancing the retention of genetic variation.

Existing chemical contraceptive treatments are effective for a limited period, and they require repeated applications to maintain infertility. Short-duration contraceptives have been used to successfully control growth of horses on Cumberland Island, Georgia and Assateague Island, VA (Kirkpatrick et al., 1997) and they may be suitable for other populations where individuals are easily approached, such as the Pryor herd. A very intensive, and probably very expensive, effort would be required to use short-duration contraceptives as the primary means to control a free-ranging horse population. These treatments are not likely to be successfully applied to widely dispersed populations, but the advantages of contraceptives over removals has stimulated active and promising research that will likely lead to longer-acting contraceptives that can be applied via a "biobullet" or other remote means (Muller et al., 1997). Infertility treatments remain a high priority because they can be far less expensive than removal and adoption programs and they generally receive widespread public support (Garrott et al., 1992; BLM, 1997).

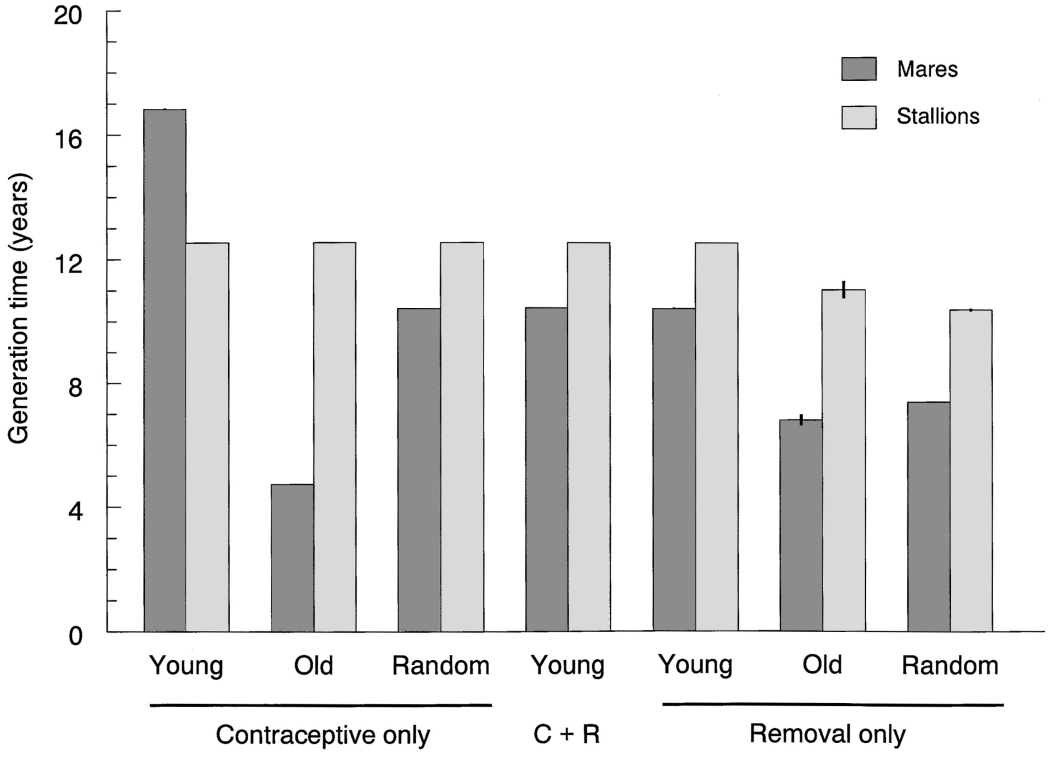

Fig. 3. Generation time of mares (dark bars) and stallions (light bars) in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or random-age horses. Vertical lines are±1 S.D. of average from populations with management objectives of 90 to 180 horses.

Regardless of the control methods used, intensive management will be necessary to restrict the size of populations with high growth potentials. Contraceptives could eliminate or reduce the need to remove and place wild horses, but a complete reliance on contraceptives can lead to other problems. Contraceptive-only treatments provide no mechanism for controlling the sex ratio of a population, which may become highly skewed, and they provide a rather weak means for controlling populations which have exceeded a size objective. The most flexible and realistic program is thus likely to combine the advantages of infertility and removals. Contraceptives can be used to slow growth rates, while removals provide a means to modify sex ratio or rapidly bring a population into compliance with a size objective.

4.2. Genetic considerations — alternatives to increasing population size?

Simulation results emphasized the importance of age structure and demography on processes that govern the rate of loss of genetic variation. Recommendations for preserving genetic variation have focused on increasing population size, and few papers even consider other strategies that may dramatically affect long-term persistence of genetic diversity. This oversight is not due to misunderstanding among geneticists (Hedrick and Miller, 1992, Fig. 5; Lande, 1995, Fig. 14.4), but rather a lack of appreciation among wildlife mangers and biologists of the important roles of generation time and effective population size in maintaining genetic variation (but see Ryman et al., 1981). Age-specific treat-

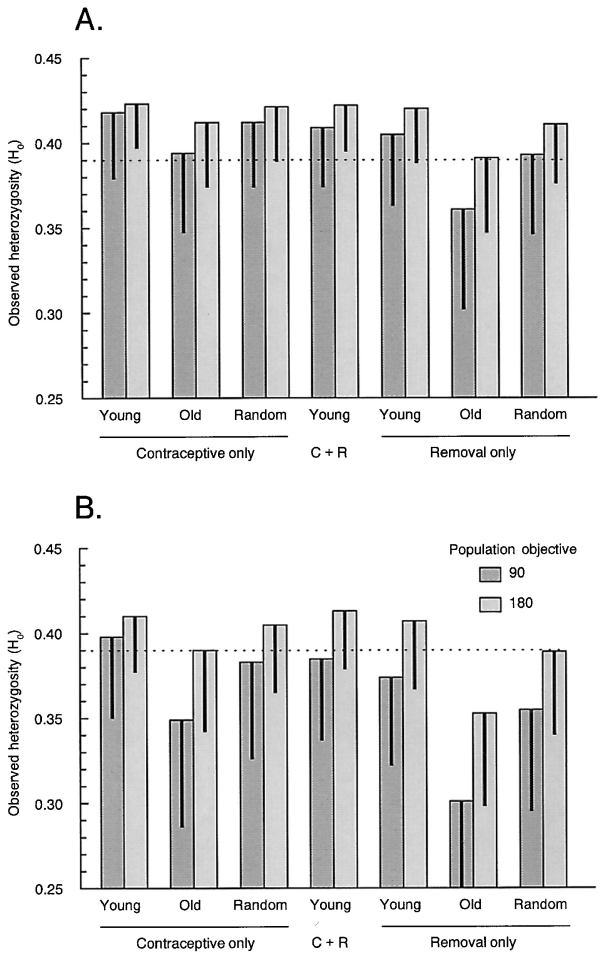

Fig. 4. Observed heterozygosity after 100 years (A) and 200 years (B) in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or a selection of random-age individuals, for population objectives of 90 (dark bars) or 180 (light bars). Vertical lines descend to the 10th percentile of observations; the horizontal line is at 90% of initial heterozygosity. Initial heterozygosity was 0.433.

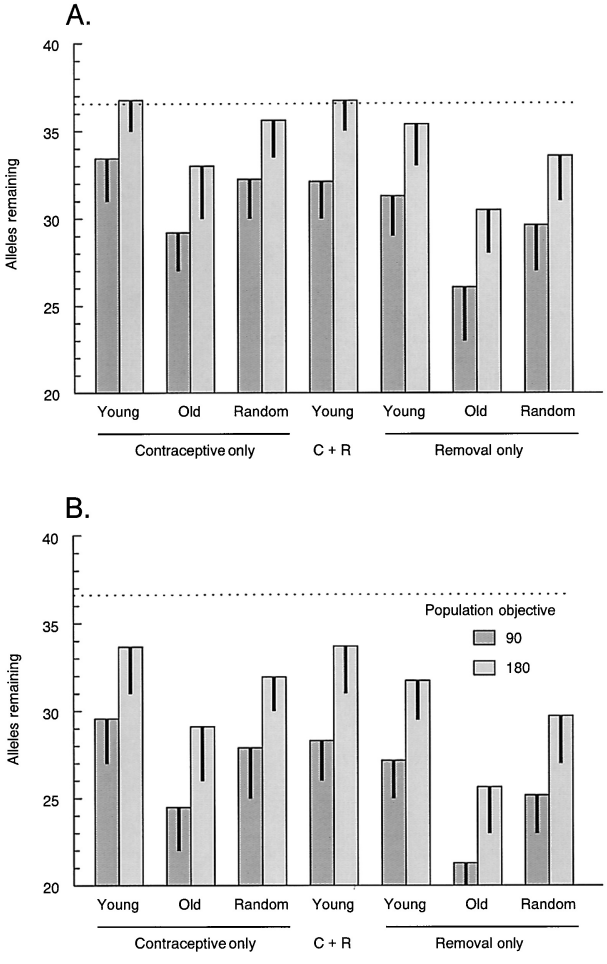

Fig. 5. Number of alleles persisting in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or a selection of random-age individuals, after 100 years (A) and 200 years (B), for population objectives of 90 (dark bars) or 180 (light bars) horses. Vertical lines descend to the 10th percentile of observations; the horizontal line illustrates 90% of the number of alleleles that were present at the start of simulations.

ments may offer viable alternatives to increases in population size for long-lived species subject to management control. Dramatic differences in the rate of loss of genetic variation between treatments that removed young or old animals are especially pertinent to evaluating management plans because many large mammals of conservation interest are still harvested, either for sport alone or as part of a community-based conservation plan. Both types of harvest usually emphasize removal of older animals from the populations. Consistent harvest of older individuals can have a large effect on retention of genetic variation even when population size exceeds those simulated here by an order of magnitude (Ryman et al., 1981).

The use of multiple measures of genetic variation revealed that under these situations allelic diversity was a much more sensitive indicator of changes in genetic variation than was H_o. Both measures indicated a high probability ($>10\%$) of losing more than 10% of initial variation, even using the best management option simulated. Additional simulations of the contraceptive-and-removal strategy revealed that a population objective of about 500 was necessary to achieve a 90% probability of retaining 90% of alleles, and an objective of 250 was necessary to achieve a 90% probability of retaining 90% of initial observed heterozygosity. It is impossible to implement management plans that achieve levels of contraception or removals as precise as those simulated, thus rates of loss of genetic variation observed under field conditions will vary from those simulated. For treatments of young animals, observed rates of loss of variation will be greater than simulated, while the opposite will likely result from treatments of older animals.

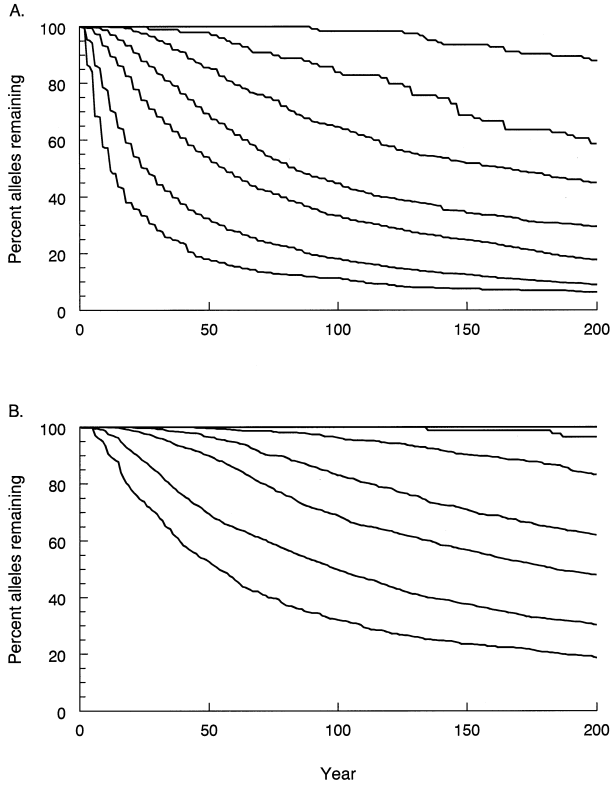

Fig. 6. Persistence of alleles with different initial frequencies over 200 years of simulation. A. Populations controlled by removal of random-aged horses with a population objective of 90. B. Population controlled by contraceptives and removal with a population objective of 150. From the bottom of the plots, lines pertain to alleles that occurred with initial frequencies of 0.005, 0.01, 0.02, 0.05, 0.10, 0.15, and 0.20.

Projected losses of genetic variation were strongly influenced by the frequency distribution of alleles used to initialize simulations. The Pryor population exhibited an unusually high level of heterozygosity (Wooten and Smith, 1985) and it contained many rare alleles. If this population had been isolated for an extended period, many of the rarer alleles would already have been lost and the effects of population size or age of treated animals would have been less. This leads to a rather surprising conclusion: as existing genetic variation declines, fewer individuals are needed to retain a high proportion of the existing variation. This can occur because rare alleles will have already been lost from the population, and those alleles that occur at a relative high frequency are lost slowly (Fig. 6). In natural populations the level of genetic variation will reflect processes that increase and decrease natural variation. Mutations increase variation, but they occur at a slow rate and new variation must be maintained to contribute to long-term heterozygosity. On the other hand, genetic drift results in loss of variation.

In this model, changes in genetic variation resulted only from genetic drift. While the inclusion of mutations would have resulted in lower rates of loss of variation, genetic drift is by far the dominant process leading to changes in gene frequencies in small populations (Nunney and Campbell, 1993; Lynch, 1996). This occurs for two main reasons. First, sampling errors are exacerbated in small populations, and second, the proportion of genetic variation that is selectively neutral increases as population size declines. Selection tends to be far less important in small populations because a much larger selection coefficient (selective advantage) is necessary for selection to act in a deterministic manner as population size declines. For quantitative characters, this situation arises from the distribution of selective forces over a large number of loci, thus selection on any one locus is small enough to be overwhelmed by random genetic drift (Lynch, 1996). A consequence of the dominance of random drift is that an allele with strongly negative effects can become fixed in the population. In large populations, a small selective disadvantage may be sufficient to reduce the frequency of a deleterious allele, whereas this is unlikely to occur in small populations.

Several factors not included in the simulation analysis could result in more rapid loss of genetic variation than these results suggest. Periodic catastrophes could lead to temporary reductions in population size. The Pryor population suffered high winter loss in 1977–1978 (Garrott and Taylor, 1990), and catastrophes are thought to be an important factor in other large mammal populations (Young, 1994, 1999; Ebb and Boyce, 1999). Other factors that may be important and that require further investigation include density dependence, compensatory reproduction, and the role of environmental stochasticity. All of these factors could increase the rate of loss of genetic variation. The results of these simulations should thus be interpreted conservatively if they are used to guide management decisions.

These simulations illustrated several important genetic and demographic concepts. For managed populations, actions that delay the age of reproduction and increase generation interval will reduce the loss of genetic variation. Allelic diversity can be a much more sensitive index to loss of genetic variation than population-level heterozygosity, especially when there are many alleles at a locus. Compared to periodic removals, use of contraceptives under simulated conditions resulted in smaller populations and a much less variation in population size. Management plans that use contraceptives to control the rate of growth and that employ occasional removals to control sex ratio and reduce population size could emphasize the advantages of both approaches, while avoiding the most undesirable characteristics. Overall, these results support use of management strategies that rely less on removal and more on infertility treatments to reduce long-term loss of genetic variation.

Acknowledgements

F. Singer and L. Coates-Markle were instrumental in identifying important processes and management strategies. F. Singer and G. Cothran graciously provided unpublished data used to initialize model runs. Comments from S. Jenkins, L. Coates-Markle, M. Kotzman, and F. Singer improved this paper. L. Zeigenfuss evaluated recent observations from the Pryor horse population. I thank all of these people. This work was supported by USGS-BRD, BLM, and NPS.

1. ABSTRACT

To minimize human-animal conflicts for habitation and burden of zoonotic diseases, it is imperative to develop new strategies for wildlife population management. In this direction, contraceptive vaccines eliciting immune response against hormones/ proteins critical for reproduction have emerged as one of the promising options. Contraceptive vaccines based on neutralization of gonadotropin releasing hormone (GnRH) have been used for inhibition of fertility in various species such as wild horses, white-tailed deer, pigs, cats, dogs etc. It has been used for immunocastration of male pigs to improve meat quality. However, additional safety studies of GnRH vaccine will be needed in light of presence of its receptor at extra-pituitary sites. Native porcine zona pellucida (PZP)-based contraceptive vaccines have shown their utility in the management of the population of both captive and free-ranging wild horses and white-tailed deer. Long-term use of the PZP-based contraceptive vaccines has also demonstrated their safety. Ideally single injection of the contraceptive vaccine should elicit long lasting immune response and desired contraceptive efficacy, which will require development of novel vaccine delivery platforms and more potent adjuvants.

2. INTRODUCTION

The uncontrolled increase in population of free-ranging animal species such as elephants in Africa, kangaroos in Australia, feral horses and white-tailed deer in USA, street dogs and cats in several developing countries, and monkeys in India etc is leading to increasing conflicts for habitation between humans and wildlife species. Further, wild as well as domesticated animals may act as vectors for viruses, bacteria or parasites and thus pose a major risk to human health (1). There is an increase in the emerging infectious diseases in humans in last 3 decades and 70% of these are zoonotic in nature (2, 3). As an example, dogs are the main vectors that maintain rabies virus circulation within human communities. Human mortality from rabies has been estimated to be 55,000 deaths per year and 90% of deaths occur in the developing world (4). In India, approximately, 20,000 people die from rabies per year and 96% of these are infected by dogs (5, 6). Almost 1.8. million people annually receive post-exposure prophylaxis against rabies following bite or exposure to rabid or suspected rabid animal. The global threat posed by zoonoses (transmitted by bats and palm civets) is also illustrated by the 2003 outbreak of severe acute

respiratory syndrome coronavirus (SARS-CoV), which emerged in Hong Kong but affected 37 countries leading to over 8,000 cases of infection and approximately 800 deaths (7). Currently, there is concern about Middle East respiratory syndrome coronavirus (MERS-CoV), which emerged in Saudi Arabia in 2012 and is suspected to be zoonotic (initially transmitted by dromedary camels) in nature with over 1,100 cases of infection and 440 deaths, including travel related cases worldwide (8).

Wildlife managers have often used lethal means such as culling to control wildlife population; however, growing public concern over animal welfare issues and new legislative laws banning culling in several countries make such an approach increasingly unacceptable. Substantially reducing the number of abundant species may have indirect effects on the population of other species. For instance, in United Kingdom culling of Eurasian badgers (*Meles meles*) in an effort to reduce the incidence of bovine tuberculosis in cattle herd led to an increase in the population of red fox (*Vulpes vulpes*) (9). It has also been observed that repeated badger culling in the same area allow badgers from neighbouring area to re-colonize culled areas leading to increased prevalence of *M. bovis* infection in badger (10). Culling also leads to disturbance in the social group of animals leading to increased movement and thus instead of reducing transmission of zoonotic diseases it results in their increase (11). Thus, culling as a measure to control wildlife population and transmission of infectious disease has proven to be inefficient (12, 13). Translocation of animals from overpopulated areas to low population areas or in a confined environment has also been used as a measure for population control of wildlife in a particular territory, to minimise human-animal conflicts, and to reduce the burden of infection in the host wild species or its transmission to other animals including humans (14, 15). However, relocation of animals to new environment may lead to both physical and mental stress, disturbances in social culture, including adequate accessibility of food.

Surgical sterilization such as spaying of female dogs and castration of male dogs is used by few countries to control their population. Newly castrated male dogs may temporarily suffer from testosterone withdrawal leading to irritability and lethargy, a phenomenon known as the “irritable male syndrome” (16). Other potential complications with surgical castration include haemorrhage and excessive swelling, especially if the spermatic cords are cut but not crushed (17). Ovariohysterectomy of female dogs may lead to complications such as haemorrhage, ovarian remnant syndrome, stump pyometra, stump granuloma, fistula draining tracts and estrogen responsive urinary incontinence (17). To control monkey (*Rhesus macaque*) population in Himachal Pradesh, India, surgical sterilization of males by thermo-cauteric coagulative vasectomy and of females by endoscopic thermo-cauteric tubectomy has been used (unpublished observations). However, long term side-effects of such a surgical sterilization program to control population of monkeys needs further investigation. Surgical sterilization by and large is more socially accepted than culling, though it is relatively expensive and required specialized facilities and staff. In addition to surgical sterilization, chemical sterilization by intra-testicular injection of zinc gluconate (Neutersol, Addison Biological Laboratory Inc.), which was approved in 2003 by the US Food and Drug Administration (FDA), that causes sclerosis of the testes and sterility has been used for controlling fertility of dogs and cats (18–20). In addition to zinc gluconate, intra-testicular injection of calcium chloride in dogs also led to dose-dependent decrease in sperm count (21). The low cost and ease of use of chemical sterilants as compared to surgical sterilization will be useful for their application at field level; however, additional field trials are needed to ascertain their safety and efficacy.

Administration of synthetic progestins such as megestrol acetate, melengestrol acetate, and levonorgestrel has been used as contraceptives for dogs and cats leading to inhibition of oestrous (For review see 22). This approach is suitable for confined companion animals or animals in zoo but unsuitable for free-roaming animals. Administration of melengestrol acetate as implants induced infertility for up to 2 years. Due to uterine pathology, long term administration of melengestrol acetate is not recommended (23). Levonorgestrel implant has also shown to be effective for prevention of fertility in tammar wallabies (*Macropus eugenii*), grey kangaroos (*Macropus giganteus*) and koala (*Phascolarctos cinereus*) females (24–26). In addition to synthetic progestins, gonadotropin releasing hormone (GnRH) agonists such as deslorelin (Suprelorin, Virbac) and azagly-nafarelin (Gonazon, Intervet International B.V.) have been used to inhibit fertility in dogs and tammar wallabies (22, 23, 27). For population management of free-ranging wildlife, hormonal contraceptive may not be a very good option due to high cost, difficulty in delivery, health risk in pregnant animals and changes in social behaviour. In addition, immunocontraception as one of the potential humane options for wildlife population management is being considered favourably by various agencies. In this article, various contraceptive vaccines that are being used for the wildlife population management will be reviewed. The efficacy and safety aspects of contraceptive vaccines will also be discussed. The current limitations for contraceptive vaccines and the plausible solutions will also be described.

3. CONTRACEPTIVE VACCINES

The basic principle of contraceptive vaccine is to generate either humoral and/or cell mediated immune response against hormones/proteins that are

© 1996-2017

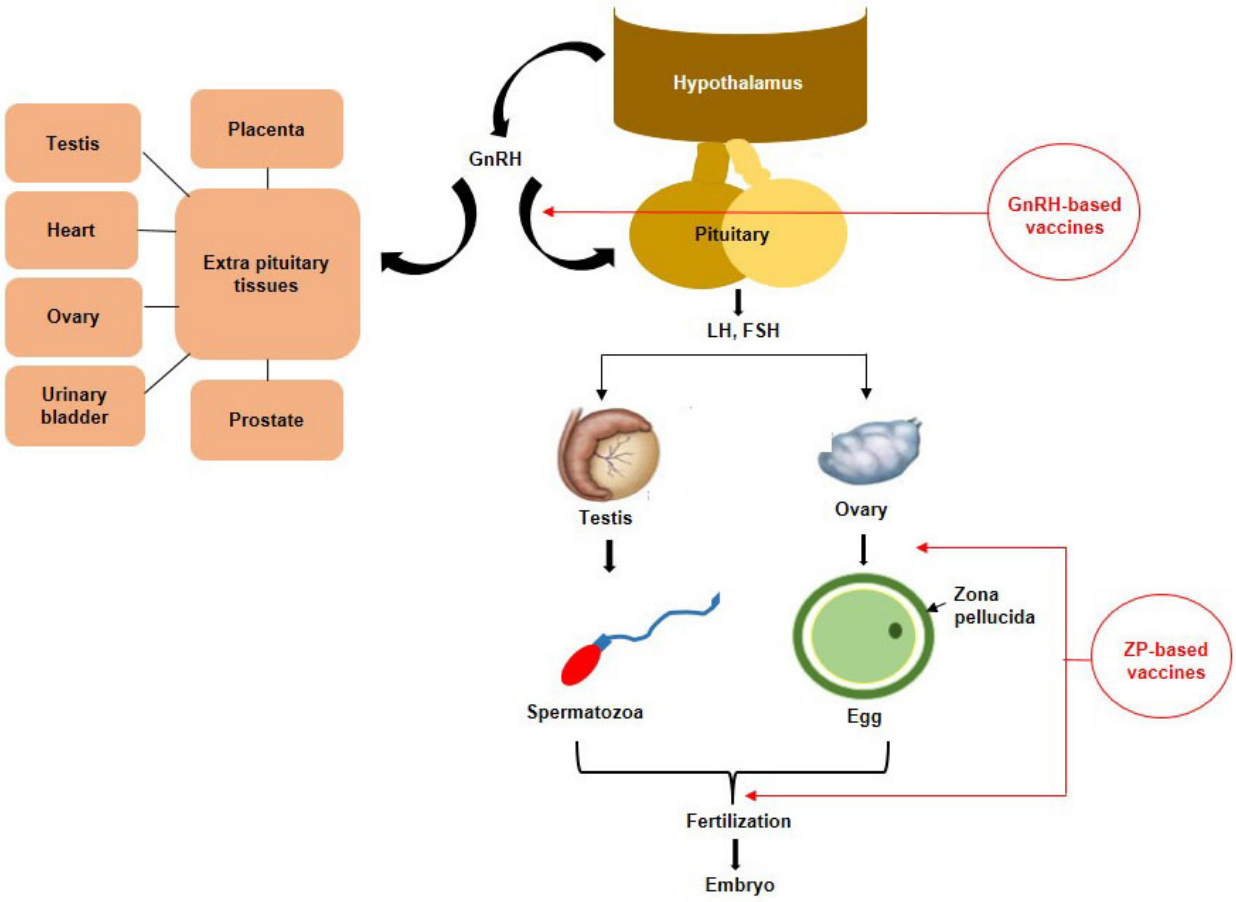

Figure 1. Schematic representation of the processes targeted by the contraceptive vaccines meant for wildlife population management. Possible sites have been shown for the action of GnRH- and ZP-based contraceptive vaccines. Antibodies against GnRH will inhibit production of LH and FSH from anterior pituitary thereby leading to inhibition of spermatogenesis in males and ovarian follicular development and ovulation in females. The anti-GnRH antibodies may also act on other extra-pituitary sites such as placenta, testis, ovary, heart, prostate, urinary bladder etc. Antibodies against ZP curtail fertility by either inhibiting folliculogenesis or fertilization or both.

critical for reproduction, which will lead to interference in their biological activity resulting in inhibition of fertility. Basically, contraceptive vaccines can be broadly categorised as those i) inhibit production of gamete (spermatozoa, egg); ii) inhibit gamete functions such as fertilization; and iii) inhibit gamete outcome. GnRH primarily synthesized and secreted by the hypothalamus (though extra-hypothalamic sites for its secretion have been reported) acts on the anterior pituitary and in turn regulate the production of luteinizing hormone (LH) and follicle stimulating hormone (FSH). Both, LH and FSH secreted by pituitary, in turn acts on testes and ovaries leading to production of sperm and oocytes, respectively. Thus neutralization of GnRH, LH and FSH or blocking LH/FSH receptor by generating specific antibodies may lead to inhibition of gamete production. Generation of immune response against spermatozoa- and/or egg-specific proteins will interfere in their respective functions thereby leading to inhibition of fertilization. Post-fertilization, the embryo synthesize and secrete human chorionic gonadotropin (hCG), which has also been used as target for development of contraceptive vaccine for women (28). In the context of wildlife population management, contraceptive vaccines based on GnRH and zona pellucida (ZP) have been tried at the field level. Figure 1 illustrates the basic principle and steps at which the GnRH and ZP-based contraceptive vaccines will act thereby leading to inhibition of fertility. In the present review, both GnRH- and ZP-based contraceptive vaccines will be briefly discussed with respect to their contraceptive efficacy and safety. In addition, the current limitations with respect to contraceptive vaccine delivery in free-ranging wildlife and plausible solutions will be discussed.

4. GnRH-BASED CONTRACEPTIVE VACCINES

GnRH, a decapeptide (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-GlyNH_2) is primarily synthesized and secreted by the hypothalamus (29), though its presence and/or secretion in other tissues such as ovary, testis,

Table 1. List of commercially available GnRH-based contraceptive vaccines and their intended use

GnRH-based vaccines	Name of the company	Observations	References
GonaCon™	National Wildlife Research Centre, USA	• Provided multi-year contraception in female white-tailed deer • Single immunization achieved 80–100% contraception in female elk • Immunized prairie dogs showed high contraception • Showed inhibition of fertility in both male and female cats	33, 35–38
Improvac®	Pfizer Animal Health, Australia	• Effective in reducing sexual and aggressive behaviour in pigs • Improvement of meat quality in male pigs • Suppressed testosterone concentration, number of sperm and sexual behaviour in boars	39–42
Equity™	CSL, West Ryde, NSW, Australia	• Suppressed testicular function in elephant • Suppressed testicular function and sexual behaviour in stallion	44, 45
Bopriva®	Pfizer Animal Health, Parkville, Australia	• Decreased testicular development, serum testosterone and physical activity in bulls • Suppressed testicular growth and testosterone secretion in male calf • Inhibit fertility in boars and dairy cattles	46–49
Improvest®	Zoetis, Kalamazoo, MI, USA	• Castration of male pigs • Suppress heat in female gilts	50, 51
Repro-BLOC™	Amplicon Vaccine LLC, Pullman, WA, USA	• Reduced uterine size, vascularity and suppressed ovarian steriodogenesis in elephant	52

prostrate and placenta has also been reported (30, 31). To develop contraceptive vaccine, GnRH being a self-peptide hormone, its conjugation with various carrier proteins such as tetanus toxoid (TT), diphtheria toxoid (DT), keyhole limpet hemocyanin (KLH), blue protein from mollusc (*Concholepas concholepas*), ovalbumin etc have been made to provide T-cell help to enable generation of antibodies against GnRH. GnRH-based contraceptive vaccines work in both males and females as neutralization of its biological activity inhibit production of sperm in males and eggs in female. After establishing proof-of-concept of GnRH-based contraceptive vaccines in laboratory experimental animals including non-human primates, currently there are at least six commercial vaccines available (Table 1).

GonaCon™ developed by National Wildlife Research Center, USA is comprised of synthetic GnRH coupled to KLH (more recently with blue protein from mollusc) and supplied with AdjuVac™ (diluted version of Jones disease vaccine containing killed mycobacteria and oil adjuvant). GonaCon™ has been approved by the Environment Protection Agency (EPA), USA for fertility regulation in white-tailed deer in urban/suburban areas and subsequently for wild horses (*Equus caballus*) and burros (*Equus asinus*) (32). Single injection of GonaCon™ induced infertility ranging from 2 to 5 years in white-tailed deer as a measure to control their population (33). It also successfully blocked the cyclic activity and ovulation in captive wild mares (34). To reduce the potential of ecological damage and spread of brucellosis, the contraceptive efficacy of GonaCon™ has also been demonstrated in female elk (*Cervus elaphus*) (35). The contraceptive potential of GonaCon™ in black-tailed prairie dogs has also been shown (36). The contraceptive efficacy ranging from 5 months to 5 years after single injection of GonaCon™ in female cats has also been reported, which depends on the immune response generated in the respective cat (37, 38). In general, the vaccine was more effective in female cats as compared to male cats (37).

Another commercial GnRH-based contraceptive vaccine, Improvac®, consists of synthetic incomplete analogue of gonadotropin-releasing factor (GnRF) linked to a carrier protein to make it immunogenic. Immunization of cross-bred Iberian female pigs with Improvac® led to reduction in the incidence of standing oestrous, serum progesterone levels, and development of uterus and ovaries (39). Immunization led to long-lasting immunity of at least 20 months after third injection (39). Immunization of male pigs with Improvac® led to a significant reduction in their sexual and aggressive behaviour as observed by reduction in mounting, fighting, pushing, head butting and tail manipulation (40). Pre- and post-pubertal rams and boars accumulates androgen derivatives namely androstenone and skatole in their adipose tissues, which gives an unpleasant odour to meat. To overcome this taint, surgical sterilization of male pigs is routinely done. Vaccination of boars with Improvac® contraceptive vaccine has shown to reduce the pig meat taint (41). Further, it has been shown that immunization of male pigs with Improvac® led to improvement in the lean meat content as compared to surgically castrated pigs (42). Immunization of adult ewes (White Alpine sheep) with Improvac® led to suppression of cyclicity concomitant with reduction in progesterone levels (43).

Immunization of a male Asian elephant with combination of two commercial GnRH-based contraceptive vaccines i.e. Improvac® and Equity™, led

© 1996-2017

to a decrease in serum testosterone concentrations, testicles diameter, penile atrophy and weight gain (44). After 1 year of initial treatment, no spermatozoa were observed in the semen suggesting that GnRH vaccine may be a useful non-invasive method of contraception for Asian elephants (44). Immunization of adult stallion with commercially available GnRH-based vaccine, Equity™, using three injections schedule led to suppression of testosterone levels, reduction in semen quality and changes in sexual behaviour, the extend of which was variable among the immunized animals (45).

Bopriva® is one of the commercially available GnRH-based vaccine, developed by Pfizer Animal Health, Parkville, Australia, which induces antibodies against GnRF. Active immunization of pubertal bulls with this vaccine led to decrease in testosterone levels in blood, testicular development and physical activity, leaving the body weight gain unaffected (46). Further, two injections of Bopriva® in the peripubertal bull also suppressed the testicular growth and blood testosterone concentration for at least 10 weeks after the booster injection (47). Bopriva® was also effective in suppression of testicular functions including sperm production in boars (48). Immunization of female dairy cattles (cyclic Swiss Fleckvieh cows) with Bopriva® showed decrease in progesterone levels without affecting estrogen levels, suppression of oestrud and impaired folliculogenesis (49).

Another commercial vaccine based on GnRH, Improvest® (Zoetis, Kalamazoo, MI, USA), has been used for castration of male pigs and improvement in the meat quality (50). Female gilts receiving two injections of Improvest® showed better growth performance and suppression of heat (51).

Repro-BLOC™ (Amplicon Vaccine, LLC, Pullman, WA, USA) is a recombinant ovalbumin-GnRH fusion protein vaccine developed for use in cattle, although there is limited data on its efficacy. Multiple injections (primary followed by 4 booster) of Repro-BLOC™ in a 59-year old Asian elephant (*Elephas maximus*) led to suppression of ovarian steriodogenesis for over a year and reduction in uterine size and vascularity (52).

4.1. Safety of GnRH-based contraceptive vaccine

GnRH-based vaccines have shown successful contraceptive efficacy in both male and female domestic horses, without any serious adverse effects (34, 45, 53–54). Suppression of oestrous and unwanted oestrud behaviour by GnRH-based vaccines (53, 54) may be desirable in domestic species including cats and dogs. However, inhibition in the production of reproductive steroid hormones (progesterone in females and testosterone in males) by GnRH-based vaccines may have impact on the complex evolutionary social organization of horses, elephants and captive exotic species in zoos, which needs to be investigated more carefully (55).

There was no significant haematological or endocrinological changes in the two groups of mongreal dogs, when either immunized with Improvac® or surgically castrated, suggesting that immunological castration may provide a safer alternative (56). No adverse effects on body weight or blood chemistry were observed in black-tailed prairie dogs immunized with GonaCon™ (36). It has also been reported that immunization with Improvac® can improve the welfare of male pigs as it was able to inhibit sexual and aggressive behaviour (40). The vaccine was well tolerated in the pigs and no injection site reactions were observed (41). However, in few female cats immunized with GonaCon™, non-painful late-onset granulomas were observed at the injection site (38). A study demonstrated that simultaneous administration of anti-GnRH (GonaCon™) vaccine along with rabies vaccine had no adverse impact on the seroconversion against rabies virus antigen suggesting that GnRH vaccination can be used along with rabies immunization program (57).

It is imperative to take into consideration that use of GnRH-based vaccine in pregnant animals may lead to abortion, if LH is critical to maintain the corpus luteum throughout during gestation such as in bison. GnRH receptors have been described at several extra-pituitary sites such as ovary, testes, placenta, prostrate including urinary bladder and heart (30, 31, 58, 59). These observations suggest that more carefully monitored field trials of GnRH-based contraceptives vaccines should be undertaken to rule out any adverse effect on other physiological processes than reproduction.

5. CONTRACEPTIVE VACCINES BASED ON ZONA PELLUCIDA GLYCOPROTEINS

In mammals, egg is surrounded by an extracellular translucent glycoproteinaceous matrix known as zona pellucida (ZP). It acts as a relatively species-specific ‘docking site’ for binding of the spermatozoa to the oocyte, induces acrosomal exocytosis in zona-bound spermatozoa, prevents polyspermy, and plays an important role in the protection of a pre-implanted blastocyst. Due to their critical role in reproduction, ZP glycoproteins have been used as candidate antigens for contraception via immunological intervention. Zona matrix is composed of either 3 or 4 glycoproteins. In mice, it is composed of 3 glycoproteins namely ZP glycoprotein -1 (ZP1), -2 (ZP2), and -3 (ZP3), whereas pig and canine ZP matrix is also composed of 3 glycoproteins but instead of ZP1, ZP glycoprotein-4 (ZP4) is present. In non-human primates and humans, ZP matrix is composed of 4 glycoproteins that are ZP1, ZP2, ZP3,

© 1996-2017

Table 2. Sequence homology of porcine ZP2, ZP3 and ZP4 with other species at amino acid level

Animal Species	Percentage sequence homology with porcine		
	ZP2	ZP3	ZP4
Mouse (*Mus musculus*)	55	66	50[1]
Dog (*Canis lupus*)	70	75	72
Horse (*Equus caballus*)	72	77	75
Monkey (*Macaca radiata*)	63	72	67[1]
Bison (*Bison bison*)	78	88	77[1]
Rat (*Rattus norvegicus*)	54	65	60
African Bush Elephant (*Loxodonta africana*)	65	73	65
Brushtail Possum (*Trichosurus vulpecula*)	51	50	56[1]

[1]Instead of ZP4, ZP1 is present

and ZP4. Structure and functions of all the four ZP glycoproteins during fertilization from various species has been investigated by various groups, which has been reviewed elsewhere (60). Characterization and sequencing of ZP glycoproteins from various species revealed that their basic structure is evolutionary conserved but have variable degree of amino acid sequence identity. For example porcine ZP3 has 66% identity at amino acid level with mouse ZP3 and 75% with canine ZP3. The extent of amino acid sequence identity of various porcine ZP glycoproteins with their respective homologues from other species is listed in Table 2. This property of ZP proteins has made heterologous immunization as a feasible proposition. It is further strengthened by the observations that polyclonal antibodies generated against porcine heat solubilised isolated zona pellucida (SIZP) cross-react immunologically with ZP of human, squirrel monkey, rabbit, rat, and mouse (61). Due to easy accessibility of porcine ovaries from abattoirs, contraceptive vaccine based on porcine ZP preparations became the antigen of choice.

5.1. Native porcine zona pellucida (PZP)-based contraceptive vaccine

Contraceptive potential of either native porcine SIZP (PZP) or its purified component (ZP3) has been demonstrated in female rabbits (62), bitches (63), non-human primates (64, 65), domestic and captive wild horses (66), captive white-tailed deer (67) and a variety of zoo animals (68). The field trial of native PZP-based contraceptive vaccine for the management of wild horses population on Assateague Island National Seashore, a barrier island off the coast of Maryland, USA demonstrated its contraceptive efficacy (69). The vaccine was delivered remotely using dart gun. Inhibition of fertility in wild horses could be maintained by giving annual booster of PZP vaccine. It was shown that third consecutive annual booster of porcine ZP led to 79% efficacy in preventing pregnancies in mares (70). Smithsonian Institute's Conservation and Research Center at Front Royal, VA, USA initiated the first field trials of PZP-based contraceptive vaccine in white-tailed deer inhabitating Fire Island National Seashore, NY, USA (71). Deer were captured, tagged, given primary injection of PZP vaccine, and then released. Subsequent booster injections were given remotely by using dart gun. Between 1993 and 1999, twinning rates among individually known vaccine treated adult female deer decreased by 78.9.% from pre-treatment rates (72). The contraceptive efficacy of PZP vaccine was also demonstrated in free-ranging African elephants (*Loxodonta africana*) in the Kruger Park, South Africa (73). Thus PZP-based contraceptive vaccine has been successfully used for the management of the population of wild horses (34, 66, 69, 70, 74, 75, 76), urban deer (71, 72, 77, 78), wapti (79), and African elephants (73, 80). Keeping in view the above, currently three commercial vaccines based on PZP are available as listed in Table 3.

5.2. Safety of PZP-based contraceptive vaccine

Ovarian specific expression of zona proteins and lack of cross-reactivity of antibodies generated against zona proteins with other tissues and protein hormones (81, 82) is of an advantage of PZP-based vaccines as compared to GnRH-based contraceptive vaccine. Zona pellucida-based contraceptive vaccine primarily works by either inhibiting fertilization and/or folliculogenesis (Figure 1). Potential changes in ovarian pathology represented by follicular atresia along with sometime depletion of primordial follicles pool in rabbits (62), dogs (63), sheep (83) immunized with porcine zona proteins was one of the main concern for the application of PZP-based contraceptive vaccine for wildlife population management. However, no changes in ovarian histology were found in PZP-based contraceptive vaccine immunized horses and deer (66, 71). Inhibition of fertility was reversible in the captive deer immunized with PZP-vaccine after one to four years of immunization (67). In another study,

Table 3. List of commercially available porcine ZP-based vaccines and their applications

Commercial PZP-based vaccines	Name of the company	Applications	References
Spayvac®	ImmunoVaccineTechnologies™, Halifax, Nova Scotia, Canada	• Showed 100% contraceptive efficacy the first year then 83% the next 3 years in wild horses • Showed 85–90% infertility in female deer	34, 78
ZonaStat-H	Humane Society of the United States, Washington, DC, USA	• Only PZP vaccine approved by the Environmental Protection Agency (EPA) for use in female wild horses and burros • Suppressed fertility by 86% in domestic and wild horses	76
PZP-22	University of Iowa, School of Pharmacy, Iowa City, USA	• Provided two years of infertility in feral horses	74, 76

no changes in ovarian histology of PZP immunized deer were reported. However, breeding season was extended by 1–2 months (71). PZP-vaccinated deer were more active and gained significantly more weight by summer following immunization than untreated deer, presumably because of avoidance of lactation, but by the following fall, all weight differences disappeared (84). Ovarian eosinophilic oophoritis was reported in PZP immunized deer, which; however, was not statistically different as compared to unimmunized group (85). Injection site abscesses were reported only in 0.5.% of PZP immunized deer, but all of them revealed the formation of granuloma at the injection site without any complication (72, 85). In elephants immunized with PZP-based contraceptive vaccine, examination of the ovaries and uteri by ultrasound revealed no adverse changes (73, 80). However, there may be species-specific differences in the ovarian histopathology subsequent to PZP-based contraceptive vaccine immunization, which should be investigated in detail in the respective target species.

Long-term treatment of wild horses with PZP-based contraceptive vaccine did not lead to any permanent or significant changes in ovarian endocrine parameters and oestrous cyclicity as monitored by urinary steroid metabolites (70). It had no adverse outcome when used in pregnant mares. The contraceptive effect was reversible (86). Increased body conditions and longevity were observed in PZP-immunized horses (87). There was no significant change in the social organization or behaviour of PZP-immunized wild horses (88). However, there is some concern over injection site reactions (55). It is likely that the remote delivery of PZP-based contraceptive vaccine by dart may result in surface bacteria and debris being pushed into the injection site resulting in injection site reactions (55).

Few significant changes in blood chemistry such as levels of urea and creatine were observed in PZP immunized deer but none of these were associated with any physiological abnormalities (85, 89). PZP immunized Dall sheep (*Ovis dalli*) and domestic goats (*Capra hircus*) also did not reveal any significant changes in blood chemistry (90).

5.3. Recombinant zona proteins as candidates for contraceptive vaccine

Due to limited availability of native porcine zona proteins from pig oocytes and to circumvent the apprehension of their probable contamination by other ovarian-associated proteins, recombinant zona proteins have also been used as candidate immunogens. Immunization of female baboons (*Papio anubis*) with *E. coli*-expressed recombinant bonnet monkey (*Macaca radiata*) ZP4 (previously designated as ZPB) coupled with diphtheria toxoid (DT) led to reversible block of fertility (91). However, immunization of female bonnet monkeys with the above immunogen led to inhibition of fertility which was not reversible. Histology of the ovaries from immunized monkeys revealed follicular atresia (92). Active immunization of female marmosets (*Callithrix jacchus*) with mammalian-expressed recombinant human ZP3 also led to inhibition of fertility associated with ovarian pathology characterized by depletion of primordial follicle pool (93). Immunization of cynomolgus monkeys (*Macaca fascularis*) and baboons (*Papio cynocephalus*) with mammalian expressed recombinant human ZP2, ZP3 and ZP4 respectively showed higher contraceptive efficacy in animals immunized with ZP4 (94). These studies in non-human primates showed the potential of recombinant zona proteins as candidate immunogens for the development of contraceptive vaccine.

In order to control the population of street dogs and thereby reduce the burden of rabies infection, it was demonstrated that non-descript female dogs immunized with *E. coli*-expressed recombinant dog ZP3 conjugated to DT failed to conceive (95). Ovarian histology of the immunized dogs revealed degenerative changes in the ZP matrix and follicular atresia. Subsequently, to avoid chemical conjugation of recombinant dog ZP3 with DT and to obtain recombinant protein without His_6-tag, it has been expressed in *E. coli* as a fusion protein with promiscuous T cell epitope of tetanus toxoid (TT, amino acid residues 830–844) with dilysine linker (TT-KK-ZP3) (96). Immunization of female mice with recombinant TT-KK-ZP3 led to significant reduction in fertility, which was associated with antibody titres (96). In Australia and

© 1996-2017

New Zealand, the potential of recombinant brushtail possum (*Trichosurus vulpecula*) ZP3 protein to control the fertility of Koalas (*Phascolarctos cinereus*) and Eastern Grey Kangaroos (*Marcopus giganteus*) has also been explored (97, 98).

In light of limited availability of native PZP-based contraceptive vaccine, recombinant porcine ZP3 and ZP4 have also been expressed in *E. coli* and their contraceptive efficacy was evaluated (99). Immunization of female mice with recombinant porcine ZP3 and ZP4 led to significant inhibition of fertility and decrease in litter size as compared to the adjuvanted control (99). Interestingly, *E. coli*-expressed recombinant porcine ZP3 and ZP4 boosted the antibody response in female mice primed with porcine native SIZP, suggesting that recombinant proteins can be used as booster doses thereby enabling wider coverage of immunization program in light of limited supply of native PZP-based contraceptive vaccine (99). Contraceptive efficacy of recombinant porcine ZP3 and ZP4 vis-à-vis PZP vaccine has also been evaluated in pony mares. Extended anoestrous was observed in 86% of the PZP immunized mares as compared to 14% in recombinant porcine ZP3/ZP4 immunized group, which correlated with basal serum oestradiol and progesterone levels (100). All mares resumed cyclicity by 10 months post-treatment. None of the PZP-immunized mare conceived whereas all the unimmunized mares became pregnant. Out of 7 pony mares immunized with recombinant porcine ZP3/ZP4, 3 failed to conceive. These experiments suggest the potential of recombinant proteins for controlling fertility in mares, which; however, need further investigations (100).

6. VACCINE DELIVERY: MAJOR CHALLENGE IN THE APPLICATION OF CONTRACEPTIVE VACCINES FOR WILDLIFE POPULATION MANAGEMENT

In the context of free-ranging wildlife population management, it will be ideal, if single injection of contraceptive vaccine generates adequate immune response leading to inhibition of fertility for several years or even permanent sterility. Though it has been shown that single injection of GnRH-based contraceptive vaccine may induce infertility ranging from 2–5 year in white-tailed deer (33), by and large booster doses of the contraceptive vaccine are required to achieve desirable contraceptive efficacy and duration of infertility. It will necessitate development of sensitive tracking technologies to distinguish unvaccinated animals from those that have been vaccinated and among vaccinated animals to distinguish how many prior booster dose(s) have been delivered. Additionally, it will be imperative to develop more potent adjuvants and novel vaccine delivery platforms.

6.1. Remote vaccine delivery by either dart gun or oral bait

It is an expensive and cumbersome exercise to capture the free-ranging animals to deliver the contraceptive vaccine by intramuscular route. Immunization of free-ranging large animals such as horses and white-tailed deer by remote delivery of contraceptive vaccine by dart-gun has been very useful (69, 72). However, vaccine delivery by dart gun may not be a feasible proposition in small free-ranging animals such as monkeys etc, as vaccine dart may hit some sensitive part of the body and thereby leading to injury. Another strategy to deliver vaccines may be to use oral baits. In the second half of the 20th Century, oral rabies vaccines in the form of different types of baits incorporating different strains of live replication-competent rabies virus strains were developed with an aim to eliminate rabies infection circulating in European wildlife in particular foxes (101). The oral baits were dropped by helicopters in the forests inhabitated by wild foxes. Within the past 30 years, the overall incidence of rabies in Europe has decreased by approximately 80% and it has been completely eliminated from Western and Central Europe (www.who-rabies-bulletin.org). However, delivery of contraceptive vaccine as oral baits for the management of free-ranging wildlife population may be a difficult proposition as it will have adverse consequences on the fertility of other animal species, who may also consume these baits beside the target species. Contraceptive vaccines as oral baits may still be a feasible proposition for captive wildlife, where the individual animal is fed under supervision.

6.2. Edible vaccine

Plants can be engineered to produce foreign proteins in large amount which can be fed to the animals thereby eliciting appropriate immune response. As a proof-of-principle, it was shown that genetically modified potatoes (by inserting gene encoding the heat labile enterotoxin unit B from enterotoxigenic *E. coli* bacteria) when fed to mice as well as humans led to generation of immune response against the heat labile enterotoxin unit B antigen (102, 103). In an effort to control the population of possums in New Zealand, attempts are being made to develop genetically modified carrots expressing possum ZP3 (104). However, the outcome of these efforts is not as yet published.

6.3. Virus-like particles and bacterial ghosts

Virus-like particles (VLPs) are essentially non-infective viruses, which comprised of self-assembled viral envelop proteins without the genetic material. VLPs have unique property to display multiple copies of small foreign peptides on its surface, without losing the self assembly property of

© 1996-2017

the envelop protein, thereby leading to potent immune response against the foreign peptide (105). Their size typically falls in nanoparticles range and is stable and versatile in nature (106). VLPs offer excellent adjuvant characteristics which can induce innate and adaptive immune responses. As a matter of fact, VLPs have shown to enhance immunogenicity of peptides and proteins which otherwise are weakly immunogenic. There are various VLP vaccines that have been evaluated such as HPV L1 VLP, norovirus VLP vaccine and chikungunya (106). Johnson grass mosaic virus (JGMV) coat protein self-assemble to form rod-shaped VLPs and can be engineered to express on its surface foreign peptides (107). Immunization of mice with JGMV coat protein-based VPLs expressing a fusion peptide comprising of mouse ZP3 and spermatozoa-specific YLP_{12} peptide separated by diglycine spacer led to sub-fertility in the immunized animals (108). The basic problem with VLPs as a platform to deliver contraceptive vaccine is that in addition to antibodies generated against the foreign peptide/protein, a more potent antibody response is also generated against the envelop/coat protein of the virus.

Bacterial ghost, made-up of non-living bacterial cell without genetic component, has also been effectively used as platform to deliver antigens for eliciting immune response. Immunization of female brushtail possum with bacterial ghost expressing either N-terminal (41–316 amino acid residues) or C-terminal (308–636 amino acid residues) fragments of possum ZP2 fused to maltose-binding protein in *E. coli* NM522 strain led to the generation of both humoral and cell-mediated immune responses (109). Animals immunized with C-terminal fragment of ZP2 showed significant reduction in fertility (109). Bacterial ghost expressing brushtail possum ZP3 has also been prepared by using bacteriophage phiX174 lysis gene E in *E. coli* NM522 and their immunogenicity demonstrated in homologous animal model (110).

6.4. Live-vector based contraceptive vaccines

By using reverse genetic approach, attenuated *Salmonella typhimurium*-expressing mouse ZP3 was developed and delivered in mice through oral route. Immunized animals showed reduction in fertility (111). Mimovirus expressing B cell epitope of spermatozoa specific protein, eppin, has also been developed (112). Intranasal immunization of male mice with the above mimovirus led to generation of anti-eppin IgA antibodies in the genital tract. Mating of immunized males with unvaccinated females showed reduction in the fertility. Interestingly, immunization with the above antigen did not lead to any histopathological changes in the testes or their function (112).

Host-specific live vectors expressing various zona proteins have also been evaluated for their contraceptive potential. For example, mice infected with recombinant ectromelia virus (a natural pathogen that causes mouse pox) expressing mouse ZP3 showed infertility ranging from 5 to 9 months that was associated with disruption of ovarian folliculogenesis (113). Immunization of female rabbits with recombinant myxoma virus expressing either rabbit ZP3 or ZP4 also showed infertility accompanied with ovarian pathology (114, 115). Infection of mice with recombinant cytomegalovirus (mouse-specific β herpes virus) expressing mouse ZP3 led to permanent infertility, primarily due to induction of the ovarian autoimmune pathology leading to progressive depletion of follicles (116). Basic concept of developing host-specific live vector-based contraceptive vaccine was to release these in the environment so that the recombinant virus gets transmitted from one animal to another thereby leading to effective management of pests such as rats and rabbits. It will save the task of individually capturing the animal, followed by vaccination and releasing the immunized animals in its natural habitat. The overall concept was good; however, it was observed that recombinant viruses have lower infectivity as compared with the wild type virus, which will eventually reduce the contraceptive efficacy of live vector-based contraceptive vaccine (117, 118). Another major concern was about the consequences on the population of other species, if by chance the recombinant virus loses its host specificity (117). Keeping in view the above, it is less likely that host specific live-vector-based contraceptive vaccine will be used in near future for population management of free-ranging pests.

6.5. Microparticles for contraceptive vaccine delivery

One of the exciting option to deliver the contraceptive vaccine is to use inert nanoparticles or microparticles which themselves may not be immunogenic but provide sustained immune response against an entrapped antigen for a long period. It is primarily due to the slow release of the antigen from such particles. Liposomes comprising of phospholipids and cholesterol is one such option. Grey seals *(halichoerus grypus*) immunized with porcine ZP entrapped in liposomes, decreased fertility in 90% of the immunized animals over a 5-year period (119). Antigen entrapped in biodegradable and biocompatible polymeric particles of poly-lactide (PLA) and poly(lactic-co-glycolic acid) (PLGA) have been used to reduce the number of injections and to generate long-lasting immune response. Immunogenicity of PLA based microparticles have been shown to improve by the use of permissible adjuvant like alum (120). Incorporation of CpG (small stretches of synthetic oligodeoxy nucleotides corresponding to unmethylated DNA of bacterial origin) motif can also enhance immune response of microparticles (121).

© 1996-2017

In general, nanoparticles favour generation of cell mediated immune response whereas microparticles favour humoral immune response (122). It has been shown that polymer particle-entrapped vaccines can elicit memory antibody response from single-point immunization (123). Therefore, a microsphere particles-based formulation supplemented with suitable adjuvant(s) is expected to reduce the number of doses of the vaccine required to achieve the desired immune response and efficacy. In addition to PLA/PLGA polymer, microparticles of water-soluble polyphosphazenes have also been used successfully as antigen delivery platform. Indeed, it was shown that microparticles of poly(di(sodiumcarboxylatoethylphen oxy) phosphazene) entrapping pertussis toxoid, CpG motif and synthetic cationic innate defense regulator peptide 1002 elicited effective immune response against *Bordetella pertussis* in mice (124). It has been shown that hCG entrapped in PLA/PLGA microparticles showed antibody response following one injection which was comparable with four injections of free hCG in rats (125). In the microparticle immunized group, antibody titres reached at peak on day 56 and maintained a steady state till day 84. Hence, it seems that contraceptive candidate proteins entrapped in PLA/PLGA based microparticles supplemented with appropriate adjuvant may lead to long-lasting immune response with lesser number of injections and thereby making single dose contraceptive vaccine a reality in future.

Most of the white-tailed eagle (*Haliaeetus albicilla*) populations in Europe experienced dramatic declines during the twentieth century. However, owing to intense conservation actions and the ban of DDT and other persistent pollutants, populations are currently recovering. We show that despite passing through demographic bottlenecks, white-tailed eagle populations have retained significant levels of genetic diversity. Both genetic and ringing data indicate that migration between populations has not been a major factor for the maintenance of genetic variability. We argue that the long generation time of eagles has acted as an intrinsic buffer against loss of genetic diversity, leading to a shorter effective time of the experienced bottleneck. Notably, conservation actions taken in several small sub-populations have ensured the preservation of a larger proportion of the total genetic diversity than if conservation had focused on the population stronghold in Norway. For conservation programmes targeting other endangered, long-lived species, our results highlight the possibility for local retention of high genetic diversity in isolated remnant populations.

Keywords: bottleneck; conservation genetics; generation time; microsatellites; mitochondrial DNA; single large or several small

1. INTRODUCTION

The white-tailed eagle (*Haliaeetus albicilla*) is used as a major flagship and umbrella species for conservation work throughout large parts of Europe. The species was once widely distributed across the continent (Helander & Stjernberg 2003), but direct persecution and low reproductive success as a result of environmental pollutants led to dramatic declines during the twentieth century (Bijleveld 1974; Helander *et al.* 2002). By the 1970s, many local populations in Europe had gone extinct and most surviving sub-populations barely reached one or a few tens of breeding pairs (figure 1). However, a stronghold remained along the Norwegian Atlantic coast with at least 700–800 breeding pairs (Folkestad 2003), corresponding to more than 70% of the northern and central European population (Helander *et al.* 2003). The population along the Norwegian coast utilized relatively uncontaminated food resources from the northern Atlantic and was thus largely saved from the detrimental effects of harmful pollutants (Helander *et al.* 1982). On the other hand, around the heavily polluted Baltic Sea, white-tailed eagles suffered strongly reduced breeding success (Helander *et al.* 1982).

With the ban in the 1970s of DDT, PCB and other detrimental chemicals, European white-tailed eagle populations soon started to recover, a process that is still ongoing (figure 1). For instance, the number of territorial pairs in southern and central Sweden increased from about 40 in 1974 to 250 in 2000 (Helander 2003*a*), and in Estonia from 10–15 between 1965 and 1975 to 116 in 2002 (Volke & Randla 2003). This population expansion appears to have been based mainly on local recruitment, since almost no inter-population exchange of breeders has been recorded from ringing data. In particular, the large Norwegian population does not seem to have acted as a major founding source for recovering populations; none of the more than 3000 eagles colour-ringed in Norway has so far been found breeding outside Norway (Folkestad unpublished data). Further, among more than 150 ringed breeding birds in Sweden, all but a few individuals from the nearby Finnish coast were offspring of resident pairs (Helander 2003*b*). Similarly, most of the few recorded emigrants from the German eagle population settled to breed nearby in Poland (Köppen 2003). Given this apparent trend of local recruitment, current populations might have been depleted of genetic diversity by the recent demographic declines.

Loss of genetic diversity can reduce both short-term viability (e.g. Saccheri *et al.* 1998) and long-term adaptability (Frankham 2005). To assess the genetic impact of population declines during the twentieth century, we therefore studied the genetic variability at mitochondrial DNA (mtDNA) control region sequences and autosomal microsatellite markers in north and central European white-tailed eagle populations.

2. MATERIAL AND METHODS

Several populations from northern and central Europe were sampled, yielding a total number of 218 presumably unrelated individuals: Estonia (EST, $n=13$ samples), Germany (GER, $n=18$), Swedish Lapland (LAP, $n=24$), southern and central Sweden (SWE, $n=117$), Kola peninsula, Russia (KOLA, $n=10$) and Norway (NOR, $n=36$). Most of the samples consisted of blood, but nine samples were moulted feathers that had been collected in the field.

Polymerase chain reaction (PCR) of 26 autosomal microsatellite loci was performed (details are given in Hailer *et al.* (2005) and the electronic supplementary material). In order to directly compare

the amount of genetic variation (expected and observed heterozygosity, H_E and H_O, and the mean number of alleles per locus, N_A) between population samples, we standardized for sample size by employing a bootstrapping procedure (see electronic supplementary material). We tested for deviation from Hardy–Weinberg equilibrium (HWE) and genotypic differentiation using GENEPOP 3.4 (Raymond & Rousset 1995). GENETIX 4.05.2 (Belkhir *et al.* 2004) was used to calculate F_{ST} and its 95% confidence interval. Assignment tests were carried out using GENECLASS 2.0.d (Piry *et al.* 2004) and demographic simulations were performed in BOTTLESIM (Kuo & Janzen 2004). For the latter, population size was held constant at 300 actively reproducing pairs for 10 years, followed by a bottleneck of 30 reproducing pairs for 40 years (see electronic supplementary material for details). The program BOTTLENECK (Cornuet & Luikart 1996) was used to detect possible traces of population bottlenecks on the allele frequency spectrum, applying the recommended settings and tests for microsatellites (two-phased model: 90% one-step mutations and 10% multi-step changes; evaluation with standardized differences and Wilcoxon tests).

A part of the mtDNA control region was amplified and sequenced using the primers *HalHVR1F* (5′-CCCCCCCTATG-TATTATTGT-3′) and *HalHVR1R* (5′-TCTCAGTGAAGAGC-GAGAGA-3′) developed for *H. albicilla*, yielding a total of 500 bp for analysis. Similar to the microsatellite analyses, we used a bootstrapping procedure to correct diversity estimates for sample size (see the electronic supplementary material). DnaSP 4.10 (Rozas *et al.* 2003) was used to determine Tajima's *D* (Tajima 1989) and G_{ST}, an estimator of genetic differentiation among populations, using haplotype identity as the underlying statistic. Sequences obtained have been placed in the EMBL database (accession numbers AM156933–AM156934 and AM156936–AM156943).

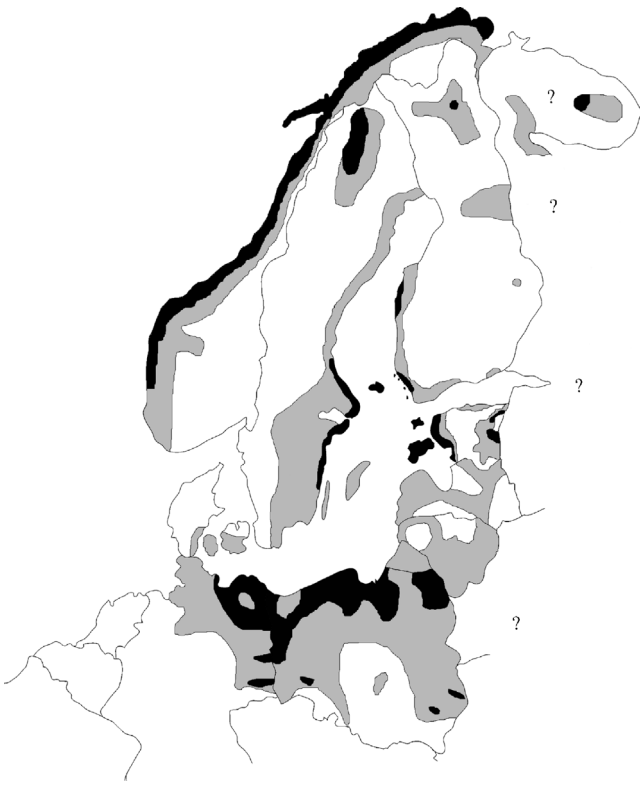

Figure 1. Distribution of the white-tailed eagle in north–central Europe. Black shading indicates regions where the species survived the mid-twentieth century population crash, light grey shading refers to regions re-colonized in the phase of population recovery since 1980.

3. RESULTS

A total of 139 alleles were observed across the 26 microsatellite markers. Significant heterozygote deficit was detected in the SWE, LAP and NOR populations. However, the signal disappeared when the locus *Hal 10* was excluded; we take this as an indication that this locus exhibits a null allele with restricted geographical distribution and that the populations otherwise do not deviate significantly from HWE.

Observed and expected heterozygosities estimated from data corrected for inter-population variation in sample size were in the range of 0.41–0.51 for all populations (table 1). Similarly, the mean number of alleles per locus did not vary much among populations, being in the range of 2.9–3.5. Importantly, there was no evidence for the large Norwegian population to show higher levels of genetic diversity ($H_E=0.48$, $H_O=0.49$, $N_A=3.1$), as compared to the other populations that had experienced a significant demographic bottleneck. Further, no population showed significant allele frequency shifts ($p>0.05$) which are expected after strong demographic bottlenecks.

One possible explanation for the homogeneous levels of genetic diversity among the populations could be that gene flow had passed unnoticed in the field surveys. Consistent with this idea, overall genetic differentiation was low ($F_{ST}=0.036$). However, F_{ST} was significantly different from zero (95% confidence intervals 0.029–0.044) and the test of genotypic differentiation found that all populations were significantly differentiated from each other ($p<0.01$ in all pairwise comparisons). Furthermore, an assignment test also indicated that populations were distinct units: despite the low overall F_{ST} value, about 80% of the analysed nestlings assigned to their natal population. Thirty-seven alleles found in other European populations were not observed in Norway, while only three of the Norwegian alleles were not found in the rest of the Europe.

Ten different mtDNA haplotypes were observed. Tajima's *D* was 1.522, but differed non-significantly from zero ($p>0.05$), compatible with neutral evolution of the DNA sequences. Haplotype frequencies differed significantly among populations, reflected by an overall G_{ST} of 0.228. The stronger population differentiation in mtDNA than nuclear markers probably reflects differences in effective population size between the marker types. Higher dispersal rates in males than in females are uncommon in birds (Greenwood 1980), and not supported by empirical data in white-tailed eagles (Helander 2003*b*).

The corrected number of haplotypes per population varied between 1.3 (Norway) and 7 (Kola peninsula; table 2), again indicating that bottlenecked populations do not contain lower levels of genetic diversity as compared to the Norwegian population. Further, our results confirm that the European populations could not have been derived largely from the coastal Norwegian population: only two mtDNA haplotypes were observed in Norway, one haplotype being very frequent (97%).

4. DISCUSSION

In summary, our data suggest that effective dispersal between populations has not been common during the past decades. We conclude that sustained genetic

Table 1. Genetic diversity at microsatellite loci. Number of samples analysed, unbiased expected (H_E) and observed (H_O) heterozygosity, mean number of alleles per locus (N_A) and their inter-locus standard deviations. For comparison between populations, standardized diversity values are also given.

population	sample size	H_E (s.d.)	corrected H_E	H_O (s.d.)	corrected H_O	N_A (s.d.)	corrected N_A
Norway	36	0.49 (0.05)	0.48	0.49 (0.02)	0.49	3.9 (2.3)	3.1
Estonia	13	0.49 (0.05)	0.48	0.50 (0.03)	0.50	3.5 (1.7)	3.1
Germany	18	0.43 (0.05)	0.42	0.42 (0.02)	0.41	3.4 (1.7)	2.9
Kola peninsula[a]	10	0.52 (0.05)	—	0.51 (0.03)	—	3.8 (2.0)	—
Lapland	24	0.51 (0.05)	0.49	0.49 (0.02)	0.49	4.2 (2.3)	3.4
mid and southern Sweden	117	0.51 (0.05)	0.51	0.50 (0.01)	0.51	4.8 (2.2)	3.5

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

Table 2. Genetic diversity at mitochondrial control region sequences. The number of analysed eagle territories (maternal lineages) is denoted by n, and N denotes the number of unique haplotypes found in each population. To correct for unequal sample sizes among populations, the mean number of alleles encountered in 100 bootstrap samples of 10 individuals each, and the standard deviation of these values, is presented.

population	n	N	corrected N (s.d.)
Norway	33	2	1.3 (0.5)
Estonia	12	5	4.0 (0.7)
Germany	18	3	2.6 (0.5)
Kola peninsula[a]	10	7	—
Lapland	22	6	3.7 (1.0)
mid and southern Sweden	44	4	2.9 (0.6)

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

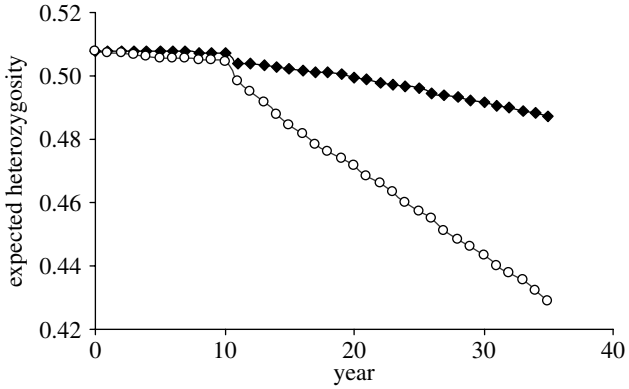

Figure 2. Loss of genetic diversity (as measured by expected heterozygosity) in a bottleneck of 30 reproducing pairs and overlapping generations. Filled diamonds and open circles consider an individual lifespan of 17 years and 1 year, respectively. The simulation was started at a population size corresponding to 300 reproducing pairs (years 0–10).

diversity in extant north–central European white-tailed eagle populations has a predominantly local origin, although some immigration may have contributed to local gene pools. We suggest that the long generation time of white-tailed eagles (average life span is around 17 years; Helander 2003*b*; Struwe-Juhl 2003) has minimized genetic drift and acted as an intrinsic buffer against rapid loss of genetic diversity. When a randomly mating population passes through a bottleneck, reduction of genetic diversity depends on population size and time according to $H_t=H_0(1-1/(2N_e))^t$; H_0 and H_t being the past and present heterozygosity, respectively, N_e the effective population size and t the time measured in number of generations. A bottleneck lasting about 20–30 years is equivalent to about two white-tailed eagle generations. Simulation of a bottleneck comprising 30 reproductive pairs (which corresponds to the situation in several European populations during the 1970s; see §1) shows that only about 4% of the original heterozygosity is expected to be lost in an eagle population during that time (figure 2). By contrast, for an organism with a generation time of 1 year, the corresponding loss of genetic diversity is considerably higher (16%; figure 2). Our results are compatible with the relatively high levels of genetic diversity seen in remnant and bottlenecked populations of other long-lived species, e.g. black rhinoceros (Swart *et al.* 1994) and greater one-horned rhinoceros (Dinerstein & McCracken 1990).

Starting in the late 1960s, several countries in Europe developed conservation programmes to protect eagles (Helander 1990). Nest site protection enabled fertile pairs to raise fledging young. Carcasses free of contaminants were laid out in winter and, as a result, juvenile survival was increased to 80% (Helander 2003*b*). Our results, therefore, indicate that these conservation efforts have led to the preservation of ample genetic diversity in local eagle populations. Moreover, conservation of eagles at local scales has resulted in the preservation of more total genetic diversity than if all conservation efforts had been centred on the coastal Norwegian population.

There has been an intense debate among conservation biologists about reserve design (the SLOSS debate—single large or several small; reviewed in Kingsland 2002). This debate was directly linked to the relative importance of local conservation versus a focus on population strongholds. Our results illustrate the high conservation value of local populations for species with a long generation time. A number of other species of conservation concern also have long generation times (e.g. raptors, turtles, large mammals and orchids) and for many of these significant genetic diversity may still exist in local populations. For the white-tailed eagle, protection of the local populations did not arrive too late.

The sampling of blood for this study was coordinated by the Swedish Society for Nature Conservation/Project Sea Eagle. We thank Kurt Elmqvist and Robert Franzén for assistance with the sampling of blood in the field in Sweden, Andreas Mertens for contributing feather samples, Torsten Stjernberg for comments on the distribution map and Mia Olsson for assistance in the lab. Deborah Dawson and Ruth Tingay kindly provided their markers prior to publication. The editor and two anonymous reviewers are thanked for constructive comments. This work was financially supported by Alvin's foundation, the Sven and Lilli Lawski foundation and the Knut and Alice Wallenberg foundation (to F.H.). H.E. is a Royal Swedish Academy of Sciences Research Fellow supported by a grant from Knut and the Alice Wallenberg foundation.

Most of the white-tailed eagle (*Haliaeetus albicilla*) populations in Europe experienced dramatic declines during the twentieth century. However, owing to intense conservation actions and the ban of DDT and other persistent pollutants, populations are currently recovering. We show that despite passing through demographic bottlenecks, white-tailed eagle populations have retained significant levels of genetic diversity. Both genetic and ringing data indicate that migration between populations has not been a major factor for the maintenance of genetic variability. We argue that the long generation time of eagles has acted as an intrinsic buffer against loss of genetic diversity, leading to a shorter effective time of the experienced bottleneck. Notably, conservation actions taken in several small sub-populations have ensured the preservation of a larger proportion of the total genetic diversity than if conservation had focused on the population stronghold in Norway. For conservation programmes targeting other endangered, long-lived species, our results highlight the possibility for local retention of high genetic diversity in isolated remnant populations.

Keywords: bottleneck; conservation genetics; generation time; microsatellites; mitochondrial DNA; single large or several small

1. INTRODUCTION

The white-tailed eagle (*Haliaeetus albicilla*) is used as a major flagship and umbrella species for conservation work throughout large parts of Europe. The species was once widely distributed across the continent (Helander & Stjernberg 2003), but direct persecution and low reproductive success as a result of environmental pollutants led to dramatic declines during the twentieth century (Bijleveld 1974; Helander *et al.* 2002). By the 1970s, many local populations in Europe had gone extinct and most surviving sub-populations barely reached one or a few tens of breeding pairs (figure 1). However, a stronghold remained along the Norwegian Atlantic coast with at least 700–800 breeding pairs (Folkestad 2003), corresponding to more than 70% of the northern and central European population (Helander *et al.* 2003). The population along the Norwegian coast utilized relatively uncontaminated food resources from the northern Atlantic and was thus largely saved from the detrimental effects of harmful pollutants (Helander *et al.* 1982). On the other hand, around the heavily polluted Baltic Sea, white-tailed eagles suffered strongly reduced breeding success (Helander *et al.* 1982).

With the ban in the 1970s of DDT, PCB and other detrimental chemicals, European white-tailed eagle populations soon started to recover, a process that is still ongoing (figure 1). For instance, the number of territorial pairs in southern and central Sweden increased from about 40 in 1974 to 250 in 2000 (Helander 2003*a*), and in Estonia from 10–15 between 1965 and 1975 to 116 in 2002 (Volke & Randla 2003). This population expansion appears to have been based mainly on local recruitment, since almost no inter-population exchange of breeders has been recorded from ringing data. In particular, the large Norwegian population does not seem to have acted as a major founding source for recovering populations; none of the more than 3000 eagles colour-ringed in Norway has so far been found breeding outside Norway (Folkestad unpublished data). Further, among more than 150 ringed breeding birds in Sweden, all but a few individuals from the nearby Finnish coast were offspring of resident pairs (Helander 2003*b*). Similarly, most of the few recorded emigrants from the German eagle population settled to breed nearby in Poland (Köppen 2003). Given this apparent trend of local recruitment, current populations might have been depleted of genetic diversity by the recent demographic declines.

Loss of genetic diversity can reduce both short-term viability (e.g. Saccheri *et al.* 1998) and long-term adaptability (Frankham 2005). To assess the genetic impact of population declines during the twentieth century, we therefore studied the genetic variability at mitochondrial DNA (mtDNA) control region sequences and autosomal microsatellite markers in north and central European white-tailed eagle populations.

2. MATERIAL AND METHODS

Several populations from northern and central Europe were sampled, yielding a total number of 218 presumably unrelated individuals: Estonia (EST, $n=13$ samples), Germany (GER, $n=18$), Swedish Lapland (LAP, $n=24$), southern and central Sweden (SWE, $n=117$), Kola peninsula, Russia (KOLA, $n=10$) and Norway (NOR, $n=36$). Most of the samples consisted of blood, but nine samples were moulted feathers that had been collected in the field.

Polymerase chain reaction (PCR) of 26 autosomal microsatellite loci was performed (details are given in Hailer *et al.* (2005) and the electronic supplementary material). In order to directly compare

the amount of genetic variation (expected and observed heterozygosity, H_E and H_O, and the mean number of alleles per locus, N_A) between population samples, we standardized for sample size by employing a bootstrapping procedure (see electronic supplementary material). We tested for deviation from Hardy–Weinberg equilibrium (HWE) and genotypic differentiation using GENEPOP 3.4 (Raymond & Rousset 1995). GENETIX 4.05.2 (Belkhir *et al.* 2004) was used to calculate F_{ST} and its 95% confidence interval. Assignment tests were carried out using GENECLASS 2.0.d (Piry *et al.* 2004) and demographic simulations were performed in BOTTLESIM (Kuo & Janzen 2004). For the latter, population size was held constant at 300 actively reproducing pairs for 10 years, followed by a bottleneck of 30 reproducing pairs for 40 years (see electronic supplementary material for details). The program BOTTLENECK (Cornuet & Luikart 1996) was used to detect possible traces of population bottlenecks on the allele frequency spectrum, applying the recommended settings and tests for microsatellites (two-phased model: 90% one-step mutations and 10% multi-step changes; evaluation with standardized differences and Wilcoxon tests).

A part of the mtDNA control region was amplified and sequenced using the primers *HalHVR1F* (5′-CCCCCCCTATG-TATTATTGT-3′) and *HalHVR1R* (5′-TCTCAGTGAAGAGC-GAGAGA-3′) developed for *H. albicilla*, yielding a total of 500 bp for analysis. Similar to the microsatellite analyses, we used a bootstrapping procedure to correct diversity estimates for sample size (see the electronic supplementary material). DnaSP 4.10 (Rozas *et al.* 2003) was used to determine Tajima's *D* (Tajima 1989) and G_{ST}, an estimator of genetic differentiation among populations, using haplotype identity as the underlying statistic. Sequences obtained have been placed in the EMBL database (accession numbers AM156933–AM156934 and AM156936–AM156943).

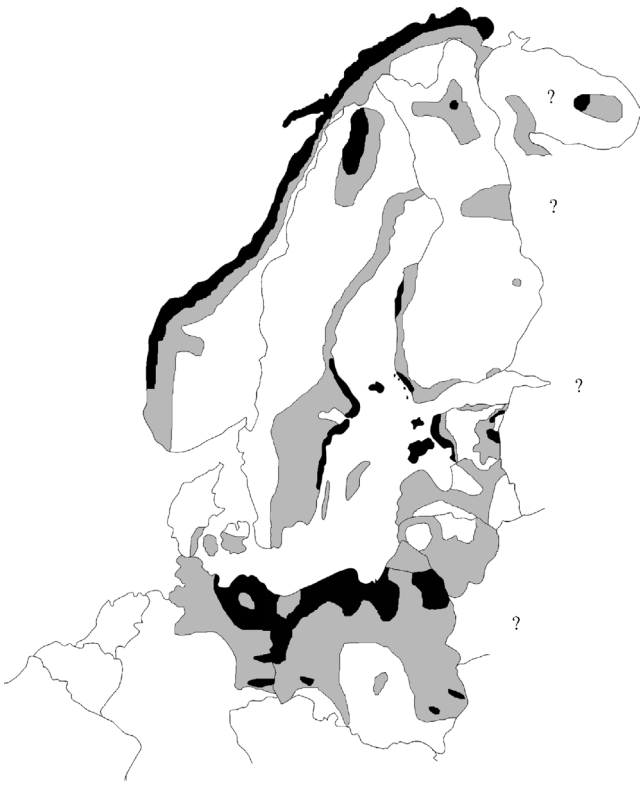

Figure 1. Distribution of the white-tailed eagle in north–central Europe. Black shading indicates regions where the species survived the mid-twentieth century population crash, light grey shading refers to regions re-colonized in the phase of population recovery since 1980.

3. RESULTS

A total of 139 alleles were observed across the 26 microsatellite markers. Significant heterozygote deficit was detected in the SWE, LAP and NOR populations. However, the signal disappeared when the locus *Hal 10* was excluded; we take this as an indication that this locus exhibits a null allele with restricted geographical distribution and that the populations otherwise do not deviate significantly from HWE.

Observed and expected heterozygosities estimated from data corrected for inter-population variation in sample size were in the range of 0.41–0.51 for all populations (table 1). Similarly, the mean number of alleles per locus did not vary much among populations, being in the range of 2.9–3.5. Importantly, there was no evidence for the large Norwegian population to show higher levels of genetic diversity ($H_E=0.48$, $H_O=0.49$, $N_A=3.1$), as compared to the other populations that had experienced a significant demographic bottleneck. Further, no population showed significant allele frequency shifts ($p>0.05$) which are expected after strong demographic bottlenecks.

One possible explanation for the homogeneous levels of genetic diversity among the populations could be that gene flow had passed unnoticed in the field surveys. Consistent with this idea, overall genetic differentiation was low ($F_{ST}=0.036$). However, F_{ST} was significantly different from zero (95% confidence intervals 0.029–0.044) and the test of genotypic differentiation found that all populations were significantly differentiated from each other ($p<0.01$ in all pairwise comparisons). Furthermore, an assignment test also indicated that populations were distinct units: despite the low overall F_{ST} value, about 80% of the analysed nestlings assigned to their natal population. Thirty-seven alleles found in other European populations were not observed in Norway, while only three of the Norwegian alleles were not found in the rest of the Europe.

Ten different mtDNA haplotypes were observed. Tajima's *D* was 1.522, but differed non-significantly from zero ($p>0.05$), compatible with neutral evolution of the DNA sequences. Haplotype frequencies differed significantly among populations, reflected by an overall G_{ST} of 0.228. The stronger population differentiation in mtDNA than nuclear markers probably reflects differences in effective population size between the marker types. Higher dispersal rates in males than in females are uncommon in birds (Greenwood 1980), and not supported by empirical data in white-tailed eagles (Helander 2003*b*).

The corrected number of haplotypes per population varied between 1.3 (Norway) and 7 (Kola peninsula; table 2), again indicating that bottlenecked populations do not contain lower levels of genetic diversity as compared to the Norwegian population. Further, our results confirm that the European populations could not have been derived largely from the coastal Norwegian population: only two mtDNA haplotypes were observed in Norway, one haplotype being very frequent (97%).

4. DISCUSSION

In summary, our data suggest that effective dispersal between populations has not been common during the past decades. We conclude that sustained genetic

Table 1. Genetic diversity at microsatellite loci. Number of samples analysed, unbiased expected (H_E) and observed (H_O) heterozygosity, mean number of alleles per locus (N_A) and their inter-locus standard deviations. For comparison between populations, standardized diversity values are also given.

population	sample size	H_E (s.d.)	corrected H_E	H_O (s.d.)	corrected H_O	N_A (s.d.)	corrected N_A
Norway	36	0.49 (0.05)	0.48	0.49 (0.02)	0.49	3.9 (2.3)	3.1
Estonia	13	0.49 (0.05)	0.48	0.50 (0.03)	0.50	3.5 (1.7)	3.1
Germany	18	0.43 (0.05)	0.42	0.42 (0.02)	0.41	3.4 (1.7)	2.9
Kola peninsula[a]	10	0.52 (0.05)	—	0.51 (0.03)	—	3.8 (2.0)	—
Lapland	24	0.51 (0.05)	0.49	0.49 (0.02)	0.49	4.2 (2.3)	3.4
mid and southern Sweden	117	0.51 (0.05)	0.51	0.50 (0.01)	0.51	4.8 (2.2)	3.5

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

Table 2. Genetic diversity at mitochondrial control region sequences. The number of analysed eagle territories (maternal lineages) is denoted by n, and N denotes the number of unique haplotypes found in each population. To correct for unequal sample sizes among populations, the mean number of alleles encountered in 100 bootstrap samples of 10 individuals each, and the standard deviation of these values, is presented.

population	n	N	corrected N (s.d.)
Norway	33	2	1.3 (0.5)
Estonia	12	5	4.0 (0.7)
Germany	18	3	2.6 (0.5)
Kola peninsula[a]	10	7	—
Lapland	22	6	3.7 (1.0)
mid and southern Sweden	44	4	2.9 (0.6)

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

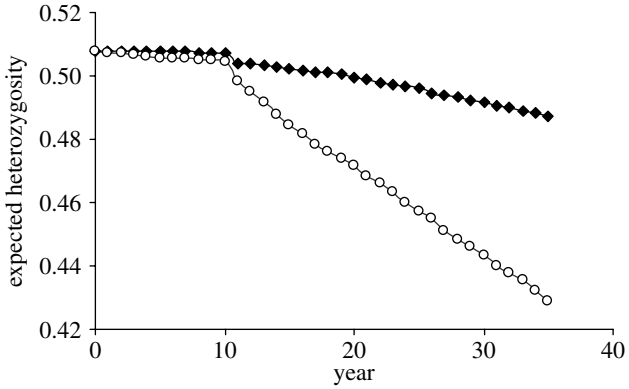

Figure 2. Loss of genetic diversity (as measured by expected heterozygosity) in a bottleneck of 30 reproducing pairs and overlapping generations. Filled diamonds and open circles consider an individual lifespan of 17 years and 1 year, respectively. The simulation was started at a population size corresponding to 300 reproducing pairs (years 0–10).

diversity in extant north–central European white-tailed eagle populations has a predominantly local origin, although some immigration may have contributed to local gene pools. We suggest that the long generation time of white-tailed eagles (average life span is around 17 years; Helander 2003*b*; Struwe-Juhl 2003) has minimized genetic drift and acted as an intrinsic buffer against rapid loss of genetic diversity. When a randomly mating population passes through a bottleneck, reduction of genetic diversity depends on population size and time according to $H_t=H_0(1-1/(2N_e))^t$; H_0 and H_t being the past and present heterozygosity, respectively, N_e the effective population size and t the time measured in number of generations. A bottleneck lasting about 20–30 years is equivalent to about two white-tailed eagle generations. Simulation of a bottleneck comprising 30 reproductive pairs (which corresponds to the situation in several European populations during the 1970s; see §1) shows that only about 4% of the original heterozygosity is expected to be lost in an eagle population during that time (figure 2). By contrast, for an organism with a generation time of 1 year, the corresponding loss of genetic diversity is considerably higher (16%; figure 2). Our results are compatible with the relatively high levels of genetic diversity seen in remnant and bottlenecked populations of other long-lived species, e.g. black rhinoceros (Swart *et al.* 1994) and greater one-horned rhinoceros (Dinerstein & McCracken 1990).

Starting in the late 1960s, several countries in Europe developed conservation programmes to protect eagles (Helander 1990). Nest site protection enabled fertile pairs to raise fledging young. Carcasses free of contaminants were laid out in winter and, as a result, juvenile survival was increased to 80% (Helander 2003*b*). Our results, therefore, indicate that these conservation efforts have led to the preservation of ample genetic diversity in local eagle populations. Moreover, conservation of eagles at local scales has resulted in the preservation of more total genetic diversity than if all conservation efforts had been centred on the coastal Norwegian population.

There has been an intense debate among conservation biologists about reserve design (the SLOSS debate—single large or several small; reviewed in Kingsland 2002). This debate was directly linked to the relative importance of local conservation versus a focus on population strongholds. Our results illustrate the high conservation value of local populations for species with a long generation time. A number of other species of conservation concern also have long generation times (e.g. raptors, turtles, large mammals and orchids) and for many of these significant genetic diversity may still exist in local populations. For the white-tailed eagle, protection of the local populations did not arrive too late.

The sampling of blood for this study was coordinated by the Swedish Society for Nature Conservation/Project Sea Eagle. We thank Kurt Elmqvist and Robert Franzén for assistance with the sampling of blood in the field in Sweden, Andreas Mertens for contributing feather samples, Torsten Stjernberg for comments on the distribution map and Mia Olsson for assistance in the lab. Deborah Dawson and Ruth Tingay kindly provided their markers prior to publication. The editor and two anonymous reviewers are thanked for constructive comments. This work was financially supported by Alvin's foundation, the Sven and Lilli Lawski foundation and the Knut and Alice Wallenberg foundation (to F.H.). H.E. is a Royal Swedish Academy of Sciences Research Fellow supported by a grant from Knut and the Alice Wallenberg foundation.

Review

Non-surgical sterilisation methods may offer a sustainable solution to feral horse (*Equus caballus*) overpopulation

Abstract. Feral horses are a significant pest species in many parts of the world, contributing to land erosion, weed dispersal and the loss of native flora and fauna. There is an urgent need to modify feral horse management strategies to achieve public acceptance and long-term population control. One way to achieve this is by using non-surgical methods of sterilisation, which are suitable in the context of this mobile and long-lived species. In this review we consider the benefits of implementing novel mechanisms designed to elicit a state of permanent sterility (including redox cycling to generate oxidative stress in the gonad, random peptide phage display to target non-renewable germ cells and the generation of autoantibodies against proteins essential for conception via covalent modification) compared with that of traditional immunocontraceptive approaches. The need for a better understanding of mare folliculogenesis and conception factors, including maternal recognition of pregnancy, is also reviewed because they hold considerable potential in providing a non-surgical mechanism for sterilisation. In conclusion, the authors contend that non-surgical measures that are single shot and irreversible may provide a sustainable and effective strategy for feral horse control.

Additional keywords: fertility, immunocontraception, oxidative stress, primordial germ cells, spermatozoa.

Introduction

Feral horses (*Equus caballus*) are a significant pest species in many parts of the world, particularly in the US, regions of Europe, Australia and New Zealand (Long 2003). The large, hard-hooved herbivore is responsible for considerable environmental damage (Dyring 1990; Andreoni 1998; English 2000), the spread of disease (Dobbie *et al.* 1993; Campbell *et al.* 2002; Cheng and Currie 2005; Dawson *et al.* 2006) and an indirect decline in native flora and fauna populations (Dobbie *et al.* 1993; Symanski 1994; Levin *et al.* 2002; Beever and Brussard 2004; Zalba and Cozzani 2004; Beever and Herrick 2006). A lack of predators and favourable environmental conditions can allow feral horse numbers to rise by 20% per annum (Eberhardt *et al.* 1982; Dobbie *et al.* 1993; Dawson *et al.* 2006; National Research Council 2013). In Australia, the population of feral horses is in excess of 600 000 brumbies, notably the largest feral horse population in the world (Berman and Jarman 1987; Clement *et al.* 1990; Dawson *et al.* 2006; Nimmo and Miller 2007). Integrated pest management strategies for feral horses include trapping and mustering, where animals are euthanased and sold for meat or trained and used as stock horses (Rolls 1969; Warren *et al.* 1993; Symanski 1994; Csurhes *et al.* 2009; Garrott and Oli 2013). However, the most extensively practiced method for population control is culling in the form of aerial shooting (English 2000; Dawson *et al.* 2006; English 2006). Although the requirements to be a shooter are high, the method remains contentious (Symanski 1994; Chapple 2005; Bradshaw *et al.* 2007; Nimmo and Miller 2007). Aerial shooting of feral horses is largely unaccepted by the public because free-ranging horses are often considered a cultural icon and an important part of national heritage (Berman 1991; Bomford and O'Brien 1997; Chapple 2005; Dawson *et al.* 2006; Bradshaw *et al.* 2007; Nimmo and Miller 2007; Killian *et al.* 2008). Furthermore, most control methods are laborious, expensive and ineffective, markedly failing to reduce the population growth rate of this pest species (Dobbie *et al.* 1993; Symanski 1994; Dawson *et al.* 2006; Killian *et al.* 2008; National Research Council 2013). Legal restrictions have been used to ban aerial shooting (English 2000; Chapple 2005), which has created an urgent need to implement secondary control strategies that are publicly accepted and offer a sustainable solution to feral horse overpopulation.

Considerable progress has been made in the area of immunocontraceptive development (Fagerstone *et al.* 2010; Gray and

Cameron 2010; Kirkpatrick *et al.* 2011; Massei and Cowan 2014), but a sustainable and effective method for free-ranging populations has yet to be implemented successfully (Bomford and O'Brien 1997; English 2000; Dawson *et al.* 2006; Hinds 2006; Killian *et al.* 2008; Powers *et al.* 2011; National Research Council 2013). This is due, at least in part, to the need for frequent readministration. One way to overcome this is by using non-surgical methods of sterilisation, which are suitable in the context of this mobile and long-lived species (Dell'Omo and Palmery 2002; National Research Council 2013; Amory *et al.* 2014; Aitken 2015; Naz and Saver 2016). The success of such a formulation is likely predicated on its ability to induce a state of permanent and irreversible sterility. It is highly desirable that the sterilant is cell and species specific and capable of affecting both sexes uniformly to cause permanent sterility after a single application. Herein we briefly discuss fertility control vaccines currently available and review novel approaches that remove the need for readministration (Table 1). Novel methods of non-surgical sterilisation may prove preferable in the context of integrated management approaches to feral horse populations.

Fertility control currently used for feral horse management

Compared with human and domestic animal contraception, the implementation of effective fertility control strategies for feral horses encompasses several unique challenges (Killian *et al.* 2008; Kirkpatrick *et al.* 2011). Issues surrounding specificity, reversibility, methods of delivery and variability in response have restricted the widespread adoption of fertility control strategies as part of integrated management approaches (Stout and Colenbrander 2004). Notwithstanding these limitations, at least two contraceptive methods based on targeting critical aspects of gonadal regulation or gamete interaction have shown promise for feral horse management (Fig. 1).

The first gonadotrophin-releasing hormone (GnRH) immunisation in horses was conducted by Schanbacher and Pratt (1985) to assess its effect on cryptorchidism in stallions. The ensuing three decades saw a proliferation of GnRH-targeting strategies implemented for fertility control (Stout and Colenbrander 2004; Fagerstone *et al.* 2010), but many methods were largely discounted for free-ranging species in favour of vaccination regimens incorporating formulations of the GnRH peptide (or a conjugated form of the hormone; Miller *et al.* 2008; Powers *et al.* 2011, 2014). Pertinent for both sexes, GnRH formulations assessed in stallions have been shown to affect sperm motility acutely before resulting in a complete loss of libido, disrupted spermatogenesis and reduction in testis size, measured 2 weeks after the second immunisation (Turkstra *et al.* 2005).

Several commercial GnRH vaccines are currently in production, including Improvac (CSL), Equity (Pfizer Animal Health) and GonaCon (United States Department of Agriculture National Wildlife Research Centre). In studies by Imboden *et al.* (2006), two doses of Improvac in the mare permitted a contraceptive coverage of 23 weeks, but this coincided with an undesirable reaction to the adjuvant formulated into this commercial vaccine. Subsequent studies using Improvac reported no adverse reaction (Botha *et al.* 2008). Equity, a vaccine created specifically for horse contraception, generated better coverage (at least 1 year) with no adverse reactions to the immunisation (Elhay *et al.* 2007). Finally, 4 years after GonaCon delivery, 40% of mares experienced a continued contraceptive effect (Killian *et al.* 2008).

In the US, these vaccines are not commercially available, leading Donovan *et al.* (2013) to instead test a commercially available canine GnRH in mares. The findings of that study revealed the vaccine inhibited ovarian function, but also altered reproductive behaviours that are integral to the maintenance of the complex social structure of herd animals such as horses.

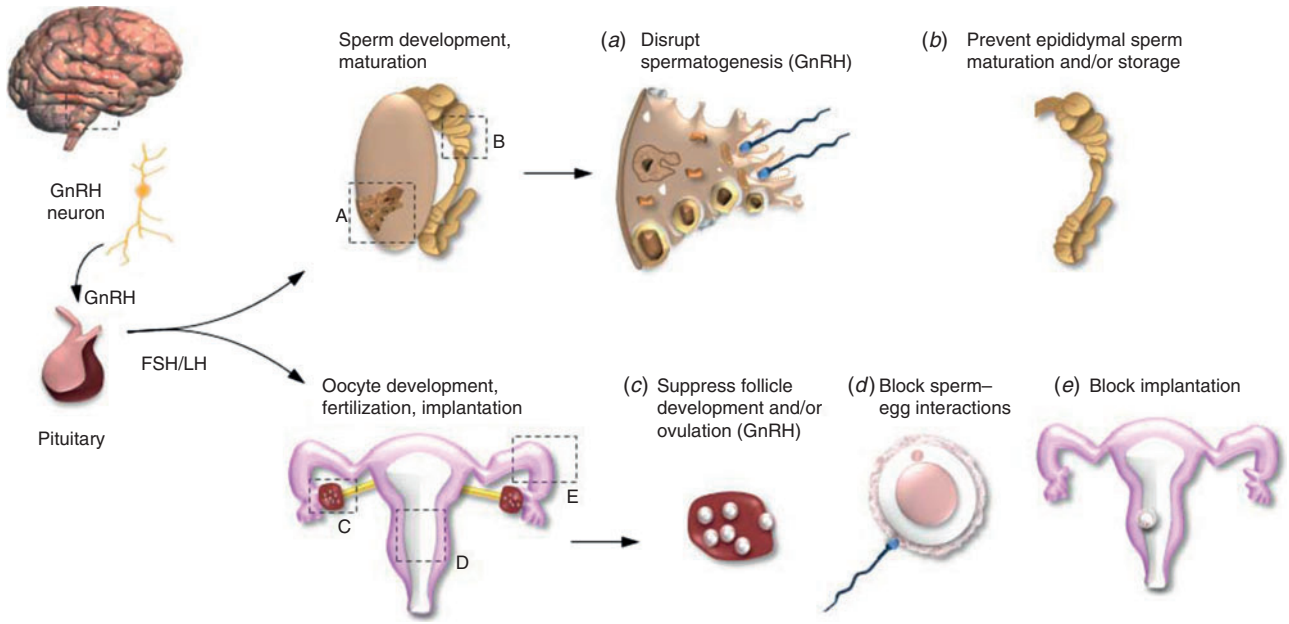

Fig. 1. Target sites for contraceptive intervention. In the male reproductive system, fertility control methods are used to disrupt spermatogenesis (gonadotrophin-releasing hormone (GnRH); A) or prevent epididymal sperm maturation and/or storage (B). In the female reproductive system, fertility control methods suppress follicle development and/or ovulation (C), block sperm–egg interactions (D) or block implantation (E).

Kisspeptin has also been investigated because it plays an important role in initiating GnRH secretion, but research is currently in its infancy and it is difficult to investigate in the horse (Decourt *et al.* 2008). Altering normal GnRH activity through the use of agonists has also proven quite difficult in mares (Fitzgerald *et al.* 1993) due to internalisation of GnRH and downregulation of GnRH receptors (Kutzler and Wood 2006; Finch *et al.* 2009). Additional issues are that these vaccines are neither tissue nor species specific (Kirkpatrick *et al.* 2011; Samoylova *et al.* 2012), and booster immunisations are required to maintain effective antibody titres (Herbert and Trigg 2005). A more promising approach has centred on the development of anti-zona pellucida (ZP) vaccines incorporating native formulations of whole ZP that have been harvested from the pig, a tissue resource that is readily available from abattoirs (Kutzler and Wood 2006; McLaughlin and Aitken 2011). Such vaccines exploit the high degree of species conservation among the ZP proteins and have been used on over 80 species, with variable degrees of efficacy (Kirkpatrick *et al.* 2011). This may be due to the unique differences in the number and localisation of ZP glycoproteins between species (Mugnier *et al.* 2009). The anti-ZP antibodies generated following immunisation bind antigenic sites on the outer surface of the ZP and thereby competitively inhibit sperm binding or prevent sperm accessing target ligands through a process of steric hindrance (Aitken and Richardson 1981; Liu *et al.* 1989).

Liu *et al.* (1989) first demonstrated the potential applicability of anti-porcine (p) ZP as an immunocontraceptive in captive mares following four injections of the vaccine. Subsequently, its efficacy in controlling feral horse populations was assessed in field trials targeting a herd of free-ranging horses inhabiting Assateague Island in the US (Kirkpatrick *et al.* 1990). That study demonstrated that remote delivery of the anti-pZP vaccine could successfully impede fertility of both pregnant and non-pregnant mares without affecting foetal health. These novel findings stimulated a series of elegant secondary studies assessing reversibility (Kirkpatrick and Turner 2002; Feh 2012), time to population decline (Kirkpatrick and Turner 2008), duration of contraceptive effect (Turner *et al.* 2008; Ransom *et al.* 2011) and changes to social behaviours (Nuñez *et al.* 2009, 2010; Madosky *et al.* 2010; Ransom *et al.* 2010). Contraceptive studies were conducted predominantly using a pelleted pZP vaccine called PZP-22, before registration of ZonaStat-H by the Humane Society of the United States as a contraceptive for free-ranging horses (Mask *et al.* 2015). However, the most recent commercially available pZP vaccine is SpayVac (IVT), a formulation that has demonstrated continued fertility control in feral horses for at least 3 years after a single administration (Killian *et al.* 2008; Bechert *et al.* 2013). Although directed against ZP glycoprotein 3 (ZP3), SpayVac is regarded as less pure than either PZP-22 or ZonaStat-H, potentially increasing its antigenicity and making it the best candidate for field application (National Research Council 2013; Mask *et al.* 2015).

In studies that have sought to directly compare the efficacy of anti-pZP vaccination with that of anti-GnRH for feral horse control, the former has generally proven more favourable (Bechert *et al.* 2013; National Research Council 2013). Two studies by Killian *et al.* (2006, 2008) found higher rates of infertility (83%) in mares 3 years after a single administration of SpayVac, compared with only 60% infertility after treatment with GonaCon. Notwithstanding these promising data, studies of anti-pZP have reported females exhibiting prolonged reproductive behaviours (Nuñez *et al.* 2010; Ransom *et al.* 2010), as well as decreased band fidelity, which significantly affects overall

harem stability (Nuñez *et al.* 2009; Madosky *et al.* 2010). Although such atypical behaviour may be a common feature of immunocontraceptive strategies (National Research Council 2013; Ransom *et al.* 2013), targeting the conserved molecular structure of the mammalian ZP proteins does impose additional limitations with regard to a lack of species specificity (Samoylova *et al.* 2012). Furthermore, the vaccine is only useful as a female contraceptive and the immunological response varies between individual animals treated (Kirkpatrick *et al.* 2012). Following SpayVac administration to eight mares, Mask *et al.* (2015) reported that although all produced elevated anti-ZP antibody titres, one mare was still able to conceive, inferring antibody titres are not a stand-alone representation of fertility cessation.

Additional consequences of anti-pZP immunisation tend to vary between species (Barber and Fayrer-Hosken 2000; Prasad *et al.* 2000), but include interference with follicle maturation and ovulation as well as primordial follicle depletion (Skinner *et al.* 1984; Paterson *et al.* 1998; Tung *et al.* 2002; Bechert *et al.* 2013). In feral horses, ovarian pathology was reported following 3 years of immunocontraception with anti-pZP (Powell and Monfort 2001). The mechanisms underpinning the induction of such pathologies warrant further investigation because they may provide insight into the development of a novel permanent fertility control agent that persists over the lifetime of the animal and thus removes the need for readministration.

Non-surgical sterilisation technologies

Induction of reproductive senescence

Most contraceptive strategies for animal population control require readministration (Asa *et al.* 2010) because they target regenerative proteins or secretory products, making the immune response a very inefficient process. Prolonging the efficacy of vaccines by lengthening the time to readministration or removing the need for readministration completely requires targeting non-renewable germ cells, and is a critically important consideration for long-term, sustainable feral horse control. Primordial follicles in the ovary and spermatogonial stem cells and Sertoli cells in the testis are essential for the expression of normal fertility. These cells represent ideal targets for fertility control in that they are terminally differentiated cell types that cannot be replenished by the reproductive system (Aitken and Curry 2011). Thus, once these cells have been depleted, the reproductive potential of the animal is lost (Meirow and Nugent 2001; Aitken *et al.* 2004; Sobinoff *et al.* 2010).

A variety of cellular insults have been identified that are capable of inducing germ cell depletion and hence infertility, including autoimmune disease, exposure to radiation, xenobiotics and other cytotoxic agents (Aitken *et al.* 2004; Silva *et al.* 2014). These insults generally lead to the production of free radicals, such as reactive oxygen species (ROS), and thus exploit the sensitivity of the developing gamete to a state of oxidative stress (Hoyer *et al.* 2001; Hanoux *et al.* 2007). The process of redox cycling has been well documented for a variety of xenobiotics, such as pesticides, insecticides, flame retardants, polycyclic aromatic hydrocarbons and dioxins (Hoyer *et al.* 2001; Aitken *et al.* 2004; Aitken 2008; Aitken and De Iuliis 2010). The generation of superoxide radicals begins a cascade of events leading to the formation of ROS, lipid peroxidation and subsequent electrophile generation (Gutierrez 2000; Aitken *et al.* 2012). Reagents responsible for redox cycling and the generation of oxidative stress could make ideal contraceptive agents (Aitken and Baker 2006), particularly in the case of horse spermatozoa, because they contain high levels of polyunsaturated fatty acids, rendering them highly susceptible to electrophile accumulation and DNA damage (Aitken *et al.* 2012).

Oxidative stress associated with excessive ROS generation and the induction of lipid peroxidation is an acknowledged cause of spontaneous infertility in human males (Aitken and Clarkson 1987; Moazamian *et al.* 2015). Similarly, in the female reproductive system, numerous studies have examined free radical production through redox cycling leading to oxidative stress capable of depleting the germ cell pool (Meirow and Nugent 2001; McLaughlin *et al.* 2003; Pujianto *et al.* 2010; Sobinoff *et al.* 2010; Kim *et al.* 2013). As a specific example, menadione, a redox active naphthoquinone, causes widespread oxidative stress in male and female gametes leading to significant DNA damage and loss of functionality (De Iuliis *et al.* 2006; Sobinoff *et al.* 2010; Aitken *et al.* 2013).

Such proof-of-concept studies provide evidence that a localised state of oxidative stress within the gonad can cause infertility. One technology that may prove amenable to selectively delivering this form of cellular insult to the gonad is that of random peptide phage display (Meloen *et al.* 2000). Initially introduced in a contraceptive context by Eidne *et al.* (2000), this technology was used to generate peptides against the sperm surface that bound to the equatorial segment and interfered with sperm–oocyte fusion. Subsequently, random peptide phage display technology was used in dogs (Samoylova *et al.* 2010) and pigs (Samoylova *et al.* 2012) and succeeded in identifying key sperm proteins that mediate adhesion to the ZP in these species. Similar techniques have also been used to increase the immunogenicity of GnRH (Sabeur *et al.* 2003), which has low antibody response due to its prevalence in the body (Samoylov *et al.* 2012). Although these reports highlight the usefulness of using targeting peptides to directly disrupt normal cellular signalling and affect fertility, there is also the opportunity to couple these peptides with redox cycling xenobiotics to ensure apoptosis of the target cells and non-surgical sterilisation (Aitken 2006). This strategy relies on iterative rounds of selection to identify bacteriophage expressing peptide inserts that bind to the target cell types (e.g. the pregranulosa cells and oocyte that make up primordial follicles in the ovary, and spermatogonial stem cells and Sertoli cells in the testis) with a high degree of affinity and specificity (Eidne *et al.* 2000; Samoylova *et al.* 2012). These peptides are then conjugated to xenobiotics engineered in a manner that permits their delivery only in the immediate vicinity of the target cell, thereby ensuring both the efficacy and safety of the approach (Humphrys and Lapidge 2008). Substantial progress with this peptide technology has been achieved in recent years, enabling xenobiotics to be coupled to phage peptides in such a way that they can be targeted directly to the gonad with a single intraperitoneal (i.p.) injection. For example, in studies by Amory *et al.* (2014), an FSHβ–melphalan peptide conjugate suppressed normal spermatogenesis in mice.

Another mechanism to recruit non-renewable germs cells is via local activation of signalling molecules within the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin (mTOR) pathway (Reddy *et al.* 2008; McLaughlin and McIver 2009; Sobinoff *et al.* 2012). During folliculogenesis, activation of the PI3K/AKT/mTOR pathway determines the rate of primordial follicle activation, mediated by phosphatase and tensin homologue (PTEN) phosphorylation (Keating *et al.* 2009; Sobinoff *et al.* 2010; Kim *et al.* 2013). Uncontrolled activation of the PI3K/AKT/mTOR pathway has been postulated as a main cause for premature ovarian failure. In a study by Adhikari *et al.* (2012), bisperoxovanadium, a known PTEN inhibitor, directly disrupted primordial follicle senescence by activating the PI3K/AKT/mTOR pathway. Exposure to 4-vinylcyclohexene diepoxide also delivered this effect, depleting ovarian follicle number in murine studies (Hoyer *et al.* 2001; Mayer *et al.* 2002; Dyer *et al.* 2013). Importantly, unregulated activation of this pathway has been associated with a concomitant increase in ROS production (Kim *et al.* 2013). Delivery of a local PTEN inhibitor could be achieved using peptides targets, but it would first be necessary to ensure gonadal signalling processes that are well characterised in the mouse model are conserved and function in the same manner in the horse. Indeed, little is known about horse gametogenesis compared with other species and, although many mechanisms are highly conserved, underpinning the mechanisms behind both spermato- and folliculo- genesis is crucial to the development of these technologies.

Generation of autoantibodies

A vaccine's efficacy is underpinned by its ability to present a foreign antigen to the body in such a way that it elicits an immune response that leaves the animal with lifelong immunity (Muller *et al.* 1997; Tung *et al.* 1999; Hardy *et al.* 2006). However, in the case of autoimmunity, events can occur whereby the immune system will fail to maintain tolerance and mount an immune response against self-antigens. Indeed, ovarian autoantibodies have been cited as responsible for reproductive failure in several cases, eliciting autoimmune oophoritis and premature ovarian failure (Garza and Tung 1995; Forges *et al.* 2004; Bakalov *et al.* 2005; Altuntas *et al.* 2006; Silva *et al.* 2014). Similarly, with regard to males, autoantibodies against sperm proteins are often generated in the male if the blood–testis barrier is breached (e.g. vasectomy; Bohring and Krause 2003). Spermatozoa are unique in that they are generated after immunological tolerance has been established in the body. Therefore, these cells have value as targets for fertility regulation because they are potentially antigenic (Alexander and Anderson 1979). In a study by Bohring and Krause (2003), the presence of anti-sperm antibodies was found to interfere with factors essential for fertilisation, including sperm morphology, sperm–oolemma binding ability and acrosome integrity. A variety of proteins have been investigated for their importance in reproductive processes and it is becoming increasingly evident that the development of these immune responses involves the targeting of a multitude of proteins, rather than singular entities, that are essential in sperm–egg binding and fertilisation (Nixon *et al.* 2007). Although oocyte- and ovarian-specific proteins are difficult to identify, many sperm-specific antigens have been discovered (Bohring and Krause 2003). An extensive overview of promising protein targets for immunocontraception in the horse can be found elsewhere (Swegen and Aitken 2016).

For feral horse control, the potential to identify antigens present on terminally differentiated cells allows for the development of innovative contraceptives with lifelong effectiveness. However, we are currently faced with a challenge of not only defining the precise subset of proteins involved in sperm–egg binding, but also delivering them to the immune system in such a manner that will elicit an immune response significant enough to cause infertility. Therefore, a method that can identify proteins essential for conception holds considerable promise. In a study by Wang *et al.* (2012), proteins were found to generate immune responses once they had been covalently modified as a result of becoming alkylated by electrophilic lipid aldehydes, such as 4-hydroxynonenal (4HNE) and malondialdehyde. In particular, Wang *et al.* (2012) found that aldehyde-modified proteins were capable of eliciting autoantibody formation and thus contribute to autoimmune disease pathogenesis. In this instance, autoimmunity arises because immunological tolerance to important protein antigens has been compromised (McLaughlin and Aitken 2011). By altering protein composition in such a way as to break tolerance, aldehyde-modified proteins are capable of eliciting an increase in immunogenicity that could result in a long-term contraceptive effect and even permanent sterility. This principle was established many years ago in dogs, where alkylation of sperm proteins using α-chlorohydrin caused lesions in the testis inhibiting spermatogenesis (Dixit *et al.* 1975). The concept of using aldehyde-modified sperm proteins as immunogens for long-term feral horse fertility control is promising given the evidence that pathological autoimmunity can be elicited in instances where proteins have become modified as a consequence of oxidative damage or adduction with small molecular mass metabolites, such as 4HNE or homocysteine thiolactone (Jakubowski 2010; Aitken *et al.* 2012; Gibb *et al.* 2014). We propose that aldehyde adducts on what are otherwise unknown proteins could be exploited to identify key proteins involved in conception and break immune tolerance to induce a state of autoimmunity in horses.

Maternal recognition of pregnancy

In the early stages of pregnancy, a process commonly referred to as 'maternal recognition of pregnancy' is initiated, whereby the conceptus secretes messages to promote the continued production of progesterone by the corpus luteum (CL), which is essential for supporting early embryonic development and survival (Bazer *et al.* 1994; Aitken 2002; McLaughlin *et al.* 2003; Gupta and Bansal 2010). In many animals, the maternal recognition of pregnancy is well understood. For example in ruminants, mononucleate cells of the trophectoderm release large amounts of interferon-τ (IFNT), which suppresses prostaglandin (PG) $F_{2\alpha}$ release from the endometrium (Roberts *et al.* 1996; Spencer and Bazer 2004). In comparison, the pig trophoblast produces oestrogen as it elongates in the uterine horn, which counteracts the effects of $PGF_{2\alpha}$ on the CL (Bazer *et al.* 1994; Klein *et al.* 2010; Swegen and Aitken 2016). However, the trophoblast of the horse

conceptus is unable to elongate due to internal turgor pressure (Allen and Wilsher 2009). Instead, $PGF_{2\alpha}$ and PGE_2 stimulate peristaltic contractions of the myometrium, allowing the embryo to travel around the uterus 12–14 times per day, sending signals to prevent luteolysis (Roberts *et al.* 1996; Stout and Allen 2001; Allen and Wilsher 2009; Klein *et al.* 2010). Many studies have tried to determine the nature of the factors emanating from the conceptus; however, the exact repertoire of signalling molecules released by the horse conceptus and their mechanisms of action remain to be fully resolved (Allen 1982; Bazer *et al.* 1994; Roberts *et al.* 1996; Allen and Wilsher 2009; Ealy *et al.* 2010; Klein *et al.* 2010; Swegen and Aitken 2016). A study by Ealy *et al.* (2010) provides strong evidence to suggest that the unknown signal, whatever it may be, likely targets the enzyme PGG/H synthase 2 to prevent luteolysis.

Using the technologies mentioned previously, it may be possible to increase the immunogenicity of as yet unknown proteins found on the blastocyst surface, perform immunisations and determine reproductive outcomes. This technology has been assessed previously, whereby peptides were developed to mimic trophoblast epitopes and their antigenicity tested by assessing their binding affinity to autoantibodies (Frank *et al.* 2005). Rather than interrupting conception, this approach inhibited the implantation of a successfully fertilised embryo. This later stage intervention alleviates any concern for changes to social dynamics and behaviours, but public acceptance of such an approach will need to be assessed to ensure its feasibility as a contraceptive for feral horses (Fagerstone *et al.* 2010). Using novel phage panning and aldehyde-modification technologies, we have the opportunity to identify proteins essential for the horse maternal recognition of pregnancy and exploit these to prevent embryo implantation, if and when fertilisation occurs.

Non-surgical sterilisation implementation and feasibility

Research into the molecular mechanisms governing mammalian reproduction has provided unprecedented insight into how reproductive processes may be compromised for the purpose of achieving long-term fertility control in feral horses. Indeed, the use of non-surgical sterilisation offers significant advantages in that it is cheaper to use than alternative methods, respects animal welfare and can be more effective than culling (Hobbs *et al.* 2000; Turner *et al.* 2001). However, incorporating non-surgical methods into our existing armoury of integrated pest management strategies faces several challenges, including stringent assessment of feral horse numbers and contraceptive suitability based on changes to reproductive cycling, animal behaviour and disruption to social dynamics between horses (Kirkpatrick and Turner 2008; Zabek *et al.* 2014*a*). As highly social animals, it remains imperative that we understand how management strategies including non-surgical sterilisation techniques may alter feral horse social structure (Madosky *et al.* 2010). It is difficult to ascertain whether compensatory factors, such as increased survival, may occur after the burden of fertility is removed from target populations (Warren *et al.* 1993; Ransom *et al.* 2014), as it has done following previous immunocontraceptive delivery (Turner and Kirkpatrick 2002; Kirkpatrick and Turner 2007), or whether selective pressure will manipulate the long-term effect of a particular contraceptive agent (Turner and Kirkpatrick 2002; Kirkpatrick and Turner 2008). However, this has not been the case in previous studies (Ransom *et al.* 2014) and changes to population demographics and social hierarchy issues have been reviewed extensively (Berman 1991; Dobbie *et al.* 1993; Fagerstone 2002; Asa and Porton 2005; Kirkpatrick *et al.* 2011; Massei and Cowan 2014).

Perhaps one of the greatest obstacles to the implementation of an efficacious contraceptive strategy is the development of a suitable delivery method that is both practical and cost-effective (Bomford and O'Brien 1997; Lapidge *et al.* 2010). Remote delivery has been thoroughly investigated for its applicability, regarded as an ideal method for reducing labour costs and minimising stress experienced by animals (Kirkpatrick *et al.* 1990, 1996, 2011). However, an in-depth review by the National Research Council (2013) describes the shortcomings of this technique, concluding that it is unlikely to be suitable for feral horses owing to the complexities associated with successful administration (Garrott 1995; Nimmo *et al.* 2007). Indeed, remote delivery also poses an environmental contamination concern, because most darts fall out of the animal and are unrecovered (Warren *et al.* 1993). Oral baiting may ultimately be the only effective delivery mechanism for free-ranging horse populations (Killian *et al.* 2006; Humphrys and Lapidge 2008; Samoylova *et al.* 2012), but it is seldom discussed for incorporation into feral horse management strategies. Peptide technology certainly meets all the requirements for oral delivery under field conditions in that it is species specific, has shown oral activity and is environmentally safe (Humphrys and Lapidge 2008). Although oral baiting mitigates the problems that apply to remote delivery, it is not without its own limitations. For example, previous work has shown that baiting is complicated by the behavioural characteristics of feral horses, which exhibit a natural tendency to avoid unknown roughage, such as hay, even when presented to them in periods of drought (Hampson *et al.* 2011). In certain instances, bait delivery may alter normal behaviour, where animals associate bait with helicopters and avoid that particular form of roughage in the future (Kirkpatrick 2007). It is therefore important to integrate suitable bait systems that are enticing to horses and are likely to be actively consumed. An important consideration for the manufacturer of such a baiting system is that both the active agent and the oral bait itself are long lasting and capable of resisting exposure to fluctuations in temperature and humidity (Humphrys and Lapidge 2008). In this regard, it is anticipated that a large block would be more appropriate than pellets, because a block would expose less surface area to the environment and be more resistant to desiccation. In pilot studies in Australia, this bait structure has been successfully implemented as part of a pest management strategy for feral deer and goats (Hunt *et al.* 2014). Although results are promising, they dictate the contraceptive agent used in the bait will have to elicit a species specific, or at least species restricted, response to avoid unintentional effects on non-target domestic and native species. Consideration of the use of adjuvants will also need to be addressed, as will the possibility of being able to deliver a contraceptive that does not contain an adjuvant and thus eliminate adverse reactions (Kirkpatrick 2007). One further consideration is that the contraceptive agent is entirely consumed within the

target species and not prone to bioaccumulation, should the animal be collected at a later point and meat sold for pet consumption (Warren *et al.* 1993; Garrott 1995).

A non-surgical sterilisation method allowing lifelong coverage for feral horses would be incredibly valuable to industry stakeholders, but it must be ensured that the contraceptive agent is not passed from the animal in waste and does not taint agricultural land and water systems. The feasibility of any new management plan is also predicated on in-depth field studies into population demographics and distribution. There is still much to learn about feral horse ecology, which has been impeded by the remote habitats in which the feral horses typically reside (Zabek *et al.* 2014*b*). Traditional immunocontraceptive strategies have primarily focused on reducing female fertility, which is appropriate in the context of feral horse herd structure. However, the opportunity to impede the fertility of both sexes simultaneously is a feature that has not been offered previously, and poses the greatest opportunity for successful control (Dell'Omo and Palmery 2002). Such studies will likely be complemented by simulated modelling approaches to inform the level of contraceptive efficacy needed to achieve the desired reduction in horse numbers and the most suitable timing for introduction of the contraceptive into the population (Garrott 1995; Hone 1999; Hobbs *et al.* 2000; Ballou *et al.* 2008). Early work by Bomford and O'Brien (1997) highlighted the merits of implementing a non-surgical sterilisation method following periods of severe drought when feral horse numbers have declined and when the density of animals is likely to increase around watering holes. This was also suggested by Berman (1991) and the National Research Council (2013). Integrated feral horse management beginning with a population decline followed by intensive delivery of a non-surgical sterilant to both sexes is likely to prove the most successful in achieving milestones for feral horse control.

Contraceptive approaches are likely to continue to need public and political approval (Powers *et al.* 2014), a major obstacle that limits the application of current methods that rely on culling via aerial shooting (Nimmo and Miller 2007). It is likely that at the time of administration animals will be pregnant. Therefore, it is important to ensure contraceptives administered mid-gestation will cover females against future pregnancy, but not affect the health of the current foetus (Powers *et al.* 2011).

Feral horse population control is a long-term project, where integrated pest management strategies incorporating non-surgical sterilisation methods will require adequate funding and resource investment before a significant population reduction is seen. Previous contraceptive application in other species has been very costly, so it is important to develop new, cost-effective and sustainable technologies for implementation in population management strategies. Feral horse management is not a short-term issue and thus long-term solutions, such as non-surgical sterilisation, will likely have important roles in containing future population growth.

Conclusion

Current control methods for feral horses meet with considerable public criticism, which has provided the impetus to explore novel contraceptive strategies. Non-surgical methods of sterilisation offer an alternative and sustainable approach based on endocrine disruption of gamete development or immunological targeting of gamete interaction. Herein we provide a review of novel mechanisms designed to elicit a state of permanent sterility, including redox cycling to generate oxidative stress in the gonad, random peptide phage display to target non-renewable germ cells and generation of autoantibodies against proteins essential for conception via modification following aldehyde alkylation. Such approaches have shown considerable promise in a laboratory setting, but successful application in free-ranging, long-lived species such as the feral horse presents several unique obstacles. No single management strategy will be a panacea for feral horse control; management strategies will need to be revised frequently and incorporated together to achieve this long-term goal.

Simple Summary: There are various fertility control methods (modalities) currently available that aim to reduce the abundance of problematic free-ranging mammalian wildlife. Here, we propose that dissimilarities in the mechanism of action indicate these methods produce great variation in animal welfare outcomes. We present a framework to assist managers in minimising animal welfare risks.

Abstract: Investigation of fertility control techniques to reduce reproductive rates in wildlife populations has been the source of much research. Techniques targeting wildlife fertility have been diverse. Most research into fertility control methods has focused upon efficacy, with few studies rigorously assessing animal welfare beyond opportunistic anecdote. However, fertility control techniques represent several very different mechanisms of action (modalities), each with their own different animal welfare risks. We provide a review of the mechanisms of action for fertility control methods, and consider the role of manipulation of reproductive hormones ("endocrine suppression") for the long-term ability of animals to behave normally. We consider the potential welfare costs of animal manipulation techniques that are required to administer fertility treatments, including capture, restraint, surgery and drug delivery, and the requirement for repeated administration within the lifetime of an animal. We challenge the assumption that fertility control modalities generate similar and desirable animal welfare outcomes, and we argue that knowledge of reproductive physiology and behaviour should be more adeptly applied to wild animal management decisions. We encourage wildlife managers to carefully assess long-term behavioural risks, associated animal handling techniques, and the importance of positive welfare states when selecting fertility control methods as a means of population control.

Keywords: behaviour; capture; endocrinology; fertility; immunocontraception; physiology; reproduction; sterilization; welfare; wildlife

1. Introduction

Animal welfare has been steadily gaining importance and society now recognises it has an obligation to consider the welfare of all animals, including free-ranging species that are perceived to be overabundant or pests. As community and ethical opposition to the killing of animals has risen, especially for charismatic species (e.g., feral horses (*Equus caballus*); [1]), more focus has been devoted to non-lethal methods, particularly fertility control [2]. Fertility control methods have often been grouped together and described using terms such as "humane" [3–5], or "benign" [6,7]. These are not universal opinions though, as some authors have urged consideration of potential animal welfare impacts [8,9], including recognition that the welfare consequences of different methods may vary considerably [10].

Despite the importance of animal welfare, there are other aspects of fertility control methods that cannot be ignored. Efficacy will always need to be considered because if a method is chosen that has a reduced welfare impact on the individual, but does not achieve its animal management goals, then arguably doing nothing at all would have resulted in better animal welfare outcomes [11]. The overall welfare impacts of fertility control techniques should also be considered alongside the impacts of other control tools that may be considered as an alternative [12]. In any context, once an "optimal" decision has been made, it should not be blindly extrapolated to all species for all circumstances. With this in mind, there are large gaps in the published literature as most research has focused on the outcomes of fertility control programs in terms of reproductive output (its efficacy). Much less research has examined how each method induces decreased reproductive output, and at what cost to the animal. This evolution of research into wildlife fertility control methods appears to be tracking the same course that investigations into the use of lethal toxins for wildlife control followed, where efficacy studies preceded assessments of welfare impacts [13].

Aims of This Review

Once it has been decided that a fertility control program will be employed, there is considerable uncertainty when choosing a specific fertility control product or technique. Several authors have attempted to address the broad side-effects associated with fertility control of wildlife, including animal welfare impacts [9,14,15], but the relative risks of each fertility control method has so far escaped critical review. However, the American Zoo and Aquarium (AZA) Contraception Advisory Group has provided several articles examining the relative risks of fertility control modalities relevant to collection animals (e.g., [16]). Equivalent critical reviews have been performed for the manipulation of reproductive hormones in human medicine [17], highlighting that divergent properties of fertility control methods are related to dissimilarities in mechanisms of action, and ultimately produce variable clinical consequences.

This review attempts to demonstrate the differences between broad categories of fertility control techniques, with a view to facilitating future selection of practices. Fertility control has been applied to non-mammalian wildlife (such as birds; [18]) but this review will restrict its examination to mammalian

wildlife. The range of fertility control approaches used to manage mammalian wildlife is discussed, with a focus on mechanisms of action, the importance of maintaining natural behaviour and the need to assess all stages of animal manipulation involved in administering required treatments. We suggest principles to advance the scientific rigour behind the selection of fertility control techniques toward a "best practice" model to maximise animal welfare outcomes.

The central aim of this study is to specifically provide a framework for assessing animal welfare risks for various fertility control methods for mammalian wildlife. It cannot be disputed that efficacy and financial costs are important considerations when management decisions are being made, however, these issues have been thoroughly addressed by other reviews [2] and so will not be discussed in detail in this study. The aims of this study are not to compare fertility control with lethal methods, and not to assess side-effects of fertility control methods as a whole. This review explicitly examines animal welfare risks specific to each class of fertility control method and presents a framework for selecting fertility control methods that minimise animal welfare risks.

2. Fertility Control Methods Currently Used

A wide diversity of methods has been applied to wildlife fertility control over several decades. Table 1 lists the most commonly applied fertility control approaches in free-ranging mammals. Fertility control methods vary greatly in the mechanism of action of the treatment applied, as well as the administration method used to deliver them to animals (e.g., surgery *versus* remote injection or "darting"). Table 1 also illustrates that within individual species (e.g., white-tailed deer (*Odocoileus virginianus*)), multiple fertility control methods, representing several mechanisms of action, have been employed. These methods, and many more, have previously been reviewed in detail [2,15]. Several approaches to classifying the various fertility control methods have been suggested (e.g., physical *versus* chemical), but given the inextricable association between any method's mechanism of action and its effect, we argue that classification according to mechanism of action is the most logical approach.

2.1. Mechanisms of Action

Owing to the diversity of fertility control techniques currently available (Table 1; [2]), an appreciation of welfare impacts is not possible unless focus is first placed upon mechanisms of action. "Mechanistic" approaches have been central to rationalising and standardising the use of other wildlife management techniques. For example, rationalisation of a vast array of trade and colloquial names has been possible for toxins [13] and kill-traps [19] that are subjected to welfare assessment. All effects are produced by a mechanism of action, and dissimilarities in these processes in fertility control need to be understood to avoid misunderstanding [20]. For this reason we recommend the use of the term fertility control modalities to highlight the importance of considering how a method works and the long term welfare outcome at the individual animal level, rather than simply considering efficacy at a population level.

Table 1. Wildlife fertility control modalities that have been trialled, categorised according to their mechanism of action.

Class	Technique	Route	Description	Duration of Effect	Examples of Products	Sex Sterilized	Example Application	
							Species	Reference
Endocrine suppression	Castration (gonadectomy)	Surgical	Removal of testicles	Permanent	N/A	Male	Eastern grey kangaroos (*Macopus giganteus*)	[21]
	Ovariectomy/ovariohysterectomy (gonadectomy)	Surgical	Removal of ovaries +/− uterus	Permanent	N/A	Female	Brushtail possums (*Trichosurus vulpecula*)	[22]
	GnRH agonism	Implant	Binds to GnRH receptors	1–2 years	Deslorelin® Suplorelin®	Female Male	Tammar wallabies (*Macropud eugenii*)	[23,24]
	GnRH immunocontraception	Injection	Induced immunity to GnRH	>3 years	GonaCon®	Female Male	Wild boar (*Sus scrofa*)	[25]
	Synthetic testosterone	Injection	Suppressed spermatogenesis	Temporary	N/A	Male	Wild horses (*Equus caballus*)	[26]
	Synthetic progestins	Implant	Prevention of ovulation	3–5 years	Norplant®	Female	Koalas (*Phascolarctos cinereus*)	[27]
	Synthetic prostaglandin	Implant/biobullet	Pregnancy termination	Temporary	N/A	Female	White-tailed deer (*Odocoileus virginianus*)	[28]
	Synthetic oestrogen	Oral bait	Prevention of implantation	Temporary	N/A	Female	White-tailed deer (*O. virginianus*)	[29]
	Synthetic oestrogen	Implant	Prevention of implantation	Temporary	N/A	Female	White-tailed deer (*O. virginianus*)	[30]
Physical non-endocrine	Vasectomy	Surgical	Ligation of vas deferens	Permanent	N/A	Male	Eastern grey kangaroos (*M. giganteus*)	[21]
	Epididymectomy	Surgical	Removal of epididymis	Permanent	N/A	Male	Feral goats (*Capra hircus*)	[31]
	Tubal ligation	Surgical	Ligation of oviducts	Permanent	N/A	Female	White-tailed deer (*O. virginianus*)	[32]
	Oviduct "webbing"	Surgical	Removal of oviducts	Permanent	N/A	Female	Feral cattle (*Bos taurus*)	[33]
	Intra-testicular injection	Injection	Sclerosis of testicles	Permanent	Neutersol®	Male	American black bears (*Ursus americanus*)	[34]
	Intra-uterine devices	Implant	Endometrium irritation	Temporary	N/A	Female	Wild horses (*E. caballus*)	[35]
Chemical non-endocrine	Zona pellucida immunocontraception	Injection	Induced immunity to ovum proteins	>3 years	ZonaStat-H® SpayVac®	Female	Tule elk (*Cervus elaphus nannodes*)	[36]

2.2. Broad Classes of Fertility Control Modalities

In order to clarify the modalities for each fertility control agent, the following broad classes should be adopted: endocrine suppression methods, physical non-endocrine methods, and chemical non-endocrine methods (Table 1).

"Endocrine suppression" [37,38] (or endocrine disruption) methods alter the actions of naturally occurring reproductive hormones. Endocrine processes may be targeted centrally, depressing all reproductive hormonal activity (e.g., gonadotrophin-releasing-hormone (GnRH) agonists) or peripherally (e.g., progestin antagonists). Such is the complex nature of reproductive endocrine feedback processes that all supplementation, agonism, antagonism, or removal of endocrine hormones will ultimately lead to the suppression of natural reproductive hormone effects. Hence, we refer to all processes that affect reproductive hormones as inducing hormonal incompetence [39]. There are four main modalities in this category. Firstly, disruption can be achieved through the surgical removal of gonads (gonadectomy). Secondly, disruption can be achieved through the supply of exogenous (synthetic or externally derived) versions of naturally occurring reproductive hormones (*i.e.*, testosterone, oestrogen, progestins; Table 1) that interfere with normal feedback control and secretion of endogenous hormones. This method is commonly utilised in human contraception [17,40,41]. Thirdly, endocrine disruption can be achieved by agonism or antagonism of naturally occurring (endogenous) reproductive hormones (e.g., GnRH), via the administration of chemicals that actively compete with hormone binding sites. Finally, immunocontraception can be used to induce an autoimmune response through vaccination against naturally occurring reproductive hormones (e.g., GnRH).

Physical non-endocrine methods rely on physical (rather than chemical) means to disrupt the normal functioning of the reproductive system, and do not alter naturally occurring reproductive hormone levels. These methods encompass surgical techniques that *occlude* reproductive passages (but do not remove endocrine reproductive organs) or the use of implants that physically irritate the female reproductive tract (e.g., non-hormonal intrauterine devices; [35]). Surgical techniques that occlude reproductive passages but leave endocrine reproductive function intact include modalities that ligate (oviduct ligation, vasectomy) or remove (oviduct removal, epididymectomy) reproductive passages, but not gonads (Table 1). It is important to note that traditional surgical techniques used for fertility control in companion animals remove gonads ("gonadectomy"), including castration and ovariectomy/ovariohysterectomy (Table 1), and render reproductive hormone patterns nonfunctional [42,43]. We therefore classify these methods as inducing endocrine suppression despite their application through physical means (surgery).

Chemical non-endocrine methods rely on inducing an autoimmune response through vaccination against naturally occurring ovum proteins, most commonly the zona pellucida (ZP) [44], to prevent fertilisation of ova. This is achieved in the same way that a vaccine is used to mount an immune response against a pathogenic microbe (e.g., virus or bacterium) except that the immune response is being directed towards the animal's own ovum proteins. Once the animal's immune system disrupts the capacity for an ovum to be fertilised, affected females are rendered infertile irrespective of how many times they are mated by a male [44]. Similarities in the effects of physical and chemical non-endocrine modalities have been demonstrated by the use of physical occlusion surgeries to model the effect of ovum protein immunocontraception in epidemiological studies [45].

This first principles approach of classifying fertility control methods according to modalities should enable more meaningful comparisons and improved assessments of welfare risks at an individual animal level. This approach should also help to clarify some misconceptions arising from the oversimplification that has been used in the past to describe classes of methods (e.g., [46]). We therefore advocate a focus on modalities, rather than colloquialisms or trade names [47], when considering the implications for individual animals for any chosen treatment.

2.3. Best Practice Approaches

For some time, many contentious lethal (e.g., shooting, toxins) and non-lethal (e.g., marking) wildlife management methods have been closely scrutinised, with strong focus placed upon animal welfare impacts, rather than efficacy in isolation [19,48]. Quantitative assessment methods have allowed ranking of humaneness for many lethal wildlife control methods [12], in combination with the development of "best practice" approaches (e.g., [49]). In contrast, animal welfare assessment of fertility control methods has not been evaluated with the same level of scientific rigour and much uncertainty remains regarding animal welfare impacts [50]. As identified in reviews [9], most research into welfare risks has used qualitative, anecdotal evidence, and/or presented opportunistic, qualitative data lacking appropriate controls, sampling methodology or time scales. For these reasons, reviews have identified the assessment of welfare risks for fertility control as a research priority [9]. In the absence of quantitative humaneness assessment templates for fertility control modalities, "best practice" standards have not been developed and methods are still largely chosen on an *ad hoc* basis, and there remains much variability in how modalities are chosen and applied.

3. Animal Welfare Risks

It is proposed that any animal treatment can have short-term adverse effects on welfare (for example those caused by an injection) followed by long-term effects, which may be very different [51]. Both should be assessed. At the same time, modern approaches to animal welfare propose that avoiding negative welfare states (harms) should be considered in addition to the provision of opportunities for pleasurable experiences (such as social play, courtship or parenting [52,53]). This approach dictates that animals need positive experiences, in addition to minimised suffering [52,54]. Below we present a list of all of the animal welfare risks associated with fertility control, from administration (short term) to the response to treatment (long term) and include those imposing negative, and restricting positive welfare outcomes, respectively.

3.1. Short-Term (Administration) Negative Animal Welfare State Risks

3.1.1. Animal Capture, Restraint, Anaesthesia, Marking and Surgery

Most stages of wildlife management techniques that involve animal manipulation are likely to impose welfare costs. This is recognised for lethal wildlife control techniques, where animal welfare assessment frameworks require consideration of stages of animal manipulation prior to the killing method [12]. Some wildlife fertility control programs require animals to be captured and handled [55] or undergo anaesthesia and surgery [21] while other techniques allow animals to be darted (remotely treated)

in situ [56]. Classes of fertility control methods that currently require animal capture are shown in Table 2. These restraint procedures, required to administer a fertility treatment, may impose animal welfare costs that are in addition to the physiological and behavioural effects of the fertility control procedure or agent.

Table 2. Animal welfare risks from administration techniques used to implement common currently used fertility control modalities in mammalian wildlife. All potential stages of animal manipulation are shown to demonstrate techniques that require multiple stages of animal manipulation and those that do not.

Mechanism	Technique	Effect of Administration					
		Capture	Anaesthesia	Surgery	Remote Administration	Multiple Doses *	Frequency of Treatment
Chemical non-endocrine	ZP immunocontraception	−	−	−	+	±	3 years
Physical non-endocrine	Vasectomy	+	+	+	−	−	Permanent
	Tubal ligation	+	+	+	−	−	Permanent
Endocrine suppression	GnRH immunocontraception	−	−	−	+	−	3 years
	GnRH agonism	±	−	−	±	−	1–2 years
	Synthetic progestins	±	−	−	±		3–5 years
	Castration	+	+	+	−	−	Permanent
	Ovariohysterectomy	+	+	+	−	−	Permanent

* 2 doses are often required to ensure the efficacy of a single treatment; ± Can be administered via remote delivery or via capture, restraint and implantation.

In contrast, other fertility control programs have recognised the potential animal welfare costs of administration procedures and have chosen methods that allow for remote delivery of a single dose of an agent [57], effectively minimising stress other than that associated with potential darting injuries [58] or injection site reactions [59]. With the use of many modalities, for example, following remote drug delivery (darting) and surgical procedures, there is a requirement for visual marking of treated animals [60,61]. Marking in itself has been demonstrated to impose animal welfare impacts in many wildlife species [48].

3.1.2. Repeated Treatments

There are variations in the durations of action for different fertility control approaches. Some methods (e.g., surgical intervention) produce permanent infertility while some exogenous endocrine methods may affect fertility for less than one year (e.g., exogenous prostaglandins used to terminate pregnancy; [28]). Some chemical fertility control methods will require repeated administration every 1−2 years (e.g., GnRH agonists; [24]) or require booster administration 1−4 weeks after initial treatment (e.g., older ZP vaccines; [60]). All repeat treatments will impose additional animal welfare costs, as animals will need to be captured/injected several times. Some programs addressed the requirement for booster doses for older ZP vaccines by maintaining wild animals in captivity between injections, a process that can be highly stressful for free-ranging species [62]. For long-lived species (>5 years), multiple rounds of administration may be required to maintain infertility in treated animals [63]. An additional consideration is the aversion behaviour of wild animals after previous exposure to a stressful method.

For example, studies requiring animals to be re-darted [60] or re-trapped [64] have observed greater difficulty in re-administration of a treatment.

3.1.3. Injection or Implantation Site Local Inflammatory Reactions

Many remotely delivered immunocontraceptive modalities, being adjuvanted vaccines that rely on stimulating the immune system, have been shown to induce granulomatous inflammation at the site of injection [59,65]. Some studies have suggested that the welfare impact of such reactions is likely to be similar to the use of any adjuvanted vaccine. Likewise, many forms of chemical implants have demonstrated similar local inflammation effects associated with their administration [66]. The incidence of such adverse reactions, and their impact on welfare in free ranging species may be unknown, given the limited monitoring of many animals post-administration.

3.2. Long-Term (Treatment) Negative Welfare States Risks

3.2.1. Physiological Changes

Significant or prolonged physiological changes may be considered an animal welfare concern as they may alter an animal's ability to perform natural behaviour [67] and/or prevent adaptation to environmental challenges. Physiological responses may affect the animal directly, in terms of increased metabolic rate or redistribution of body reserves, or indirectly, in terms of loss of fitness, such as loss of appetite or decreased immunity [68]. All animals have the capacity to make behavioural changes in response to stimuli but marked physiological changes may restrict the capacity of animals to express the full range of natural behaviour [69]. Physiological changes have been demonstrated for several fertility control modalities, particularly those that derive their effect from endocrine suppression. Many studies on endocrine suppression methods have demonstrated weight gain in treated animals [25,27,70], but have considered the change to be positive or neutral, from a health perspective, without considering the effect of natural behaviour for a free-ranging species required to thermoregulate, forage, escape predators, compete with cohort animals or migrate. Immature male animals subjected to endocrine suppression generally do not grow as large as untreated males, as seen in white-tailed deer (*O. virginianus*; [71]) and tammar wallabies (*Macropus eugenii*; [66]). Endocrine suppression in immature male tammar wallabies (*M. eugenii*) also resulted in increased fat deposition [66]. Changes have also been demonstrated from endocrine suppression modalities to processes such as antler shedding in deer species [72]. Especially when endocrine suppression modalities are applied to juvenile animals, sex-specific phenotypes often fail to develop and male animals can become "feminized". This alteration in natural development means that these impacts are permanent [66,72]. Such altered physiology will likely reduce the capacity of such animals to express a full range of normal behaviour, and adapt to environmental changes.

3.2.2. Altered Behaviour

The importance of natural behaviour, and the ability of animals to experience positive welfare states, is a central tenet of modern animal welfare science [54]. Behavioural repertoires indicating satisfactory welfare should include the expression of normal patterns of maintenance and social behaviour, such as grooming, rest and play [52]. Deprivation of normal behaviour may compromise welfare by limiting

an animal's opportunities for positive experiences [52]. Changes in behaviour can be difficult to measure, but the importance of maintaining natural behaviour has been recognised for wildlife fertility control [73]. Of the few studies that have explicitly assessed behavioural changes in free-ranging wildlife (e.g., [74]), changes have been demonstrated to feeding, resting and dispersal behaviour.

For example, behavioural effects in free-ranging feral horses (*E. caballus*) subjected to endocrine suppression (GnRH immunocontraception) included observations that treated animals fed less, rested more, and travelled less [75]. Endocrine suppression in immature captive male tammar wallabies (*M. eugenii*) resulted in decreased agonistic (related to fighting) behaviour with intact males, lower dominance, and higher sexual interest from intact males [66]. Other behavioural changes are less predictable. For example, it has been demonstrated that male eastern grey kangaroos (*Macropus giganteus*) prefer to be associated with females that have not been subjected to endocrine suppression [76]. On the basis of such non-intuitive findings in an inherently complex field, we hypothesise that the real effect of altered social structures and disrupted social cohesiveness is not yet fully understood.

3.2.3. Extended Breeding Seasons

Beyond any welfare impact suffered by individual animals subjected to fertility control treatment, there are also often non-intuitive welfare costs to other animals of the same species, through social interactions. Specifically, fertility control modalities that prevent pregnancy occurring without preventing oestrus behaviour (physical non-endocrine and chemical non-endocrine methods) often induce a prolonged breeding season. This phenomenon has been observed for white-tailed deer (*O. virginianus*; [4,77,78]) and feral horses (*E. caballus*; [79]). The prolongation of natural breeding seasons can represent animal welfare risks for treated and untreated animals, specifically males. For example, the study of Ji *et al.* [80] demonstrates a pronounced impact on the body condition and welfare of male brushtail possums (*Trichosurus vulpecula*) with the extension of a breeding season through the presence of sterile, but hormonally competent, females. The average body condition of these males was significantly poorer than that of males in control areas. Similar effects have been observed in male deer [81]. It has been argued that extension of reproductive cycling may have important social consequences for feral horses (*E. caballus*; [79]) and African bush elephants (*Loxodonta africana*; [82]). In addition, increases in the cumulative number of mating attempts (social contacts) with non-endocrine modalities may increase infectious disease transmission risks [45].

3.3. Long-Term (Treatment) Positive Welfare States Risks

3.3.1. Deprivation of Parental Behaviour in Nurturing Species

Despite the central intended effects of fertility control agents in preventing the birth of offspring, and hence the opportunity for animals to express parental behaviour, the loss of this positive welfare state has not commonly been cited as a welfare concern for treated wildlife. In comparison, the welfare risks of deprivation of this natural behaviour have been recognised in zoo animals. The European Association of Zoos and Aquaria [83] stated: "limiting the opportunity to breed in species which display nurturing parental behaviour, by definition, reduces an individual animal's opportunity to express one of the most

important and complex sets of natural behaviour and can thus lead to a decrease in welfare". Contention surrounding the importance of this deprivation has been at the heart of many discussions of ethical practices in zoos worldwide [4,84,85].

The impact of this animal welfare risk is not easily demonstrated with empirical evidence. However, deprivation of freedom to express natural behaviour is universally considered an animal welfare concern [54] as it alters an animal's nature or "telos" [67]. Preventing such freedoms may affect animal wellbeing by reducing their ability to seek and gain pleasurable experiences and/or denying individuals the satisfaction of desires or preferences [86]. However, it must be noted that there are also welfare costs associated with reproduction, involving energetic costs and mortality risks that animals must trade-off with reproductive success [87]. Maternal behaviour in particular is complex, involving birth, nursing, and care of young. This loss of an important natural behavioural repertoire to many nurturing mammalian species warrants much greater discussion and consideration in the wildlife management sector.

3.3.2. Deprivation of Courtship and Mating Behaviour

Another positive welfare state that may be deprived of animals is the freedom to express natural reproductive behaviour, including courtship and mating. Endocrine suppression modalities often reduce or eliminate courtship and mating behaviour [81], through their mechanism of action targeting endocrine processes centrally, and depressing all reproductive hormonal activity [88]. For example, white tailed deer (*O. virginianus*) males subjected to an endocrine suppression modality (GnRH immunocontraception) display very few mating attempts with untreated (hormonally competent) females [78]. Courtship and mating behaviour are considered essential components of natural behaviour for many free-ranging mammal species and the deprivation of this natural behaviour must also be considered an important animal welfare impact, whether or not it is experienced as deprivation given the lack of reproductive hormonal stimulation for the behaviour to occur.

4. Fertility Control in Other Species

Many fertility control modalities currently applied in wildlife management were initially developed to meet the economic and emotional needs of owners of domesticated animals, such as companion or production animals. Some endocrine suppression modalities (e.g., GnRH immunocontraception) were developed for livestock species to intentionally alter physiology (to influence meat quality) and behaviour (to reduce aggression) to benefit production, rather than to prevent reproduction [89]. Fertility control of wildlife was initially performed as an extension of the practices used by veterinarians for domestic animal control and ownership, primarily gonadectomy [42,61]. However, gonadectomy is not a universally supported practice for companion animals, and the considerable welfare costs associated with the profound endocrine suppression it induces has seen its use considered unethical or even illegal in some countries (e.g., Sweden, Norway) [42,90]. The justification of the need for routine gonadectomy of companion animals is not uniform between countries, and these inconsistent views are based on value differences [42].

In livestock management, hormonally incompetent animals have been viewed as "modified" by many scientists, with concerns about the welfare of treated animals as well as human health from consuming treated animals [51]. Many studies of domestic animals subjected to endocrine suppression modalities

have demonstrated (often desired) physiological and behavioural changes, when observation methods have been intensive and long-term [89]. Despite the paucity of similar studies examining long-term changes in wildlife species, it would be naïve to assume that similar welfare costs would be unexpected in free-ranging animals that were similarly treated. It is worth considering if modalities that were originally considered humane in domestic animals should also be considered to be humane in wildlife.

5. Improving Assessment of Animal Welfare Risks

Animal welfare is complex and guidelines for how it should be assessed have evolved over time [91,92]. Modern approaches require that both negative and positive welfare states are considered [53], and that measures used to assess welfare states include both physiology ("health") and behavioural measures, as well as measures of mental state [93]. Fertility control studies have primarily focused on efficacy (reproductive output) in the short term but many studies have explicitly or opportunistically assessed health side-effects [9]. Few studies have assessed broader animal welfare impacts beyond short-term health effects, such as the impact on animal wellbeing when reproductive and social behaviour patterns are disrupted in response to altered physiology, or deprivation of positive welfare states.

5.1. Welfare Is More than Just Health

Although animal welfare is a complex entity, the Five Domains model was proposed over 20 years ago as a conceptual framework to simplify welfare considerations for research animals [94], but it has since been extended to incorporate positive welfare states [92]. The model proposes four physical/functional domains (nutrition, environment, health, and behaviour) and the fifth domain is mental state [94].

The majority of studies that have addressed animal welfare during fertility control programs have effectively restricted their assessments to domain 3 of the model; health, as typically only measures of injury rate, the presence of disease, and body condition have been examined [59]. The high frequency with which local reactions to chemical modalities at injection/insertion sites are described in the literature [9] suggest focus on this in the past has been disproportionally high given the low intensity and duration of suffering involved. However, it has been recognised for more than a decade that assessment of animal welfare must be based on a wide range of measures in addition to health indices [95]. Community debate about intensive livestock farming has demonstrated clearly the difference between concern for animal health and welfare. While intensively raised pigs and chickens demonstrate very high health outcomes (body condition, absence of parasitism *etc.*), their welfare is considered by a large majority of the general public to be severely impaired through impedance of natural behavior, and an absence of positive experiences, that is imposed by small, restrictive housing [69,96,97].

For the majority of wildlife fertility control studies, the length of time that any side-effects have been monitored for has been restricted to short time frames (*i.e.*, 2–3 years [55,77]). However, there have also been longer term studies performed [78]. The potential for, and occurrence of, long-term behavioural changes not detected by short-term studies, has been demonstrated for marine mammal marking techniques [48], and terrestrial chemical capture techniques (bear species; [98]). These studies have urged researchers to look beyond short-term health approaches for holistic assessment of welfare. While the "short-term health" approach is deemed appropriate for assessing lethal methods where death

is expected to be an acutely reached endpoint [19], it is less appropriate for non-lethal methods where duration of suffering may be chronic (years). Long-term welfare risks clearly exist for all fertility control modalities, but until evidence exists to the contrary it should be assumed that the magnitude of the impact of these effects on welfare could be significant.

5.2. Maintenance of Natural Behaviour in Free-Ranging Animals

Similar approaches have been used for fertility control in domestic and free-ranging animals, but there are important differences in society's perception of our duty of care for animals in each context. There is broad acceptance that the maximisation of health should be the focus of animal welfare for the keeping of companion animals [90], while the focus of stewardship for wildlife centres on the maintenance of natural behaviour. For this reason, practices such as supplementary feeding and veterinary treatment of wildlife populations have been consistently discouraged [99–101], For a discussion of the role of ethics in wildlife management decisions related to health and welfare, see the study of Rolston [102].

Many fertility control methods that do affect behaviour and physiology (e.g., altered fat deposition; [103]) for companion animals are considered acceptable (by some scientists [42]) because human owners take full responsibility for the care of these animals. Decreasing a companion animal's survival skills, such as the ability to hunt, survive adverse climatic conditions and defend itself against another competitor are deemed acceptable by society because humans can continue to provide food, shelter and protection for these animals. "Nuisance behaviour" in companion animals [104] such as fighting, roaming, territory marking, and oestrus calling, that are prevented or reduced by endocrine suppression, are all examples of natural behaviour essential for the welfare of free-ranging animals. This distinction between the behavioural needs of companion and free-ranging animals has not been adequately recognised by authors studying species that may exist in either state (e.g., feral/domestic cats (*F. catus*); [103,104]). We accept that the management of some free-ranging species blurs the line between domestic and wild animals (e.g., zoo animals; [84], or animals partially confined in fenced urban reserves; [21]). For these contexts, preservation of natural behaviour may be argued to be ethically less important if animals are not required to escape predation, or extensively forage. This consideration is particularly important given that many studies attempting to assess welfare impacts of fertility control modalities have provided *ad libitum* access to resources (water and feed) for study animals [105,106]. In some contexts where animals are not considered clearly domestic *or* wild (e.g., "street dogs" [42,61]), some management programs have explicitly aimed to modify natural behaviour when it creates conflict with human values (e.g., aggression leading to attacks on humans [61]).

The same logic should not apply for all wild animals, as the duty of care provided by humans often ends for managed wildlife at the point of release from restraint or administration of treatment (e.g., [107]). For this reason in feral horse (*E. caballus*) fertility control, approaches that impact upon androgenic (male) behaviour [26] are no longer considered humane or appropriate. In another context, it has been argued that the only fertility control options that should be considered for coyotes (*Canis latrans*) should be those that allow the animals to remain hormonally competent, such is the importance of the endocrine system for the maintenance of natural behaviour [108]. We argue that the preservation of hormonal competence is important to maximise the welfare of wild animals, due

to the profound effects of endocrine suppression on important behaviour such as mating, aggression and dominance.

6. Case Studies

To illustrate the dissimilarities in approaches that have been taken to fertility control in different species and jurisdictions, we present two case studies. The first describes refinement of modalities used for feral horses (*E. caballus*) in North America and the second describes the relative lack of refinement in modalities considered suitable for Eastern grey kangaroos (*M. giganteus*) in Australia.

6.1. Case Study: Feral Horses (E. caballus) in North America

Fertility control modalities for feral horses have been investigated for several decades in the USA [26,109]. While a range of modalities were used in the past (e.g., exogenous testosterone; [26], intrauterine devices; [35]; Table 1), more recently, remotely delivered GnRH immunocontraception [110] and particularly ZP immunocontraception [62,74,79,111], have become the focus. Importantly, it was recognised decades ago that the short-term welfare risks associated with immobilisation and capture necessitated that fertility control modalities were administered remotely [56]. Immunocontraception vaccines may be administered via remote delivery, removing the need for capture, anaesthesia or surgery, but the requirement for booster administration with older ZP vaccines led some authors to maintain horses in captivity between treatments [62]. However, ZP vaccines also often lead to extended breeding seasons, and therefore there are accompanying increased energetic costs and injury risks from increased mating attempts [112]. The focus on ZP immunocontraception developed from a formal process initiated by the Bureau of Land Management (BLM) [111] in the USA to identify the most humane and practical fertility manipulation options. This departure from *ad hoc* trials of many different methods has seen progress towards adoption of "best practice" methods.

6.2. Case Study: Eastern Grey Kangaroos (M. giganteus) in Australia

Many different fertility control modalities have been trialed for easily captured eastern grey kangaroos in Australia [20]. The fertility control modalities that have been applied to kangaroos and their accompanying welfare risks have recently been reviewed [113]. Much recent research has focused on the use of a range of endocrine suppression modalities. GnRH agonists [24,105], and synthetic progestins [20,63,114], have been the subject of several studies. Chemical non-endocrine (ZP immunocontraception; [115]) and physical non-endocrine (vasectomy; [21]) modalities have also been investigated less frequently. However, eastern grey kangaroos are still managed with physical endocrine suppression modalities (castration; [21]) that are rarely applied to other wildlife species. In addition, modalities that have been delivered via remote injection in other contexts (e.g., GnRH agonists; [116]) are often delivered to eastern grey kangaroos as implants, following capture, restraint and anaesthesia ([105]). There have been no formal attempts to standardise modalities (but see [113]), and no apparent progress toward development of "best practice" guidelines for kangaroo fertility control in Australia, and so *ad hoc* methods continue to be used without careful consideration of animal welfare impacts.

The management of Australian eastern grey kangaroos contrasts strongly with the management of American feral horses. In the USA, management goals have included minimising animal welfare impacts of fertility control on wildlife, particularly feral horses [4], by using methods that only rely on darting animals. In Australia, marsupials are still regularly caught, and subjected to anaesthesia and surgery to administer fertility control treatments that, when compared to ZP immunocontraception, have greater effects on their natural behaviour and physiology [21,63,66]. In Australia, similar modalities have not only been used in several kangaroo species [24], but also wallaby species [66,117] and koalas (*Phascolarctos cinereus*) [27,115,118].

These case studies have shown the different approaches taken towards fertility control in two wildlife contexts and highlight the need for increased consideration for the welfare risks of current practices. For this reason, we propose a framework to better enable researchers and managers to understand the animal welfare risks of any fertility control modality and to improve the balance between meeting animal interests with management needs.

7. Suggested Future Improvements

Given the several decades over which wildlife fertility control research has been performed, we contend that sufficient information exists to move from a *carte blanche* approach towards a "best practice" approach for refining methods to minimise animal welfare impacts. It is our contention that methods that induce endocrine suppression, and requiring repeated or multi-stage interventions, are likely to represent poorer animal welfare outcomes than those methods that do not (Table 3). We suggest where duration is similar, the modality inducing the least changes to natural behaviour and physiology will pose the least welfare risk. Likewise for administration risks, the total welfare risk should be considered as the cumulative total of the invasiveness of the procedure, and the duration and frequency of the procedure. For this reason, we propose that welfare risks associated with long-term treatment effects are considered a higher welfare priority than short-term administration risks.

We contend that the deprivation of parental behaviour is an unavoidable welfare cost common to all fertility control modalities. Beyond this cost, several studies have identified that the modalities that minimise welfare risks prevent pregnancy but do not disrupt endocrine function, thus ensuring that reproductive/social behaviour changes are minimised [39,79]. However, with the availability and marketing of modalities that induce endocrine suppression but have appealing ease of administration benefits (e.g., GonaCon™), many researchers have opted to induce endocrine suppression in treated animals despite the existence of alternative modalities that do not (e.g., ZP immunocontraception). We recognise that GnRH vaccines offer increased efficacy and convenience through their effectiveness against both sexes, single injection administration, and lack of extended breeding seasons. However, these efficacy advantages should be balanced against clearly increased welfare costs for a method that causes changes to natural behaviour and physiology [89].

Table 3. Suggested principles for assessing cumulative animal welfare impacts for wildlife fertility control modalities. Methods are listed from top (least animal welfare impact) to bottom (most impact). For example, administration methods requiring capture, anaesthesia, and surgery are given a +++ rating. ZP = zona pellucida. GnRH = gonadotrophin releasing hormone.

Mechanism	Technique	Impact of Treatment	Impact of Administration
Chemical non-endocrine	ZP immunocontraception	+	+
Physical non-endocrine	Vasectomy	+	+++
	Tubal ligation	+	+++
Endocrine suppression	Synthetic progestins	++	++
	GnRH agonism	++	++
	GnRH immunocontraception	+++	+
	Gonadectomy	+++	+++

We suggest that methods requiring capture, anaesthesia, and/or surgery, or frequently repeated administration (in long-lived species) represent poorer animal welfare outcomes when compared to remotely deliverable methods (Table 3). Given the above animal welfare risks associated with treatment (long-term) and administration (short-term), we contend that remotely deliverable non-endocrine vaccines (*i.e.*, ZP immunocontraception) are likely to be the most humane fertility manipulation methods currently available (Table 3). While welfare impacts are high for administration of physical non-endocrine modalities (vasectomy, tubal ligation), repeated treatments are not required and hormonal competence is maintained. For all non-endocrine modalities, important positive welfare states (courtship, mating) are maintained. However, the effects of extended breeding season associated with all non-endocrine modalities suggests that species specific traits need to be considered to avoid welfare impacts relating to large increases in mating attempts (e.g., [80]) or the birth of offspring in non-favourable seasons [78].

On the same mechanistic basis, we contend that gonadectomy represents the least humane of the currently available fertility control technique for wildlife. Gonadectomy requires capture, often major (abdominal) surgery, anaesthesia, and induces complete and irreversible reproductive endocrine suppression, and accompanying permanent changes in natural behaviour and physiology [42,90]. We suggest that the welfare impacts associated with gonadectomy render it appropriate only for domestic animals where a human duty of care is provided, and where behavioural changes are desired (e.g., [119]). GnRH immunocontraception and agonism both induce partial suppression of hypothalamic-pituitary-gonadal axis function [106], but the effects are not as profound as those of gonadectomy. GnRH immunocontraception is likely to pose the lowest welfare risks of all endocrine suppression modalities due to its' favourable administration method (Table 3). GnRH agonism and exogenous progestin modalities both induce endocrine suppression and require repeated administration (sometimes via remote delivery but often requiring capture), but not major surgery (Table 3). However, there has been progress toward developing remote delivery systems for both progestin implants [56] and GnRH agonists [116], reducing the short-term welfare risks associated with their administration.

Suggested Principles for Selection of Fertility Control Methods

In an attempt to improve the present approach to the choice of fertility approaches, some authors have suggested the use of formal criteria for the selection of methods that are appropriate for field applications [2]. While we support the criteria approach of Massei and Cowan [2] for assessing efficacy, we suggest that more holistic scientific rigour should be applied to assessing welfare impacts. We present Table 3 as a framework for assessing the welfare pros and cons of commonly used modalities. The challenging nature of making welfare decisions does not justify averting from the central tenets of scientific logic: observation, hypothesis and experiment. Many decisions on the choice of fertility control modalities have been *carte blanche* and this represents the antithesis of scientific reasoning. We have attempted to address the short-term and long-term animal welfare risks, as per Broom [51], in a framework using a weighting approach (as per Dubois and Fraser [101]). Table 3 summarises the parameters that we consider most important for selecting control methods, and we suggest the following principles for selecting the most humane fertility control methods for wildlife populations:

(1) It should be recognised that all fertility control methods impose animal welfare impacts. The deprivation of the opportunity to display parental behaviour in nurturing species is an animal welfare impact,
(2) Methods should be chosen that pose the lowest cumulative animal welfare cost, including capture, administration and frequency of treatment,
(3) All domains of animal welfare should be considered, including behaviour and the opportunity for animals to have positive experiences,
(4) Methods that maintain hormonal competence, thus promoting natural behaviour, should be chosen over methods that induce endocrine suppression, and
(5) Where uncertainty exists regarding welfare impacts, fertility control modalities should not necessarily be chosen over alternative lethal or non-lethal methods.

Any decisions regarding wildlife management will involve seeking a balance between the interests of the wildlife and other stakeholders. The suggested use of our framework in ethical decision-making has some unavoidable subjectivity relating to the difficulty in comparing various types of risks (e.g., long duration-low intensity welfare impacts with short duration-high intensity welfare impacts), which value-based ranking systems (e.g., [12]) may address. However, we contend that the proposed weighting approach will be more informative for wildlife managers than a list of comparative features without commentary. In addition, the weighting approach has been widely applied for welfare studies lacking comprehensive empirical evidence of all aspects (e.g., [101]).We present this framework as a provocation to wildlife researchers and wildlife managers to improve the rigour with which they assess management options, and to broaden their understanding of animal welfare.

We recognise that the range of species and contexts for which wildlife fertility control is desired makes the proposal of a single preferred method impossible [40]. We accept that efficacy, economic costs, ecological side-effects, and other factors are also important considerations for fertility control programs [2]. We present this framework to help with objective assessment of animal welfare, and to aid managers in achieving balance when weighing welfare impacts against other management considerations. It is an accepted reality that methods representing optimal animal welfare outcomes

may not be appropriate for all management contexts. We contend that understanding the complexities of both reproductive physiology and animal welfare science should be improved in wildlife management. Claims that fertility control modalities pose "no undesirable physiological or behavioural side-effects" from limited observations [105] are unrealistic and display a poor understanding of animal welfare. Likewise, the lack of consideration for the importance of depriving animals of positive experiences when comparing fertility control to other management options requires re-consideration. The lack of standardisation of wildlife fertility control modalities in many contexts is indicative of the enduring misconception that non-lethal reproductive manipulation is synonymous with benign outcomes. We contend that wildlife fertility control should not always be assumed to be humane.

8. Conclusions

Efforts to apply fertility control to wildlife have now been performed for over 30 years but there has been little standardisation of procedures over this time. Research into this area has primarily focused on the important aspect of efficacy but this has meant that the associated impacts on animal welfare have only seldom been addressed. Consequently, there is a growing need for more meaningful interchange between animal welfare scientists, wildlife biologists and wildlife managers [120]. Understanding the mechanisms of fertility control modalities and the resultant impacts on natural behaviour are important and have been under-appreciated. Broader understanding of modern animal welfare science and the importance of positive welfare indicators are required for wildlife managers. We contend that endocrine suppression in free-ranging animals is an undesirable outcome because of its long-lasting alterations to natural behaviour and physiology. Not all fertility control modalities induce endocrine suppression and these methods that do not should be treated preferentially. Likewise, administration methods that require capture, surgery, or frequently repeated treatment are similarly undesirable. Animal welfare impacts should be recognised and carefully balanced against existing management goals to ensure continuous improvement in wildlife fertility control methods.

Author Contributions

Jordan Hampton and Teresa Collins were largely responsible for the generating of ideas and writing of the manuscript. Tim Hyndman and Anne Barnes provided input and associated literature on specific topics, and reviewed the manuscript.

Conflicts of Interest

The authors declare no conflict of interest.

Abstract: Most wildlife contraceptive studies to date have evaluated treatment efficacy on individuals, but little research has evaluated the potential behavioral effects associated with inhibiting conception in polyestrous species. During autumn 1993 and 1994, we compared the behavior of 10 free-ranging, radiocollared cow elk (*Cervus elaphus*) vaccinated with porcine zona pellucida (PZP) immunocontraceptive vaccine with 10 unvaccinated cow elk. We tested the hypothesis that breeding behavior would be prolonged in PZP-treated cows due to repeated estrus cycling. Sexual interaction rates of treatment and control cows were similar during the normal breeding season ($P = 0.96$) but differed significantly during the postbreeding season ($P < 0.001$), when almost no sexual interactions were observed in control cows. Postbreeding season interaction rates in treated cows remained at the level observed during the breeding season. We did not detect any significant changes in activity patterns or social structure of the elk during the postbreeding season as a consequence of the apparent PZP-induced cycling ($P > 0.50$). It is uncertain whether the results of this study apply to possible effects of PZP treatment for management-level applications where a large proportion of the females would be treated. We recommend population-level experiments to further our understanding of the effects of contraceptive technologies on the behavior and dynamics of free-ranging ungulate herds.

JOURNAL OF WILDLIFE MANAGEMENT 62(1):243–250

Key words: breeding, *Cervus elaphus*, estrus, immunocontraception, porcine zona pellucida, PZP, reproduction, Washington.

The manipulation of reproduction in ungulates has been explored by biologists and physiologists for nearly 30 years (Kirkpatrick and Turner 1985). Several female-oriented contraceptive technologies have potential applications to ungulate populations; however, most recent investigations have focused on immunocontraception by zona pellucida (ZP) vaccines (Liu et al. 1989, Kirkpatrick et al. 1990, Turner et al. 1992). Immunocontraception attempts to stimulate the target animal's immune system to interfere with some critical reproductive event (Glass and Hanson 1974). In the case of ZP vaccines, the immunological response prevents the sperm from penetrating the acellular glycoprotein layer surrounding the mammalian oocyte (zona pellucida), thus blocking fertilization (Sacco et al. 1984, Liu et al. 1989). Porcine ZP vaccine has proven an effective contraceptive for a variety of ungulates, including feral horses (*Equus caballus*), Przewalski's horses (*E. przewalski*), sika deer (*Cervus nippon*), sambar deer (*C. unicolor*), axis deer (*C. axis*), and white-tailed deer (*Odocoileus virginianus*; Kirkpatrick and Turner 1991). The vaccine also has been tested on captive North American elk, inhibiting reproduction in 7 of 8 treated cows (Kirkpatrick et al. 1996). Although numerous studies have evaluated the efficacy of contraceptive technologies on individual captive or free-ranging animals, little attention has been given to behavioral changes potentially caused by reproductive inhibition (Garrott 1995). Because ZP vaccines block fertilization, treated females may continue estrous cycles beyond the normal breeding season, which normally concludes once most females have been fertilized (Morrison 1960, Guinness et al. 1971). If the breeding season is extended in this manner for elk, the normal postbreeding activity budgets of both cows and bulls may be affected because of prolonged rutting activities, which, in turn, could have energetic and demographic consequences (Flook 1970).

We performed an experiment in a free-rang-

ing population to investigate the potential behavioral consequences of blocking conception in elk. Our objectives were as follows: (1) to determine if blocking conception through immunocontraception would result in extending sexual interactions beyond the normal breeding season, and (2) to determine if normal activity budgets were affected if prolonged breeding behavior was detected.

STUDY AREA

Our study was conducted on and near the 330-km^2 Fitzner-Eberhardt Arid Lands Ecology (ALE) Reserve located in southcentral Washington (46°23′N, 119°32′W). The study area is classified as interior cold desert, with arid, hot summers and moderately cold winters. The ALE Reserve is a remnant of the shrub–steppe ecosystem (Daubenmire 1970) and is dominated by big sagebrush (*Artemesia tridentata*) with an understory of bluebunch wheatgrass (*Pseudoregnaria spicata*) or Sandberg's bluegrass (*Poa sandbergii*). Detailed descriptions of the study area are provided by Rogers and Rickard (1988) and Hinds and Rogers (1991).

The elk population inhabiting the Reserve was apparently established during winter 1972 by natural colonization (Rickard et al. 1977). The herd is nonmigratory and isolated from the nearest elk population by over 80 km. The rate of increase displayed by the population is among the highest recorded for the species (McCorquodale et al. 1988, Eberhardt et al. 1996). Aerial counts of the population increased from 190 to 257 animals during this study.

METHODS

Treatment and Observation

In March 1993, we immobilized 20 cow elk by darting from helicopters with 3.5 mg of Carfentanil citrate (Wildlife Pharmaceuticals, Fort Collins, Colorado, USA). Target animals were randomly selected from elk groups encountered. One upper canine was extracted for aging via cementum annuli, and pregnancy status was determined by rectal palpation (Greer and Hawkins 1967). We reversed the effect of the immobilizing drug with 325 mg of naltrexone Hcl (Wildlife Pharmaceuticals, Fort Collins, Colorado, USA). Prior to immobilization, we performed a Bernoulli trial to determine if each consecutively captured cow received a PZP vaccine or would serve as a control. We continued this random draw until 10 animals were assigned to the vaccination group or the control group, with the balance of the 20 captured animals assigned to the remaining treatment. The PZP vaccine was prepared from porcine ovaries as described by Liu et al. (1989) and stored at −5°C until used in the field. The inoculation was prepared as an emulsion of 0.5 cc vaccine (equivalent to approximately 5,000 zonae or 64.3 μg of protein) in phosphate buffer and 0.5 cc of Freund's Complete Adjuvant. We mixed the 2 vaccine components in the field using 100 plunger strokes of 2 5-cc glass syringes joined with a double-hubbed needle. The emulsified vaccine-adjuvant mix was then administered to treatment elk via intramuscular injection in the rear leg (Liu et al. 1989). We fitted white butyl radiocollars with distinct symbols on treatment animals and placed similar yellow collars on control animals.

We planned to administer an initial dose of PZP vaccine to treatment animals and a placebo containing only adjuvant to control animals at the time elk were immobilized for radiocollaring. However, our adjuvant supply was depleted after inoculating 5 treatment and 5 control cows; hence, the remaining 10 cow elk were marked with the appropriate radiocollars and released. We later discovered that the glass syringes were manufactured poorly, which allowed fluid to leak behind the plunger. This leakage caused larger volumes to be drawn into the syringes than indicated by the graduations, which depleted our adjuvant supply prematurely and possibly reduced the amount of vaccine administered to each animal by an unknown amount; the problem was rectified for all subsequent treatments. In August 1993, we remotely treated the 10 designated treatment animals with PZP vaccine administered via darting from helicopters. The 5 cows initially treated in March received a booster vaccination of 0.5 mL of PZP 5000 and Freund's Incomplete Adjuvant, and the remaining 5 treatment cows received an initial dose of PZP 5000 and Freund's Complete Adjuvant. In August 1994, all 10 treatment cows were administered booster vaccinations via darting from helicopters. We attempted to evaluate the calving status of all experimental animals during 1994 and 1995 by relocating each elk weekly during June and July; however, animals occupying private agricultural lands adjacent to the ALE Reserve were inaccessible. We used nursing and social grooming

as indicators that a calf was the offspring of a radiocollared cow.

We collected behavior data from all radiocollared elk from September through late November 1993 and 1994. After this time, cow–calf associations became difficult to determine because of their aggregation into larger winter herds (McCorquodale 1987). We attempted to sample the behavior of each cow twice weekly. The order and frequency with which animals were sampled was determined via a restricted randomization design, which attempted to balance observations as much as possible among all experimental animals throughout the field season.

Once a breeding group containing the desired instrumented animal(s) was located via radiotelemetry, the observer, depending on environmental conditions and available cover, attempted to approach the group undetected to within 150–1,000 m. We conducted observations with the aid of a 15–60-× spotting scope and a field computer. Three types of data were collected during each observation session: breeding group attributes, focal animal behavior records, and an all-occurrences log of predefined, stereotyped behavioral events. We began a new observation session if any new animals moved into the social group; thus, the duration of watching a group may be longer than an individual observation session. We terminated <10% of the observation sessions because of animal disturbance by the observer.

We used focal animal sampling with an instantaneous recording method to sample activity states of all experimental animals in a breeding group at 2-min intervals (Altmann 1974, Martin and Bateson 1986). Four behavior states were identified. Elk were classified as feeding when standing with head lowered into the vegetation. Idling was recorded when an elk was upright and not feeding, or in a prone position. Moving was recorded when a female was actively locomoting, and not visible was recorded when an elk was not visible to the observer.

The observer temporarily interrupted focal animal sampling and immediately recorded into the all-occurrences log any predefined sexual interactions between a bull and experimental cow (Altmann 1974). We considered 2 behavioral events as sexual interactions: sniff–lick (Clutton-Brock et al. 1982) and mounting. A sniff–lick event was recorded when a bull muzzled or licked the perineum region of a cow or smelled fresh cow urine in the specific area where a cow was previously bedded or had just urinated. We recorded mountings as described by Struhsaker (1967).

Statistical Analyses

Because the PZP vaccine blocks fertilization, we expected treated females to cycle beyond the normal breeding season. We tested 2 null hypotheses: (1) there would be no difference in the rate of sexual interactions displayed by treatment and control cows following the normal breeding season, and (2) there would be no difference between treatment and control cows in the proportions of activity states following the normal breeding season. We assumed there would be no difference in sexual interaction rates or activity patterns during the normal breeding season between treatment and control cows; however, we tested these assumptions as secondary hypotheses.

To test hypotheses, we categorized the observation sessions as occurring during either the normal breeding period or the postbreeding period. These periods were defined by evaluating temporal patterns in the rate of bull sexual searches toward control cows. The onset of sexual interactions toward control cows established the start of the normal breeding season; we subjectively defined the end of the normal breeding season based on a decline of interactions.

We could not consistently identify individual experimental animals during observation sessions because of obstruction or distortion of collar markings by heat waves, vegetation, and other animals. The white-and-yellow collars of treatment and control animals, however, could always be distinguished, and thus provided reliable discrimination of the 2 groups. Thus, our experimental unit for analyses was the subgroup of treated or control cows in each breeding group observed. To test if blocking conception through immunocontraception resulted in extended breeding behaviors, we calculated sexual interaction rates as acts per animal per hour for both treated and control cow subgroups. We used activity–state proportions to test whether PZP treatment affected normal activity budgets. To test these hypotheses, we selected an appropriate data model and adjusted means by the principle of least squares (SAS Institute 1982). To test our specific hypotheses, we used pairwise comparisons of adjusted means for treatment and control cows during the normal and

This content downloaded from 159.189.162.80 on Thu, 27 Apr 2017 15:45:49 UTC
All use subject to http://about.jstor.org/terms

postbreeding periods (SAS Institute 1982). We transformed the response variable to natural logs if residual plots indicated a problem with homogeneity of variance.

Because our sampling unit was the observation session of a breeding group, the continuous covariates of breeding group composition (number of cows and adult bulls, number of treatment and control cows), total group size, and the categorical covariate of time of day (morning, 0500–1030; midday, 1031–1500; late day, 1500–2000) may have affected each of the 4 response variables measured. Exploratory model building was used to determine if any of these potential covariates were significant. We determined significant covariates for each of the 4 data models by performing a backwards elimination of covariates from saturated models with P-values < 0.05. Once significant covariates for each of the models were determined, we initiated hypothesis testing by using a regression approach with the main effects of treatment condition, breeding period, and year included in the data model, as well as the covariates that were significant in each model. We included year as a main effect because differences in vaccine treatments between years potentially resulted in differences in contraceptive efficacy, and hence behavioral responses. We included all possible 2- and 3-way interaction terms that included the main effects. To test our hypotheses, we used the adjusted means of the treatment × period interaction term and performed pairwise comparison on these adjusted means with a P-value < 0.05 considered as significantly different.

If both treated and control subgroups were present in the same observation session, we used both response rates with the attribute data for that session. Thus, our observations are not strictly independent. To help protect against Type I or Type II errors, we also performed analyses of the difference in rates on the subset of data where both control and treatment animals were present during the same observation sessions. This has the advantage of reducing the variation from individual experimental units and provided confirmation of conclusions derived from the analysis of the entire dataset (Johnson and Bhattacharyya 1987).

RESULTS

Experimental cows ranged in age from 1 to 14 years ($\bar{x}$ = 4.17, SD = 3.35), and 19 of the 20 cows were determined pregnant at capture. One control animal, aged 14, was found dead 2 weeks after radiocollaring, apparently because of complications from the immobilizing drugs. One treatment and 1 control cow were harvested during the 1994 hunting season. Following the 1993 treatment, 20% (1 of 5) of the cows that received the 2-dose treatment and 60% (3 of 5) of the cows that received the 1-dose treatment were observed with a calf, compared with 33% (2 of 6) of control cows being observed with a calf. Following the 1994 treatment, 0% (n = 9) of the treated cows were observed with a calf, compared to 100% (n = 7) of the control cows being observed with a calf.

We analyzed 81 observation sessions during 1993 that included 123 animal-hours (1 animal observed for 1 hr) of observation on treatment animals and 65 on control animals. In 1994, we performed 58 observation sessions including 60 animal-hours of observation on treatment animals and 33 animal-hours on control animals. During the study, the length of observation sessions ranged from 0.13 to 1.12 hr ($\bar{x}$ = 0.59, SD = 0.23). Total group size ranged from 2 to 136 animals ($\bar{x}$ = 29.4, SD = 24.0), with a range of 1–23 adult bulls ($\bar{x}$ = 3.7, SD = 4.1) and 1–61 cows ($\bar{x}$ = 15.2, SD = 11.4). The number of treated cows in an observation session ranged from 0 to 7 ($\bar{x}$ = 2.2, SD = 1.3), and the number of control cows ranged from 0 to 6 ($\bar{x}$ = 1.1, SD = 1.0). There were 86 observation sessions where both treatment and control cows were present in a social group, 38 observation sessions with only treatment cows present, and 15 observations sessions with only control cows present. We observed the first sexual interaction in both years on September 17 and a marked decline in sexual interactions of control cows by October 13. Thus, observation sessions occurring during this period were considered "breeding period" sessions, whereas later sessions were categorized as "postbreeding period" observations.

To test our primary hypothesis, we used sexual interaction rate as the response variable; the response variable was transformed because the untransformed data did not meet the assumption of homogeneity of variance as indicated by residual plots. We detected no difference in rate of sexual interaction between years ($F_{1,220}$ = 0.31, P = 0.53); so, data from both years were pooled. Number of control cows present was a significant covariate ($F_{1,220}$ = 5.79, P = 0.02),

Table 1. Pairwise comparison of sexual interaction rates (events per hr observation) and proportion of time spent in various actives for PZP-treated and control cow elk during the breeding (17 Sep–13 Oct) and postbreeding season (14 Oct–28 Nov), 1993 and 1994. Values are adjusted means with standard errors reported in parentheses (SAS Institute 1982).

Behavior	Season breeding		Postbreeding season	
	Control	PZP-treated	Control	PZP-treated
Sexual interaction rate	0.58 (0.06)	0.57 (0.06)	0.01[a] (0.07)	0.57 (0.07)
Proportion time feeding	0.40 (0.03)	0.42 (0.03)	0.34 (0.04)	0.36 (0.04)
Proportion time idling	0.47 (0.03)	0.48 (0.03)	0.49 (0.04)	0.47 (0.04)
Proportion time moving	0.11 (0.02)	0.08 (0.02)	0.14 (0.02)	0.13 (0.02)

[a] Significant difference (t-test, $P \leq 0.05$). All other tests were not significant ($P > 0.05$).

and there was a treatment × period interaction for adjusted means of the transformed sexual interaction rate ($F_{1,220} = 19.00$, $P < 0.001$). During the normal breeding period, there was no difference in the frequency of sexual interactions of treatment and control cows (t-test, $P = 0.96$); however, during the postbreeding period, sexual interaction rates for treatment cows were different than control cows (t-test, $P < 0.001$; Table 1). The postbreeding interaction rate for treated cows was similar to the rates observed for both experimental groups during the breeding season. We obtained similar results using only the subset of observation sessions where both treatment and control cows were present in the observed group.

The residual plots for all 3 activity category models (feeding, idling, moving) indicated constant variance on the error term; hence, these data were not transformed. Year was not an influential covariate for any of the models; thus, data from both years were pooled. The only significant covariate detected in the feeding model was time of day ($F_{1,219} = 44.51$, $P < 0.001$). There was no treatment × period interaction for adjusted means of proportion of time spent feeding, idling, or moving ($F_{1,215-219} = 0.01–0.26$, $Ps = 0.60–0.91$). There were no differences in the proportion of time treatment and control cows spent feeding, idling, or moving during either the breeding (t-tests: $Ps = 0.28–0.85$) or postbreeding season (t-tests: $Ps = 0.64–0.73$).

DISCUSSION

This study was not designed to test the contraceptive efficacy of PZP vaccine; from the results of a study with captive animals (Kirkpatrick et al. 1996), we assumed that the treatment would block conception. Failure to detect any calves associated with treated cows in the second year of the study, while all control cows calved, suggests high contraceptive efficacy, although sample sizes are too small to warrant either statistical tests or strong conclusions. We attribute the relatively high proportion of treated cows associated with a calf in spring 1993 to the problem of the syringe leakage of the adjuvant-vaccine emulsion beyond the plunger during the initial year of treatment. Because we did not detect differences in the measured behavioral parameters between years, and because PZP-treated cows during the initial year of the study continued sexual interaction rates during the postbreeding season that were comparable to breeding season rates, the data strongly suggest the vaccination treatment the first year was indeed effective for at least the first 1–2 estrus cycles. This interpretation is supported by results of a recently completed study of antibody response of PZP-treated captive elk that indicates the elk immune system is particularly sensitive to challenge with the PZP vaccine; antibody responses are essentially maximal from a single injection (R. A. Garrott, unpublished data). Although most elk in the field experiment probably received less than the planned dose of PZP-adjuvant per injection during the first year of the study, all animals received 2 injections (1 in March when they were first radiocollared and a booster via darting from helicopter a month prior to the breeding season). These data suggest that even animals that may have received less than target doses during the initial year of treatment probably incurred at least a short-term elevation of antibody titers for several months posttreatment. A similar phenomenon has been documented for white-tailed deer. Investigators reported delayed parturition dates for does treated with a single dose of vaccine, which indicated elevation of antibody levels during at least the first estrous cycle (McShea et al. 1997).

Sexual interaction rates of treatment and control cows were similar during the normal breed-

All use subject to http://about.jstor.org/terms

ing season but differed significantly during the postbreeding season. We observed almost no sexual interactions in control cows during the postbreeding season, but interaction rates in treated cows remained at the level observed during the breeding season. We interpret the elevated postseason sexual interaction rates as evidence of recurrent estrous cycling of PZP-treated cows because of a failure to conceive during the normal breeding season. Repeated cycling and resultant sexual interactions, however, did not appear to disrupt normal activity patterns of the treated cows, because we failed to detect any difference in the proportion of time treatment and control cows spent in feeding, idling, and moving during the postbreeding period. Hence, the treatment-induced postbreeding activity appeared to have no bioenergetic consequences for the cows. These results are very similar to those obtained by McShea et al. (1997) for captive white-tailed deer treated with various PZP vaccine regimes.

MANAGEMENT IMPLICATIONS

Results of this study suggest that the behavioral and biological consequences of recurrent estrus are not overly deleterious when only a small proportion of the females in a population is treated with PZP vaccine. Effective management regimes, however, will in all likelihood require treatment of a relatively high proportion of the females in a population (Garrott et al. 1992, Hone 1992). Recurrent estrous cycling in large numbers of females may stimulate bulls to maintain extended breeding behaviors such as bugling, harem formation, and defense, as well as antagonism with conspecifics. The mechanisms by which estrous cycling terminates are unknown (Lincoln 1985); hence, the potential duration of such an extended breeding season is uncertain. When our postbreeding observations terminated in late November, the rate of sexual interactions of treated cows was similar to the rates observed for the normal breeding period, which demonstrates extended breeding activity for a minimum of 6 weeks. Breeding could extend well beyond the period monitored in this study because both bulls and cows are capable of remaining reproductively active until March, which is effectively 5 months beyond normal breeding activities (Haigh and Hudson 1993).

Possible consequences of extended breeding could include disruption of normal postbreeding activity and spatial distribution patterns of both cows and bulls. Major disruptions of normal behavioral patterns are probably not a desirable side effect of contraceptive treatment in many situations. Behavioral modifications may also result in demographic consequences such as increased vulnerability to human harvest and higher overwinter mortality of breeding bulls because of greater depletion of body reserves from extended breeding (Flook 1970, Bowyer 1981). Cow activity patterns also could be affected if harem associations are maintained, which could increase energy expenditures, decrease foraging efficiency, or both. Such potential effects, however, may be offset by a decrease in energetic requirements of late gestation and lactation because of the failure of treated cows to conceive. Repeated estrous cycling also raises the potential of cows conceiving and giving birth months after the normal calving season, if PZP antibody levels fall below the threshold needed for effective contraception. Hence, repeated estrous could result in serious disruption, asynchrony, or both in breeding and birthing seasons, similar to that demonstrated by computer simulation of male-oriented contraception in feral horse populations (Garrott and Siniff 1992).

All of these possible scenarios are speculative, and their legitimacy and significance cannot be evaluated with small-scale, individual-based experiments such as this study. These questions, like those related to practical, contraceptive-based management of populations, can only be addressed with carefully designed and implemented population-level experiments where a large proportion of the animals are treated and adequate pre- and posttreatment data are available (Garrott 1995). Although logistic constraints and a lack of individually identifiable bull elk required that this study focus only on cow behavior, we recommend that investigators performing population-level experiments also devote considerable effort to evaluating the potential behavioral consequences of PZP treatment on bulls, because bioenergetic effects may be particularly pronounced in this segment of the population.

LITTERFALL: AN OVERLOOKED FOOD SOURCE FOR WINTERING WHITE-TAILED DEER

STEPHEN S. DITCHKOFF,[1,2] Department of Wildlife Ecology, University of Maine, Orono, ME 04469, USA
FREDERICK A. SERVELLO, Department of Wildlife Ecology, University of Maine, Orono, ME 04469, USA

Abstract: Litterfall in mature forest stands may be a significant food resource for white-tailed deer (*Odocoileus virginianus*) wintering in northern regions, but has received little study. To determine forage production, we measured biomass of litterfall in unharvested stands of 3 wintering areas, and biomass of browse from deciduous trees and shrubs in unharvested stands and harvested patches of the same wintering areas during January–March 1994. Mean biomass of northern white-cedar (*Thuja occidentalis*), eastern hemlock (*Tsuga canadensis*), arboreal lichens (*Usnea* spp. and *Evernia* spp.), and hardwood leaves in unharvested stands was 18.4 kg/ha (SE = 4.80). At mean digestible energy (DE) levels of 1.5 and 1.7 kcal/g dry matter (DM), biomass of hardwood browse and litter biomass did not differ ($P > 0.15$) between harvested patches and unharvested stands. At greater mean levels of digestible energy (1.9 and 2.1 kcal/g DM), biomass was greater ($P < 0.05$) in unharvested stands than harvested patches because of the relatively high DE content of litterfall. We concluded that litterfall in unharvested stands was high relative to the availability of more commonly measured browses (e.g., understory trees and shrubs), and may be more palatable and of greater nutritional value. However, availability of hardwood browse during winter may be more predictable than litterfall.

JOURNAL OF WILDLIFE MANAGEMENT 62(1):250–255

Key words: deer wintering area, forage, lichen, litterfall, Maine, nutrition, *Odocoileus virginianus,* white-tailed deer.

Wintering areas are critical habitat for white-tailed deer in northern regions because of reduced snow depths and enhanced thermal cover on these conifer-dominated sites (Telfer 1967, Ozoga 1968). However, the mature conifer canopy also reduces production of hardwood browse in the understory (Blouch 1984), and preferred browses such as northern white-cedar and eastern hemlock are typically unavailable because of overbrowsing (Frelich and Lorimer 1985, Verme and Johnston 1986). In addition, most browse species readily available in wintering areas are relatively low in nutritional value (Robbins and Moen 1975, Mautz et al. 1976).

There is some evidence that litterfall may be an important winter food for white-tailed deer, but litterfall has rarely been included in studies of food availability. Crawford (1982) and Shively (1989) reported that tame white-tailed deer ate eastern hemlock shoots that collected on the snow surface following periods of strong winds. Stevenson and Rochelle (1984) and Hodgman and Bowyer (1985) found that black-tailed deer (*O. hemionus columbianus*) and white-tailed deer consume considerable amounts of arboreal lichens during winter. Arboreal lichens have a substantially greater digestibility than other common winter foods (Robbins 1987) and may be an important winter food resource.

We quantified litterfall deposited during winter in forest stands typically used by deer in Maine wintering areas. To evaluate the potential significance of litterfall to wintering deer, we also compared biomass and nutritional quality

Applications of GnRH in the control and management of fertility in female animals☆

Abstract

Gonadotropin releasing hormone (GnRH) has long been recognized as a potential target for the control and management of fertility in female animals. Attempts to apply GnRH-based technology to manage fertility have focussed on the development of GnRH agonists, antagonists and vaccines. All of these methods have potential, but the widespread application of these technologies has been limited to date.

The greatest advance in the use of GnRH-based technology for long-term fertility control in recent years has been the development and commercialization of depot formulations that release GnRH agonists for periods of up to 1 year. These products have a broad range of potential applications in production and domestic animal management.

The further development and commercialization of GnRH vaccines has been hampered by the variability of response between individual animals. The need to use adjuvant and multiple boosters also make this a less attractive option than the current GnRH agonist technology. However, GnRH vaccines have the advantage that they do not induce the initial stimulatory response that follows GnRH agonist administration. GnRH antagonists and GnRH-toxin conjugates show promise but are in an earlier phase of development. To date, no depot or long-acting formulations of antagonists have been developed. GnRH-toxin conjugates have yet to achieve permanent sterilization, but further dose-response trials may advance this approach.

1. Introduction

GnRH is a desirable target for contraception because it acts through specific, high affinity receptors on gonadotropes. Traditionally, there are three different ways that GnRH can be employed to inhibit reproduction by direct suppression of the pituitary-gonadal axis at the level of the gonadotrope: (1) chronic administration of GnRH agonists causing down regulation of GnRH receptors and desensitization of pituitary gonadotropes; (2) immunization against GnRH resulting in the neutralization of GnRH in the hypophyseal portal blood by antibodies; and (3) the use of GnRH antagonists to block pituitary GnRH receptors to occupancy by endogenous GnRH (Fraser, 1982). A more recent phenomenon has been the development of GnRH-toxin conjugates that disrupt pituitary gonadotropes (Sabeur et al., 2003).

Long-term fertility control agents based on GnRH are of interest for the management of reproduction in humans, domestic animals and wildlife. Control of reproductive activity in farm animals is an important management issue from both a behavioral and fertility standpoint, as is the case with domestic dogs and cats. Historically, fertility control has been achieved through surgical sterilization. However, in some species the permanent nature of these procedures is a disadvantage. Other disadvantages include the associated trauma, production setbacks and potential death (D'Occhio, 1993). Fertility control has also become a popular concept for the management of highly valuable but overabundant wildlife species. Here the aim is to decrease population size by reducing the fertility of the population. Since GnRH is highly conserved in mammals, fertility control technology founded on this hormone has a wide range of applications in different species.

2. GnRH agonists

2.1. GnRH agonists and pituitary down regulation

GnRH agonists are peptides that are similar to GnRH but are modified at sites of enzymatic degradation of GnRH. This increases resistance to peptidases and enhances receptor-binding affinity, with GnRH agonists having a longer half-life in circulation. Substitution of a D-amino acid instead of the glycine at position 6 and replacement of the C-terminal glycinamide residue with an ethylamide group produces agonists that are up to 200 times more potent than native GnRH (for review see Padula, this volume; Karten and Rivier, 1986). GnRH agonists were originally developed to treat infertility but paradoxically inhibited reproduction because the importance of pulsatile administration had not been realized (Schriock, 1989). This discovery led to numerous indications for the use of GnRH agonists today, including contraception and the treatment of hormone-dependent diseases.

GnRH agonist treatment initially induces a large increase in LH and FSH concentrations (the acute phase), which can last for several days, followed by a return to basal levels (D'Occhio et al., 2000). Continued exposure abolishes pulsatile secretion of LH as a result of down regulation of GnRH receptors on gonadotrope cells (Hazum and Conn, 1988) and an uncoupling of second messenger systems (Huckle and Conn, 1988). This results in a decrease in the synthesis of LH and FSH, which appears to be effected specifically through

suppression of production of β-subunit mRNA (Aspden et al., 1997). These conditions affect normal pituitary function such that the pituitary response to endogenous GnRH is impaired. The end-point of these changes is a decline in the concentration of gonadal steroids. In females this is accompanied by an inhibition of follicular development as FSH secretion is suppressed below the threshold required for follicular development and inhibition of the oestrogen induced positive feedback mechanism and ovulation (reviewed by Fraser, 1993). A lack of pulsatile secretion of LH is maintained as long as the GnRH agonist is present above a threshold in the circulation (D'Occhio and Aspden, 1996). The chronic effects of GnRH are further reviewed (this volume).

2.2. Delivery

While the potential fertility control applications of GnRH agonists have been recognized for almost three decades, successful development of a commercial product for animals has been limited by failure to develop a suitable delivery system (Trigg et al., 2001). Recent development of bio-compatible GnRH agonist formulations which are easy to use, cost effective and release sufficient quantities of GnRH agonist over long periods of time are now overcoming the previous impediments to long-term fertility control applications (Table 1). The mode of delivery ranges from smooth microspheres (20–30 μm diameter) suspended in vehicle, which are administered by subcutaneous or intramuscular injection, to depot polymer implants that are injected subcutaneously. The majority of these formulations have been developed for the treatment of GnRH-dependent diseases in humans and have a lifespan of 1–3 months. To date only one product has been developed specifically for long-term (6 month) fertility control of domestic animals. This product, with the trade name Suprelorin, releases the GnRH agonist deslorelin from a matrix consisting predominantly of low-melting point lipids and biological surfactant (Peptech Animal Health Sydney Trigg et al., 2001). It has been approved for sale in male dogs in New Zealand and Australia in a 6 month duration form, and a 12 month product is in advanced development for both sexes.

2.3. Long-term fertility control

Administration of GnRH agonist formulations can achieve long-term reversible suppression of the pituitary–ovarian axis in a wide range of species (Table 2). Treatment of cats with implants containing 6 and 12 mg of deslorelin suppressed oestradiol secretion for periods of at least 14 months in 80% of animals (Munson et al., 2001). Comparable levels of response to the same peptide have been observed in bitches (Trigg et al., 2001). Large-scale trials of similarly formulated deslorelin in female cattle have demonstrated that implants containing higher doses (12 mg) can inhibit reproduction for >300 days in 100% of animals and >400 days in 90% of animals ($n = 99$) (D'Occhio et al., 2002). These figures demonstrate the extremely high contraceptive success rate achieved using these products. The long duration of release of agonists like deslorelin (1 year) suits livestock production schedules and domestic pet veterinary regimes.

One of the advantages of GnRH agonists is that contraception is effected after a single injection without the need for use of adjuvants. Treatment with agonists has so far proved to be safe, with no serious side effects. Occasionally animals will develop a local reaction at

the injection site, e.g. in cats minimal oedema developed at the site of implant insertion for 3–5 days (Munson et al., 2001), but these effects were transient and not widespread. In dogs, there was no evidence of inflammation or oedema following treatment of 55 animals (Trigg et al., 2001), and subsequent treatment of 387 dogs (T. E. Trigg, unpublished observations).

The results of numerous studies suggest that a longer duration of fertility control can be achieved using higher doses of agonist within similar formulations. In male dogs there was a positive relationship between the dose of agonist (mg kg^{-1}) and the duration of suppression

(Trigg et al., 2001). Similar relationships have been observed in heifers (D'Occhio et al., 2002). The reason(s) for this dose-dependent increase in duration are not clearly understood. It is possible that a higher starting dose of agonist in a slow release system means that the release rate can be maintained above a theoretical critical threshold for down regulation for a longer period of time. It is also possible that the pituitary takes longer to recover from a higher dose. The exact nature of the dose-response relationship for GnRH agonist-induced pituitary down-regulation requires further investigation, as it does not always hold true for all species (Table 2).

The initial stimulatory gonadotropin response to GnRH agonist treatment can induce oestrus in some species. In cats this was characterised by an initial oestrus-like increase in faecal oestradiol concentrations in all animals (Munson et al., 2001). In dogs, oestrus was generally induced within 4–8 days when plasma progesterone concentrations were $<5\ \text{ng ml}^{-1}$ (Trigg et al., 2001). This agonist-induced oestrus can be suppressed in bitches by progestin treatment initiated before agonist administration ($2\ \text{mg progestin kg}^{-1}$ body weight orally for 1 week before and 1 week after) (Wright et al., 2001). This dose needs further titration and other progestin products should be analyzed. Trials should also be conducted on a range of species, as simultaneous progestin and GnRH agonist treatment in wild carnivores did not prevent agonist-induced oestrus (Bertschinger et al., 2001). Although agonist-induced oestrus has been observed in many species, not all animals which display oestrus behaviour will allow mating, e.g. female cheetahs and lionesses (Bertschinger et al., 2001).

There can be a wide range of variation between individuals in the interval to resumption of oestrous cycles during GnRH agonist treatment. This variability may be the result of genetic variations in the sensitivity of individual animals to GnRH-induced down-regulation. As the variability is often greatest at lower doses it may represent a dose-response relationship where a particular dose may be sub-threshold for some individual animals. An alternative hypothesis is that there may be some variability in the implant manufacture process.

There also appears to be a proportion of animals that continue to cycle during GnRH agonist treatment, i.e. 'non-responders'. The proportion of these animals can be difficult to determine in larger scale trials that do not regularly monitor progesterone concentrations or ovarian cycles, e.g. if you get a much shorter duration of action in an individual, is this 'non-response' or is this an earlier return to oestrous cycles for a different reason? There is sufficient data to determine that non-responders are present at a very small percentage in some populations (e.g. heifers, wild dogs). The basis of this variability is probably genetic, as repeated treatment of animals and administration of higher doses does not seem to elicit a contraceptive response (Herbert, unpublished data from kangaroo trials).

3. Immunization against GnRH

Active immunization against GnRH creates an immunological barrier between the hypothalamus and the anterior pituitary gland. Antibodies bind to GnRH in the hypothalamo-hypophyseal portal circulation, which prevents GnRH from binding with receptors on pituitary gonadotropes. This results in suppression of gonadotropin secretion, inhibiting follicular development and ovulation, as well as reproductive behavior. Because

wppv, weeks post primary vaccination; *N*, number of treated (*T*) and control (*C*) animals.
[a] Recombinant vaccine.
[b] Immune response significantly lower in non-responders.
[c] Determination of fertility based on plasma progesterone.
[d] Determination of fertility based on uterine and ovarian histology.
[e] Determination of fertility based on births.

GnRH is a weak antigen (due to its low molecular weight) and also a 'self' hormone, it needs to be conjugated to a large carrier in order to elicit an immune response. Common carriers include ovalbumin (OVA), keyhole limpet hemocyanin (KLH), tetanus toxoid (TT) and diptheria toxoid (DT) (Talwar, 1997).

Immunization against GnRH was initially used to gain a further understanding of the role of GnRH in mammalian reproduction. However, scientists soon realized the potential therapeutic applications of this approach for both human and domestic animal medicine. Active immunization against GnRH has been investigated in a range of domestic animals and wildlife species (Table 3). Contraceptive success rates typically range from 50 to 90%, with occasional 100% success rate in some small trials. Long-term fertility control (i.e. ∼12 months) can be achieved with this approach, but usually requires multiple vaccinations. The duration of contraception is typically quoted from the time of primary vaccination, which can make comparison with other "single-shot" methods misleading.

Immunization against GnRH has the advantage that it does not have the initial stimulatory acute phase that GnRH agonists have, which thereby avoids the problem of treatment-induced oestrus/ovulation. However, this immunocontraception approach introduces a range of other problems.

The primary problem with immunization against GnRH (or indeed all other 'self' antigens) is the highly variable response between individual animals. In almost all trials it is evident that non-responders are present within the population. These are animals that do not have a contraceptive response to the vaccine. In many cases reproductive function is maintained despite an immunological response to the vaccine. When Chinese female pigs (Zeng et al., 2002), feedlot heifers (Adams and Adams, 1990) and mares (Dalin et al., 2002) were immunised against GnRH, the non-responders mounted immune responses that were significantly lower than those successfully immunocontracepted. This suggests there is a critical immunological threshold that must be attained to adequately neutralize GnRH (Adams and Adams, 1990; Zeng et al., 2002). In the case of feedlot heifers the variability was unlikely to be the result of insufficient dose of immunogen as the number of non-responders was evenly spread across three different dosage groups (Adams and Adams, 1990). It is widely thought that the variation in immune response between individual animals is a result of genetic variation (Cooper and Herbert, 2001). If this genetic foundation of non-response is heritable, the number of non-responders will increase with successive generations, particularly if there is high selective pressure (e.g. if non-responders are the only individuals to breed). Under this scenario the lifespan of these products would be severely curtailed.

Another drawback is that most immunization regimes require repeated secondary immunizations to ensure the production and maintenance of high anti-GnRH titres. In some cases it may take up to three immunizations to see a significant antibody response compared with control animals (e.g. mares; Garza et al., 1986). The need for repeated immunizations can be costly, time consuming and impractical, particularly in large-scale farming operations and free-range wildlife situations. Development of single-injection controlled-release vaccines of 1 year duration could overcome this drawback (Turner Jr. et al., 2002), but they are difficult to successfully develop.

Currently there is a need to use an adjuvant to obtain sufficient immunogenicity to inhibit reproduction. In a study of white-tailed deer, the use of diethylaminoethyl (DEAE)-

dextran as the adjuvant caused local reactions ranging from inflammation, minor alopecia and erythema to dry necrosis, sloughing of the skin and purulent lesions (Becker et al., 1999). In heifers, transient injection site reactions to DEAE were noted in 30% of animals (Hoskinson et al., 1990). Mares immunised against GnRH–BSA with Equimune® adjuvant showed a range of reactions to the booster ranging from fever to oedematous swelling and front leg lameness (Dalin et al., 2002). These reactions at the injection site are not uncommon with adjuvants and animal ethics committees and regulatory bodies throughout the world either do not allow their use or are fazing out the use of some adjuvants, in particular Freund's adjuvant, because of animal welfare concerns. These negative effects can be reduced in some species by reducing the amount of adjuvant used (Dalin et al., 2002), altering the route of administration (e.g. subcutaneous instead of intramuscular) and by using alternative adjuvants (Leenaars and Hendriksen, 1998; Leenaars et al., 1998). Some of these alternative adjuvants (e.g. Specol) cause fewer pathological changes than Freund's adjuvant.

Other concerns about immunization against GnRH and other types of immunocontraception relate to the potential for unknown side-effects. The unforseen consequences of provoking an autoimmune reaction are a concern that may limit the development of a contraceptive vaccine for women (Baird, 2000). In addition, there is concern that as animals with a poor immune response are less likely to be affected than other animals, immunocontraception may artificially select for immunocompromised animals which are more susceptible to diseases (Oogjes, 1997).

The concerns outlined above are likely to affect the successful commercialization of GnRH vaccines. Other impediments include the high cost of antigen, which results from a low efficiency of conjugation. In addition, the fact that these vaccines will be active in humans means that there is also a risk of self-inoculation. This risk is greater with a vaccine than with a GnRH agonist implant. The first GnRH vaccine that was released commercially for prevention of pregnancy in animals (Vaxstrate®, Peptech Animal Health Pty Limited, North Ryde) is no longer on the market due to the need for two injections.

Recent advances in GnRH vaccine technology have included the development of a recombinant vaccine. The antigen consists of eight copies of GnRH linked to each end of a proprietary carrier protein, making it greater than 50 kDa, which is large enough to elicit an immune response (reviewed by Rhodes and Moldave, 2002). This vaccine has successfully inhibited reproduction in 100% ($n = 10$) of prepubertal female cats for periods in excess of 2 years. The vaccine was also effective in 75% ($n = 4$) of male cats following two immunizations (Robins, 2002).

4. GnRH antagonists

GnRH antagonists act on the same receptors as native GnRH. When administered, they bind to GnRH receptors in the pituitary but are devoid of stimulatory activity. Receptor occupancy by GnRH antagonists blocks the receptor to occupancy by endogenous GnRH causing an immediate suppression of gonadotropin release (Conn and Crowley, 1994; Schalley, 1999). From the early 1970s an increasing number of GnRH antagonists have been developed. The development process involves a stepwise introduction of hydrophobic residues

that block proteolysis, increase GnRH receptor affinity and increase the pharmacokinetics of the molecule (Fraser, 1988). Initially GnRH antagonists exhibited significant histamine-releasing ability which almost halted their further development (Conn and Crowley, 1994).

GnRH antagonists have successfully been employed to inhibit the LH surge and ovulation in gilts (Brussow et al., 2001) and they have been used to help determine the endocrine control of follicular development in a range of species (e.g. mares; Watson et al., 2000). While GnRH antagonists have the advantage that they do not provoke the initial stimulatory effect of agonists and their effects are immediate, the high dose required to prevent oestrous cycles and the failure to develop an efficient controlled-release system has reduced their practicality. Until an efficient delivery system can be developed, the use of these products is likely to be limited to short-term treatment, e.g. down-regulation of the pituitary during IVF treatment regimes.

5. GnRH-toxin conjugates

The approach of coupling a protein synthesis inhibitor (usually cytotoxic) to GnRH is a more recent approach to long-term fertility control. Because GnRH receptors are highly specific a variety of cytotoxic agents could be used in an attempt to disrupt pituitary gonadotropes by conjugating them to GnRH or GnRH analogues. Death of the gonadotrope will occur when the gonadotropes internalise the GnRH conjugate as part of the normal process of receptor deactivation. Following a sufficient reduction in the number of gonadotrope cells, there will be inadequate production of LH and FSH to maintain reproductive function (Nett and Jarosz, 2002). A recent study has attempted to inhibit reproductive function in male dogs with the use of GnRH conjugated to pokeweed antiviral protein (PAP) (Sabeur et al., 2003). GnRH–PAP caused a reduction in basal LH and testosterone concentrations and testes size. By week 20 post-treatment basal LH and testosterone concentrations showed evidence of recovery (Sabeur et al., 2003). The resumption of reproductive activity may be the result of insufficient dose, or it may be the result of undifferentiated stem cells in the pituitary.

6. Conclusions

GnRH agonists and vaccines are the only two GnRH-based fertility control methods that have successfully been used in a wide range of domestic animal species and are approaching the commercialization stage. There are now many commercially available GnRH agonist formulations, but most are designed for human use and may therefore be hard to access for animals and/or be prohibitively expensive. There is now one GnRH agonist formulation that has been specifically developed for domestic animals (Suprelorin®) and this is approved in two countries and commercialisation worldwide is proceeding.

The impetus for the development of GnRH-based fertility control has been founded on the potential applications in domestic animals and humans, but a new and emerging field has been the use of these products to control overabundant wildlife. The fact that research and development of this technology has been funded from the more lucrative fields of

human medicine and production animal health has made the transfer of this technology to wildlife relatively cheap (i.e. compared to the development of species specific zona pellucida vaccines for example). The highly conserved nature of the role of GnRH in reproduction has allowed easy transfer of this technology to other species.

GnRH agonists have a much higher contraceptive success rate and less negative side effects than immunization against GnRH in both domestic animals and wildlife. The high variability of response to GnRH vaccines is a problem that may eventually see the pursuit of such 'self' vaccines abandoned. Attempts to further develop GnRH antagonist and GnRH-toxin technology may provide useful products with a range of potential applications.

EFFECTS OF FERTILITY CONTROL ON POPULATIONS OF UNGULATES: GENERAL, STAGE-STRUCTURED MODELS

N. THOMPSON HOBBS,[1] Colorado Division of Wildlife and Natural Resource Ecology Laboratory, Colorado State University, Fort Collins, CO 80523, USA

Abstract: Regulating the abundance of ungulate populations using hunting can prevent populations from reaching levels that cause harm to natural and human dominated systems. However, there are an increasing number of cases where hunting is infeasible, and in such cases, fertility control has been widely advocated as an alternative means for controlling populations. Here, we develop simple analytical models offering general insight into the feasibility of using fertility control to regulate the abundance of ungulates. The models are structured in stages to represent variation in the duration of effect of fertility control agents. Analysis of these models offers several predictions, amenable to testing in field studies. (1) More than 50% of fertile females will need to be maintained infertile to achieve meaningful reductions in ungulate numbers even when fertility rates are low. (2) The relationship between the proportion of females maintained infertile and the steady state density is highly nonlinear. This means that small errors in estimating levels of infertility can lead to large errors in achieved density. It also means that managers should expect to see little change in steady-state density across a broad range of delivery rates. (3) The efficacy of fertility control as a management technique depends strongly on the persistence of the effect of the fertility control agent and the ability of managers to recognize previously treated animals. (4) Fertility control using long-lived agents can be more efficient than culling in regulating ungulate numbers. (5) Treating small populations with irreversible agents magnifies the likelihood of population extinction relative to treatment by culling. As with all techniques, managing population fertility must extend from a sound understanding of the influence of management actions on the state and dynamics of the population.

JOURNAL OF WILDLIFE MANAGEMENT 64(2):473–491

Key words: contraceptives, hunting, management, population persistence, modeling, fetility control, sterilization, ungulate.

Controlling the abundance of ungulates by regulating harvest is one of the prevailing activities of wildlife managers throughout North America. Regulated harvest offers a variety of benefits to society, including recreation for citizens and revenue for agencies and private enterprise. An additional benefit is a reduction in animal numbers, which if left unchecked, can cause significant harm to natural and human-dominated systems (Jewell and Holt 1981, Diamond 1992, Garrott et al. 1993, McCullough et al. 1997).

Although harvest can be an effective method for manipulating ungulate numbers, there are a growing number of situations where it is not feasible. The rapid expansion of urban and suburban areas during the last decade has brought populations of ungulates in close proximity to high densities of people (Adams 1994, McCullough et al. 1997). This proximity restricts the use of hunting as a management tool because it poses unacceptable risks to human safe-

ty (Decker and Connelly 1989, Brush and Ehrenfeld 1991, McAnnich 1993, Wright 1993), and because urban residents often oppose hunting animals on ethical grounds (Decker and Connelly 1989, McCullough et al. 1997). In addition, there are many conservation areas, national parks prominent among them, where hunting is proscribed by law and policy (Leopold et al. 1963, Wright 1993, Porter et al. 1994, Wagner et al. 1995, Frost et al. 1997, Porter and Underwood 1999). In all of these situations, culling animals to regulate populations has significant liabilities, and as a result, wildlife managers are seeking innovative alternatives to lethal methods of population control (Kirkpatrick and Turner 1985, Bomford 1990, Brush and Ehrenfeld 1991, Diamond 1992, Garrott et al. 1993, McCullough et al. 1997).

Fertility control has been widely advocated as an alternative to culling (reviewed by Kirkpatrick and Turner 1985, Bomford 1990, Tuyttens and Macdonald 1998). Field and laboratory studies have evaluated efficacy of delivery of contraceptives to ungulates (Jacobsen et al. 1995, McCallum 1996, DeNicola et al. 1997, Fayrer Hosken et al. 1997, Kirkpatrick et al. 1997, Nielsen et al. 1997, Turner et al. 1997), and models have been developed to represent effects of fertility control on the population dynamics of individual species (Garrott and Siniff 1992, McAninch 1993, Swihart and DeNicola 1993, Boone and Wiegert 1994, Seagle and Close 1996). However, despite these efforts, a broad understanding of effects of fertility control on ungulate populations has failed to emerge. The absence of such understanding retards efforts to apply fertility control as a method to control ungulate numbers.

Here, we develop a general theory of regulation of ungulate populations using fertility control agents. Specifically, our objective was to develop simple analytical and simulation models offering general insight into the following questions. (1) What proportion of females in a population must be infertile to maintain the population at target densities? (2) How does fertility control compare with culling as a means to regulate ungulate populations? (3) How does duration of efficacy of contraceptives influence the number of animals that must be treated to achieve target population levels? (4) To what extent does timing of delivery (pre- or post-breeding) influence the ability of contraceptives to regulate ungulate numbers? (5) Do assumptions on the operation of density dependence modify the insights gained above? (6) Is fertility control a "safe" method for regulating small populations vulnerable to stochastic, local extinction? We provide a general mathematical basis for screening the feasibility of fertility control before developing detailed, species-specific models or conducting extensive field applications.

METHODS

Base Model

Because our purpose was to develop general insights, we used a model that was as simple as possible (Levins 1966, Starfield et al. 1990, Starfield and Bleloch 1991, Starfield 1997). The model needed to be sufficiently detailed to mimic the behavior of ungulate populations in a reasonable way, but it also needed to avoid detail peripheral to the questions posed above. To meet this challenge, we began with a simple formulation and incrementally added detail needed to meet our objectives.

Our starting point was a stage-structured model representing species where adult survivorship is high and where density dependence operates primarily on recruitment, characteristics that are particularly faithful to the life histories of many species of ungulates (McCullough 1979, Houston 1982, Skogland 1990, Bartmann et al. 1992, Gaillard et al. 1993, Putman et al. 1996). The model was formulated as

$$F_{t+1} = F_t(S + m - \beta(F_t - H_t)) - H_t, \quad (1)$$

where F_t is the density of females at time t, S is the annual per-capita survival rate of females, m is the maximum number of breeding females annually recruited to the population per breeding female, β is the linear slope of the relationship between recruitment of females to breeding age and female density, and H_t is the number of females culled at time t. The model predicts the preharvest population density of females using 3 parameters (S, m, β) and a single decision variable, H_t. Although the model represents a single stage explicitly (adult females), it implicitly represents sexually immature juveniles via the recruitment term. The explicit juvenile stage drops out of equation (1) via model reduction (Caswell 1989:100).

The model is based on several simplifying assumptions. First, we assume that the probability of survival of adults does not change with age. Thus, we treat longevity as the outcome of a

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

series of independent Bernoulli trials rather than being fixed at a specific age (Gurney and Nisbet 1998:80). Culling is assumed to occur after breeding, but before recruits are born. We assume that density dependence is linear and operates entirely on recruitment. That is, the number of new breeding females recruited to the population is directly proportionate to the postharvest population density of females. Effects of nonlinear density dependence will be included as part of the analysis of the model.

It is possible to formulate the model using an explicit parameter for the density at which recruitment = 0 (i.e., $K_r = m/\beta$). Alternatively, we can represent effects of density dependence using a slope (β) and intercept (m) for the relationship between density and recruitment. We used this approach because we believe these parameters offer useful biological interpretations; the parameter β represents the "strength" of density dependence and the parameter m represents the maximum possible recruitment rate. Both of these representations prove useful when interpreting model analysis.

Although this model is extremely simple, it can represent the dynamics of ungulate populations with reasonable fidelity (Fig. 1). A more detailed model would achieve higher levels of realism, but only at the expense of reduced clarity and generality.

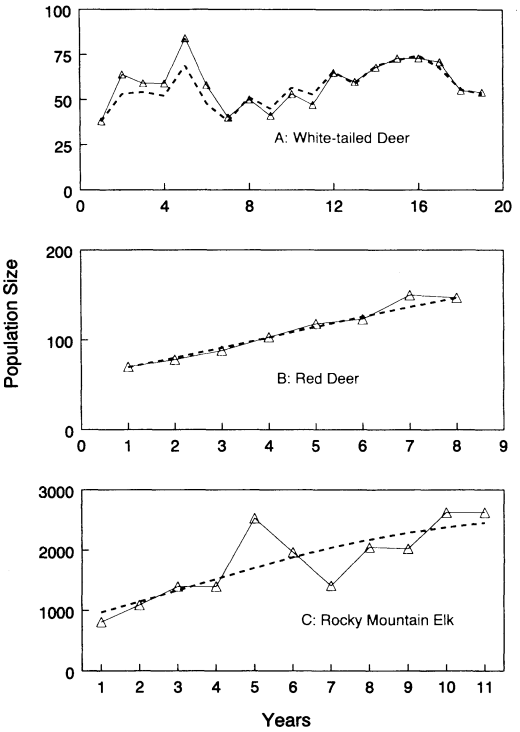

Fig. 1. Comparison of model projections (dashed line) with observed trajectories of ungulate populations (triangles). Model parameters were estimated by minimizing the squared difference between observations and predictions. A close fit between observations and predictions allows the conclusion that the model contains sufficient detail to reasonably represent trajectories of ungulate populations if its parameters are properly estimated. Data are from [A]—McCullough (1979: Table 3.2), [B]—Clutton-Brock et al. (1982), [C]—Houston 1982.

Model Development

We modified equation (1) to represent effects of fertility control as an alternative to culling. Node diagrams and the matrix form of the model are shown in Fig. 2. Here, we summarize our modifications using finite difference equations.

We defined the number of animals harvested annually as

$$H = cF_t. \quad (2)$$

Thus, c is the per capita rate of culling, the number of breeding females culled annually per breeding female in the population. It follows that the effects of culling can be represented in the model as

$$F_{t+1} = F_t(1 - c)(S + m - \beta(1 - c)F_t). \quad (3)$$

We will refer to equation 3 as the culling model.

To allow comparison with fertility control, we redefined c as the per capita rate of delivery of contraceptives. There are now 2 stages that we wish to track in the population; females that are fertile (i.e., F_t) and those that are infertile (i.e., I_t). We define fertile animals as those that are capable of breeding and carrying a fetus to term. We define infertile animals as those that cannot successfully breed. When the effect of the contraceptive persists for a single breeding season, then the dynamics of the fertile (F_t) and infertile stages (I_t) can be represented as

$$F_{t+1} = F_t(1 - c)(S + m - \beta N_t) + (1 - c)I_t, \text{ and} \quad (4)$$

$$I_{t+1} = F_t c(S + m - \beta N_t) + I_t Sc, \quad (5)$$

where

$$N_t = F_t + I_t. \quad (6)$$

However, if the effects of the contraceptive persist for more than 1 breeding season, then we must account for the time since the animal was treated. This accounting can be accomplished

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

by adding stages to the model. If the duration of the contraceptive is finite, then the dynamics of the fertile and infertile stages can be represented as

$$F_{t+1} = F_t(1-c)(S + m - \beta N_t) + (1-c)I_{\tau_t} \quad (7)$$

$$I_{1_{t+1}} = F_t c(S + m - \beta N_t) + I_{\tau_t} Sc \quad (8)$$

$$I_{2_{t+1}} = I_{1_t} S, \quad (9)$$

$$I_{3_{t+1}} = I_{2_t} S, \quad (10)$$

$$I_{4_{t+1}} = I_{3_t} S, \quad (11)$$

$$I_{\tau_{t+1}} = I_{\tau-1_t} S, \quad \text{and} \quad (12)$$

$$N_t = F_t + \sum_{i=1}^{\tau} I_{i_t}, \quad (13)$$

where τ = the duration of the contraceptive in number of breeding seasons. Thus, the number of stages in the model is $\tau + 1$, 1 stage for the breeding females and 1 stage for each year that animals are infertile following treatment. The total population of females is the number of animals summed across stages (equation 13). We will refer to equations 7–13 as the fixed duration model.

It is possible to develop agents that will render animals infertile for life (reviewed by Muller et al. 1997, Tuyttens and Macdonald 1998). To represent effects of such agents, only 2 stages need to be tracked (fertile and infertile animals), and the dynamics of these stages are connected only by the rate of addition of animals to the infertile pool and the effect of total density on recruitment. Thus, the dynamics of the population are given by

$$F_{t+1} = F_t(1 - c)(S + m - \beta N_t), \quad (14)$$

$$I_{t+1} = F_t c(S + m - \beta N_t), \quad \text{and} \quad (15)$$

$$N_t = F_t + I_t. \quad (16)$$

We will refer to equations 14–16 as the lifetime duration model.

The fixed and lifetime duration models depend on the same set of assumptions described for the culling model. However, these models require the additional assumptions that treatment is applied immediately before breeding occurs and that managers can differentiate between animals that have been treated and those that have not been treated. We will examine the consequences of these assumptions as part of model analysis. Time of census in the model is

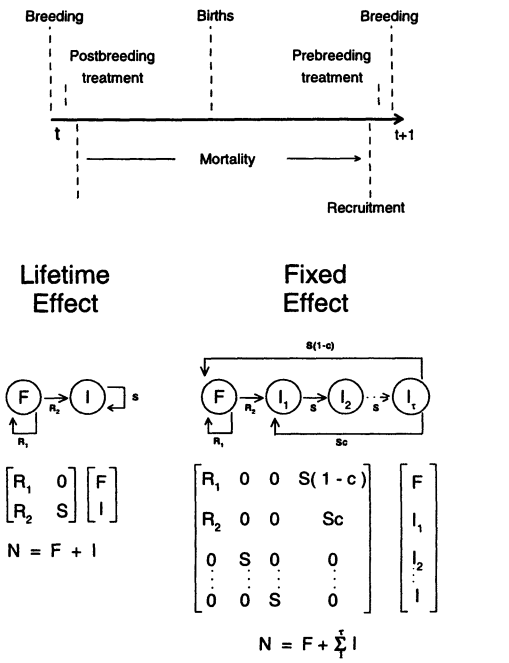

Fig. 2. Schematic of model structure and assumptions. The upper panel depicts assumptions on timing of events represented in the model. The central panel shows the structure of the model in node and matrix formats. The lower panel shows representations of assumptions about timing of delivery and the operation of density dependence.

assumed to occur annually, immediately after breeding (Fig. 2), and all fertile animals are assumed to be bred at the time of census. We chose breeding rather than births as the point of reference for census because the state of the animal that influences model behavior is its fertility rather than its age.

Model Analysis

Deterministic Analysis.—We used standard matrix techniques and algebraic manipulations (see Appendix I for details) to derive several quantities of interest. These included: K_e, the equilibrium density of animals in the absence of fertility control or culling; K_c, the equilibrium

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

density of animals as a function of delivery or culling rate; c^*, the delivery rate required to maintain a target population density; P, the proportion of the population that must be infertile to maintain a target population density; and n^*, the number of animals that must be treated or culled annually to maintain a target population density. To examine the effects of timing of delivery on model predictions, we changed model formulations to represent delivery after breeding (Fig. 2). In this case, delivery of contraceptives did not prevent birth by treated animals during the current time step (because treated animals were assumed to be pregnant at the time of delivery) but did prevent births during the subsequent time step (Fig. 2). To examine effects of nonlinearity in density dependence, we reformulated the model (Fig. 2) so that recruitment remained relatively constant at low population density and then declined as threshold densities were reached (Bartmann et al. 1992). To examine consequences of relaxing assumptions on known fertility status of animals, we developed an estimator to show how many animals must be treated to achieve a treatment target, given unknown fertility status. This estimator deals with the multinomial case of sampling with replacement, and estimates necessary treatment rates, assuming that animals could be treated more than once.

Stochastic Analysis.—We performed Monte Carlo simulations to examine the relative ability of culling and fertility control to regulate animal numbers near a target density. These simulations were organized in 4 model scenarios that included 2 types of management and 2 sources of stochastic variation. Management types include static and adaptive. Static management applied the same per capita rate of delivery annually, a rate that would achieve a target population density if applied accurately. Adaptive management changed the delivery or culling rate in response to differences between realized density and an acceptable range of target densities. The acceptable range was defined as the target ±25%. If the population exceeded the target by ≥25%, then the culling or delivery rate was increased by 10% until the population returned to acceptable levels. If the population dropped below the target by ≥25%, then culling or fertility control was discontinued until the population recovered to a density within the acceptable range.

In addition to 2 types of management, model scenarios included 2 sources of stochastic variation; process and observer. Process variation was included to mimic density independent effects of the environment on population dynamics. To represent this variation, adult survival varied according to a log-normal distribution with mean 0.9 and variance 0.1. We varied the effect of density on recruitment (i.e., β) using a normal distribution with a mean of 0.009 and variance 0.01. To assure that stochastic effects on mortality and recruitment were correlated, we derived them from the same normally distributed variate at each time step. Observer variation was included to mimic the error in estimates of population size that are typical in managing ungulate populations. To represent observer variation, delivery and culling rates were based on an estimate of the current population density derived by sampling from a normal distribution with a mean equal to the model density at time t (F_t) and a standard deviation equal to 15% of the mean. Initial conditions for population density were set at the target density. Initial conditions for population composition (i.e., fertile–infertile stages) were set at levels equivalent to the deterministic steady-state at that target density. We conducted 1,000 model runs of 50 years each for 2 target densities, set as percentages (25 and 75%) of the steady state that would occur in the deterministic model when culling or fertility control was not applied (i.e., K_e). We applied 4 methods of population control: culling, and fertility control with the duration of treatment equal to 1 year, 3 years, and lifetime. For each set of model runs, we recorded the total number of animals treated or culled, the overall variance in population density, and the number of years that the population was outside the acceptable ranges. We also recorded the frequency of extinction and the persistence time of the population.

Procedures for Analysis and Plotting.—Analytical results were obtained using Maple V (Waterloo Maple, Waterloo, Ontario, Canada). All analytical results were checked for accuracy using simulation of difference equations with Microsoft Excel (Microsoft Corporation, Redmond, Washington, USA). Monte Carlo simulation experiments were conducted using Visual Basic for Applications running under Excel. For the purpose of illustrating analytical results in plots, we chose parameter values that are reasonable for white-tailed deer (*Odocoileus virginianus*; $m = 0.6$, $S = 0.9$, $\beta = 0.005$) and that

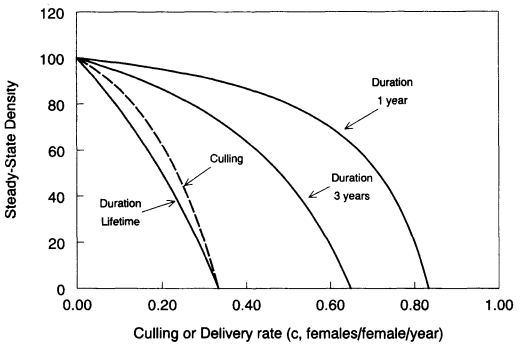

Fig. 3. Model predictions (equation 18) of steady-state density as a function of culling or delivery rate using parameter values $m = 0.6$, $S = 0.9$, $\beta = 0.005$. Different lines show differences due to variation in duration of efficacy of contraceptives.

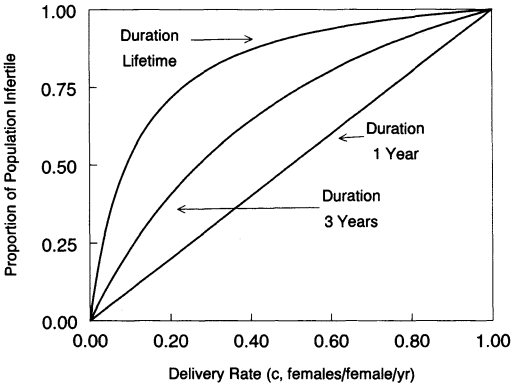

Fig. 4. Model predictions (equation 19) of effects of delivery rate on the proportion of the female population that is infertile. Different lines show differences due to variation in duration of efficacy of contraceptives. Parameter values are $m = 0.6$, $S = 0.9$, $\beta = 0.005$.

produced an equilibrium value of population density = 100 in the absence of any treatment or culling. Because density can scale to any unit area, our plots can be viewed in absolute or relative terms. For example, $N = 90$ can be accurately interpreted as an absolute density (e.g., 90 animals per unit area) or as a percentage of steady state population density that would be achieved in the absence of treatment (e.g., 90% of K_e).

RESULTS

Equilibrium Population Density and Composition

In the absence of treatment or culling (i.e., $c = 0$), all models predicted that the population would reach a steady state density, K_e,

$$K_e = \frac{S + m - 1}{\beta}. \quad (17)$$

As the rate of treatment with contraceptives increases, models predicted that steady state density declines in a nonlinear fashion (Fig. 3) according to

$$K_c = \frac{S + m + S^{\tau}c - Sc - cm - 1}{(1 - c)\beta}. \quad (18)$$

In the lifetime case, the S^{τ}_c term drops out of equation (18).

Fixed-effect models predicted a nonlinear, threshold relationship between equilibrium density and treatment rates. We found a broad range of treatment rates that exert relatively weak effects on steady state density, particularly for short-duration models (Fig. 3). Increasing duration of fertility control tended to make this relationship more linear (Fig. 3).

Fixed-effect models illustrated that when the duration of the contraceptive is 1 breeding season, the proportion of the population that is infertile (P) is equal to the treatment rate (i.e., $P = c$). However, when effects persist beyond a single season, infertile animals accumulate in the population treated annually, and as a result, $P > c$ (Fig. 4). Analysis of the model (Appendix A) suggests that the relationship between P and c depends on the duration of the effect of the contraceptive and the adult survival rate, i.e.,

$$P = \frac{(1 - S^{\tau})c}{1 + Sc - S - S^{\tau}c}, \quad (19)$$

but does not depend on birth rate (m) or the strength of density dependence (β). In the lifetime case, this simplifies to

$$P = \frac{c}{1 - S + Sc}. \quad (20)$$

The relationship between target density (N^*) and the proportion of the population that is infertile (P) is identical for all fertility control models (Fig. 5),

$$N^* = \frac{S + m - Pm - 1}{\beta(1 - P)}. \quad (21)$$

Equation 21 shows that increasing dependence of recruitment on density amplifies the effect of fertility control on the steady state population size. That is, achieving a given target density will require a smaller proportion of infertility in populations where density-dependent effects

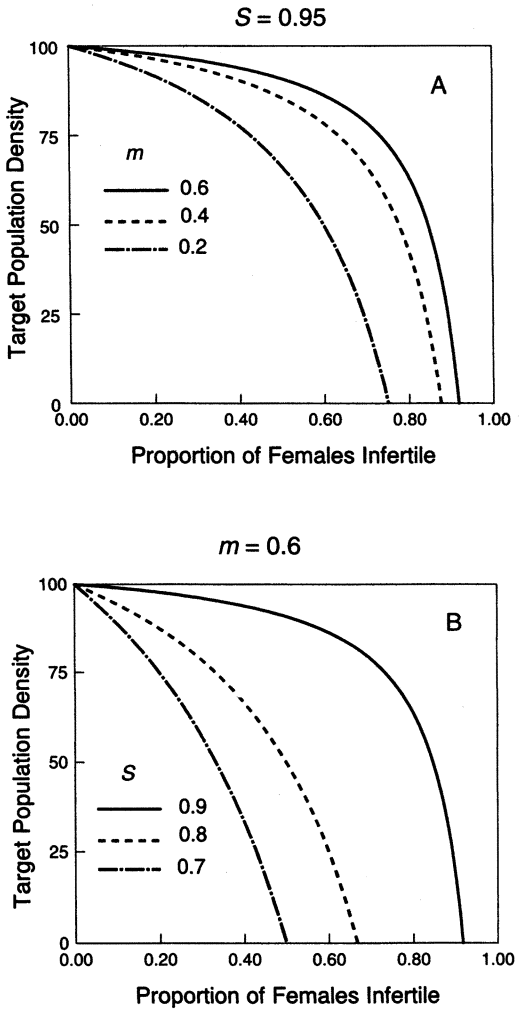

Fig. 5. Model predictions (equation 21) of the proportion of the females that must be infertile to achieve a target population density assuming a constant ecological carrying capacity of K_e = 100. Panel A shows this proportion with adult female survival rate held constant (S = 0.95) and maximum recruitment rate varying. Panel B shows this proportion with maximum recruitment rate held constant (m = 0.6) and survival rate varying.

are stronger than in populations where such effects are weak.

Population managers need a relatively easy way to estimate the proportion of the population that would need to be maintained infertile to achieve a given target density. This can be obtained as follows. By rearranging equation 21, we find P as a function of the target density:

$$P = 1 - \frac{1 - S}{m - \beta N^*}. \quad (22)$$

This result simply says that for any steady-state population density, N^*, the proportion of the population that is fertile (i.e., $1 - P$) must equal the adult per capita mortality rate divided by the per capita recruitment rate (i.e., females per female per year). When this is true, the number of animals recruited will equal the number that die.

Note that the duration of the contraceptive determines the rate of delivery that must be applied each year to achieve a given level of population infertility, (equation 19), but the duration does not affect the level of infertility required to achieve a given steady-state density (equation 22). Equation 22 also illustrates that the necessary proportion infertile will increase with increasing adult survival and maximum recruitment. It will decline with increasing "strength" of density dependence.

Equation 22 requires an estimate of β, which can be difficult to obtain. However, it is possible to derive an expression for P that does not depend on estimating β. Defining Δ as a proportion of the steady-state density (i.e., $N^* = \Delta K_e$) and substituting the right hand side of

$$\Delta K_e = \Delta\left(\frac{S + m - 1}{\beta}\right) \quad (23)$$

for N^* in equation 22, we obtain an expression for the proportion of animals that must be infertile to achieve a target density specified as a proportion of the untreated steady state, i.e.,

$$P = 1 - \frac{1 - S}{m + \Delta(1 - S - m)}. \quad (24)$$

Thus, when $\Delta = 1$, there is no reduction in density; when $\Delta = 0$, the population goes extinct. Equation 24 is an important result because it provides a general rule of thumb for estimating the effort required to regulate a population using fertility control without knowing the strength of density dependence. This rule requires estimates of only 2 parameters (adult female survival rate and maximum recruitment rate of females) and a decision on the targeted reduction, Δ.

Vital Rates and Population Composition at Equilibrium

Equation 24 also reveals that a relatively large proportion of the population must be infertile in order to achieve meaningful reductions in density (Fig. 5). When adult survival is high (>95%),

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

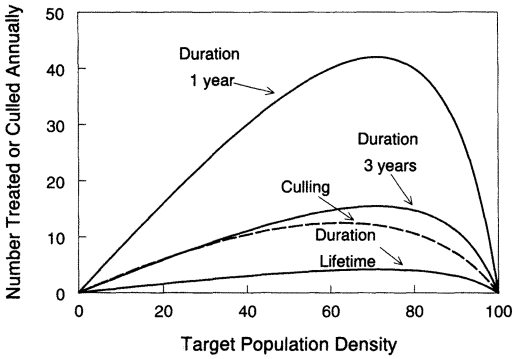

Fig. 6. Model predictions (equations 25–28) of the number of animals that would need to be treated or culled to maintain a population at the specified target density. Parameter values are $m = 0.6$, $S = 0.9$, $\beta = 0.005$. Different lines show differences due to variation in duration of efficacy of contraceptives.

it is reasonable to assume that >60% of the breeding females will need to be infertile to achieve meaningful reductions in population density, even for species with very low intrinsic rates of increase (e.g., $m = 0.2$, Fig. 5). The shape of the relationship between the proportion of the population that is infertile and steady-state density is more sensitive to differences in adult survival than to differences in maximum rates of recruitment. This relationship remains strongly nonlinear as long as adult survival is high. However, as adult survival declines, the relationship approaches linearity (Fig. 5).

Number of Animals Treated or Culled at Equilibrium

When effects of fertility control agents persist for only 1 year, then the proportion of the population that is infertile equals the delivery rate. Moreover, in this case, the number of animals that must be treated the first year to achieve a given target is the same as the effort required in subsequent years. However, when regulating populations with fertility control agents that persist for >1 breeding season, there are 2 types of effort required: the effort required to achieve a specified level of infertility in the population, and the effort required to maintain that level of infertility. Here, we examine this maintenance effort and compare it with culling.

In populations regulated with culling, the number of animals harvested annually (n) to maintain a given target density, N^*, at steady state is simply

$$n = c^*N^*, \quad (25)$$

where c^* is the culling rate needed to maintain a population at the target density. For the culling model, c^* is given by

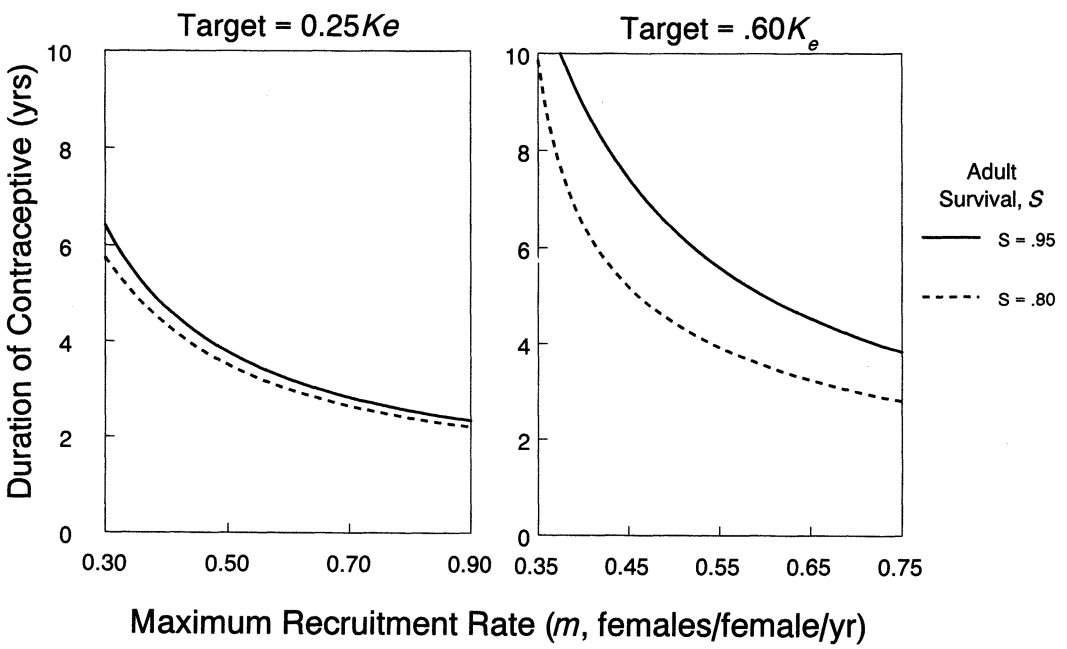

Fig. 7. Model predictions of the duration of contraceptive delivered to an animal needed to cause the same effect on population growth as culling the animal (equations 25 and 28).

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

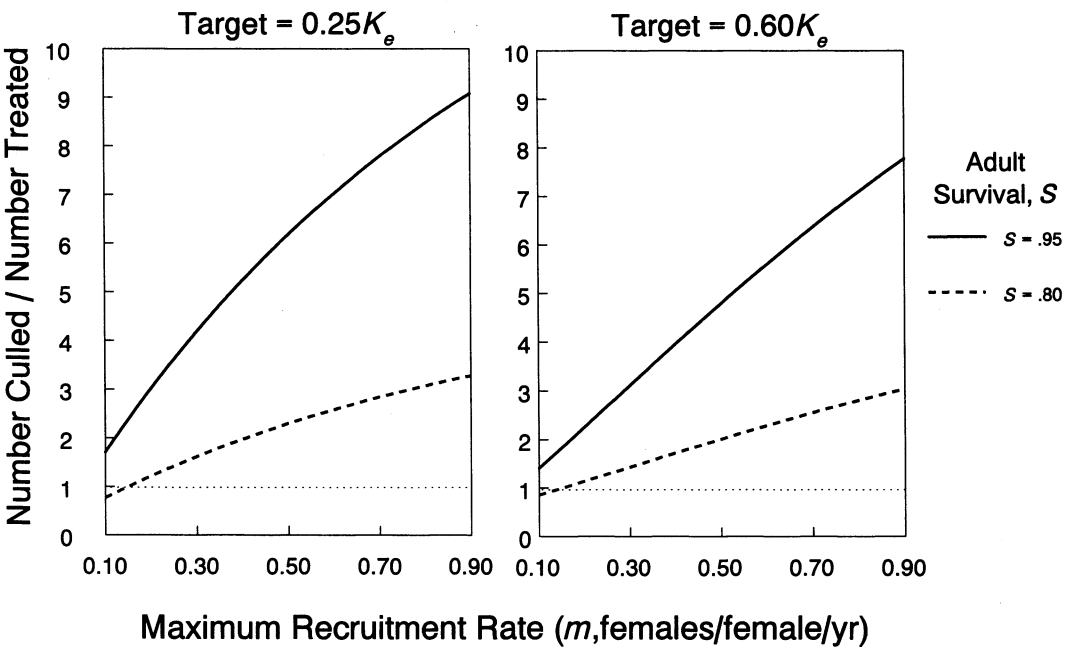

Fig. 8. Model predictions of the ratio of the number of animals that would need to be culled relative to the number treated with contraceptives to maintain steady states at target densities. The horizontal dotted line shows where the number culled equals the number treated (equations 25–28).

$$c^* = \left(2N^*\beta - S - m + \sqrt{S^2 + 2Sm + m^2 - 4N^*\beta}\right)/(2N^*\beta). \quad (26)$$

In populations regulated with fertility control, there are 3 cases relevant to the number of animals treated annually (n) to maintain a given target density. In the case of fixed duration agents lasting a single year, the delivery rate at equilibrium (c^*) is the same as the proportion of the population that is infertile, so using equation 22, we calculate the number treated as

$$n = c^*N^* = PN^* = \left(1 - \frac{1 - S}{m - \beta N^*}\right)N^*. \quad (27)$$

In the case of agents with duration >1 year and greater than a lifetime, the number that must be treated annually is

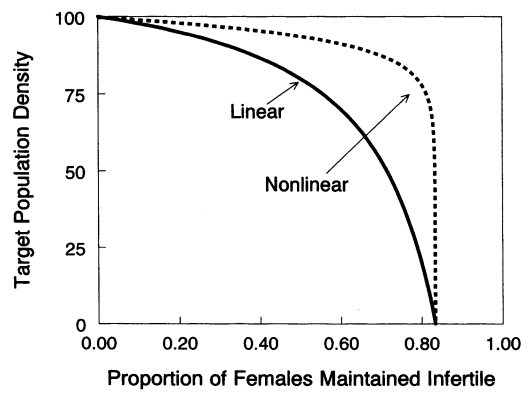

Fig. 9. Comparison of model predictions of the relationship between the target density and the proportion of the population that is infertile, assuming linear (solid line) and nonlinear (dashed line) representations of the effects of density dependence on recruitment.

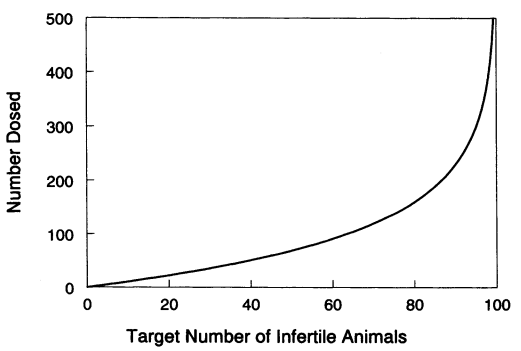

Fig. 10. Predictions of the number of animals that would need to be dosed to achieve a given level of infertility in a population, assuming animals are not marked and are subject to treatment more than once. The axes can be interpreted as a number of individuals in a population of 100, or as percentages.

Table 1. Results of 1,000 model runs of 50-year duration with stochastic variation. Static management applied a constant, per capita culling or delivery rate needed to achieve the target density. Adaptive management adjusted the culling or delivery rate to keep the population within ±25% of the target density. Process variation mimicked stochastic environmental effects on adult survival and juvenile recruitment. Observer variation mimicked uncertainty in estimating population size. Control methods included culling and 4 contraceptives differing in duration, compared with the no management case (i.e., "Natural"). Results include average population size (*N*) and its coefficient of variation. We also report percentage of runs for which population density dropped below 1 (% extinct) and mean time to extinction averaged across model runs (persistence time in yr).

Management type	Variation type	Control method (duration of contraceptive)	Target density							
			25				75			
			N	CV	% extinct	Persistence time	*N*	CV	% extinct	Persistence time

Table 2. Modeling estimates of proportion of the target sex that must be infertile to achieve target population objectives. Assumed annual growth rate in absence of treatment = 1.49.

Species	Population objective	% infertile	Reference
White-tailed deer	Negative growth rate[1]	90%	(Swihart and DeNicola 1993)
Feral horses	Reduce population from 600 to range of 300–600	68–82% depending on treatment regime	(Garroutt et al. 1992)
White-tailed deer	Maintain at ½ carrying capacity	80%	(Boone and Wiegert 1994)
Feral horses	Reduce growth rate (i.e., lambda) to 1	90–95%	(Garrott and Siniff 1992)
White-tailed deer	Reduce population size	>50%	(Seagle and Close 1996)
White-tailed deer	Maintain at ½ carrying capacity	96%	(Nielsen et al. 1997)

$$n = c^*(1 - P)N^*(S + m - \beta N^*) + c^*\rho N^*, \quad (28)$$

where c^* is the treatment rate required to achieve a given target density, N^*P is the portion of the population that is infertile at time t as a result of applying c^*, and ρ is the proportion of the population that becomes fertile during $t \rightarrow t + 1$ given a treatment rate = c^*. The components of equation 28 are as follows. The variable P is given by equation 22. The equilibrium treatment rate is

$$c^* = \frac{S + m - 1 - \beta N^*}{S + m - S^\tau - \beta N^*}. \quad (29)$$

The proportion of the population that will become fertile during a time step is

$$\rho = \frac{S^{\tau-1}(1 - S)c^*}{1 + Sc - S - S^\tau}. \quad (30)$$

In the lifetime duration case, the S terms with exponents drop out of the expression for c^* and $\rho = 0$.

Equations 25 and 28 allow comparison of the effort required to control populations using culling or fertility control. Because these equations predict the number of animals that must be treated or culled to maintain populations below K_e (Fig. 6), they are analogous to classical production functions, also known as yield curves (Roughgarden 1997).

Effect of Duration of Contraception

We asked the question, "On average, how long must the effect of a contraceptive persist in an animal to exert the same effect on population-level production as culling that animal?" To address this question, we chose a broad range of parameter values to represent diverse life-history characteristics of ungulates, and applied those values to equations 25 and 28. Models suggested that for a broad range of assumptions about survival and maximum recruitment, delivery of a contraceptive to an individual animal would have the same effect as culling that animal if the effects of the contraceptive persisted for 2–5 years (Fig. 7). Briefer duration is needed when adult survival rates are low. Increasing strength of density dependence reduces the required duration; weakening it increases the required duration.

When contraception persists for the lifetime of the animal, models predicted that in most cases, the effort required to regulate a population at a specified density using fertility control will be less than the effort required by culling (Fig. 8). Exceptions to this result occur when adult survival is low and recruitment is low, that is, when populations grow slowly (Fig. 8). For species with high rates of adult survival and high recruitment rates, the number of animals culled could be almost an order of magnitude greater than those treated with contraceptives at the same target density (Fig. 8). Thus, if we define efficiency of control in terms of the number of animals that must be culled or treated annually to maintain a population at a specified target, then culling will be more efficient than lifetime duration contraception only for slowly growing populations. In all other cases, models suggest that treatment with lifetime effect contraceptives is likely to be more efficient than culling. However, it must be understood that these estimates of effort specify the number of animals that must be treated annually to maintain a steady state population with a proportion infertile, P (equation 22). These are not estimates of the effort required to achieve P in the pretreatment population.

Consequences of Changing Model Assumptions

Assumed Pre-breeding Delivery.—In all results above, we assumed that contraceptives were delivered to females before breeding occurs. It is possible to change the model to represent delivery after breeding by assuming that treated animals give birth during the current time step but are infertile during the subsequent one (Fig. 2). An important result emerged from this analysis. We found that when contraceptives are delivered postbreeding, there is a fundamental limit to the magnitude of the reduction in population density that can occur using fertility control,

$$N^* \geq \frac{m - 1}{\beta}, \tag{31}$$

or, solving in terms of a proportionate reduction,

$$\Delta \leq \frac{m - 1}{S + m - 1}. \tag{32}$$

The right-hand-side of equation 32 gives the steady-state density of females that occurs when the delivery rate = 100%. At this density, each fertile female produces exactly 1 female offspring surviving to reproductive age and the proportion of fertile females in the population equals the adult mortality rate.

Equations 31 and 32 are important because they reveal that it may not be possible to achieve meaningful regulation of populations where contraceptives are delivered after animals have been bred, even when the entire population of fertile females is treated. If animals can breed at 1 year of age, then a cohort of animals always escapes the postbreeding treatment, and this escape may allow populations to grow to levels that are close to K_e, if recruitment rates are sufficiently high. Equations 31 and 32 raise serious doubt about the efficacy of fertility control as a means of regulating populations whenever yearlings contribute significantly to breeding and contraceptives are delivered after they are bred.

Assumed Linear Density Dependence.—Changing the form of the relationship representing density dependence from linear to nonlinear did not change the qualitative results obtained above (Fig. 2). The composition of the population at equilibrium (i.e., equations 19 and 20) does not depend on the form of density-dependent relationships. However, the relationship between equilibrium population size and the proportion of the population infertile changed when we changed the formulation for density dependence. In the case of nonlinear density dependence,

$$N^* = \frac{\ln\left(\frac{S + m - Pm - 1}{1 - S}\right) + \alpha}{\theta}, \tag{33}$$

where α and θ are parameters controlling the shape of the nonlinear relationship between recruitment and density.

Note that this expression does not depend on the duration of the effect of the contraceptive, as we saw earlier for the linear case. Plotting equation 33 shows that nonlinearity in density dependence can sharpen the threshold relationship between N^* and P (Fig. 9). In the neighborhood of this threshold, small errors in estimating the proportion of the population that is infertile can lead to very large errors in equilibrium population size. Nonlinear density dependence amplifies the consequences of such errors. Nonlinearity in density dependence also expands the range of levels of infertility in the population (i.e., P) over which we expect virtually no change in equilibrium density (Fig. 9).

Assumed Knowledge of Fertility Status.—One of the assumptions of our base model is that managers can differentiate between fertile and infertile animals when delivering fertility control treatments. There are cases where this assumption is reasonable, for example, when treated animals can be visually marked, or when it is possible to achieve the desired delivery rates by treating young of the year. However, there will be many cases where the fertility status of animals is unknown. This means that some animals are likely to be treated more than once, thereby increasing the number of "doses" of fertility control agents that must be delivered to achieve a target delivery rate.

This is essentially a problem in multinomial sampling with replacement. That is, after an animal is given a dose of contraceptives, it is released into the population unmarked, and is subject to "resampling" a later time. Because it is unmarked, its fertility status is unknown, and it will be redosed if it is resampled. We are interested in estimating the number of doses (d) that must be delivered in order to treat a target number of animals (η) in a population of size

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

N. We first consider the case where the duration of contraceptives is a single breeding season and all infertile animals must be dosed annually to maintain infertility. In this case, it can be shown (Appendix B) that the number of animals (d) that must be dosed to expect η animals to be infertile at the end of the treatment campaign can be estimated as

$$d = \frac{\ln\left(\frac{N-\eta}{N}\right)}{\ln\left(\frac{N-1}{N}\right)}. \quad (34)$$

Alternatively, when the duration of contraceptives persists for more than a year, there will be some animals in the population that will remain infertile and do not need to be retreated. Define I as the number of animals in the population that are infertile at the start of a treatment campaign and that remain infertile during the subsequent year. In this case the number of animals that must be dosed to expect that η additional animals are infertile is given by

$$d = \frac{\ln\left(\frac{N-I-\eta}{N-I}\right)}{\ln\left(\frac{N-1}{N}\right)}. \quad (35)$$

Equations 34 and 35 portray the large inefficiencies associated with treating a significant proportion of a population whenever treated animals are not easily distinguished from untreated ones (Fig. 10). For example, a population of 100 fertile animals would require dosing 160 animals to reasonably expect 80 infertile animals in the population after treatment (Fig. 10). A population of 100 animals, 80 of which are infertile at the time of delivery, would require dosing 69 animals to expect that only 10 additional animals would be infertile during the subsequent year. This result illustrates that the feasibility of treating populations with fertility control agents depends in a fundamental way on knowing the fertility status of individual animals at the time of treatment. In the absence of such knowledge, achieving meaningful reductions in steady state density could require delivering doses in excess of the total number of females in the population.

Stochastic Models

We compared the ability of different control regimes to maintain populations at target densities in the face of environmental stochasticity and error in estimation of population size. For all model runs, simulations of fixed-effect fertility control with single year duration showed the lowest coefficients of variation around target population densities, lowest likelihood of extinction, and longest persistence times (Table 1). Results from the culling model resembled those of single-year duration fertility control, but tended to show slightly higher variability and slightly greater probability of extinction. Lifetime effect fertility control models predicted the highest levels of variability and greatest chance of extinction. In the extreme case, extinctions occurred in >40% of all model runs for lifetime effect representing static application of fertility control with process and observer variation to populations at 25% of K_e (Table 1). Population variability and indicators of extinction risk for models of fertility control with 3-year duration showed effects intermediate to the culling model and the lifetime model. For all models, simulations of adaptive management scenarios increased variability in population density (as measured by coefficients of variation), but reduced probability of extinction and increased persistence time.

DISCUSSION

Relationships to Earlier Models

The models we offer differ in 4 fundamental ways from previous modeling efforts directed at understanding effects of fertility control on vertebrates (Garrott 1991, Garrott and Siniff 1992, Swihart and DeNicola 1993, Boone and Wiegert 1994, Seagle and Close 1996, Pech et al. 1997, White et al. 1997). First, our models are structured in stages where each stage represents the time since a female was treated. Earlier models have been structured by animal age, irrespective of time since delivery. As a result, previous efforts failed to consider effects of duration of contraceptives or the interaction of duration with other model parameters. Stage structure allows us to offer the first analysis of the consequences of variation in the duration of fertility control agents. As a result, we are able to show that animals with long lifetimes (i.e., high adult survival rates) can be effectively controlled with long duration contraceptives, even

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

when they have relatively low fertility rates. This contrasts with earlier efforts that argued that r-selected species with short lives and high fertility were most appropriate targets for regulation by controlling fertility (e.g., Hone 1992).

Second, we offer closed-form solutions for relationships among delivery rate, proportion of the population infertile, number of animals treated, and target population densities. In the past, estimating these relationships demanded laborious trial and error using simulations (Garrott et al. 1992, Boone and Wiegert 1994, Seagle and Close 1996). Unlike previous results, our models enjoy analytical solutions that provide a rapid and general way to approximate the effort required to stabilize a population using fertility control, without developing detailed simulation models.

Third, our models are the first to consider effects of different fertility control regimes on risks of extinction of small populations. We demonstrate that small populations regulated with long-lived contraceptives will be vulnerable to stochastic extinction.

And finally, we are the first to explicitly consider the inefficiencies associated with resampling unmarked animals when delivering fertility control agents. We show that failing to know the fertility status of individuals can create large inefficiencies in achieving desired levels of infertility in real-world populations.

Although our models differ in important ways from earlier ones, we also reinforce previous findings. Similar to other modeling results, we found that more than half of the breeding females must be infertile to achieve meaningful reductions in population density (Fig. 5). It is true that a smaller infertile fraction may be required for species with low adult survival and low recruitment rates (Fig. 5), but these are not usually the species that cause problems of overabundance. These general results are consistent with several, more detailed studies of effects of fertility control on ungulates (Table 2), as well as, field tests in small mammals (McCallum 1996). It follows from these results that there may be situations where it is logistically impossible to treat a sufficient portion of the population to achieve population objectives. This may explain, in part, why field studies have failed to demonstrate that fertility control can maintain populations at lower densities (McCullough et al. 1997). We should not expect any change in steady state when the proportion of the population treated is small (McCullough et al. 1997).

Our models reveal that this problem is exacerbated by the nonlinear relationship between the proportion of the population treated and the steady-state density (Fig. 4). That is, there is a broad range of levels of infertility producing essentially no change in population equilibrium. This relationship could make it very difficult to assess the effect of different levels of population infertility in field studies because widely differing levels of infertility could result in very similar steady-state densities. Similar nonlinear relationships have been identified in other modeling efforts (Boone and Wiegert 1994, McCallum 1996, Seagle and Close 1996). This problem is magnified in populations where the fertility status of animals is not known (e.g., equations 34 and 35, Fig. 10). In this case, the number of doses that would need to be delivered to achieve a meaningful reduction in population density could easily exceed the total number of animals in the population.

Efficiency of Fertility Control Relative to Culling

There is broad disagreement about the relative efficiency of lethal and nonlethal means of controlling animal abundance. It has been argued that fertility control is more efficient than culling because infertile animals remain in the population, maintaining density-dependent feedback to recruitment and survival (Knipling 1959, Sturtevant 1970, Knipling and McGuire 1972). In contrast, others contend that there are virtually no circumstances in which fertility control will be more efficient than lethal methods (Bomford 1990, Garrott 1995, Nielsen et al. 1997, Swinton et al. 1997). Some workers even assert it is not possible to reduce population numbers with nonlethal control (Seal 1991).

The models we offer can resolve these differences of opinion. There are 2 types of efficiency in population regulation. The first type assesses the amount of time required to bring an overabundant population to an acceptable lower density. There is no question that culling is more efficient than fertility control when efficiency is defined in these terms. Using lethal methods, it is theoretically possible to bring a population to a desired lower density in 1 season of effort. In contrast, the maximum rate of reduction of a population regulated by fertility control is simply $1 - S$, the natural adult mor-

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

tality rate. Assuming that all fertile females are treated ($c = 1$), our models show that the annual growth rate of the population (λ) is S. Because $S < 1$, the population will decline when $c = 1$, but it may decline very slowly if the adult survival rate is high.

In contrast, it is also possible to define efficiency in terms of the number of animals that must be treated annually to maintain a population at a specified target density. By defining efficiency as the number of animals that must be treated, we deliberately ignore the time required to treat them or the monetary expense of treatment. These costs are highly variable and situation specific. Thus to achieve generality, we will restrict our discussion to the number of animals that must be treated or culled and will allow the reader to apply cost estimates to weight efficiency in a case-specific fashion.

When efficiency is defined in terms of the number that must be treated annually, our models reveal that long-duration fertility control agents can be more efficient than lethal methods if the fertility status of treated animals is known. Although this result may be surprising at first glance, a small thought experiment reveals the intuitive basis for our result. Assume that you have 100 breeding animals with a survival rate of 0.9. On average, each of these animals produces a single female offspring every year. Nine of these offspring must enter the population to offset the losses of adults who die annually. It follows that 91 recruits must be culled to maintain the population at 100 animals. Now, presume instead that the population is stabilized by controlling fertility. Ninety animals are sterilized, leaving 10 fertile. One of the fertile animals dies each year after reproducing. Thus, there are 10 fertile offspring, replacing 9 infertile deaths and 1 fertile death. Only 9 of the recruits must be sterilized to maintain a level of infertility in the population = 90%. However, this result does not hold for short-duration agents. In this case, the 90 fertile adults and 90 recruits must be treated to maintain 90% infertility in the population.

Obviously, this is a grand oversimplification of population dynamics, but it illustrates the fundamental logic underpinning the efficiency of fertility control relative to culling. The number of females that must be treated or culled to maintain a given density depends on the difference between the total number of births and the total number of natural deaths. When a large proportion of long-lived species is sterile, this difference will be likely smaller than in fertile populations that are culled because very few animals will be reproducing. Reducing the duration of the fertility control agent increases the number that must be treated annually until this number eventually exceeds the number culled.

MANAGEMENT IMPLICATIONS

We can provide 4 general insights for implementing fertility control relative to culling. First, the efficacy of fertility control as a means to regulate populations pivots on the ability to develop agents with persistent effects. Second, we also point out that the expense of fertility control will never compete favorably with the revenue that can be provided by licensed hunting, regardless of the duration of contraceptives. Fertility control will only be cost-effective for situations where recreational hunting isn't feasible and where population control can only be achieved by professional treatment, lethal or nonlethal. Third, the feasibility of achieving target levels of infertility in the population will require knowledge of fertility status of individuals. In cases where this status is not known, the inefficiencies associated with redosing animals can increase the number of animals that must be treated by several fold. Finally, the greatest efficiency can be obtained by combining culling with contraception such that an initial reduction in animal numbers is maintained by annual treatment of marked animals with long-acting fertility control agents.

The reason that lifetime duration fertility control can be an efficient method for maintaining a population at target densities also explains why the approach is difficult to implement initially and why it poses grave risks to the persistence of small, closed populations. Our models suggest that it is relatively easy to maintain a population near a given steady state, once a sufficient number of animals have been sterilized. Achieving this initial level of infertility in the population will often be a formidable task, however, and accomplishing that task means that the breeding population will be small. Such breeding populations are subject to stochastic risks of loss of genetic variability and even extinction, as our models illustrated. It follows that while fertility control may not affect survival of individuals, it can easily be lethal to populations.

This creates a genuine dilemma for manag-

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

ers. Small, closed populations are the most likely candidates for regulation by fertility control. This is simply because delivery of fertility control agents to a sufficient number of animals is most likely to be logistically feasible when populations are small and bounded in space. However, these populations are also the most prone to extinction if managers make mistakes in applying fertility control agents. The nonlinearity in many of the relationships we observed magnifies the likelihood of such errors. It follows that although fertility control can be an efficient means of regulating animal numbers, that efficiency creates risk for the population manager. As with all other techniques, managing population fertility must be grounded in a fundamental understanding of the state of the population and the role of management in influencing its dynamics. This simple fact reinforces the conclusions of Garrott (1995) that careful field studies applying control techniques over long time periods are needed to thoroughly understand effects of fertility control.

We offer a suite of predictions that can be usefully tested in field studies. Our models provide a sketch of the dynamics of populations regulated by fertility control. Offering a sketch rather than a blueprint requires that we avoid many details. Understanding those details will no doubt prove necessary to minimize unpleasant surprises in managing fertility of ungulate populations (Caughley et al. 1992, Nettles 1997). However, by offering general rather than detailed models, we provide broad insights useful as a starting point for future studies.

We identify 2 urgent needs for future work on fertility control agents. Development of techniques that render animals infertile with a single dose offer a promising alternative to culling in situations where it is feasible to mark animals to know their fertility status. Thus, work at the level of the individual animal should emphasize increasing the duration of effect of fertility control agents. Studies at the level of the population must demonstrate that fertility control can achieve meaningful reductions in rates of increase in the field. Although models like ours can suggest situations where fertility control could be efficacious in controlling abundance of ungulates, such efficacy remains in doubt until field studies demonstrate such control in real-world populations.

AKNOWLEDGMENTS

Discussions with G. C. White and B. C. Lubow motivated our analytical approach. We appreciate helpful comments on manuscript drafts from J. E. Gross, P. J. Weisberg, D. M. Swift, L. Clark, and 2 anonymous referees. R. B. Gill provided administrative support and encouragement.

APPENDIX A

Example Derivation of Deterministic Results

We used a standard series of steps to analyze all models. Here, we illustrate those steps using fixed-effect model, assuming prebreeding delivery of contraceptives. We begin with a state vector $[F\ I_1\ I_2\ I_3]$ for the case where duration of fertility control persists for 3 years. The corresponding projection matrix is

$$\begin{bmatrix} (1-c)(S+m-\beta N) & 0 & 0 & S(1-c) \\ c(S+m-\beta N) & 0 & 0 & Sc \\ 0 & S & 0 & 0 \\ 0 & 0 & S & 0 \end{bmatrix} \quad (36)$$

We obtain the characteristic polynomial of the matrix:

$$0 = \lambda^4 - \lambda S^3 c - S\lambda^3 - m\lambda^3 + \beta N\lambda^3 + Sc\lambda^3 + cm\lambda^3 - c\beta N\lambda^3. \quad (37)$$

By iterating over several values of τ, we observe a general series in characteristic polynomials for all $(\tau + 1 \times \tau + 1)$ matrices:

$$0 = \lambda^{\tau+1} - \lambda S^\tau c - S\lambda^\tau - m\lambda^\tau + \beta N\lambda^\tau + Sc\lambda^\tau + cm\lambda^\tau - c\beta N\lambda^\tau. \quad (38)$$

When the population is at equilibrium, $\lambda = 1$. Therefore, to find a general expression for the equilibrium density as a function of delivery rate we set $\lambda = 1$ and solve equation 38 for N, obtaining:

$$N^* = \frac{S + m + S^\tau c - 1 - Sc - cm}{\beta(1-c)}. \quad (39)$$

Solving for c, we find the delivery rate (c^*) needed to achieve a specified target density (N^*),

$$c^* = \frac{S + m - N^*\beta - 1}{S + m - N^*\beta - S^\tau}. \quad (40)$$

To find the composition of the population (i.e., the proportion of each stage of infertility in the population) we obtain the eigenvectors of several projection matrices corresponding to different values of τ. For each matrix, we extract the first element ($v[1]$) of the normalized vector (corresponding to an eigenvalue of 1), which gives the proportion of the population that is fertile,

$$v[1] = \frac{1-c}{(1-c)/c + 1 + S + S^2 + S^3 \ldots + S^\tau}. \quad (41)$$

To find the infertile proportion (P), we subtract $v[1]$ from 1 and simplify,

$$P = \frac{(1 - S^\tau)c}{1 + Sc - S - S^\tau c}. \quad (42)$$

In a similar way, we observe the last normalized element of the eigenvector for several values of τ and find that the proportion of the population that is in the final stage of infertility (ρ) is given by a series which simplifies to

$$\rho = v[\tau + 1] = \frac{(1-S)S^{\tau-1}c}{1 + Sc - S - S^\tau c}. \quad (43)$$

We then derive a general expression for the proportion of the population (P) that must be infertile to achieve a target density N^*. We substitute the right hand side of equation for c in equation 42, and after some algebra, obtain

$$P = 1 - \frac{1-S}{m - N^*\beta}. \quad (44)$$

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

To remove β from the denominator, we observe from equation 39 that the equilibrium density in the absence of fertility control (i.e., $c = 0$) is

$$K = \frac{S + m - 1}{\beta}. \quad (45)$$

Defining Δ as the proportional reduction in population density below K (i.e., $N^* = \Delta K$), it follows that

$$N^* = \Delta K = \frac{\Delta(S + m - 1)}{\beta}. \quad (46)$$

Substituting the right hand side of equation 46 for N^* in equation 44,

$$P = 1 - \frac{1 - S}{m + \Delta(1 - S - m)}. \quad (47)$$

To derive an expression for the number of animals treated (n) to maintain a target density, we observe from the projection matrix and the state vector that the number of animals treated at equilibrium is

$$n = c^*F_t(S + m - \beta N^*) + c^*I_{t_\tau}, \quad (48)$$

which is simply the treatment rate multiplied by the steady state number of fertile females at time t plus the number of females that are recruited plus the number that regain fertility during $t \rightarrow t + 1$. Substituting $(1 - P)N^*$ for F_t and ρN^* for I_{t_τ} we have

$$n = c^* (1 - P)N^* (S + m - \beta N^*) + c^* \rho N^*, \quad (49)$$

Substituting the right-hand-side of equation 40 for c^*, rhs equation 44 for P and rhs equation 43 for ρ provides the needed expression for n in terms of the decision variable N^* and the parameters m, S, and β.

APPENDIX B

Derivation of an Unbiased Estimator for the Number of Doses that must be Delivered to a Population of Unknown Fertility to Achieve a Target Level of Infertility

We assume that a simple random sample of d animals is selected with replacement from a population of N animals. All of the animals in the sample are dosed. At the beginning of the sampling effort, the population contains I infertile animals. In order to establish the results shown in equations 34 and 35 we note that equation 35 is a special case of equation 36 where $I = 0$. We define t_i as an indicator random variable that equals 0 if the *ith* fertile animal is still not dosed after d selected animals are treated and equals 1 if it has been dosed at least once for $i = 1, 2 \ldots, N - I$. We define a as the number of additional infertile animals that are added to the population after d doses are delivered,

$$a = \sum_{i=1}^{N-I} t_i. \quad (50)$$

The expected number of additional infertile animals is given as

$$\eta = E(a) = \sum_{i=1}^{N-I} E(t_i) = (N - I)E(t_i). \quad (51)$$

Define $P(t_I = 1)$ as the probability that $t_i = 1$; then,

$$E(t_i) = P(t_i = 1) = 1 - P(t_i = 0) = 1 - \left(\frac{N - 1}{N}\right)^d. \quad (52)$$

Thus,

$$\eta = (N - I)\left(1 - \left(\frac{N - 1}{N}\right)^d\right). \quad (53)$$

Solving equation 53 for d gives equation 35. The variance of a can also be easily determined.

Extrapituitary Action of Gonadotropin-Releasing Hormone: Direct Inhibition of Ovarian Steroidogenesis

Abstract. *Gonadotropin-releasing hormone (GnRH) and its agonistic analogs inhibited the follicle-stimulating hormone (FSH)-induced increase of estrogen and progesterone production in vitro by rat ovarian granulosa cells. Likewise, GnRH analogs inhibited FSH-induced changes in ovarian function in hypophysectomized rats in vivo. These results indicate that GnRH, in addition to its well-known gonadotropin-releasing action in the pituitary, exerts a direct inhibition of ovarian steroidogenesis.*

Gonadotropin-releasing hormone (GnRH) stimulates pituitary gonadotropin production (*1*). However, pharmacological doses of GnRH and its agonists have been shown to inhibit a variety of female reproductive functions, such as ovarian steroidogenesis, ovulation, ovum transport, ovum implantation, pregnancy, and ovarian-dependent mammary tumorigenesis (*2*). The mechanism by which GnRH inhibits reproductive function is unknown. Although it is generally believed that the inhibitory effects of GnRH are mediated at the pituitary level, the possibility that GnRH may act at the level of the gonads is not excluded. We now report that GnRH and its agonistic analogs act independently of the pituitary to inhibit gonadal function: blockage of the gonadotropin-induced increases in ovarian steroidogenesis in vitro and antagonism of the follicle-stimulating hormone (FSH)-induced changes in ovarian function in hypophysectomized rats in vivo.

Follicle-stimulating hormone stimulates production of estrogen and progestin in primary cultures of ovarian granulosa cells (*3*). The effect of GnRH on these FSH actions was investigated. Granulosa cells from immature intact (23 to 25 days of age) and hypophysectomized diethylstilbestrol-treated (27 to 30 days of age, 5 days after operation) rats were cultured for 2 days (*4*). In the presence of estrogen synthetase (also called aromatase) substrate ($10^{-7}M$ androstenedione), purified FSH (100 ng/ml; Papkoff G4-150C, FSH potency equal to 50 NIH-FSH-S1 standard units per milligram) stimulated estrogen production by 40- to 60-fold. Concomitant treatment with GnRH or GnRH agonists ([D-Leu^6-(N$^\alpha$Me)Leu^7]GnRH, analog 1; des-Gly^{10}-[D-Try^6, Pro^9-NHEt]GnRH, analog 2) (*5*, *6*) inhibited FSH-stimulated increase in estrogen production (Fig. 1A). Similarly, GnRH and its agonists inhibited the FSH-induced increase in progesterone production by the granulosa cells (Fig. 1B). These results indicate that GnRH exerts a direct inhibition on ovarian steroidogenesis.

The in vivo effects of GnRH agonists on ovarian function were also examined in hypophysectomized estrogen-treated rats. Four days after hypophysectomy, immature estrogen-treated female rats were injected subcutaneously, twice daily, for 2 days with 100 μg of ovine FSH (NIH-FSH-S12) or the same amount of FSH plus GnRH analogs (50 μg of analog 1 per 0.1 ml of saline; 10 μg of analog 2 per 0.1 ml of saline). The ovarian weight and steroidogenic potential were determined 12 hours after the last injection. The FSH induced a significant increase in ovarian weight (control, 12.2 ± 1.1 mg, N = 11; FSH treated, 29.0 ± 2.0 mg, N = 8). In contrast, concomitant treatment with GnRH agonists inhibited the FSH-induced increase in ovarian weight (FSH plus analog 1, 15.6 ± 2.0 mg, N = 8; FSH plus analog 2, 14.7 ± 1.3 mg, N = 8). In vivo FSH treatment for 2 days induced a substantial increase in aromatase activity in ovarian granulosa cells. Granulosa cells were harvested from control and treated animals and incubated for 3 hours in the presence of a saturating dose of estrogen synthetase substrate ($10^{-7}M$ Δ^4-androstenedione). The estrogen production was stimulated from an undetectable level in granulosa cells of control animals to 1.65 ng per 10^5 granulosa cells in FSH-treated animals. Concomitant treatment with GnRH agonists inhibited the FSH-induced increase in estrogen production (FSH plus analog 1, 0.29 ng per 10^5 cells; FSH plus analog 2, 0.25 ng per 10^5 cells). The results indicate that treatment in vivo with GnRH agonists in hypophysectomized animals interferes with the FSH action at the ovarian level.

Our results demonstrate that GnRH and its agonists exert extrapituitary action as shown by their ability to inhibit ovarian function directly. This finding may serve as the basis for explaining the inhibitory effect of GnRH on reproductive functions. Thus, in addition to their well-known releasing action on the pituitary gonadotrophs, pharmacological doses of GnRH and its agonists could decrease ovarian estrogen production by directly interfering with normal ovarian function. A GnRH-induced decrease in estrogen production offers an expla-

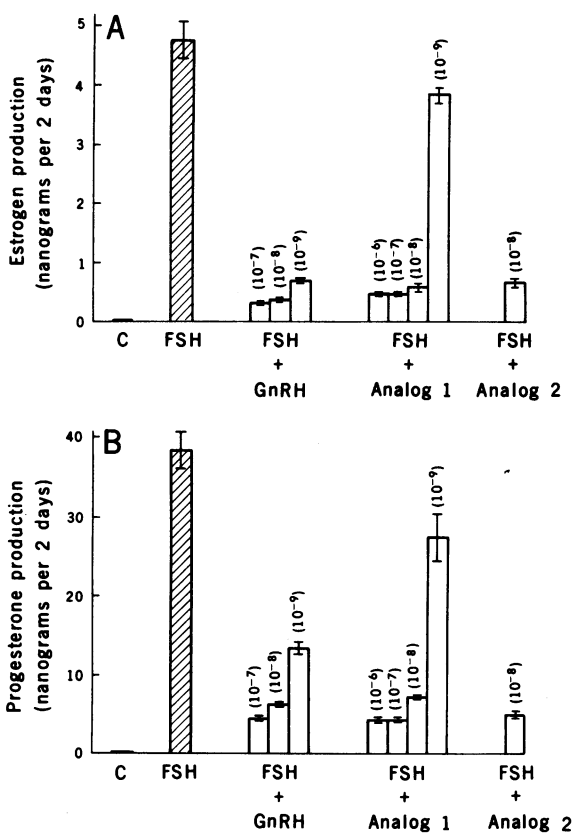

Fig. 1. Effect of GnRH and its agonistic analogs on FSH-induced increase in steroid production by ovarian granulosa cells. (A) Estrogen production; (B) progesterone production. Ovarian granulosa cells were obtained from hypophysectomized estrogen-treated immature female rats and cultured for 2 days in the presence of $10^{-7}M$ androstenedione. Ovine FSH (100 ng/ml), with or without GnRH or its agonists, was added to the media at the beginning of the culture. Estrogen and progesterone content in the media after 2 days culture was determined by radioimmunoassay. Similar results were obtained with granulosa cells from intact immature rats. Each data point represents mean ± standard deviation of four to six separate cultures. The numbers inside the parentheses represent the final concentration of GnRH or analogs in culture medium.

nation for the reported blocking effect of GnRH on various estrogen-dependent processes, including ovulation, ovum transport, ovum implantation, and mammary tumorigenesis. Moreover, the inhibitory effect of GnRH and agonists on FSH-induced progesterone production in cultured granulosa cells could offer a possible explanation for the interference by GnRH and its agonists in such a progesterone-dependent process as pregnancy. Our results, however, do not exclude the possibility that administration in vivo of pharmacological doses of GnRH in intact animals may also cause imbalances in pituitary gonadotropin production that also result in the inhibition of various reproductive functions (*7*).

The mechanisms by which GnRH exerts inhibition on ovarian granulosa cells are not known. Although GnRH receptors have been identified in the anterior pituitary by radiotracer binding technique and by immunocytochemical methods (*8*), their tissue specificity has not been demonstrated. Bernardo *et al.* (*9*) have reported putative GnRH binding sites in the mouse adrenal cells. It is possible that ovarian granulosa cells may have GnRH receptors and that the inhibitory effect of GnRH that we observed is mediated through hormone-receptor interactions.

Periodicity of Deoxyribonuclease I Digestion of Chromatin

Abstract. *Two methods have been used to measure the single-strand lengths of the DNA fragments produced by deoxyribonuclease I digestion of chromatin. The average lengths obtained are multiples of about 10.4 bases, significantly different from the value of 10 previously reported. This periodicity in fragment lengths is closely related to the periodicity of the DNA double helix in chromatin, but the two values need not be exactly the same.*

The first level of condensation of DNA in chromatin is brought about by its interaction with histones to form nucleosomes, the elementary subunits of the structure. For a detailed understanding of how the DNA is folded, it is necessary to know both the path of the double helix and its periodicity, or the number of base pairs per turn, in the nucleosome. X-ray crystallographic studies indicate a path in which the DNA is wrapped twice around the histones (*1*). This appears to conflict with measurements on closed, circular DNA extracted from SV 40 chromatin showing nearer one superhelical turn (*2*). The conflict can be resolved by postulating a change in the periodicity of the DNA as it is folded into a nucleosome (*1*). A decrease of only about 5 percent is required, and so before firm conclusions can be drawn it is necessary to know the relevant parameters as accurately as possible.

Noll (*3*) has suggested that the perio-

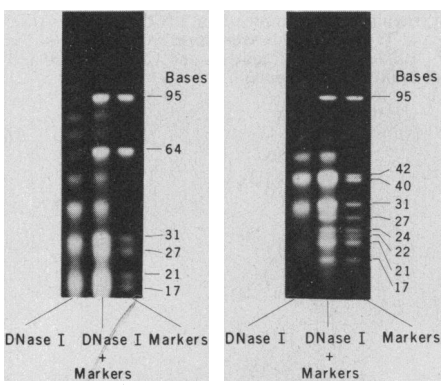

Fig. 1 (left). Comparison of DNase I and marker fragments in polyacrylamide gels. DNase I fragments were prepared by DNase I digestion of rat liver nuclei and extraction of the DNA (*3*). Marker fragments were prepared as described in Table 1. All fragments were labeled with ^{32}P as follows. DNA (40 μg/ml) in 50 m*M* sodium acetate (*p*H 4.6) and 1 m*M* EDTA was boiled for 1 minute and treated with spleen acid phosphomonoesterase B (*16*) (0.1 unit per milliliter) for 2 hours at 37°C. The *p*H was then raised to 8.0 by the addition of tris base to 85 m*M* and the mixture was boiled for 1 minute, supplemented with $MgCl_2$ (10 m*M*), 2-mercaptoethanol (15 m*M*), and γ-^{32}P-labeled ATP (tenfold excess over 5′-OH termini), and treated with polynucleotide kinase (20 unit/ml) (New England Biolabs) for 1 hour at 37°C. The labeled DNA was purified by filtration through Sephadex G-25 in a mixture of 0.1*M* NaCl, 10 m*M* tris-HCl (*p*H 7.5), and 1 m*M* EDTA and subjected to electrophoresis in 12 percent (left panel) and 20 percent (right panel) polyacrylamide–98 percent formamide gels (*17*). Negatives of autoradiograms of the gels are shown.

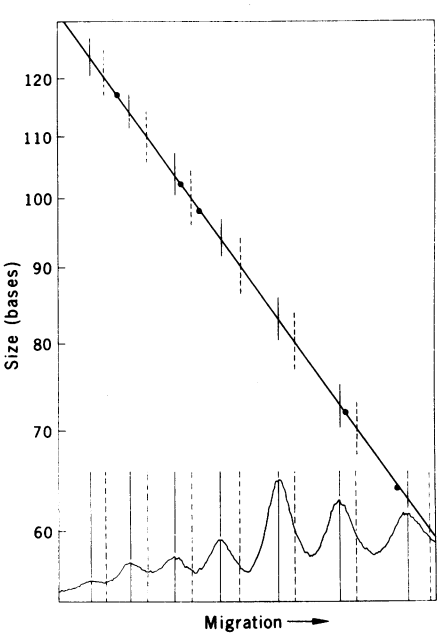

Fig. 2 (right). Size determination of DNase I bands. Densitometer traces of lanes in left panel of Fig. 1 containing DNase I (bottom) and marker fragments were aligned. The sizes and distances of migration of the marker fragments (filled circles) were used to construct a calibration curve from which the sizes of the DNase I fragments were derived. The distances of migration of the DNase I fragments (solid vertical lines) are contrasted with those expected if the fragments were multiples of 10.0 bases (dashed vertical lines).

Abstract

The aim of this study was to evaluate the effect of active immunization against GnRH on ovarian activity, plasma progesterone and estradiol concentrations and on estrous behavior in adult mares. Eighteen cyclic mares were randomly divided into a treatment and control group. Nine mares were immunized twice with 2 mL (400 μg GnRH-protein conjugate) of a GnRH-vaccine (Improvac®, CSL Limited, Australia) administered intramuscularly, 4 weeks apart. Control mares received the same amount of saline solution. Ovaries and uterus of all mares were examined weekly by ultrasonography from 3 weeks before to 60 weeks after the first immunization. Thereafter, vaccinated mares were evaluated monthly until 100 weeks after the first vaccination. In addition, mares were teased with a stallion for assessment of estrous behavior and blood was collected for progesterone, estradiol-17β and GnRH antibody titer determination. Results demonstrate that vaccination against GnRH significantly (P<0.05) influenced all parameters, except estradiol-17β concentration. All vaccinated mares ceased reproductive cyclicity (plasma progesterone <1 ng/mL, follicles <3 cm) within 8 weeks after the first injection and ovarian activity remained suppressed for a minimum of 23 weeks. Five mares resumed cyclicity (follicles >3 cm, progesterone >1 ng/mL) while 3 mares showed only follicular activity (follicles >3 cm) and 1 mare remained completely suppressed for the entire duration of the study. In spite of ovarian suppression, 4 mares expressed sporadic and 1 mare continuous estrous behavior. All 9 control mares showed regular development of large follicles and associated periods of estrous behavior during the breeding season. During the winter months, 6 of them became acyclic, whereas the other 3 continued showing reproductive cyclicity and estrous

behavior. In conclusion, reproductive cyclicity in adult mares can be successfully suppressed by immunization against GnRH but the timing of resumption of cyclicity is highly variable and estrous behavior may occur in spite of ovarian suppression.

1. Introduction

The suppression of sexual behavior in mares has long been an issue for both veterinarians and horse owners. Undesirable behavioral traits, especially during estrus, can make a mare difficult to handle and may have detrimental effects on performance. There are numerous methods for managing this problem. One of the most wide spread is the use of progesterone or progestins to artificially simulate diestrus [1]. However, the possibility of a negative effect on the future breeding prospects after repeated use in prepubertal fillies has been reported [2] and the short duration of action of this hormone, necessitating repeated administration, make its use costly and impractical. More drastic means of suppressing estrous behavior are breeding a mare and accepting the ensuing break in the mares' sporting career, or terminating the pregnancy after maternal recognition and maintenance of the primary Corpus luteum (CL) [3], which poses ethical problems. Ovariectomy is a further alternative, though not always effective, as some mares can continue to show estrous signs [4-6], furthermore it carries the disadvantage of surgical risk and permanently eliminating a mare's reproductive potential. Other methods of reversible suppression of sexual activity that warrant being mentioned are the administration of GnRH antagonists or agonists [7]. The antagonist antarelix has been shown to reliably postpone ovulation after administration and increase the inter-ovulatory interval [8,9]. Treatment with high doses of agonists can effectively desensitize the pituitary to GnRH in various species [10]. Horses are on the whole less sensitive to down-regulation, however, prolonged or high dose administration can also result in increased inter-ovulatory intervals [11,12] and in some individuals even in a temporary cessation of ovarian activity [13,14]. As all these treatments require frequent administration and generally result in only a short-term effect with highly individual responses, their use for behavioral control is limited.

The manipulation of the reproductive activity of both males and females through the use of a GnRH vaccine has been extensively studied in many species, including humans and with a wide variety of objectives. In farm animals, this method offers an alternative to surgical castration for minimizing sexual and aggressive behavior, suppressing reproductive function and preventing pregnancy [15-18]. In wild animals, vaccination against GnRH is considered an effective method for population control [19,20]. Its application in human medicine is as a treatment for prostate cancer [21]. In the field of

equine reproduction the first report of GnRH vaccination was also as a possible alternative to surgical castration in either cryptorchid [22] or normal males [23,24]. The principal aims were the evaluation of its effectiveness at inhibiting sexual behavior and libido while safeguarding the reproductive potential of an animal. The first studies in mares [25,26] were aimed primarily at investigating the effect of GnRH vaccination on gonadotropin secretion. Observations of follicular activity and estrous behavior were not a major part of the experimental design and mares were ovariectomized [25] or the study was terminated [26] before the mares returned to normal ovarian cyclicity; neither study concentrated on the possibility of using this method as an alternative to ovariectomy. Two further studies have been reported [27,28]: one documented effective suppression of ovarian function and estrous behavior along with a subsequent reversal of these effects in six 2-year-old fillies [27]; the second study on mature mares showed a greater individual variation and less reliability of the vaccination [28] .

The aim of the present experiment was to investigate the influence of active immunization against GnRH on reproductive cyclicity, hormone levels and antibody titers in a relatively large group of mature mares. This included evaluation of its influence on the ovaries and uterus, the duration of action, effects on estrous behavior and adverse reactions to the vaccine.

2. Materials and methods

2.1. Experimental design

Eighteen barren light-horse mares, aged between 3 and 17 years, (mean age 7.8 years) were used for the experiment. They had variable reproductive histories, but none had been bred within the last 2 years. All mares showed normal reproductive cyclicity with typical signs of behavioral estrus prior to treatment. The mares were randomly allocated to a control and a treatment group of nine mares each (mean age 7.2 and 8.4 years respectively). The treatment consisted of two vaccinations four weeks apart using a commercially available anti-GnRH vaccine (Improvac®, CSL Limited, Australia) developed in Australia to control boar taint in pigs. Improvac® contains a synthetic analogue to GnRH linked to a carrier protein and accompanied by an aqueous adjuvant (200 μg GnRH-protein conjugate per mL). The dosage used for both initial and booster vaccination was 400μg GnRH-protein conjugate (2 mL). Control animals received an equivalent volume of saline solution. All injections were applied intramuscularly into the left side of the neck. The experiment started at the end of March and initial vaccination took place at the end of April. Adverse effects were monitored by twice daily clinical examination with particular regard to body temperature, signs of tissue reaction at the site of injection and stiffness of the neck. Mares were examined for 3 days after vaccination or until all reactions had subsided.

2.2. Ovarian activity, uterine changes and estrous behavior

The mares' genital tracts were examined by means of transrectal ultrasonography with a 5 MHz linear array probe (Aloka Echocamera SSD-500, Aloka Holding Europe, Zug, Switzerland). At each scanning session, the ovaries were measured in two perpendicular dimensions. The number and diameters of all follicles larger than 1 cm in diameter were recorded and assigned to one of 3 categories: small follicles, <2 cm in diameter; medium follicles, 2-3 cm in diameter and large follicles, >3 cm in diameter. The diameter of the largest follicle (to the nearest 0.5 cm) present on either ovary was recorded separately. The presence of a CL was also noted. The amount of edema in the uterine wall was scored as 1 (homogeneous in appearance, non edematous), 2

(mildly heterogenous, slightly edematous) or 3 (“wagon wheel” appearance, highly edematous) [29].

Mares without a clearly visible CL were teased with a stallion after each scanning session. Four characteristic estrous signs were noted: tail raising, receptivity to the stallion, clitoral eversion and urination. Excessive kicking, flattening of ears and total lack of interest in the stallion were judged as negative signs. For a mare to be considered as showing typical estrus, at least 3 of 4 positive signs and no negative signs had to be observed. Over the course of 64 weeks (3 weeks before to 60 weeks after the primary immunization) mares were examined at weekly intervals (period 1). Mares in the treatment group that had not yet returned to normal reproductive cyclicity after week 60 were examined monthly until they showed a resumption of ovulation (period 2). Examinations were discontinued after a maximum of 100 weeks.

2.3. Definition of reproductive activity

Mares were considered to be acyclic when no large follicles were recorded, no CL was visible and progesterone values were lower than 1 ng/mL for at least 4 consecutive weeks. If the criteria were fulfilled only during short periods of 1 to 3 weeks, these were regarded as periods of temporary follicular quiescence. After an acyclic period, mares were judged as having resumed follicular activity when large follicles (>3 cm diameter) were recorded. When the mares with follicular activity showed a rise in progesterone (plasma progesterone concentration >1 ng/ml) indicating ovulation and formation of a functional CL, they were judged as having resumed ovulatory activity. The period of ovarian suppression was defined as the number of weeks between cessation of all cyclic activity and resumption of follicular activity (no less than 4 weeks).

2.4. Hormone analysis and GnRH antibody titers

Blood samples (EDTA) were collected at each examination by jugular venipuncture, immediately centrifuged (4000 x *g*, 10 min) and the plasma frozen (-20°C) until analysis. Progesterone and estradiol-17ß concentrations were measured using electrochemiluminescence immunoassay (Elecsys 2010, Roche Diagnostics, Basel, Switzerland). The detection limit of the assay was 0.03 ng/mL for progesterone and 3.1

pg/mL for estradiol-17ß. Inter- and intraassay coefficients of variation for progesterone were 2.8% and 2.2% respectively and for estradiol-17ß 6.5% and 2.5% respectively.
Antibody titers against GnRH were determined using a radio ligand binding assay as described previously [30]. Results are presented as percentage of total I^{125}-labelled GnRH bound at a plasma dilution of 1:40.

2.5. Statistical analysis

Statistical analysis was performed using the Statview 5.0 software program (SAS Institute, Switzerland). A multivariate analysis of variance (ANOVA) was carried out to assess the effects of treatment and time on ovarian and uterine parameters as well as on plasma progesterone and estradiol concentrations. Differences between the groups in weekly parameter means were compared with the unpaired *t*-test. Values were considered to be statistically significant at $P<0.05$.

3. Results

3.1. Ovarian and uterine changes

Means (± S.E.M.) of all parameters measured in the treatment and the control group from week 1 to 60 are presented in Table 1.

Table 1
Mean (± S.E.M.) of reproductive activity parameters examined weekly during 60 weeks in GnRH immunized (Improvac®) and control mares (n=9, each) and the statistical significance of the influence of treatment and time of examination

Parameter	GnRH immunized	Control	Treatment (*P*)	Time (*P*)
Number of small follicles	4.9 ± 0.20	6.7 ± 0.20	<0.0001	<0.0001
Number of medium follicles	0.8 ± 0.10	3.0 ± 0.10	<0.0001	0.0004
Number of large follicles	0.1 ± 0.02	0.8 ± 0.05	<0.0001	0.0228
Diameter of largest follicle (cm)	1.5 ± 0.04	2.8 ± 0.05	<0.0001	<0.0001
Ovarian diameter (cm)	4.2 ± 0.03	5.3 ± 0.03	<0.0001	<0.0001
Number of CL	0.2 ± 0.02	0.7 ± 0.03	<0.0001	<0.0001
Uterine edema score [a)]	1.3 ± 0.03	1.7 ± 0.03	<0.0001	0.0113
Progesterone (ng/mL)	1.2 ± 0.17	6.8 ± 0.36	<0.0001	<0.0001
Estradiol-17β (pg/mL)	24.4 ± 0.44	24.8 ± 0.35	0.216	<0.0001

[a)] 1: homogenous, 2: slightly heterogenous, mildly edematous, 3: wagon wheel appearance, highly edematous

Vaccination against GnRH significantly (*P*<0.05) influenced all parameters, except plasma estradiol-17β concentration. Fig. 1 shows the mean number of large follicles (a), mean diameter of the largest follicle (b) and mean ovarian diameter (c) in treated and control mares from 3 weeks before until 60 weeks after first immunization.

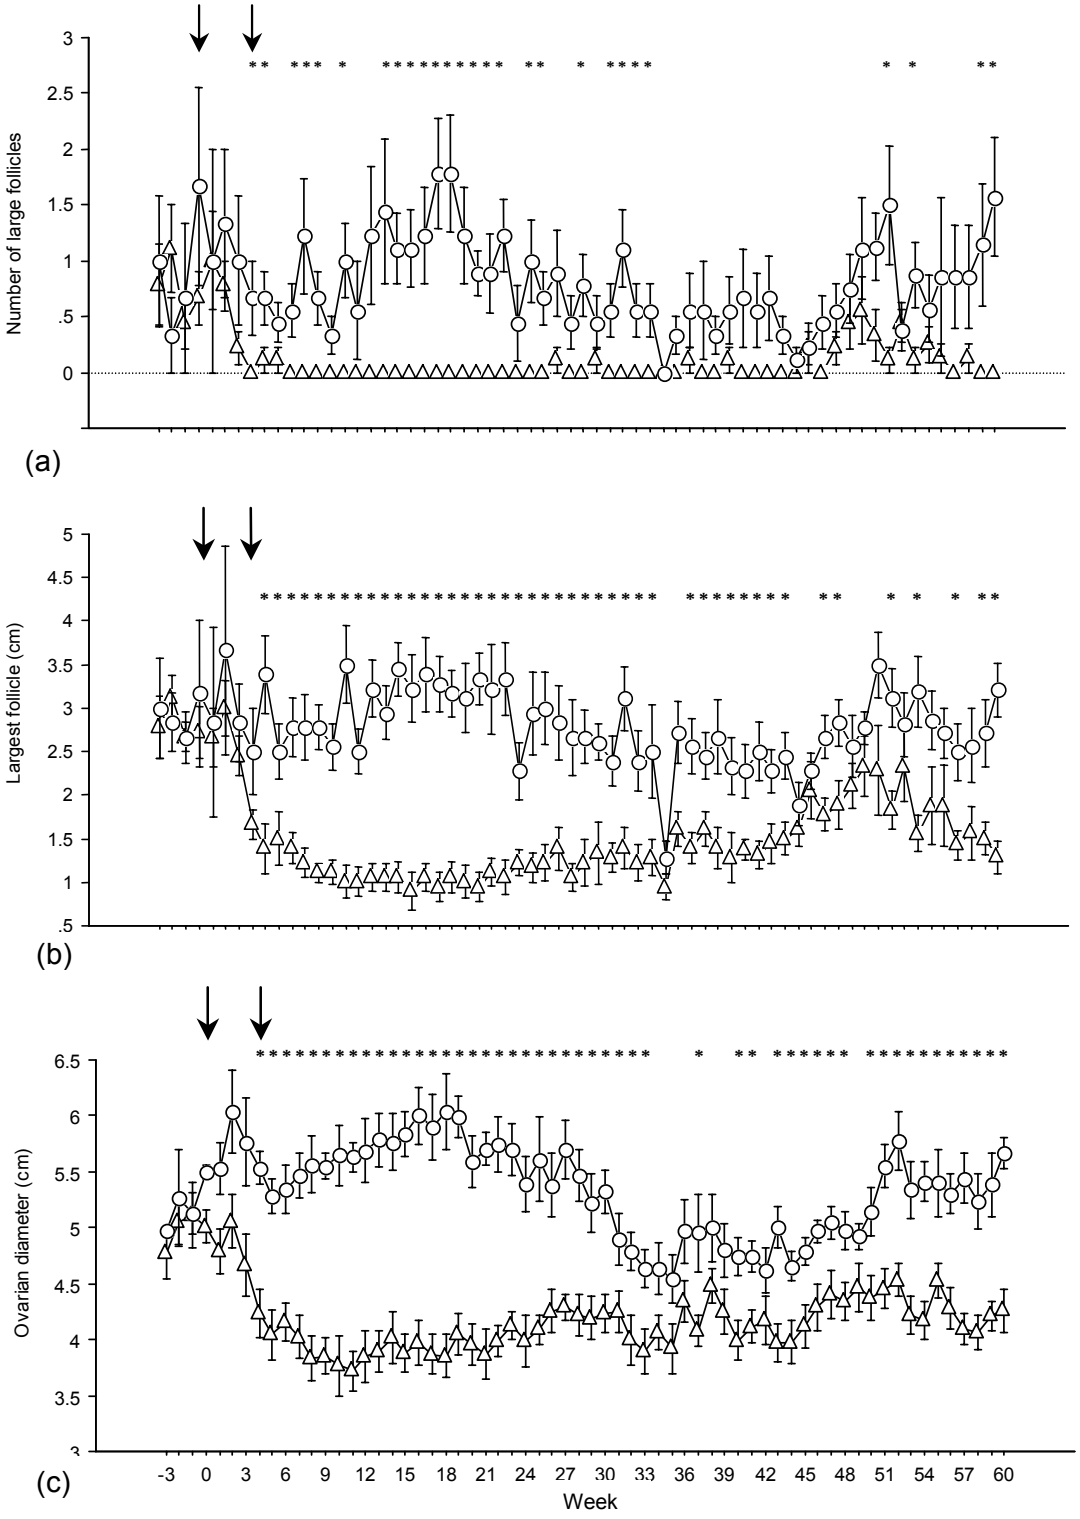

Fig. 1. Mean (±S.E.M.) number of large follicles (a), diameter of the largest follicle (b) and ovarian diameter (c) in vaccinated (△) and control (○) mares before and after immunization (↓). Asterisks indicate a significant difference (P<0.05, unpaired t-test) between groups.

Before the first vaccination there were no significant differences between the groups. The mean number of large follicles (Fig. 1a) in vaccinated mares decreased rapidly after the first vaccination and large follicles were completely absent from weeks 7 to 26. The mean number of large follicles remained below 1 until the end of period 1. These changes were also reflected by the mean diameters of the largest follicle (Fig. 1b), which in vaccinated mares dropped below 2 cm in week 4 and remained between 1 and 2 cm for 41 consecutive weeks. Mean diameters of the largest follicle in control mares only dropped below 2 cm in weeks 35 and 45. The difference between the groups was significant ($P<0.05$) during weeks 5 to 35. Mean ovarian diameters were also significantly ($P<0.05$) lower in vaccinated mares from week 4 to 33 (Fig. 1c).

Fig. 1 shows that mares in the control group continued normal cyclic activity with regular development of large follicles. As the study progressed into the winter months (weeks 32 to 46), most of the control mares gradually entered seasonal anestrus, showing reduced follicular activity and ovarian diameter. The weekly differences between the 2 groups were no longer significant. The period of ovarian suppression was accompanied by an equivalent period in which no CL were observed. In both treatment and control groups, the reappearance of a CL was preceded by a notable increase in follicular activity and indicated return to cyclic activity.

Uterine changes mirrored the changes in ovarian activity. The vaccinated mares had little ultrasonographically detectable uterine edema from the time when ovarian activity ceased until follicular activity recommenced. In control mares, uterine scores of 2 and 3 were always observed at regular 2 to 4 week intervals, except during the winter months.

3.2. Plasma progesterone and estradiol-17β concentrations

Fig. 2a shows the mean concentrations of plasma progesterone in treated and control mares from 3 weeks before to 60 weeks after first vaccination. Before treatment, the mean progesterone values in mares of both groups fluctuated between 1.7 and 11.7 ng/mL. After initial vaccination, the mean plasma progesterone concentration in the treated group fell below 1 ng/mL in week 4 and remained at this level until week 28. From week 28 small episodic increases in mean progesterone concentration were observed, which became more pronounced towards the end of period 1. In control

mares, mean plasma concentration of progesterone rose to 15.4 ng/mL during the breeding season and declined during winter months (weeks 32 to 46), remaining below 2.5 ng/mL from week 37 to 44 (January and February). Values rose again to 17 ng/mL as the study progressed into the new breeding season. Significant differences (P<0.05) between groups were present continuously during weeks 4 to 30 and at single weeks during the following breeding season.

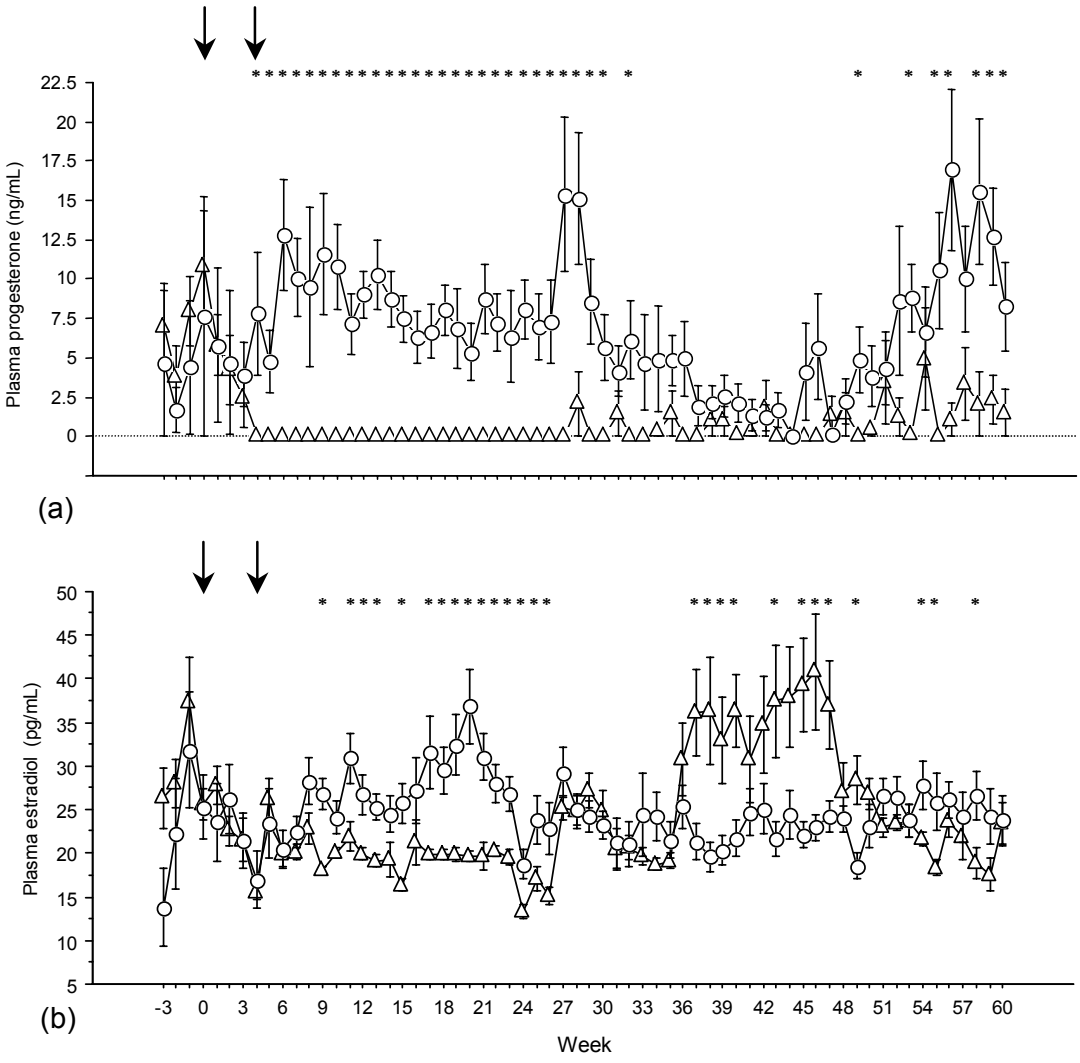

Fig. 2. Mean (±S.E.M.) plasma progesterone (a) and estradiol-17β (b) concentrations in vaccinated (△) and control (○) mares before and after immunization (↓). Asterisks indicate a significant difference (P<0.05, unpaired t-test) between groups.

Changes in mean concentrations of plasma estradiol-17β during period 1 are shown in Fig. 2b. Before treatment, mares of both groups had mean plasma estradiol-17β values fluctuating between 13.8 and 37.3 pg/mL. After the first vaccination the mean estradiol-17β concentrations in treated mares declined and fluctuated between 13.4 and 27.8 pg/mL until week 35. From week 36 to 47 (January to March) a clear increase in mean plasma estradiol-17β concentrations occurred in treated mares with values up to 40.9 pg/mL. Thereafter estradiol-17β concentrations rapidly decreased to levels observed before week 36. In control mares mean plasma estradiol-17β concentrations varied between 17.0 and 36.9 pg/mL during weeks 1 to 60. Significant differences (P<0.05) between groups were mainly observed between week 9 to 26 and 36 to 50.

3.3. Duration of ovarian suppression and effect on estrous behavior

All 9 immunized mares ceased cycling within 8 weeks of the first vaccination and the minimum period of ovarian suppression was 23 weeks. During period 1, three mares resumed both follicular (weeks 27, 46, 53) and ovulatory activity (weeks 28, 51, 54). In period 2, another two mares resumed both follicular (weeks 80, 96) and ovulatory activity (weeks 84, 100). Of the 4 treated mares that did not resume ovulatory activity during the study, 3 resumed follicular activity at weeks 48, 64 and 100. Of these, one showed regular development of large follicles for over 50 weeks without a progesterone rise, and one was destroyed for reasons unrelated to the study shortly after resumption of large follicle development. One mare remained completely suppressed for the entire duration of the study.

Six of 9 control mares became acyclic during weeks 33 and 41 (December to January) and cyclic activity was reestablished between weeks 45 and 56 (March to May). The other three control mares never fulfilled the criteria of acyclicity. Fig. 3 shows the plasma progesterone concentration together with the diameter of the largest follicle of 4 individual mares during period 1. Mare A from the control group shows an acyclic period between weeks 31 and 47. Mares B, C and D treated with Improvac® illustrate different types of reaction to the vaccine. Mare B showed the shortest period of suppression, followed by cyclic activity throughout the winter period, mare C showed a gradual return to follicular activity before achieving ovulation and mare D remained suppressed throughout period 1.

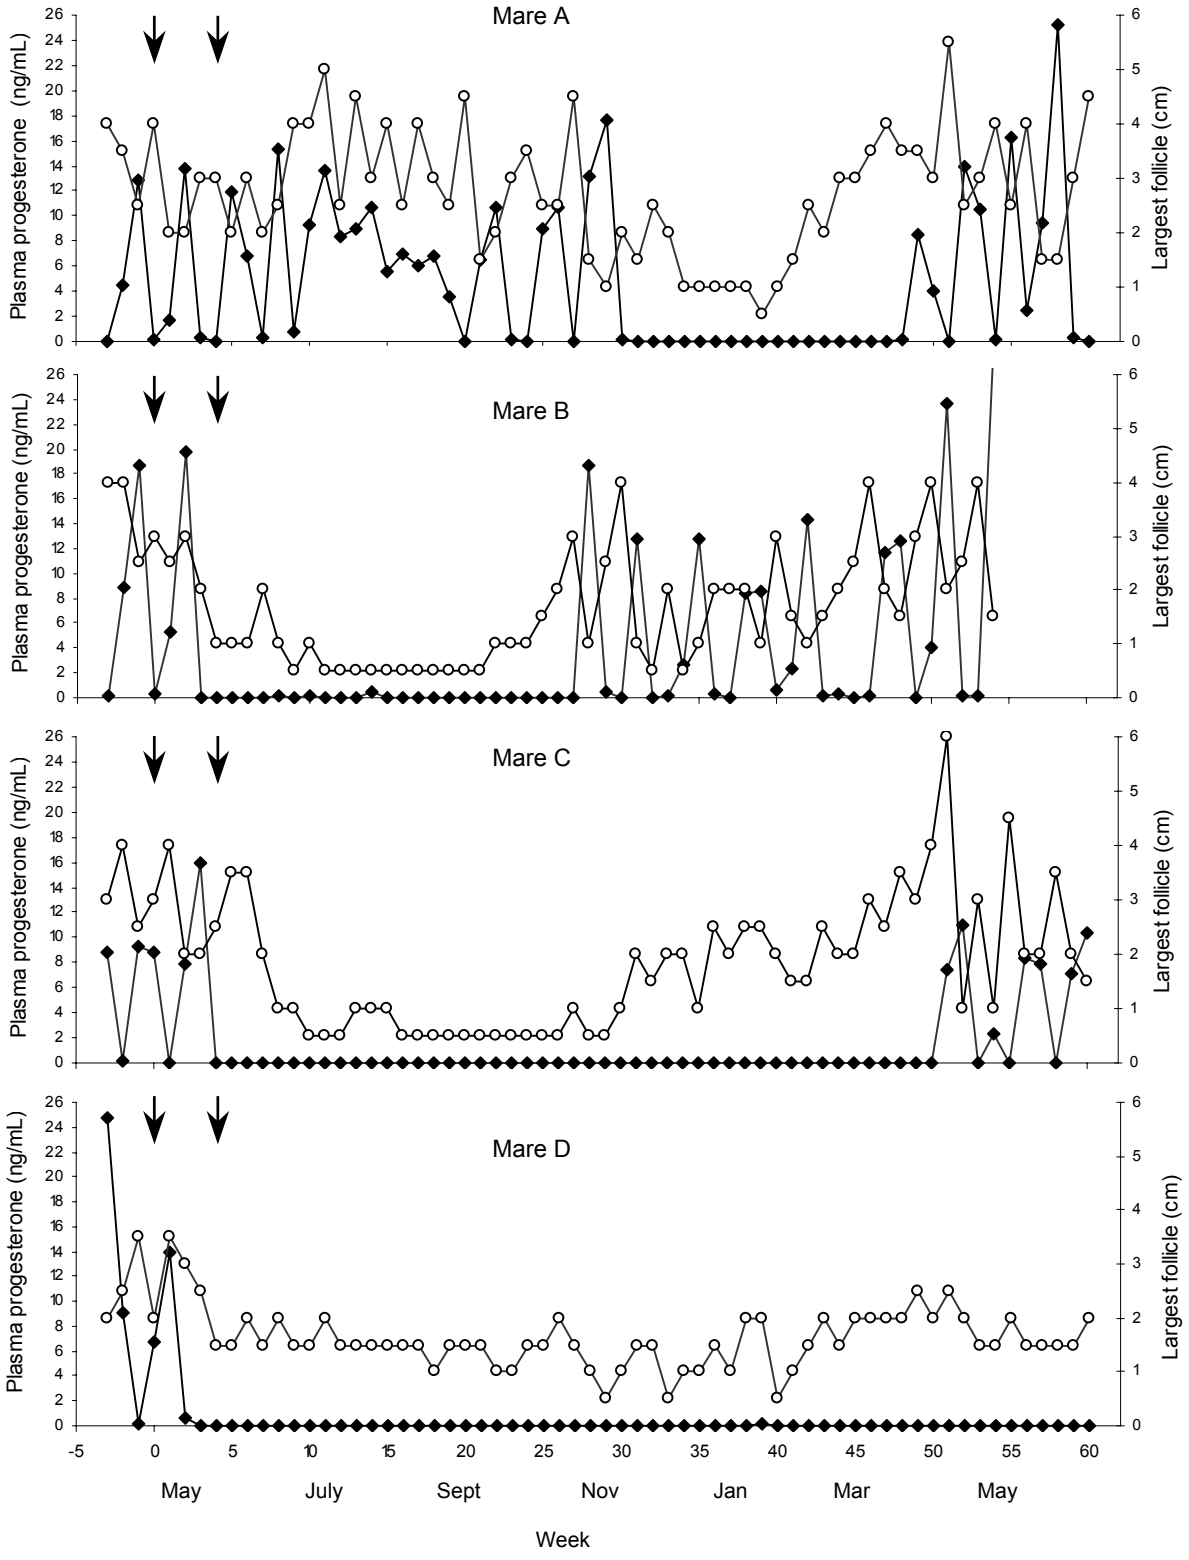

Fig. 3. Individual plasma progesterone concentration (◆) and diameter of largest follicle (○) of a control mare (A) and 3 vaccinated mares (B,C,D) before and after immunization (↓) during period 1.

In 4 vaccinated mares, estrous signs were absent during ovarian suppression and the first occurrence of large follicles was accompanied by estrous behavior. The other 5 mares expressed estrous signs that were not obviously related to follicle growth. Three of these mares showed sporadic estrous behavior, one was in estrus for several weeks before resuming follicular activity, while the last mare displayed estrus continuously from week 5 after vaccination until plasma progesterone concentration increased (week 84). All control mares demonstrated regular periods of estrous behavior throughout the study, except during seasonal anestrus.

3.4. Antibody titers

Antibody titers (Fig. 4) began to rise immediately after the first vaccination in all 9 mares and reached peak values 2 to 3 weeks after the booster injection. Maximum titers showed large individual variations and ranged between 35 and 70% binding (1:40 dilution). Thereafter, they slowly decreased to values between 15 to 40% binding at week 100 after the first vaccination. Values at resumption of ovulatory activity ranged from 24 to 35 % binding.

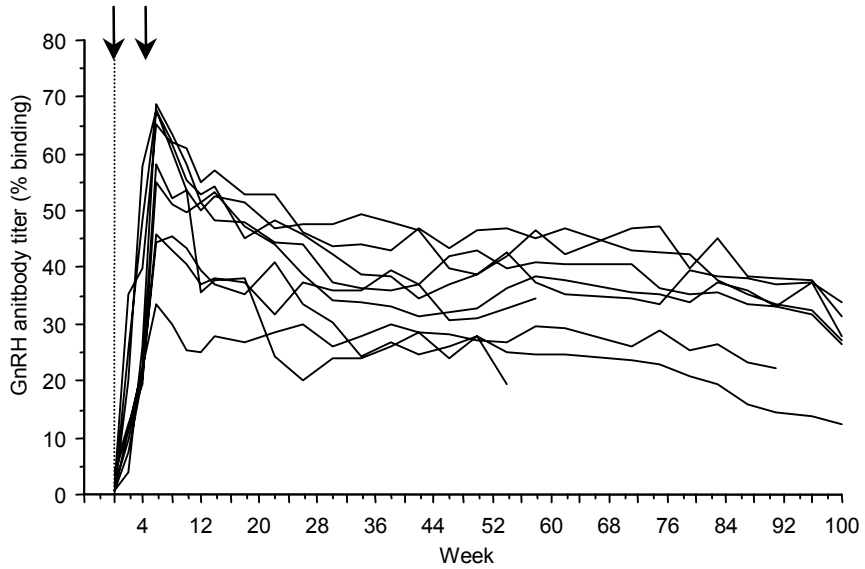

Fig. 4. GnRH antibody titers in 9 mares after GnRH immunization (↓) at weeks 0 and 4 (% binding at a 1:40 plasma dilution).

3.5. Adverse effects

Eight of 9 mares, which received 2 ml of Improvac®, showed reactions of varying severity, including swelling and pain at the injection site, stiffness of the neck, pyrexia and apathy (Table 2). The degree and duration of reactions varied individually and were more serious after the booster injection. A mean increase in body temperature was only evident on the day after each vaccination (mean 38.8 and 38.7°C). However, individual peaks up to 39.8°C were recorded. Swelling and pain was most evident on the second day after vaccination. All reactions had subsided by 4 and 5 days after primary and booster vaccination, respectively.

Table 2

Incidence of adverse effects of immunizing mares against GnRH using Improvac®

Effect	Number of mares	
	Primary immunization	Booster immunization
Number of mares immunized	9	9
Pyrexia	8 (88.9%)	7 (77.8%)
Pain at site of injection	4 (44.4%)	7 (77.8%)
Swelling at site of injection	3 (33.3%)	6 (66.7%)
Stiffness of the neck	0	7 (77.7%)
Apathy	0	2 (22.2%)

4. Discussion

The results of this study demonstrate that administration of the GnRH vaccine Improvac® to mares elicits clear inhibitory changes in endocrine, ovarian, uterine and behavioral parameters.

The effect of immunization against GnRH on ovarian activity was dramatic and rapid, and allowed clear differentiation between treated and control mares. Follicular development decreased such that by 4 weeks after the first vaccination, the number of medium and large follicles differed significantly between the treatment and control group. The variation in the amount of time (2-7 weeks) from vaccination to cessation of ovarian activity was probably due to immunization at different stages of the cycle. In mares with large follicles (estrus), cessation time was longer than in mares vaccinated during the luteal phase (diestrus). A similar study [27] carried out with a smaller number of mares also showed a rapid response to vaccination with follicular atresia and significant reduction in ovarian length 3 to 4 weeks after the first injection. In our study the ovarian response was always bilateral and the marked decrease in number and size of follicles resulted in ovaries that were significantly smaller than those in the control mares for 30 consecutive weeks. Resumption of ovulatory activity was achieved in 5 of 9 mares and varied between 27 and 100 weeks after the first vaccination. In these mares the period of time that elapsed between the first signs of follicular activity and the appearance of a progesterone-secreting CL was 1-5 weeks. These results demonstrate that resumption of follicular and ovulatory activity after immunization against GnRH is highly variable in spite of all mares being immunized at the same time with the same dose of the vaccine and despite showing a similar decline of anti-GnRH titers. A highly individual duration of ovarian suppression in vaccinated mares was also reported by Dalin et al. [28], where one mare showed a large time lapse between resumption of follicular activity and first ovulation and another was completely suppressed for approximately 14 months. The suppression of ovarian activity is brought about by the binding of endogenous GnRH to circulating antibodies, preventing GnRH from binding to receptors in the anterior pituitary. Studies on mares have shown that secretion (and possibly production) of LH is highly dependent on GnRH, while FSH secretion is at least partially independent of GnRH stimulation [25,26]. Therefore, the growth of small antral follicles that we observed in all vaccinated mares and that has been previously

described in mares [26,28], heifers [17] and ewes [31], may be relatively independent of GnRH availability. Because of the more comprehensive suppression of LH then of FSH achieved by vaccination against GnRH [25], further development, maturation and ovulation may be prevented.

Resumption of follicular and ovulatory activity in vaccinated mares may be comparable to the transitional period seen in mares between seasonal anestrus and the breeding season [32] where large (≥3 cm) anovulatory follicles grow and regress before an ovulatory follicle develops with sufficient estradiol production to increase LH secretion and induce ovulation.

A significant finding of the current study was that 3 mares showed no signs of luteal activity despite regular development of large follicles and that one mare showed neither luteal activity nor follicle development for 2 years after vaccination. Without having conducted further tests we are unable to say whether immunization resulted in reduced sensitivity of the pituitary gland to GnRH or decreased pituitary production and / or secretion of LH and FSH. Furthermore, we cannot entirely exclude the possibility of some degree of permanent impairment of hypothalamic or pituitary function, as observed after the immunization of ewes against GnRH early in life [31].

Levels of plasma progesterone and estradiol-17β concentration also showed marked differences between the treatment and control groups. Plasma progesterone concentration is considered the best indicator for the resumption of estrous cycles in mares [27,28]. Cyclic activity in control mares was demonstrated by regular progesterone increases, which correlated with recent ovulations. In all vaccinated mares the indirect effect of GnRH inactivation on LH secretion was best evidenced by the low progesterone concentrations (<1 ng/ml), indicating the absence of ovulations, during at least 5 months. The effect of vaccination on estradiol-17β concentrations was less dramatic. In control mares, levels fluctuated throughout the whole study and higher concentrations were observed when the number of large follicles was increased. In vaccinated mares, plasma estradiol-17β concentrations generally fluctuated at a lower level than in control mares until the end of the breeding season. From January to March mean estradiol-17β concentrations in vaccinated mares were significantly higher than in control mares due to abnormally elevated levels seen in 3 mares. As the number and size of the follicles during this time was not higher than at any other time during period

1, it is speculated that the origin of the estradiol-17β may be increased production by granulosa cells of small and antral follicles. It is also possible that the estradiol was of adrenal origin since sexual steroids are also produced by the adrenal cortex in response to ACTH [5].

The manifestation of estrous behavior in anovulatory mares as seen in this study is a phenomenon that has been described after vaccination against GnRH [28], after treatment with a GnRH agonist [14] and following ovariectomy [5]. In the absence of significant progesterone concentrations, only small amounts of estradiol are needed for induction of estrous signs. That estrous behavior in ovariectomized mares was successfully suppressed by dexamethasone treatment [5] further underlines the possible involvement of sexual steroids originating from the adrenal cortex.

All mares showed an immediate and distinct antibody response after the first vaccination with peak levels obtained 2 to 3 weeks after the booster injection. The titer decline was similar in all mares, with a rapid fall during the first few weeks followed by a steady decline until 100 weeks after the first vaccination. Antibody titers were not clearly related to the duration or the degree of ovarian suppression and titers at reversal varied considerably. Other studies in mares [26,28], heifers [17] and ewes [33] also report a large variation in antibody response, duration of suppression of reproductive activity and antibody titer at reversal. It may be concluded that thresholds at which antibody titers retain effectiveness are variable between individuals, and may well be related to genetic factors and the individuals' specific immune response [33].

The adverse effects to vaccination with Improvac® were quite severe, similar to those described by Dalin et al. in mares [28] and Dowsett at al. in stallions [23] using different vaccine formulations. Improvac®, originally developed to control boar taint in pigs has been shown to be well tolerated in pigs [34,35]. The high incidence of adverse effects using Improvac® in horses may either be caused by the adjuvant or the carrier protein present in the vaccine. A new vaccine (Equity™, Pfizer Animal Health, Australia), with a modified adjuvant and carrier protein has been designed specifically for use in the horse and is well tolerated (authors: unpublished observations).

In conclusion, this study demonstrates that reproductive cyclicity in adult mares can be reliably suppressed by active immunization against GnRH. However, the duration of the inhibitory effect is highly variable, not clearly related to GnRH antibody titers and

resumption of ovulatory activity may require more than 100 weeks. Moreover, ovarian suppression does not always prevent the occurrence of sexual behavior. Because of the failure of some mares in this study to return to reproductive cyclicity, it would be of practical significance to determine the long-term effects of repeated vaccination on the fertility of mares.

Acknowledgements

We would like to thank J.-F. Johner, Chalet a Gobet, for providing the mares and G. Cosentino of the Laboratory Dr. Risch, Liebefeld, for the hormone analyses.

Zusammenfassung

Das Ziel dieser Arbeit war es, die Wirksamkeit einer anti-GnRH Vakzine auf die Zyklusaktivität beim adulten Schaf während der Zuchtsaison abzuklären. Für die Untersuchungen standen 22 zyklische Weisse Alpenschafe im Alter zwischen 2 und 4 Jahren zur Verfügung, die zufällig einer Versuchs- und Kontrollgruppe mit je 11 Tieren zugeordnet wurden. Die Schafe der Versuchsgruppe erhielten 2-mal im Abstand von 4 Wochen 2 ml (400µg GnRH-Protein-Konjugat) Improvac™ (Pfizer Animal Health, Australien) und die Kontrolltiere erhielten die entsprechende Menge physiologischer Kochsalzlösung subkutan am Hals verabreicht. Der Progesterongehalt im Blut wurde wöchentlich während 3 Wochen vor bis 32 Wochen nach der 1. Impfung und der Antikörpertiter monatlich nach der 1. Impfung bestimmt. Bei allen geimpften Schafen trat innerhalb von 2–8 Wochen nach der 1. Impfung eine Azyklie auf. Die Unterdrückung der Progesteronsekretion dauerte mindestens 12 Wochen (2 Schafe) mit individuellen Abweichungen von 14 (1 Schaf), 25 (1 Schaf) und mehr als 25 Wochen (7 Schafe). Bei 4 Tieren war die Impfwirkung reversibel, während die restlichen 7 Schafe bis zum Ende des Versuchs azyklisch blieben. Die Antikörpertiter erreichten 4 Wochen nach der 2. Impfung Maximalwerte und fielen anschliessend kontinuierlich bis Versuchende (8 Monate nach der 1. Impfung) auf Werte zwischen 10.9 und 40.8 % Bindung ab. Aufgrund unserer Ergebnisse kann gefolgert werden, dass beim adulten Schaf nach zwei Impfungen mit Improvac™ im Abstand von 4 Wochen die Zyklusaktivität während mindestens 12 Wochen gehemmt wird. Die Unterdrückung der Ovarfunktion ist jedoch individuell verschieden und kann mehr als 31 Wochen anhalten.

Schlüsselwörter: Schaf, GnRH Vakzine, Zyklus, Progesteron

Suppression of reproductive cyclicity by active immunization against GnRH in the adult ewe

The objective of the present study was to evaluate the effect of an anti-GnRH vaccine on cycling activity in the adult ewe during the breeding season. For the experiments 22 cycling White Alpine sheep, aged between 2 and 4 years, were randomly divided into a treatment and control group of 11 animals, each. Sheep of the treatment group were immunized twice at an interval of 4 weeks with 2 ml (400µg GnRH-protein conjugate) of Improvac™ (Pfizer Animal Health, Australia) subcutanously in the neck. Sheep of the control group received the same amount of saline solution. Blood progesterone concentrations were measured weekly from 3 weeks before to 32 weeks after first immunization and anti-GnRH titers were determined monthly. All vaccinated ewes ceased cycling within 2–8 weeks after first immunization. Plasma progesterone was suppressed for a minimum of 12 weeks (2 ewes) with individual variation of 14 (1 ewe), 25 (1 ewe) and more than 25 weeks (7 ewes). Four animals resumed cyclicity while 7 animals remained suppressed until the end of the study. Antibody titers peaked one month after the booster injection and thereafter continuously dropped until the end of the study (8 months after first immunization) to values between 10.9 and 40.8 % binding. From our results it can be concluded that two vaccinations with Improvac™ 4 weeks apart suppress cycling activity in adult ewes for at least 12 weeks. The inhibitory effect on ovarian activity, however, varies individually and may last more than 31 weeks.

Einleitung

Die Steuerung des Sexualzyklus gewinnt beim kleinen Wiederkäuer zunehmend an Bedeutung. Neben der Zyklusinduktion ausserhalb der physiologischen Fortpflanzungsperiode und der Synchronisation ist auch die Unterdrückung der Brunst während der Alpung ein häufig geäussertes Anliegen der Schafhalter. In einem früheren Versuch (Janett et al., 2004) konnten wir zeigen, dass nach einmaliger Verabreichung hoher Gestagendosen (50 mg Chlormadinonazetat oder 140 mg Medroxyprogesteronazetat) der Sexualzyklus während mindestens 4 (Chlormadinonazetat) beziehungsweise 6 Wochen (Medroxyprogesteronazetat) unterdrückt werden konnte. Aufgrund der relativ kurzen Wirkungsdauer eignet sich diese Methode jedoch nicht für eine Unterdrückung der Brunst während einer gesamten Alpungsdauer von 3–4 Monaten. Eine Alternative zur hormonellen Brunstunterdrückung stellt die aktive Immunisierung gegen GnRH dar, die grundsätzlich bei allen Säugetieren (D'Occhio, 1993) möglich ist und bei Rind (Robertson et al., 1979; 1982; Jeffcoate et al., 1982), Schwein (Dunshea et al., 2001; Jaros et al., 2005), Pferd (Turkstra et al., 2005, Imboden et al., 2006), Hund (Ladd et al., 1994), Katze (Levy et al., 2004), Wildtieren (Miller et al. 2000; 2004), Ziegenbock (Godfrey et al., 1996) und Schaf (Jeffcoate et al., 1982; Brown et al., 1994; 1995; Janett et al., 2003; Earl et al., 2006) mit Erfolg angewendet wurde. Eigene Untersuchungen (Janett et al.; 2003) beim männlichen Lamm mit der mittlerweile in der Schweiz registrierten Schweinevaccine Improvac™ (Pfizer Animal Health, Australia) haben gezeigt, dass die Hodenfunktion nach einer 2-maligen Impfung im Abstand von 3 Wochen während mindestens 3 Monaten gehemmt werden kann. Da entsprechende Untersuchungen beim weiblichen Schaf fehlen, bestand das Ziel der vorliegenden Studie darin, die Auswirkungen einer Impfung mit Improvac™ auf die Zyklusaktivität sowie den Verlauf von Progesteron und des GnRH Antikörpertiters im Blut genauer abzuklären.

Tiere, Material und Methoden

Tiere

Für die Untersuchungen standen 22 adulte pluripare, klinisch gesunde, zyklische Schafe der Rasse Weisses Alpenschaf (WAS) im Alter von 2–4 Jahren zur Verfügung. Während des Versuchs, der von September 2004 bis Mai 2005 dauerte, wurden die Tiere zusammen mit einem vasektomierten Widder auf der Weide (Herbst und Frühling) oder im Stall (Winter) gehalten. Die Winterfütterung bestand aus Heu oder Grassilage und Wasser stand ad libitum zur Verfügung.

Versuchsanordnung

Vor Versuchbeginn wurde bei allen Schafen mittels vier aufeinanderfolgenden wöchentlichen Plasmaprogesteronbestimmungen die Zyklusaktivität nachgewiesen und je 11 Tiere zufällig einer Versuchs- (GnRH-Impfung, n=11) und einer Kontrollgruppe (physiologische NaCl-Lösung, n=11) zugeordnet. Anschliessend wurden die Tiere der Versuchsgruppe 2-mal im Abstand von 4 Wochen mit 2 ml (400µg GnRH-Protein-Konjugat) Improvac™ (Pfizer Animal Health, Australien) subkutan seitlich am Hals geimpft. Die Kontrolltiere erhielten jeweils die gleiche Menge physiologischer NaCl-Lösung.

Blutentnahme, Progesteron- und Antikörper-Bestimmung

Bei allen Schafen wurde wöchentlich in der Zeit von 3 Wochen vor bis 32 Wochen nach der 1. Impfung mittels heparinisierter Röhrchen (S-Monovetten™, Sarstedt, Sevelen) aus der V. jugularis Blut entnommen. Die Proben wurden unmittelbar nach der Gewinnung zentrifugiert (4000 x g, 10 Min.) und Plasma bis zur Analyse bei -18°C gelagert.
Die Progesteronbestimmung erfolgte mit einem Radioimmunoassay (Kit Prog-CTK-4 P001906, DiaSorin, Saluggia, Italien) unter Verwendung eines für Progesteron sehr spezifischen Antikörpers. Die Nachweisgrenze lag bei 0.05 ng Progesteron pro ml Plasma und der Intra- sowie der Inter-assay Variationskoeffizient betrugen 5.8% beziehungsweise 9.0%.
Die Antikörpertiter gegen GnRH wurden in monatlich gewonnenen Plasmaproben mit einem standardisierten ELISA (Röhn et al., 2006) unter Verwendung eines am N-Terminal konjugierten Peptids (RNase-Cys-GnRH-Konjugat) als beschichtetes Antigen (10µg/ml) und einem polyklonalen Kaninchen anti-Schaf-IgG Antikörper (Millipore, Zug) als sekundärer Antikörper bestimmt. Die Messergebnisse werden als Prozentsatz der Probe mit der höchsten Antikörperbindung bei einer Plasmaverdünnung von 1:540 angegeben.

Statistik

Die statistische Auswertung der Daten erfolgte mit dem Programm StatView 5.0 (SAS Institut, Dübendorf). Der Einfluss der Gruppeneinteilung, des Zeitpunktes der Blutentnahme und der Behandlung (Interaktion von Gruppe und Zeitpunkt) auf die Progesteronkonzentration wurde mit einer multivariaten Varianzanalyse (ANOVA) geprüft. Die Überprüfung von Gruppenunterschieden an einzelnen Zeitpunkten erfolgte mittels ungepaartem t-Test. Die Signifikanzschwelle wurde auf 0.05 festgelegt.
Als Beginn der Impfwirkung wurde der Zeitpunkt bezeichnet, ab dem in mindestens drei aufeinanderfolgenden Wochen die Progesteronkonzentration < 1 ng/ml Plasma war. Die Dauer der Impfwirkung wurde als Peri-

ode mit anhaltend tiefen Progesteronwerten (< 1 ng/ml) definiert. Der Impfeffekt wurde als reversibel bezeichnet, wenn als Hinweis für eine stattgefundenen Ovulation, erneut Progesteronwerte > 1 ng/ml Plasma gemessen wurden.

Ergebnisse

Progesteronverlauf vor und nach der Impfung

Der durchschnittliche Progesteronverlauf aller Schafe mit und ohne Improvac™ ist in Abbildung 1 dargestellt. Vor der Impfung schwankten die Progesteronkonzentrationen bei beiden Gruppen zwischen 2.0 und 4.3 (Improvac™) beziehungsweise 2.0 und 4.8 (Kontrolle) ng/ml Plasma. Während dieser Zeit bestanden keine signifikanten Unterschiede zwischen den beiden Gruppen (Tab.1).
Hingegen konnte nach der Behandlung ein signifikanter

Tabelle 1: Einfluss von Gruppe und Zeitpunkt der Blutentnahme sowie Interaktion von Gruppe und Zeitpunkt auf die Progesteronkonzentration im Blut vor der Behandlung.

Parameter	Gruppe *P*	Zeitpunkt *P*	Interaktion *P*
Progesteron	0.2667	0.0076*	0.7197

*Signifikant (P < 0.05)

(P < 0.05) Einfluss der Gruppe, des Zeitpunktes der Blutentnahme sowie der Behandlung (Interaktion von Gruppe und Zeitpunkt) festgestellt werden (Tab. 2).
Bei allen geimpften Tieren fiel das Progesteron 2 Wochen nach der 1. Immunisierung kontinuierlich auf Werte unterhalb 0.5 ng/ml Plasma ab und blieb, mit Ausnahme von Woche 7, bis zur Woche 19 auf diesem tiefen Niveau. Anschliessend stiegen die Progesteronwerte während der

Tabelle 2: Einfluss von Gruppe und Zeitpunkt der Blutentnahme sowie Interaktion von Gruppe und Zeitpunkt auf die Progesteronkonzentration im Blut nach der Behandlung.

Parameter	Gruppe *P*	Zeitpunkt *P*	Interaktion *P*
Progesteron	< 0.0001*	< 0.0001*	< 0.0001*

*Signifikant (P < 0.05)

Wochen 20–26 vorübergehend leicht an bevor sie ab Woche 27 bis Versuchende erneut auf Werte < 0.5 ng/ml Plasma sanken. Die durchschnittlichen Progesteronkonzentrationen der Kontrolltiere schwankten in den Wochen 1 bis 20 zwischen 1.6 und 6.6 ng/ml Plasma. Ab Woche 21 war ein deutlicher Progesteronabfall mit anhaltend tiefen Werten < 0.5 ng/ml Plasma in den Wochen 27 bis 32 zu beobachten. Signifikante (P < 0.05) Gruppenunterschiede waren in den Wochen 3–6, 8–20, sowie 25 und 27 vorhanden.

Individueller Progesteronverlauf, Wirkung und Reversibilität der Impfung

In Abbildung 2 sind die individuellen Progesteronverläufe bei allen 11 geimpften Schafen dargestellt. Es ist deutlich zu erkennen, dass die Progesteronwerte in den ersten 8 Wochen bei verschiedenen Schafen zwischen 0.13 und 10.00 ng /ml Plasma schwankten. Von Woche 8 bis 19 bewegten sich die Werte stets unterhalb 1 ng/ml Plasma. Ein erneuter Anstieg von Progesteron in den folgenden Wochen war bei 4 Schafen zu beobachten, während die restlichen 7 Schafe bis Versuchende azyklisch blieben. Die individuelle Wirkungsdauer und der Zeitpunkt des erneuten Zyklusbeginns sind in Tabelle 3 zusammengefasst. Daraus geht hervor, dass die Impfwirkung 2–8 Wochen nach der 1. Immunisierung einsetzte und mindestens 12 Wochen dauerte. Die individuelle Unterdrückung

der Ovaraktivität betrug 12 (2 Schafe), 14 (1 Schaf), 25 (1 Schaf) und mehr als 25 Wochen (7 Schafe).

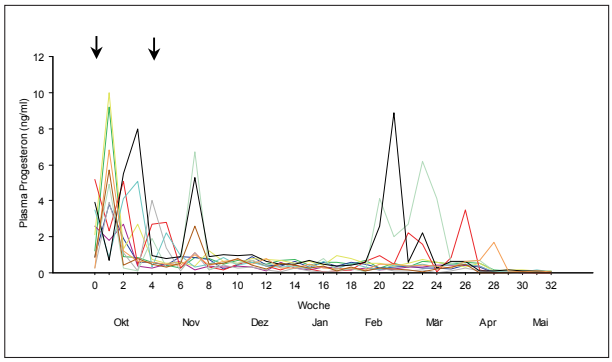

Abbildung 2: Individueller Progesteronverlauf bei 11 mit Improvac™ geimpften (↓) Schafen.

Antikörpertiter

Ein Monat nach der 1. Impfung stiegen die Antikörpertiter (Abb. 3) individuell auf Konzentrationen zwischen 41.5 (Schaf 260) und 89.7% Bindung (Schaf 258) an, erreichten dann 4 Wochen nach der 2. Impfung Maximalwerte zwischen 72.9 (Schaf 267) und 100% (Schaf 258) Bindung und fielen anschliessend bis Versuchende kontinuierlich ab. Am Ende des Versuchs, 32 Wochen nach der 1. Impfung, lagen die Antikörpertiter zwischen 10.9 und 40.8 % Bindung.

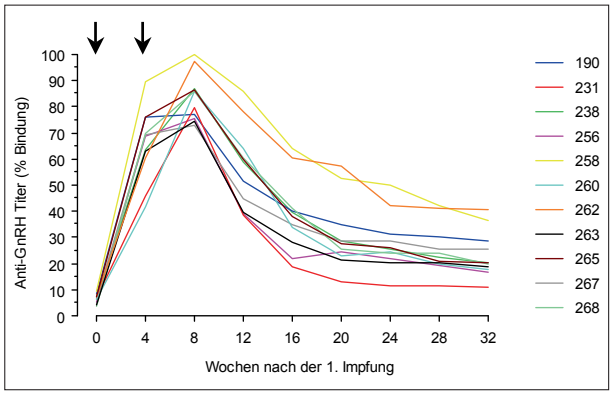

Abbildung 3: Individueller anti-GnRH Titer (% Bindung bei einer Verdünnung von 1:540) bei 11 mit Improvac™ geimpften (↓) Schafen.

Diskussion

Die Ergebnisse der vorliegenden Untersuchung zeigen, dass beim adulten Schaf eine 2-malige Vakzinierung mit Improvac™ im Abstand von 4 Wochen die Zyklusaktivität während mindestens 12 Wochen zu hemmen vermag. Die Impfwirkung setzte spätestens 4 Wochen nach der 2. Impfung ein und war bei 4 Tieren reversibel. Bei den übrigen 7 Schafen blieb der Zyklus während mindestens 25 Wochen bis zum Ende des Versuchs (8 Monate nach der 1. Impfung) gehemmt.

Aufgrund des Titerverlaufs konnten wir bei allen Schafen feststellen, dass im Gegensatz zum Schwein (Dunshea et al., 2001), bereits die 1. Impfung eine deutliche Immunreaktion mit Bildung von spezifischen Antikörpern (42–90% Bindung) auslöste. Ein rascher Titeranstieg bereits nach der 1. Impfung mit Improvac™ haben wir in früheren Untersuchungen (Imboden et al., 2006) auch bei der Stute beobachtet. Dies weist darauf hin, dass Improvac™ im Vergleich zu anderen GnRH Vakzinen bei Pferd (Turkstra et al., 2005) und Schaf (Earl et al., 2006) eine stärkere Immunreaktion hervorrufen kann.

Der Verlauf der individuellen Antikörpertiter zeigte, dass bei einem deutlich erhöhten Titer (> 70% Bindung) die Ovaraktivität zuverlässig gehemmt werden konnte. Tiefere Titer hingegen, liessen keine eindeutige Aussage über die Hemmwirkung zu. So zeigte Schaf 262 bei einem Titer von 41% Bindung in der Woche 28 einen erneuten

Tabelle 3: Beginn und Dauer der Impfwirkung nach 2-maliger Immunisierung im Abstand von 4 Wochen mit Improvac™ bei 11 adulten Schafen.

Progesteronanstieg, während dieser bei Schaf 258 mit einem ähnlich hohen Titer (42% Bindung in Woche 28) ausblieb.

Bei Schafen mit tiefem Antikörpertiter muss als mögliche Erklärung der Azyklie die saisonale Fortpflanzung bei gewissen Rassen berücksichtigt werden. So war ein jahreszeitlicher Einfluss auf die Kontrolltiere in den letzten 3 Monaten unseres Versuches (März–Mai), aufgrund der tiefen Progesteronwerte, deutlich zu erkennen. Dies ist ein weiterer Hinweis, dass das Weisse Alpenschaf entgegen der allgemeinen Annahme nicht asaisonal ist.

Bezüglich Reversibilität der Impfung muss erwähnt werden, dass nach Ende des Versuchs die azyklischen Tiere für weitere Untersuchungen nicht mehr zur Verfügung standen. Es kann jedoch davon ausgegangen werden, dass bei abnehmender Antikörperkonzentration die Zyklusaktivität wieder einsetzt (Keeling und Crighton, 1984). In diesem Zusammenhang ist von besonderem Interesse inwieweit, bei geimpften azyklischen Tieren, eine fertile Brunst induziert werden kann. Beim Einsatz einer GnRH Impfung bei präpubertären Schafen ist zu beachten, dass es zu einer bleibenden Hemmung der Fortpflanzungsfunktion und zu Sterilität kommen kann (Brown et al., 1994; 1995; Clarke et al., 1998; Janett et al., 2003). Aufgrund dieser Erkenntnisse sollte die Impfung gegen GnRH bei Jungtieren, die zur späteren Zucht vorgesehen sind, nicht angewendet werden.

Schlussfolgerung

Unsere Ergebnisse haben gezeigt, dass beim adulten Schaf eine 2-malige Impfung mit Improvac™ im Abstand von 4 Wochen zu einer zuverlässigen Hemmung der Fortpflanzung während mindestens 12 Wochen führt, die Impfwirkung jedoch individuell verschieden ist und länger als 31 Wochen anhalten kann.

Dank

An dieser Stelle möchten wir Urban Lanker und seiner Frau Gaby für die Tiere und ihre Hilfsbereitschaft ganz herzlich danken.

Blocage de l'activité reproductrice chez les moutons adultes par une immunisation active contre la GnRH

Le but de ce travail était d'étudier l'efficacité d'un vaccin anti GnRH sur le cycle de moutons adultes durant la période d'élevage. Pour cette étude, 22 brebis Blanc des Alpes, au cycle normal, âgées de 2 à 4 ans étaient à disposition; elles ont été réparties au hasard en un groupe d'essai et un groupe de contrôle de chacun 11 animaux. Les animaux du groupe d'essai ont reçu 2 fois à 4 semaines d'intervalle 2ml (400µg de conjuguât protéinique de GnRH) d'Improvac™ (Pfizer Animal Health Australie) et les animaux de contrôle une quantité correspondante de solution saline physiologique appliquée par voie sous-cutanée à l'encolure. Le taux sanguin de progestérone a été mesuré hebdomadairement dès 3 semaines avant à 32 semaines après la 1ère vaccination et le titre d'anticorps, mensuellement, après la 1ère vaccination. Chez tous les animaux vaccinés, une acyclie est apparue 2 à 8 semaines après la 1ère injection. Le blocage de la sécrétion de progestérone a duré au minimum 12 semaines (2 animaux) avec des variations de 14 (1 animal) 25 (1 animal) et plus de 25 semaines (7 animaux). Chez 4 brebis, l'effet de la vaccination a été réversible alors que les 7 autres sont restées acycliques jusqu'à la fin du test. Les taux d'anticorps ont atteint des valeurs maximales 4 semaines après la 2ème injection et ont décru ensuite continuellement jusqu'à la fin de l'essai (8 mois après la primo vaccination). Sur la base de ces résultats, on

Soppressione dell'attività riproduttiva tramite attiva immunizzazione contro il GnRH nelle pecore adulte

Scopo di questo studio è di chiarire l'efficacia di un vaccino anti-GnRH sull'attività del ciclo riproduttivo nelle pecore adulte, durante la stagione dell'accoppiamento. Per l'esame sono state messe a disposizione 22 pecore alpine bianche durante il ciclo riproduttivo di età tra i 2 e i 4 anni che sono state attribuite ad un gruppo sperimentale e uno di controllo con ciascuno 11 animali. Alle pecore del gruppo sperimentale è stato somministrato, per 2 volte a distanza di 4 settimane, 2 ml (400µg di proteine coniugate GnRH) Improvac™ (Pfizer Animal Health, Australia) mentre agli animali del gruppo di controllo si è somministrata la stessa quantità di soluzione salina per via subcutanea alla gola. Il contenuto di progesterone nel sangue è stato controllato settimanalmente a partire da 3 settimane prima fino a 32 settimane dopo la 1° vaccinazione e il titolo di anticorpi mensilmente a partire dalla 1° vaccinazione. In tutte le pecore vaccinate è sopravvenuta un'aciclia entro 2–8 settimane dopo la 1° vaccinazione. La soppressione della secrezione di progesterone è durata al minimo 12 settimane (2 pecore) con differenze individuali di 14 (1 pecora), 25 (1 pecora) e più di 25 settimane (7 pecore). In 4 animali l'effetto della vaccinazione è stato reversibile, mentre le restanti 7 pecore sono rimaste senza ciclo fino alla fine dell'esperienza. Il titolo di anticorpi raggiunse 4 settimane dopo la 2° vaccinazione dei valori massimi e di-

© 2009 by Verlag Hans Huber, Hogrefe AG, Bern

peut conclure que chez les brebis adultes le cycle est interrompu pendant au moins 12 semaines après une double vaccination à l'Improvac™ avec un intervalle de 4 semaines. Le blocage de la fonction ovarienne est toutefois individuel et peut se prolonger plus de 31 semaines.

minuì in modo continuo fino alla fine dell'esperienza (8 mesi dopo la 1° vaccinazione) mostrando dei valori tra 10.9 e 40.8%. Sulla base di questi risultati si può dedurre che, l'attività riproduttiva nelle pecore adulte dopo due vaccinazione con Improvac™ a distanza di 4 settimane è inibita durante al minimo 12 settimane. La soppressione della funzione ovarica può essere bloccata per più di 31 settimane ed è differente a seconda dell'animale.

Abstract

The aim of this study was to evaluate the effects of an anti-GnRH vaccine on testosterone concentration, antibody titer, scrotal width, semen quality and sexual behavior in the stallion. Adverse reactions to the vaccine were also determined. Eight clinically healthy sexually experienced stallions aged between 6 and 15 years from the National Stud in Avenches (Switzerland) were used. Five stallions were immunized 3 times at an interval of 4 and 8 weeks, respectively, with 200 μg of a GnRH-protein conj (Equity™, CSL Limited, Australia) intramuscularly in the neck and 3 control animals received an equivalent volume of solution. Plasma testosterone concentrations and GnRH antibody titers as well as semen quality and libido were deter weekly during 1 year (52 weeks). In addition, scrotal width was measured in all stallions before and 4, 8 as well as 12 months after first vaccination. Our results demonstrate that in 4 stallions plasma testosterone started to decrease after the second vaccination and remained suppressed for at least 6 months whereas one stallion showed no effect. Until the end of the experiment 2 stallions reached prevaccination testosterone values. Antibody titers varied individually in all 5 stallions and reached peak concentrations within 2 weeks after the third vaccination. Scrotal width was significantly ($P < 0.05$) lower in vaccinated than in control stallions 8 months after first vaccination. Semen quality started to decreased after the second vaccination and improved towards the end of the experiment. In 4 stallions libido was clearly reduced after the second immunization but normalized in 2 animals before the end of the study while 2 stallions continued to show poor libido. From our results we conclude that three immunizations with Equity™ are well tolerated in the stallion and may effectively suppress testosterone secretion and reduce semen quality as well as sexual behavior. The inhibiting activity of Equity™ on these parameters is individually different and may last for a minimum of 6 months.

Short title: Bruce effect and infanticide in feral horses

ABSTRACT

Journal Pre-proof

Infanticide, related to a stallion's aggression toward a foal sired by another stallion, and feticide related to a new stallion's aggression and/or pheromonal influence (the Bruce effect) inducing loss of a fetus sired by another stallion, a female's counteraction to infanticide, have been proposed for domestic horses *(Equus caballus*) in human-managed conditions. The aim of the present study was, in conditions close to natural, to investigate the influence of the natural succession of a harem stallion on the mares' subsequent reproductive performance.

In a population of semi-feral Konik polski horses observed for 31 years (reproductive seasons) in 8 bands, harem stallion changed 10 times. These changes involved 26 out of 48 mares and 60 out of 609 observed mare-seasons (MS, a year in which a mare experienced a reproductive event). Binary distribution and log link function were assumed. The marginal model included the classification variable (SCH) and the continuous variables (age of the mare and calendar year of reproductive event (birth of a live foal, abortion, foals lost or barrenness) in a given MS was analyzed with generalized linear mixed model. The reproductive fitness of mares and their reproductive success (foal surviving $\geq$ 1 year), did not differ between MS with and without SCH. Older females were more likely to stay barren, with chances increasing by 21% with each successive year; and less likely to give birth to a foal (13% decrease of chance), and rear a foal to one year of age (12% decrease of chance). The age did not affect the probability of abortions.

Of the 26 MS when mares were pregnant when the stallion had changed, there were 25 healthy foals born. For the entire 31 years of monitoring, no aggression toward any foal was observed and all foals that were born in the harem of a new, succeeding stallion successfully reached adulthood.

Due to the lack of incidents of infanticide and the lack of evidence suggesting that the presence of a new harem stallion leads to the termination of pregnancies sired by another stallion, the Bruce effect was not confirmed as a biological strategy to reduce investment in pregnancy and potential infanticide in studied population of semi-feral horses.

KEYWORDS: Horse, Bruce effect, Infanticide, Reproductive performance, Pregnancy

1. INTRODUCTION

Equine reproductive biology and mechanisms underlying reproductive success are still far from being well understood. In conditions closed to natural, horses usually achieve high reproductive performance [1]. However, in human-controlled conditions, the mares may experience reduced pregnancy rate due to various factors [2, 3], among which are sub-optimal conditions for expression of normal behavior [4, 5]. Decreased libido in stallions [4], silent estrus, equivocal agonistic behavior during pregnancy or pseudo-receptive behavior in early pregnancy in mares [6, 7] may mislead breeders, especially when ultrasound examination is not a routine stud practice. Also, other behavioral mechanisms such as infanticide and feticide are proposed to be responsible for decreased pregnancy rates in mares [8-10].

Infanticide and feticide, two phenomena related to a male's aggression potentially enhancing his reproductive success, have been suggested for several mammalian species [11-25], including wild equids [16, 26]. Infanticide is defined as killing vulnerable infants by a male who has not sired them, especially after taking over a group of females [16, 20, 23]. The rationale for this

male behavior is that it brings direct benefits, such as the more rapid return of the female to fertility than would not otherwise occur or the prevention of misled parental care [20].

In feral horses, only single cases of stallions killing foals have been described [13, 16, 18]. Moreover, the observed cases of stallions' infanticide occurred mainly under unstable conditions such as high population density [16] or in populations in which stallions were released only occasionally to breed with mares during the reproductive season [13].

Another potential aggression-related mechanism – termination of early pregnancy in females exposed to an unfamiliar male or its chemical signals (‘Bruce effect') – is believed to be females' counterstrategy to male infanticide [19, 20]. The Bruce effect was first observed and described in mice [27-29]. Since the costs of pregnancy and offspring upbringing are high for females, terminating a pregnancy sired by a predecessor prevents energy waste in production of offspring that most likely will be lost due to possible infanticide of successor males. The Bruce effect has been studied and described thoroughly in rodents; however, observations have also been performed for other species [9, 14, 30-33]. In a feral horse population, Berger [34] observed forced copulations by stallions when taking over a band of mares that he concluded led to abortions of early pregnancies. However, such behavior has not been described by any other author. Recently, questionnaire-based surveys of horse owners were conducted for domestic mares [8-10]. The results suggest that mares inseminated away from home, either naturally or artificially, were at higher risk of abortion after returning home compared to mares pregnant from the home stallion, especially when they experienced contact with a male separated by a fence. In this case, as suggested by latter authors, the mare cannot confuse the home stallion about his paternity, which may occur when she is placed in the same enclosure as the home stallion, so she " ‘manipulates' the male's paternity assessment by promiscuous mating (which)

may explain a common increased incidence of foetal loss in domestic horses" [8]. In contrast, Asa et al. [35], who observed a group of pregnant mares with a stallion that had not sired their pregnancies, never noticed such cases. Clearly, except for the cited studies, there is still much to learn about the drivers of variation in female reproduction in free-roaming horses.

The aim of the present study was, in conditions close to natural, to investigate the negative influence of the succession of a new harem stallion on the mares' subsequent reproductive performance. We discussed the concept of potential infanticide and feticide in horses [8-10, 13, 16, 18] regarding the hypothetical reproductive benefits. We hypothesize that if both infanticide and feticide occur in horses, the reproductive fitness of mares measured in terms of the numbers of abortions, foals born, and foals that survived ≥ one year will differ before and after stallion takeovers of the mares or after mare's migration. With direct observation, we can document stallions' aggression toward foals and forced or allowed copulations with pregnant mares. To investigate our hypotheses, we reviewed the database from 31 years detailing the migration and reproduction of a herd of Konik polski horses managed under semi-feral conditions. Such a long timeframe of observations provides detailed information about reproductive events. Considering the longevity of horses up to 30 years or greater, these records spanned the lifetimes of many of individuals.

2. MATERIAL AND METHODS

2.1 Ethical note

The study involved the analysis of breeding records and regular observations of animals from a distance. No experimentation was performed given European directive 2010/63/EU and the

105 Polish laws related to ethics in animal experimentation. The animals were under the care of the
106 staff of the Experimental Station of Polish Academy of Science in Popielno, Poland.

107 ***2.2 Study site***

108 Between 1986 and 2017 semi-feral Konik polski horses were observed daily in their
109 sanctuary situated on a peninsula in northeastern Poland by one of the coauthors (ZJ). Konik
110 polski horses were introduced to the sanctuary in 1956 as probable descendants of extinct
111 Tarpans (*Equus caballus gmellini Ant. forma silvatica Vet*.) to experimentally prove their
112 adaptability to and survival in natural East European environmental conditions [1, 36, 37]. The
113 available area is 16.2 km^2 of forests, some grassland, and wetlands. The sanctuary is surrounded
114 on the east and west by lakes, which are natural borders. On the north and the south, the
115 sanctuary is fenced. With annual surplus offspring removal, the habitat meets the nutritional and
116 spatial needs of all horses throughout the year, limiting the influences of ecological pressures
117 such as feed shortage or a high stocking rate on social structure of herds.

118 ***2.3 Animals***

119 For the present study we defined a "harem" as a social group of an individual stallion and
120 his mares (male-females group) while as a “band” we define a stable group of mares that can be
121 harems of several stallions in case they change. Horses run freely and are unmanaged except for
122 the annual removal of young offspring due to restricted area available to horses. Some colts and
123 fillies are left for parents' replacement. When remaining in the herd, young horses naturally
124 disperse from the natal group, usually at the age of 25 months ± 11 months. Male offspring
125 generally remain in their natal harem band longer than young females. Sporadically, new horses
126 from other sanctuaries are introduced. For approximately ten generations, this system has

Journal Pre-proof

ensured the persistence of the population with minimal inbreeding. Individual horses are recognized based on markings and freeze brands. The horses live in distinct, freely formed bands. The succession of harem males occurs as a result of fights between stallions, mostly between a young stallion and its sire. In the majority of cases, the defeated stallion dies in the following months. Young mares are accepted by another stallion, and their lifetimes often reach 25 years or more (up to 34 years old for the most long-lived mare).

Over the 31 years of this study, the number of separate harem bands in the sanctuary at any one time ranged from three to five. Each band consisted of 1-10 mares and one stallion. No multi-stallion or bachelor groups were formed during the observation period. Altogether 8 bands, 11 harems, 11 stallions and 50 mares were observed and recorded. All horses are under a genetic resources protection program according to the Convention on Biological Diversity (https://www.cbd.int/) and are entered in the Konik polski studbook.

All dates of birth and death of the horses in the sanctuary were recorded. Additionally, the dates of the introduction of new horses were noted. The parents were recorded for each newborn foal; additionally, the parentage was genetically confirmed in a laboratory certified by ISAG (International Society of Animal Genetics). There was no discrepancy in parentage assignment between the manager and genetic assessment. The records also included, for each group, all cases of harem stallion change resulting from a harem stallion death or fight, the assignment of mares to a given stallion and the migration of mares from the natal band (forced) and between bands as adults (voluntary). During monitoring, observed estrous signs, matings, changes in harem and band composition, and all cases of birth, and death were noted.

2.4 Breeding records

149 Stallion change (SCH) is defined as a situation in which the stallion was succeeded by
150 another one within the same group of mares or a mare had migrated (changed the harem
151 voluntarily or as result of natal dispersal).

152 For each mare, the mare-seasons (MS), i.e. reproductive units (calendar years) in which a
153 mare experienced a reproductive event (foaling, abortion, foal loss), was reviewed for the whole
154 life or until 2017 (for dead and alive individuals, respectively). The death cause of individual
155 foals was inspected for cases of infanticide (general necropsy for evidence of external and
156 internal signs of physical abuse). Since the stallions changed usually for a group of mares, one
157 SCH is reflected in a given MS of several mares.

158 To assess the effect of stallion change, mares' reproductive fitness per MS included the
159 following outcomes (yes/no):

160 · foal born live;

161 · barrenness (defined as no pregnancy in a given reproductive season)

162 · abortion (defined as pregnancy loss after the 40th day of pregnancy, only in cases in which we
163 could see or find the fetus);

164 · reproductive success (foal raised to 1 year of age);

165 To assign reproductive indices to the above classification, we used the method based on
166 conception-to-foaling duration (in days). To calculate the probable conception date, we assumed
167 that first postpartum estrus (foal heat) occurred within 8-14 days and that pregnancy lasted 325
168 days [38]. First mating season of the maiden fillies was treated as MS0 and was not taken for

169 calculations as its result could be observed the next year (season). Also, two mares with evident
170 clinical signs of reproductive dysfunctions (throughout the observation period they got pregnant
171 and gave birth only to two per 12 MS and six per 27 MS foals respectively) were excluded from
172 the studied population since we focused on behavioral infertility only.

173 ***2.5 Statistical analyses***

174 The effect of SCH on the probability of the occurrence of the reproductive event of mares
175 (foals born alive, reproductive success, abortion, and barrenness per MS) was evaluated with the
176 generalized linear mixed model (PROC GLIMMIX, SAS 9.4 Statistical Package). As the
177 dependent variables have a binary outcome, a binary distribution and log link function were
178 assumed. The marginal model included the classification variable (SCH) and the continuous
179 variables (age of the mare and calendar year of reproductive event). Logit scale parameter
180 estimates (coefficient, Co) and odds ratio (OR) were presented for foals born alive, reproductive
181 success, abortion, and barrenness. Effect of age was reported as the mean probability (LSM ±
182 SE) of foals born alive, reproductive success, abortion, and barrenness. Effect of the increasing
183 age of the mare (by one year) to deliver live foals, reproductive success, abortion and barrenness
184 was given in percent. The mare nested in band was considered a residual random effect with a
185 compound symmetry covariance structure. A pseudo-likelihood estimation method and the
186 empirical Sandwich estimates for the standard error of the fixed effects were used. Average
187 number of foals born per mare was presented as mean ±SD.

188 Data used for the calculations are presented in the Supplementary Material 1.

189 **3. RESULTS**

Journal Pre-proof

3.1 Stallion changes

A total of 609 mare-seasons (MS) for 48 mares were recorded. In total, SCH in 10 harems were recorded. On average, a mare changed harem stallion 0.8 ± 1.0 times (range: 0 – 3 times), and regarding whether the mare was dead or alive at the moment of database formation (2017) 0.7 ± 1.0 and 1.0 ± 1.0 times, respectively. Twenty-three mares experienced no SCH, 25 experienced at least one SCH: 15 mares one SCH, 5 mares two SCH and 5 mares three SCH.

3.2 Reproductive performance of mares

Altogether, 443 foals were born during the 31 years. No effect of calendar year upon reproductive efficiency: foal born alive (Co=0.01, F=0.33, P>0.05), barrenness (Co=-0.02, F=1.31, P>0.05), abortions (Co=-0.01, F=0.12, P>0.05) and reproductive success (Co=0.02, F=0.40, P>0.05) was stated. The majority (419) of foals survived either until their removal from the sanctuary (when the foals were approximately 7-9 months old) or at least until one year old in cases they remained in the sanctuary. Twenty-four foals died before 1 year of age due to congenital defects and/or disease (14 foals), natal isoerythrolysis (five foals), in accidents (two foals), and three were stillborn. The average number of foals born and raised per mare amounted to 9.0 ± 6.7 and 8.6 ± 6.3, respectively. Notably, within the observed timeframe and according to the age at database formation, some mares did not raise any or raised just one foal (eight very young or very old mares) and some raised 18 foals (five mares), with the most outstanding mare raising 24 foals.

3.3 Stallion change and the reproductive performance of mares

During the breeding seasons in which the stallion changed, there were 26 MS when mares were pregnant and nine MS when mares were barren; in the cases of the other seven MS, we were not able to diagnose the pregnancy in investigated mares with 100% certainty. Out of these 26 pregnancies, there were 24 healthy foals born, one mare gave birth to a healthy foal that was killed in a car accident in its 1st week of life, and one mare aborted. This particular mare was 22 years old and had previous reproductive problems: she aborted the year before, and the aforementioned abortion (in approximately the 7th month of pregnancy) occurred three months after the band had been taken over by a new stallion.

The reproductive fitness of a mare in the season following SCH, as compared to socially stable seasons, did not differ for the probability of giving birth to live foal (SCH seasons: 0.86 ± 0.07 vs. stable seasons: 0.91 ± 0.02, F=0.81, P>0.05; OR=1.63), to abort (0.04 ± 0.03 vs. 0.03 ± 0.01, F=0.45, P>0.05; OR=0.58), to stay barren (0.10 ± 0.05 vs. 0.06 ± 0.02, F=2.15, P>0.05; OR=0.52) or to have a reproductive success in a given season (0.79 ± 0.07 vs. 0.85 ± 0.02, F=0.79, P>0.05; OR=1.45).

Among 443 healthy foals, 28 were born in the harem of a new, succeeding stallion. All of these foals successfully reached adulthood. No forced copulations or copulations allowed by pregnant mares were ever witnessed. Additionally, no cases of stallion aggression toward pregnant mares or foals sired by other stallions were observed.

3.4 Age effect

Older females were more likely to stay barren (Co=0.19, F=20.5, P<0.0001), with chances increasing by 21% with each successive year; and less likely to give birth to a foal (Co=-0.13, F=12.0, P<0.0001, 13% decrease of chance), and rear a foal to one year of age (Co=-0.13,

232 F=24.7, P<0.0001, 12% decrease of chance). The age did not affect the probability of abortions
233 (Co=0.04, F=1.31, P>0.05).

234 Detailed reports for the seven mares for which we were not able to classify the reproductive
235 status at the moment of SCH is presented in Supplementary Table 1. Of these mares, five gave
236 birth to a foal sired by a new stallion in the year following the stallion change.

237 **4. DISCUSSION**

238 Our analyses showed that the seasonal reproductive fitness of observed mares was similar
239 whether a mare experienced harem stallion change or not. An important factor challenging
240 mare's reproduction was an advanced age. Since age is widely recognized as adversely affecting
241 reproduction and has been extensively studied [39 – 44], in the present work we focus on
242 mechanisms of purported male-provoked subfertility in mares. The analysis of reproductive
243 records of Koniks population does not support the hypothesis of the Bruce effect in semi-feral
244 horses with two findings: infanticide as underlying cause of early pregnancy failure was never
245 observed, and the negative effect of a stallion change on reproductive performance of mares was
246 not detected.

247 ***Male infanticide***

248 It was proposed that the potential gains from infanticide are: using the neonate as a
249 resource (i.e. as food), elimination of the potential competitor for resources, enhanced
250 reproductive success of a partner and the "increased access for individuals of one sex for
251 reproductive investment by the other sex at the expense of same-sex competitors"[12]. However,

252 any of the suggested reasons, including the last one assumed as rationale for decreased
253 reproductive performance in domestic mare [8 – 10], was not observed in studied population.

254 Infanticide is believed to bring direct benefits to the male due to the faster return of the
255 female to fertility [20, 23]. In the case of horses, mares start cycling within 8 – 14 days
256 *postpartum* and remain fertile the entire breeding season [45]. Thus, killing the newborn foal
257 would not change the mare's fertility and might be pointless in terms of male's reproductive
258 benefit. In contrast to lions and other animal species, for which infanticide may serve some
259 biological functions and has been observed in nature [46 – 50], no rationale for such a
260 mechanism is evident neither in domestic horses under natural conditions nor in Przewalski
261 horses after infanticide [16].

262 Observations of Feh and Munkhtuya [16] showed that Przewalski mares whose foals
263 were sporadically killed did not allow breeding with the infanticidal stallions. Therefore, these
264 stallions did not gain any reproductive benefits from the infanticide, as has been postulated for
265 other species. Since in wild equids males' incidental infanticide is observed towards unrelated
266 but also related foals [16] a pathological social behavior rather than a reproductive strategy in
267 horses was proposed as explanation [16]. Moreover, it can be hypothesized that wild equids,
268 especially zebra, have a generally higher level of aggression, especially toward neonates [51] of
269 own and other species like antelopes [52]. Importantly, no infanticide was confirmed by our
270 study, as none of 443 foals was killed by a stallion over 30 years of observations; although the
271 harassment of adults by other stallions present in the sanctuary and the succession of stallions
272 occurred spontaneously, and the animals were free to choose sexual partners from available
273 groups within the sanctuary. No attacks of a new stallion on newborn foals sired by the previous
274 stallion or on any other foals were ever witnessed or confirmed with the necropsy of dead foals.

In the observed population, twenty-eight foals were born after takeovers, and all of them successfully reached adulthood. Additionally, we observed that when these foals were left in the sanctuary, the stallion expelled unrelated immature horses as in case of own offspring as reported by other studies [53]. Twenty-five years of daily observations of the University of Pennsylvania's semi-feral pony herd have shown that of 375 foals born into that herd, 66 neonates have been with harem stallions that were not their sire (McDonnell, personal communication). No infanticide or aggressive behavior of stallions to foals has been observed and detailed focal observations have similarly indicated no difference in parenting behavior of harem stallions toward sired and non-sired foals in their band (McDonnell, personal communication). In the studied population, the finding that no foals were lost due to male aggression compared to 24 foals lost for other reasons before 1 year of age, questions the hypothesis that mares have to employ any strategy to avoid foal loss due to possible infanticide [8-10]. Hitherto results on possible Bruce effect in domestic mares were based on questionnaires filled by owners of mares kept in stabling conditions [8-10, 13, 16, 18] with no direct observation of the animals' behavior. Comparing to our results including regular inspection and behavior observations, we think that the question of whether females' reproductive counterstrategy to infanticide, i.e., the Bruce effect, has any biological rationale in domestic mares remains open and requires further research.

Bruce effect

Previous studies [8-10] imply that mares, similar to mice, may terminate pregnancy in the presence of a male that did not sire the fetus, especially when a female has not the direct access to the dominant male. The pregnancy rate was compared between mares mated or inseminated with home or unfamiliar stallions. The results suggest that when a mare was bred with an unfamiliar stallion and then kept in an enclosure adjacent to a home stallion or gelding, the

probability of pregnancy termination was the highest. However, the distribution of factors between compared groups that undoubtedly influence the reproductive performance, such as age, detailed reproductive and veterinary history of mares, use of pregnancy diagnostic technique (palpation or ultrasound examination since the questionnaire reaches back to the 1980s, when the use of ultrasound was uncommon), possible differences in feeding, stage of pregnancy after returning home [8-10], in which the placentation is one of the critical points [54], or the method of insemination (natural or artificial, the latter often including hormonal treatment) [8, 10], were not given. In general, the pregnancy rate in domestically managed mares is approximately 60 – 69% per cycle [41, 55]. Factors influencing conception and embryo development, including the signal of maternal recognition of pregnancy, are still not elucidated in horses [41, 53, 56]. Thus, without a scrutinized follow-up of the mare's reproductive history, behavior observations, and physiological and health status examinations, it may be difficult to interpret the results. A detailed analysis of the collected data yielded a large amount of relevant information in our study (Supplementary Table 1). The problematic cases (barrenness) following stallion change involved mare's congenital subfertility, advanced age, refusal to be mated by a son, poor post-winter condition and the refusal to be mated by a new stallion. Such information sheds additional light on the interpretation of potential causes of barrenness.

Misleading parental care

It has been proposed that mares manipulate their pregnancy status to avoid potential infanticide when not able to mislead a dominant male about his paternity [8]. In our study, three mares with evident reproductive problems, including serological incompatibility with the stallion, did not leave the harem to join a new stallion with whom they could improve the reproductive outcome. Based on this observation we speculate that mares may not be able to

predict the outcomes of their pregnancies to counteract possible loss, and manipulate the pregnancy outcome.

We acknowledge that the only human intervention, the annual removal of almost all born offspring, may have disturbed the natural composition of groups present in the sanctuary. Thus, the distribution of males and females of different ages is not completely natural and may affect the outcomes of the present study. However, to our knowledge, there is actually no completely natural (feralised) domestic horse population that would not be managed somehow (by area restriction, surplus young removal or contraception) otherwise it leads either to overpopulation or unnatural reduction of fertility. The example of the catastrophic outcome of uncontrolled reproduction of horses in a reserve where unlimited reproduction on limited area resulted in deaths of over half of the animals, mostly from starvation [57] shows that with no predators' harassment, present populations of feral horses have to be managed somehow in order to maintain the horses' welfare. It is proposed that feed availability is a probable reason for the formation of separate harems [58]. Also, in polygynous ungulates, the sex ratio is expected to be biased toward females [53] due to higher dispersal mortality of expelled males travelling to novel places in unrestricted areas. Nevertheless, the sanctuary area is limited, and the welfare of the horses is a priority, as a high stocking rate of horses would influence their behavior and condition. In such a case, the collected data might not reflect the natural behavior of horses but rather pathological one caused by shortages of food and space [4, 16, 59 - 61].

We recognize that another issue which could potentially bias the results is the frequency of stallion changes. Available literatures as well as our own observations indicate that a harem stallion manages a group of mares as long as he is able to defend them from other stallions [62, 63]. This period may significantly differ from stallion to stallion because the factors such as feed

and water availability, presence of other stallions, stallion's age, its qualities or random accidents may influence the leadership [52, 62, 63]. To our knowledge there is no reference research on average/routine feral stallion change and we believe that observational period of more than 30 years evidences for the first time how frequent changes of harem stallions are. Every SCH in our study occurred by defeating the predecessor harem stallion by the successor, that is as it has been reported for other feral populations. Hence, we think that the number of SCH in our study may reflect natural situation in feral equine population.

CONCLUSIONS

Due to the lack of incidents of infanticide and the lack of evidence that the presence of a new stallion leads to the termination of pregnancies sires by another stallion, our results suggest that the Bruce effect is unlikely to be a biological strategy to reduce investment in pregnancy and prevent potential infanticide in horses. No benefits underlying such mechanism were evidenced in horses living in semi-feral groups. Thus, our findings do not support the concepts of both infanticide and feticide (the Bruce effect) in *Equus caballus*, as they did not occur and seemed to have no biological justification, as shown by our long-term studies involving semi-feral horses. However, the limited number of closely monitored animals in feral groups, as well as subject-related research and contradictory results encourage further investigation of these phenomena in *Equus caballus* species.

Funding

This work was supported by grant 2015/19/N/NZ5/00655 from the Polish National Science Center.

Acknowledgments

We are highly grateful to Magdalena Sobczyńska PhD DSc for her help in the statistical part of this work.

Conflict of interest

We declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Authors' contributions

JJ analyzed the data and wrote the manuscript. ZJ collected and analyzed the data. SMM contributed to the data analysis and manuscript preparation. AGB supervised the work and contributed to the data analysis and manuscript writing and preparation. All authors critically revised and approved the final version of the manuscript.

Highlights:

- Stallions experiencing increased female turnover engage in more frequent contests
- These stallions engage in more escalated contests and spend more time vigilant
- Habitat visibility but not female turnover influenced male-female aggression
- Home range overlap also influenced male-male interactions
- Immunocontraception management indirectly affects stallion behavior

Abstract

In social species like the feral horse (*Equus caballus*), changes in individual

ACCEPTED MANUSCRIPT

ACCEPTED MANUSCRIPT

behavior are likely to affect associated animals. On Shackleford Banks, North Carolina, USA, mares treated with the contraceptive agent porcine zona pellucida (PZP) demonstrate decreased fidelity to their band stallions. Here, we assess the effects of such decreased mare fidelity on male behavior and address potential interactions with habitat visibility, a component of the environment shown to significantly affect feral horse behavior. We compared the frequency and escalation of male-male contests, rates of aggressive and reproductive behaviors directed toward females, and the percentage of time spent vigilant among males experiencing varying levels of mare group changing behavior. We found that regardless of habitat visibility, males experiencing more female group changes engaged in contests at a higher rate ($P = 0.003$) and escalation ($P = 0.029$) and spent more time vigilant ($P = 0.014$) than males experiencing fewer group changes. However, while visibility had a positive effect on aggression directed by stallions toward mares ($P = 0.013$), female group changing behavior did not influence male-female aggressive or reproductive behaviors ($P > 0.1$), showing that decreases in mare fidelity altered male-male but not male-female interactions. These results have important implications for feral horse management; PZP-contracepted mares demonstrating prolonged decreases in stallion fidelity may have a disproportionate effect on male behavior. Moreover, our results shed light on the relative influences of female behavior and environmental factors like habitat visibility on male behavior. Such findings can ultimately improve our understanding of how the social and physical environments interact to shape male-male and male-female interactions.

vigilance

1. Introduction

Ungulate populations in the United States have expanded greatly in recent history (Eberhardt et al., 1982), demanding some form of management that balances efficient control of animal numbers and public opinion of the adopted strategy (National Research Council, 2013). While easily overlooked, maintenance of natural behaviors is an important consideration if management strategies are to sustain the health and wellbeing of wildlife populations. The feral horse (*Equus caballus*) provides an interesting case study for the impacts of management strategies on behavior and physiology at multiple levels. With few predators on the continent, feral horse populations have grown rapidly in the United States (Garrott et al., 1991; Turner et al., 1992; Turner and Morrison, 2001; DOI-OIG 2010). Subsequent overgrazing can be detrimental to native vegetation and wildlife communities and also conflicts with land use practices (Beever and Brussard, 2000; Levin et al., 2002). Viewed as both a culturally valuable species protected by federal law and a nuisance to humans and wildlife, feral horses present a unique challenge to wildlife managers (United States Congress, 1971). Recently, fertility control has become a popular option for managing feral horse populations. The immunocontraceptive agent porcine zona pellucida (PZP) has been used to manage several populations of feral horses and other social species including white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus*) (Kirkpatrick et al., 1997; McShea et al., 1997; Heilmann et al., 1998; Ransom et al., 2010).

In feral horses, both physiological and behavioral effects of PZP on treated mares

ACCEPTED MANUSCRIPT

have been widely documented, with varying results among populations (Kirkpatrick et al., 1996; Powell, 1999; Turner and Kirkpatrick, 2002; Nuñez et al., 2009; Nuñez et al., 2010; Ransom et al., 2010; Madosky, 2011; Nuñez et al., 2014). However, the potential effects of immunocontraception management on non-target individuals have received less attention (Ransom et al., 2010). Such effects are especially important to consider in social species like the feral horse, as the behavior of one individual is likely to influence the behavior of its associates. Feral horses live in social groups (called bands) consisting of one or sometimes multiple stallions, one or more associated females, and their offspring (Feist and McCullough, 1976; Rubenstein, 1981). Bands are typically stable groups with females staying with the same male (band stallion) for most of their adult lives (Klingel, 1975).

However, this stability may be compromised when the behavior of individual group members changes. The feral horse population on Shackleford Banks, North Carolina, USA provides such an example. Between 2000 and 2009, the population was managed by treating a subset of females with PZP. This resulted in several changes in the behavior and physiology of treated mares (Nuñez et al., 2010; Nuñez et al., 2014) including increased group changing behavior (Nuñez et al., 2009). While PZP treatment was largely suspended in 2010, increased group changing behavior is still exhibited by previously treated mares experiencing prolonged subfertility (Nuñez et al., 2017). The resulting decrease in group stability may have implications for other group members, particularly the band stallions (Madosky, 2011).

During periods of social instability, males exhibit increases in aggression and

ACCEPTED MANUSCRIPT

testosterone across diverse taxa including primates, birds, and fish (Wikelski et al., 1999; Cavigelli and Pereira, 2000; Hirschenhauser and Oliveira, 2006; Arlet et al., 2009). On Shackleford, the social instability primarily created by decreases in previously treated mares' fidelity to band stallions is likely to similarly increase the frequency and escalation of stallion contests. Furthermore, changes in female behavior and movement patterns are likely to influence how males interact with these females. For example, male harassment of females is common in ungulate mating systems, with males more likely to initiate mating than females (Bro-Jørgensen, 2011). However, harassment intensity can vary greatly with the strength of social bonds between males and females (Linklater et al., 1999). Females demonstrating weaker bonds with the dominant male and/or female associates often experience increased male harassment (Linklater et al., 1999). On Shackleford Banks (and in the western United States), treated mares demonstrate prolonged reproductive cycling (Nuñez et al., 2010; Ransom et al., 2010) and weakened social bonds (Nuñez et al., 2009; Madosky, 2011). Not surprisingly, treated mares are often subject to increased stallion harassment when compared to untreated mares (Madosky, 2011), demonstrating the profound impacts female behavior can have on male behavior.

Still, to fully understand how males respond to changes in female behavior, male behaviors should be considered in the context of the animals' surrounding environment. The interactions between animals and various facets of their physical environment such as visibility and resource distribution profoundly influence mating systems by dictating how males exploit female movement and dispersal patterns (Emlen and Oring, 1977;

ACCEPTED MANUSCRIPT

Rubenstein, 1981). Historically, Shackleford has been defined by three distinct habitats: the East, which is flat and open with limited water sources (Marr, 1996); the Mideast, which is also flat and open with more evenly distributed water sources (Rubenstein, 1981); and the West, which contains two primary water sources and is dominated by high dunes and dense brush (Rubenstein, 1981). These regions vary in their resource availability and landscape features, both of which influence stallions' ability to defend territories (Rubenstein, 1981). For example, water and vegetation distribution determine the location and extent of horses' home ranges (Feist and McCullough, 1976; Miller, 1983; Manning and McLoughlin, 2017). Furthermore, the degree of visibility across a landscape can affect a stallion's ability to defend his band against intruders (Rubenstein, 1981). The history of territoriality in the eastern region of Shackleford demonstrates how high visibility and evenly distributed resources allow for the maintenance and defense of distinct boundaries (Rubenstein, 1981; Rubenstein, 1986). Therefore, shifts in resource availability or distribution, visibility, and the resulting degree of overlap between band home ranges are likely to impact the frequency of intergroup interactions and the degree of competition among stallions. Investigating the influences of both female behavior and ecological factors on male behavior can broaden our understanding of how these factors interact to shape male mating strategies and even the evolution of mating systems.

Here, we assessed the effects of decreased mare fidelity on male behavior in the feral horse population on Shackleford Banks, NC. We tested how the rate of female turnover experienced by males affected 1) the frequency and escalation of male-male contests and vigilance behavior and 2) the frequency of male aggression and reproductive

ACCEPTED MANUSCRIPT

behaviors directed toward mares. In addition, we tested the effects of ecological variables including visibility and home range extent on these behaviors. We hypothesized that males experiencing more group changes by females, defined as the number of times females enter or leave a stallion's band, would engage in contests with other males more frequently and at a higher intensity than those experiencing fewer group changes. Furthermore, we predicted that stallions experiencing increased female turnover would exhibit increased rates of aggression and reproductive behavior toward females. Finally, we hypothesized that increased habitat visibility and overlap among home ranges would heighten aggression between males and increase male aggression and reproductive interest directed toward females. Because females previously treated with PZP exhibit prolonged decreases in stallion fidelity, this study can improve our understanding of the potential for indirect effects of contraception management on non-target animals. In addition, our evaluation of the relative effects of female behavior and ecological factors on male behavior may provide insights into their influence on the expression (and evolution) of male mate-guarding and reproductive behaviors, critical components of male mating strategies.

2. Methods

2.1. Study Site and Subjects

The focal population of feral horses lives on Shackleford Banks, a barrier island off the coast of North Carolina, USA. The island is approximately 15 km long and ranges from 0.2 to 1.2 km wide. As a part of Cape Lookout National Seashore, Shackleford Banks is visited by approximately 100,000 tourists annually (National Park Service,

ACCEPTED MANUSCRIPT

2017). Therefore, the horses on the island are somewhat habituated to human activity (i.e., at distances of at least 15 m). The study was conducted during two breeding seasons, June through July, 2016 and May through August, 2017. In both years, we observed all band stallions and their females: 21 males and 70 females organized into 18 bands in 2016 and 20 males and 69 females organized into 19 bands in 2017. Most bands had one dominant stallion with the exception of two double-male bands in 2016 and one double-male band in 2017.

2.2. PZP Contraception

This feral horse population is federally protected under the Shackleford Banks Wild Horses Protection Act of 1997 and is managed jointly by the National Park Service and the Foundation for Shackleford Horses (United States Congress, 1997). To maintain the population at the predetermined size of approximately 120 animals, the National Park Service began utilizing immunocontraception in 2000. Mares received initial and booster doses of PZP, which were administered from February through April in designated years. Injections contained 100 µg of PZP plus an adjuvant, and initial doses contained Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem #344 289). Booster doses contained Freund's Incomplete Adjuvant (Sigma #F5506). In 2010 and 2011, when the NPS and Foundation realized that some mares treated repeatedly experienced prolonged subfertility post-treatment, PZP treatment was suspended to allow the population to increase (Stuska, personal communication).

2.3. Behavioral Data

Behavioral data were collected primarily by one observer (M.M. Jones) and were

ACCEPTED MANUSCRIPT

supplemented with additional data from two other observers (M. Fatka and C.M.V. Nuñez). Both M.M. Jones and M. Fatka were trained by C.M.V. Nuñez. Study bands were located twice per week, and GPS location and group composition were noted. Individuals were identified with freeze brands, distinctive markings, coloration, and other identifying features. As witnessing group changing behavior by females was rare (n = 1), presence and absence of females in the band were noted to monitor this behavior. These data were used to calculate the number of group changes experienced by males (the number of times females entered or left a male's band).

Instances of rare behaviors were recorded *ad libitum* (Altmann, 1974). These included 1) male-male aggression (including biting, kicking, pushing, and kick threats), 2) male-female aggression (including both mate-guarding behaviors such as herding and chasing and the aggressive behaviors listed above), and 3) reproductive interest (including copulation, mounting, genital sniffing, and rump rubbing (Nuñez et al., 2009)). In addition, the amount of time that stallions spent vigilant was recorded during 15-minute focal samples (Altmann, 1974). The escalation of male contests was scored based on a scale of one to six adapted from Hynes (1998) with scores as follows:

1. Visual displays including parallel prance, pawing the ground, neck arch, and approach-retreat without physical contact.
2. Olfactory assessment including nose-to-nose and nose-to-genital contact and fecal pile sniff without physical contact.
3. Auditory assessment using aggressive male vocalizations called squeals.
4. Low intensity physical contact including pushing and kick threats.

ACCEPTED MANUSCRIPT

5. Moderate intensity physical contact including hind and front kicks that may result in injury.
6. High intensity physical contact including biting and rearing while kicking with front legs that are likely to result in injury.

Frequencies of observed behaviors were significantly correlated with the total time individuals were observed (male-male contests: $\rho = 0.330$; $P = 0.035$; male-female aggression: $\rho = 0.486$; $P = 0.001$; male-female reproductive behavior: $\rho = 0.663$; $P < 0.001$). To control for this bias, rates of male-male aggression, male-female aggression, male-female reproductive interest, and female group changes were calculated as the number of instances an individual was observed engaging in those behaviors divided by the total time each horse was surveyed during the season (expressed as observation days, defined as 12 hour periods (the approximate length of daylight during our study period)). Additionally, the escalation scores of all male-male contests that a single stallion engaged in were averaged to calculate a mean escalation score for that stallion. Finally, percentage of time spent vigilant, which was characterized by ears erect and directed forward, head and neck held high, and eyes alert (Figure 1) (Feist and McCullough, 1976), was measured as the minutes spent vigilant over all focal samples conducted for each male divided by the total number of focal minutes for each male.

During observations, detailed descriptions of the behaviors exhibited, identity of the participating individuals, and the date and time were recorded. All observations were conducted by eye or with the aid of binoculars (Nikon Monarch M511 10x42) when necessary at least 15-20 meters away from the animals (National Park Service, 2004) to

ACCEPTED MANUSCRIPT

ensure that they were not disturbed by our presence.

2.4. Assessing Visibility Across Shackleford Banks

We assessed visibility across the island as a potentially important environmental factor that can influence male behavior and inter-band conflict (Rubenstein, 1981). Visibility was quantified through viewshed analysis in ArcMap 10.4.1 (Alonso et al., 2012; Aben et al., 2017). Digital surface models were created using USGS LiDAR point cloud data to account for both bare earth elevation and vegetation structure (U.S. Geological Survey, 2015). GPS locations collected at every band sighting using Garmin eTrex 10 units were used as observer points, and an observer offset of 1.2 m was used as the average height of the horses (Stuska, personal communication). The Visibility tool in ArcMap was then used to predict the cells visible from each point, and the number of visible cells was averaged across all points for each stallion to produce an average visibility score.

2.5. Estimating Home Range Size and Overlap

To quantify band home range size and degree of overlap, as these factors can also influence stallion behavior (Rubenstein, 1981), we used the R package *adehabitatHR* (Calenge, 2006). Home ranges for each band were estimated with GPS locations collected at all band sightings in 2016 and 2017 using the 95% adaptive kernel method as described by Worton (1989). Home range area and each band's degree of overlap with other home ranges were then assessed in ArcMap. Home range overlap was calculated as the percentage of one stallion's home range area that was overlapped by other home ranges. Home ranges for each year were estimated separately, and bands with fewer than

ACCEPTED MANUSCRIPT

ten GPS positions were excluded from the analysis (Börger et al., 2006).

2.6. Statistical Analysis

To assess whether the increased group changing behavior by females previously treated with PZP reported by Nuñez et al. (2017) persisted during our study period, we used a permutation test with a significance level of 0.05 in the *geomorph* package in R (version 3.4.1) (Adams et al., 2017; R Development Core Team, 2017). The rate of group changing behavior by females was the response variable, and mare age and a binary variable representing whether or not a mare had been previously treated with PZP were the independent variables. For this permutation test, F-statistics with total and residual degrees of freedom and *P*-values are presented.

We used generalized linear mixed-effects models to examine how changes in female behavior influenced male behavior. Separate models were run for each of the following dependent variables: male-male contest rate, average male-male contest escalation, male-female aggression rate, male-female reproductive interest rate, and percentage of time males were vigilant. Each model included the following independent variables as fixed effects: the number of group changes a male experienced divided by the total time he was surveyed (female turnover rate), average visibility score, male age, average female age (within the band), and the average number of adult females present. The latter three variables were included to control for their potential impacts on male behavior (Berger, 1977; Vervaecke et al., 2007; Nuñez et al., 2017). Finally, all models included stallion identity as a random effect to control for pseudo-replication.

For all models, dependent variables were log or square root transformed as

ACCEPTED MANUSCRIPT

necessary to account for non-normality of model residuals. Best fit models were then selected via backward elimination with a cutoff level of $P = 0.1$ to eliminate variables from the models. Additionally, Spearman correlation tests were used to assess correlations among independent factors and to avoid collinearity within models. Final models did not include any highly correlated variables. The significance level of 0.05 was used to evaluate the effects of predictor variables on male behavior.

All band stallions that were observed for more than two hours were included in the analysis (n = 23 (18 stallions were observed in both 2016 and 2017, 3 additional stallions were observed only in 2016, and 2 were observed only in 2017)).

While male rank is also often a predictor of male aggression (Vervaecke et al., 2007), it was not included in these models because dominance data were not available for approximately one third of the stallions. However, age is typically associated with rank, with older males having higher ranks, and thus the inclusion of male age in the models likely controlled for at least some of the variation due to dominance status (Vervaecke et al., 2007). Further, for those stallions whose dominance could be determined, rank was not significantly correlated with any dependent variables in Spearman correlation tests, and thus it is unlikely that including rank in the models would have altered our conclusions (Table 1).

Finally, because home ranges could only be estimated for 17 stallions (there was sufficient data to estimate home ranges for the same 8 stallions in both 2016 and 2017, 1 additional stallion in 2016 only, and 8 additional stallions in 2017 only), including home range size and overlap in our models reduced our sample size. Therefore, we ran two

ACCEPTED MANUSCRIPT

subsets of models: those that included home range size and overlap and those that did not. For these generalized linear mixed-effects models, parameter estimates, standard errors (SE), t-values, and *P*-values are presented in Tables 2 and 3.

3. Results

3.1. PZP Treatment and Female Group Changing Behavior

When accounting for mare age ($F_{1,136} = 0.62$, $P = 0.432$), females that were previously treated with PZP made on average 2.4 group changes per day more than those that had never been treated ($F_{1,136} = 4.72$, $P = 0.026$).

3.2. Male-male Interactions

The rate of female group changes experienced (Table 2, Figure 2a) and male age (Table 2) both had positive effects on the number of male-male contests that stallions engaged in per day. Similarly, males experiencing more group changes by females per day (Table 2, Figure 2b) and older males (Table 2) engaged in more highly escalated contests.

3.3. Male-female Interactions

Males living in higher visibility areas initiated more aggressive behaviors toward females per day (Table 2). However, the number of female group changes experienced per day did not affect male-female aggression and was dropped from the final model ($P > 0.1$).

Male age was the only variable retained in the final model investigating factors affecting the rate of reproductive behaviors per day but did not have a significant effect on this behavior (Table 2). The number of female group changes that males experienced

ACCEPTED MANUSCRIPT

was dropped from the final model, suggesting it did not explain variation in the rate of male reproductive behavior ($P > 0.1$).

3.4. Vigilance Behavior

The percentage of time males spent vigilant during focal samples increased with a greater number of female group changes experienced per day (Table 2, Figure 2c). Additionally, males with younger females in their bands also spent more time vigilant (Table 2).

3.5. Analyses Including Home Ranges

Both the percentage of home range overlap and the rate of female group changes had positive effects on the rate of male-male contests (home range overlap: estimate = 1.430, t = 2.93, $P = 0.008$; group changes: estimate = 0.048, t = 2.43, $P = 0.024$). Additionally, contests between males with a high degree of home range overlap were more highly escalated than those between males with a lower percentage of overlap (estimate = 3.505, t = 2.93, $P = 0.008$). Finally, stallions experiencing more female group changes per day tended to exhibit higher rates of reproductive behavior (estimate = 0.048, t = 1.90, $P = 0.071$). The behavioral and ecological variables of interest (female group changes, home range size, home range overlap, and visibility) did not affect the rate of aggressive behaviors directed toward females or the percentage of time males spent vigilant (Table 3).

4. Discussion

Effects of PZP treatment on female behavior, including increased group changing behavior and extended reproductive behavior and cycling, have been observed among

ACCEPTED MANUSCRIPT

feral horses on Shackleford Banks and in three western populations (Nuñez et al., 2009; Ransom et al., 2010). However, the potential consequences of such changes for their male associates have not yet been fully explored. Here, we demonstrate that increased group changing behavior by mares is correlated with an increase in aggression among stallions and heightened male vigilance. The implications of these results for management strategies deserve careful consideration and further investigation. Specifically, treating females with immunocontraceptives or other agents that decrease social fidelity can have broader behavioral impacts on males in the population. Moreover, our results provide new insights into the relative influences of female behavior and the surrounding environment, specifically habitat visibility and home range overlap, on male behavior and the expression of reproductive and mate-guarding behaviors involved in mating strategies.

4.1. Effects of Female Behavior on Male Behavior

Stallions that experience increased rates of group changes by females engage in contests with other males more often and at more escalated levels than those experiencing fewer group changes (Figure 2a, Figure 2b). The feral horse social system is typically characterized as harem defense polygyny, in which females form stable groups defended by males (Emlen and Oring, 1977; Rubenstein, 1986). Typically, mares stay with the same stallion for most of their adult lives, and attempts by intruding males to gain access to a resident male's females are usually unsuccessful (Feist and McCullough, 1976; Rubenstein, 1981). In the Shackleford population, decreased female fidelity has compromised this group stability (Madosky, 2011); in response, it appears that males

ACCEPTED MANUSCRIPT

have responded by increasing their defense of females against rivals.

In addition, males that experience increased mare turnover spend a greater percentage of time vigilant than those experiencing fewer group changes (Figure 2c). Similar increases in vigilance behavior have been demonstrated across diverse taxa; during periods of high intrasexual competition, males spend more time monitoring conspecifics (Guillemain et al., 2003; Li et al., 2012). Such monitoring behavior allows males to guard female associates from rival males as well as detect and respond to wandering females (Guillemain et al., 2003; Li et al., 2012; Girard-Buttoz et al., 2014). In the Shackleford population, increased vigilance may allow stallions to monitor both rival males and group changing mares in the context of decreased social stability and high intrasexual competition.

Such changes in male behavior could have consequences for the overall health and wellbeing of these individuals. Male contests, particularly ones that are highly escalated, are costly, demanding significant energy expenditure and potentially leading to injury or even death in extreme cases (Feist and McCullough, 1976; Berger, 1986; Grogan and McDonnell, 2005). Devoting more time to vigilance behavior can detract from time available for other behaviors like foraging, limiting males' energy intake (Lima, 1998; Watson et al., 2007). This may be particularly consequential if this increase in vigilance behavior is also exhibited during the winter when horses spend more time grazing on lower quality forage (Stevens, 1990; Watson et al., 2007). Future work should explore the consequences of these changes in male-male competition and vigilance behavior on stallion health.

ACCEPTED MANUSCRIPT

4.2. Male-female Interactions

Contrary to our expectations, the number of group changes experienced by males did not affect the rate of aggressive or reproductive behaviors initiated toward females. Although previous work with the same population indicates that PZP-treated females receive more harassment and reproductive interest from males (Nuñez et al., 2009; Madosky, 2011), it does not appear that males engage in varying rates of male-female interactions based on the rate of female turnover they experience. It may be that stallion harassment and reproductive interest directed toward treated females are influenced more by differences in estrous cycling among treated versus untreated mares (Nuñez et al., 2010; Ransom et al., 2013) rather than the differences in group changing behavior that we examined here. As they rarely become pregnant, treated mares exhibit increased reproductive cycling, which can persist even after immunocontraceptive treatment is suspended (Ransom et al., 2010; Nuñez et al., 2017).

However, it is important to note that this study was conducted solely during the breeding season, when reproductive behaviors and male-female interactions are at a peak (Stevens, 1990). In horses and other ungulate species, behavioral effects of PZP on mares are often more evident during the non-breeding season when reproductive behavior is more variable (McShea et al., 1997; Heilmann et al., 1998; Nuñez et al., 2009). Similarly, variation in stallions' interactions with females may be more evident during the non-breeding season when behavioral differences between treated and untreated mares are more pronounced (Nuñez et al., 2010). For example, on Assateague Island, Powell (1999) found no difference in the harassment received by untreated versus treated mares during

ACCEPTED MANUSCRIPT

the breeding season, though that study lacked true controls (mares that had never been treated with PZP) for comparison. On the other hand, Madosky (2011) found that treated mares on Shackleford did receive more harassment from stallions than untreated mares during the breeding season. Unfortunately, the definition of "harassment," specifically whether or not it included reproductive behaviors, is unclear, making it difficult to directly compare these studies.

Studies of other species examining male behavior in populations managed via fertility control reveal similar inconsistencies (Ji et al., 2000; Poiani et al., 2002; Druce et al., 2013; Duncan et al., 2017). Ji et al. (2000) found that male brushtail possums (*Trichosurus Vulpecula*) were attracted to sterilized females during and after the mating season; however, Druce et al. (2013) found no evidence that bull African elephants (*Loxodonta africana*) associated more with family groups containing more estrous females, suggesting that PZP treatment did not alter male-female associations. This level of variation among species supports the need for careful monitoring not only of target animals', but also non-target animals', behavior in response to contraception management.

4.3. Effects of Visibility

Habitat openness (or visibility) often plays an important role in male behavior because higher visibility allows males to defend home range or territory boundaries and track band member activity more easily (Rubenstein 1981). Our data show that males residing in higher visibility areas are more aggressive toward band females (herding, biting, and kicking their females more often) than males in lower visibility areas (Table

ACCEPTED MANUSCRIPT

2). However, contrary to our predictions, we saw no effect of visibility on the frequency or intensity of male-male interactions (Table 2).

In high visibility areas, males can more easily see one another and each other's females, perhaps increasing the perceived threat of rival males. Males in these areas may herd their females more frequently to prevent them from wandering towards rivals. A higher frequency of herding behavior in high visibility areas may therefore allow for a lower frequency of male contests over roaming mares. In comparison, this pressure may be decreased in low visibility areas where stallions and their mares cannot readily see neighboring bands. In these areas, landscape features such as high dunes and dense brush likely make encounters between rival males relatively uncommon, limiting the frequency of male-male contests. Therefore, similar contest levels might be maintained in areas of low and high visibility albeit via different mechanisms, though future work should further explore this issue. Our use of viewshed analysis to assess the effects of visibility on feral horse behavior adds to a new but growing body of work that uses this GIS tool to explore questions in behavioral ecology (Alonso et al., 2012; Aben et al., 2017). Our results show that habitat visibility is an important environmental factor to consider in future studies. Visual cues are integral to the behavior of diverse taxa, and the reception and interpretation of these cues depend heavily upon the structure of the environment and the resulting visibility, as outlined by Aben et al. (2017).

4.4. Effects of Home Range Overlap

While both home range overlap and female group changes had positive effects on the frequency of male-male contests, only home range overlap influenced the escalation

ACCEPTED MANUSCRIPT

of those contests (Table 3). Because home range overlap affected both the frequency and escalation of these contests while female turnover only influenced contest frequency, home range overlap seems to be a stronger driver of whether and how males engage in fights with rivals. These results suggest that while female behavior is important, home range overlap and, potentially, habitat features like forage and water availability (which largely dictate the extent of home ranges), have a greater influence on male-male interactions (Feist and McCullough, 1976; Rubenstein, 1981; Miller, 1983; Manning and McLoughlin, 2017). In habitats necessitating a high degree of overlap between home ranges, inter-band interactions are likely to increase, with more heightened competition among band stallions over both females and resources (Michener and McLean, 1996; Haenel et al., 2003). However, the sample size from our analysis including home range variables was significantly reduced compared to our full analysis without those variables. Therefore, our results regarding the potential effects of home range size and overlap should be interpreted cautiously.

Nonetheless, these results provide preliminary but important insights into the factors driving the expression of behaviors involved in male mating strategies, specifically reproductive and mate-guarding behavior. In most wild populations, the effects of ecological patterns and female behavior on male behavior are nearly impossible to separate because ecological patterns typically dictate female behavior (Emlen and Oring, 1977; Kraus et al., 2003). However, on Shackleford, the increase in group changing behavior by previously treated females suggests that their behavior is now at least somewhat divorced from their physical environment; mares that would typically

ACCEPTED MANUSCRIPT

form stable groups are instead demonstrating behavior akin to a fission-fusion society (Rubenstein, 1986; Nuñez et al., 2009). Therefore, this system provides a rare opportunity to examine how female behavior and ecological factors may act separately or in interaction to drive male behavior. While visibility, home range size, and home range overlap do not encompass the full range of ecological variables that can influence animal behavior, they have been shown to be particularly important in determining stallion behavior and provide a platform for examining the effects of the surrounding environment (Rubenstein, 1981). Our data suggest that while both the social and physical environment influence male behavior, ecological factors may have a greater impact on the means by which males retain access to females (i.e. through herding of females and contests with rival males) than does female behavior itself. Future studies of similar populations (McShea et al., 1997; Ransom et al., 2010; Duncan et al., 2017), with larger sample sizes and long-term data have the potential to improve our understanding of how these factors influence important reproductive and mate-guarding behaviors that shape male mating strategies.

While we provide evidence that ecological factors like visibility and home range overlap play an important role in determining how males respond to changes in female behavior, much work remains to be done. Future studies should consider forage and water use and availability across seasons as these are dynamic factors that are likely to influence both male and female behavior (Feist and McCullough, 1976; Miller, 1983; Marr, 1996; Manning and McLoughlin, 2017). Furthermore, more intensive sampling of band locations to improve home range estimates, and use of more nuanced overlap

ACCEPTED MANUSCRIPT

calculations would allow for a clearer interpretation of how home range size and overlap influence males' intra- and inter-band interactions (Linklater et al., 2000; King, 2002; Fieberg and Kochanny, 2005; Börger et al., 2006). It is also important to note that while the extent of home ranges is strongly dictated by facets of the physical environment like food and water distribution (Feist and McCullough, 1976; Miller, 1983; Manning and McLoughlin, 2017), it can also be influenced by social factors such as dominance status (Höjesjö et al., 2007; Murray et al., 2007). How home range size and overlap represent an interaction between the social and physical environment should be considered when using these measures to assess the effects of the surrounding environment on behavior. Comparative studies in diverse environments with varying population densities may provide more generalizable conclusions about the influences of ecological factors on male behavior under different conditions.

4.5. Management Implications

While previous work has demonstrated the impacts of PZP on treated females in feral horses, white-tailed deer, and elk, this is one of only a few studies to explore the potential consequences of immunocontraception management for non-target individuals (Ji et al., 2000; Poiani et al., 2002; Gray and Cameron, 2010; Druce et al., 2013). If behavioral changes among treated females are likely to alter the behavior of untreated animals, we may need to reevaluate how we assess the behavioral impacts of immunocontraception. Our results show that increased mare group-changing behavior leads to increases in male-male competition and vigilance. Given the increased group changing among contracepted mares (Nuñez et al., 2009; Nuñez et al., 2017), it stands to

ACCEPTED MANUSCRIPT

reason that PZP-treated mares could have a disproportionate effect on these male behaviors. These results are not anomalous: indirect impacts of fertility control on male behavior have been demonstrated in three western horse populations in addition to brushtail possums (*Trichosurus vulpecula*) and eastern grey kangaroos (*Macropus giganteus*) (Ji et al., 2000; Poiani et al., 2002; Ransom et al., 2010). Compared to alternatives like gathers and removals, PZP is one of the best available options for controlling feral horse populations because it is generally highly effective, reversible, safe for pregnant animals, and relatively cost effective (Kirkpatrick et al., 1996; Kirkpatrick et al., 2009). However, when possible, care should be taken to develop management strategies that consider and attempt to minimize unintended consequences. Furthermore, as new methods of controlling these populations are developed (Ransom et al., 2014; Hall et al., 2016; Collins and Kasbohm, 2017), behavioral consequences for target animals and their associates should be monitored to ensure animal welfare and effective management.

Highlights

- Males were more vigilant after squeals (aggressive signals) than control playbacks
- Stallions were more likely to approach the speaker following squeals than controls
- Female turnover rate did not affect stallion responses to squeals
- Stallion responses were heightened during and after female group changes
- Altered social contexts in managed populations may affect male responses to rivals

Abstract

Management tools like immunocontraception can alter the behavior of target animals, but the extent to which they affect non-target individuals has received less attention. The feral horse (*Equus caballus*) population on Shackleford Banks, North Carolina is an ideal system with which

Journal Pre-proof

Journal Pre-proof

these questions may be explored, as management of the population with the immunocontraceptive agent porcine zona pellucida (PZP) has resulted in an increased propensity for females to change social groups and thus, decreased social stability. During the study, on average, females made 1.4 group changes per day (range = 0—18.5 group changes per day): females previously treated with PZP made 1.8 group changes per day, while females that had never been treated made 1.2 group changes per day. Between May and August, 2017, we used playbacks of aggressive male vocalizations (squeals) and human voices (reciting "hello horse") to assess changes in stallion responses to male rivals versus socially irrelevant stimuli in the context of female turnover. Over the course of the study, males were observed for 9.4 hours on average (range = 2.4—20.5 hr). Males spent more time vigilant (estimate = 12.431, $P = 0.016$, $\bar{x}_{\text{squeal}} = 30$ s, $\bar{x}_{\text{control}} = 19$ s) and were more likely to approach the speaker following squeal playbacks than controls (estimate = 2.325, $P = 0.039$). Males' latency to return to normal behaviors varied depending on whether the playback was conducted in the weeks before, during, or after group changes occurred ($P = 0.025$, $\bar{x}_{\text{before}} = 26$ s, $\bar{x}_{\text{during}} = 39$ s, $\bar{x}_{\text{after}} = 53$ s). Male responses were not affected by the total number of female group changes a male experienced during the observation period ($P > 0.4$), suggesting the effects are more context-dependent and not long-lasting. These findings suggest mare turnover can impact stallion responsiveness to potential rivals. As previously contracepted mares change groups more often than untreated mares and stallions exhibit prolonged responses to aggressive vocalizations after experiencing a female group change, contraception-induced changes to mare behavior may lead to increased male aggression in response to intruding rivals, which could be associated with greater energy expenditure. Finally, our work demonstrates that playback experiments are a useful tool for studying feral horse behavior in the wild. As the need for population control of different species continues to expand, rigorous investigations of

Journal Pre-proof

immunocontraception's effects on non-target animals are critical if agencies are to manage populations most effectively.

Keywords: *Equus caballus*, female turnover, immunocontraception, male aggression, playback, vocalization

1. Introduction

In the United States, feral horses (*Equus caballus*) are protected under federal law and are valued by much of the public for their historical and cultural associations (United States Congress, 1971). However, with few predators, feral horse populations have expanded rapidly (Garrott et al., 1991; Turner et al., 1992; Turner and Morrison, 2001; DOI-OIG, 2010), coming into conflict with human land use practices and certain native species (Beever and Brussard, 2000; Levin et al., 2002). As such, feral horses present a unique management concern. In lieu of traditional management practices like gathers and removals that tend to be costly, ineffective, and unpopular with the public, fertility control, and in particular the immunocontraceptive agent porcine zona pellucida (PZP), has become a popular option for managing feral horses and other ungulate populations (Kirkpatrick and Turner, 1991; Kirkpatrick et al., 1997; McShea et al., 1997; Heilmann et al., 1998; National Research Council, 2013).

In social species like the horse, maintenance of natural behaviors is an important consideration for managers trying to preserve the health and wellbeing of populations. Impacts of PZP on the behavior and physiology of treated mares have been explored in several populations (Kirkpatrick et al., 1996; Powell, 1999; Turner and Kirkpatrick, 2002; Nuñez et al., 2009; Nuñez et al., 2010; Ransom et al., 2010; Madosky, 2011; Nuñez et al., 2014), yet consequences of this management tool for non-target conspecifics have received considerably less attention (Ransom et al., 2010). Feral horses live in bands, social groups that remain together year-round and consist

Journal Pre-proof

of one or sometimes multiple stallions, one or more associated females, and their offspring (Feist and McCullough, 1976; Rubenstein, 1981). Given this complex social structure, changes in the behavior of one individual are likely to affect the behavior of its associates. The potential effects of changes in the behavior of PZP-treated mares on their associates are important to consider if managers aim to preserve more naturally functioning feral horse populations.

PZP was used to manage the feral horse population on Shackleford Banks, North Carolina between 2000 and 2009. In this population, mares treated with PZP change bands up to ten times more often than untreated mares (Nuñez et al., 2009). Regardless of contraception status, mares with a greater proportion of years pregnant are less likely to change groups (Nuñez et al., 2009), suggesting that decreases in pregnancy (and possibly lactation) may be the mechanism(s) by which PZP treatment increases mare propensity to change groups (Nuñez et al., 2009). Despite suspension of PZP administration in 2010, mares previously treated with PZP experience prolonged subfertility and still exhibit this increased group changing behavior, with previously treated mares making 1.8 group changes per day compared to untreated females making 1.2 group changes per day (Nuñez et al., 2017; Jones and Nuñez, 2019). Before PZP treatment began on Shackleford, only 10.8% of mares in the population changed groups (Rubenstein, 1981). While the immunocontraception program was active, this number increased to approximately 69.5%, and in 2017, after the suspension of treatment, group changing behavior remained more frequent with 34.8% of females changing groups throughout the breeding season (Madosky, 2011; Jones and Nuñez, unpublished data). These changes to female behavior have decreased the typically high degree of social stability that characterizes feral horse bands (Klingel, 1975; Madosky, 2011). Historically, contests between intruding and resident stallions were won by the resident; furthermore, in fights to regain mares separated from the band, the females were usually recovered

Journal Pre-proof

(Feist and McCullough, 1976; Rubenstein, 1981). However, mare retention is now destabilized (Nunez et al., 2017), increasing male-male competition in this population (Jones and Nuñez, 2019). Such changes in male competition are not unique to feral horses: similar decreases in social stability have been associated with increases in male aggression in other species including ring-tailed lemurs (*Lemur catta*) and gray-cheeked mangabeys (*Lophocebus albigena*) (Cavigelli and Pereira, 2000; Arlet et al., 2009).

In feral horses, vocalizations are commonly used in a number of social contexts including mating, aggression, and the formation of social bonds, with different types of vocalizations containing varying social information (Feist and McCullough, 1976; Proops et al., 2009; Yeon, 2012). Specifically, squeals are often used during contests between rival males and indicate dominance status, with more dominant stallions emitting longer and more forceful squeals than subordinates (Rubenstein and Hack, 1992). Most male-male contests are characterized by a typical sequence of behaviors, beginning with approaches, olfactory assessment, and acoustic signaling (Feist and McCullough, 1976; Miller, 1981; Hynes, 1998). If contests become escalated, these assessments are followed by physical contact ranging from pushing to kicking and biting (Feist and McCullough, 1976; Rubenstein and Hack, 1992). As squeal vocalizations are a clear indicator of male-male conflict, they may be used to experimentally assess how males respond to signals from intruding males, including whether or not they choose to engage rivals and how escalated the response becomes.

Here, we use experimental playbacks of squeals to determine how stallions with varying levels of experience with female group changing behavior respond to these aggressive signals. To our knowledge, ours is the first experiment to assess the effects of female turnover on male competition in a natural setting. We predicted that all stallions would respond more aggressively

Journal Pre-proof

toward squeal playbacks than unrelated control stimuli (human voices), regardless of experience with female turnover. We also hypothesized that stallions experiencing more female group changes would exhibit heightened responses to squeal playbacks. We expected these males to approach the speaker more often and to exhibit decreased latency to respond, prolonged vigilance, and an increased latency to return to their normal behaviors when compared to stallions experiencing fewer group changes. This experiment provides a more complete understanding of the influence of female behavior on male competition. Furthermore, it provides insights into how playback experiments can be implemented as useful tools to assess feral horse behavior. Because mares previously treated with PZP demonstrate prolonged decreases in fidelity (Nuñez et al., 2017; Jones and Nuñez, 2019), investigating how increased female turnover affects male behavior will improve our understanding of the potential consequences of immunocontraception management for non-target animals.

2. Methods

2.1. Study site and subjects

The focal population of feral horses lives on Shackleford Banks, a barrier island off the coast of North Carolina, USA. The island is approximately 15 km long and ranges from 0.2 to 1.2 km wide. As a part of Cape Lookout National Seashore, Shackleford Banks is visited by approximately 100,000 tourists annually (National Park Service, 2017); therefore, the horses on the island are somewhat habituated to human activity (i.e., at distances of at least 15 m). The study was conducted during the breeding season from May through August, 2017. We observed all band stallions and their females: 20 males and 69 females organized into 19 bands. Most bands had one dominant stallion with the exception of one double-male band. Individuals were identified by their sex, color, facial markings, and, in some cases, freeze brands. We conducted all observations from at least 15-20 meters away (National Park Service, 2004) to ensure the horses were not disturbed

Journal Pre-proof

by our presence. All observations were conducted by eye or with the aid of binoculars (Nikon Monarch M511 10x42) when necessary.

This study was approved by the Iowa State University Institutional Care and Use Committee (3-17-8456-E) and the National Park Service Institutional Care and Use Committee (1024-0265). The National Park Service granted permission to collect all observational data (CALO-2017-SCI-0006).

2.2. PZP contraception

This feral horse population is federally protected under the Shackleford Banks Wild Horses Protection Act of 1997 and is managed jointly by the National Park Service and the Foundation for Shackleford Horses (United States Congress, 1997). To maintain the population at the predetermined size of approximately 120 animals, the National Park Service began managing the population via immunocontraception in 2000. Designated mares received initial and booster doses of PZP, which were administered annually from February through April. Injections contained 100 micrograms of PZP plus an adjuvant, and initial doses contained Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem #344 289). Booster doses contained Freund's Incomplete Adjuvant (Sigma #F5506). In 2010 and 2011, when the NPS noted that some mares treated repeatedly experienced prolonged subfertility post-treatment, PZP treatment was suspended to allow the population to increase (Stuska, personal communication).

2.3. Stimuli acquisition

Squeals made by stallions during male-male contests in a population of Misaki feral horses in Japan were recorded by L. Proops. Squeals tend to vary in duration with significant acoustic noise and medium to high amplitudes and tonality (Figure 1), differing in their acoustic properties from other vocalizations like whinnies and nickers (Yeon, 2012). Although stallions generally recognize familiar rivals using olfactory rather than auditory cues (Rubenstein and Hack, 1992),

Journal Pre-proof

we used recordings of males from another population to avoid any question of potential confounds related to individual recognition by Shackleford stallions. Stallions are capable of discriminating between dominant and submissive males on the basis of acoustic cues in squeals (Rubenstein and Hack, 1992). To help control for the potential effects of rank on stallion behavior, we used vocalizations from band-holding (relatively dominant) Misaki males exclusively. Recordings were collected using a Sennheisser ME66/K6 directional microphone attached to a Marantz PMD661 audio recorder at a sampling frequency of 44.1kHz and bit depth of 32 at distances between 5 and 30 m from the subjects. Seven high-quality recordings were chosen and used as auditory stimuli. Selected squeals ranged in duration from 0.6 s to 2.0 s with an average duration of 1.0 s.

Control recordings were made at Iowa State University. Seven adult males ranging in age from 22 to 68 years (mean = 41 years) were recorded reciting the phrase "hello horse" using an AKG D790 microphone and a Focusrite Scarlett 18i8 preamp connected to a Dell Latitude E7470 PC. Recordings were captured using Audacity 2.1.3 (Audacity Team 2017) at a sampling frequency of 44.1kHz and bit depth of 24. All squeal and control recordings were normalized to 75 dB in Praat (64-bit edition) (Boersma and Weenink, 2017) and were standardized to play at the peak sound pressure of 98 dB at 1 m from the source (Proops et al., 2009).

2.4. Playback procedure

All playback trials were conducted by a single observer (M. M. Jones) between June and August 2017. Vocalizations were played to all band stallions throughout the study, with each stallion receiving one squeal and one control playback, randomized in order with at least one day between trials. In the case of the double-male band, we presented the same squeal and control sounds to both males only once and recorded each male's response separately.

Historically, Shackleford has been defined by three distinct habitats: the East, which is flat and open with limited water sources (Marr, 1996); the Mideast, which is also flat and open with

Journal Pre-proof

more evenly distributed water sources (Rubenstein, 1981); and the West, which contains two primary water sources and is dominated by high dunes and dense brush (Rubenstein, 1981). The East, Mideast, and West were treated as blocks to account for the effect of region on stallion responses. Within each region, stallions were randomly assigned to different pairs of control and squeal exemplars.

Vocalizations were played on an Apple iPod Nano (2nd generation) connected to a small portable speaker (MIPRO MA-101C Personal PA System) hidden in vegetation approximately 20 m from the stallion. For each recorded exemplar, two minutes of silence were added before the vocalization to allow the observer time to move away from the speaker and out of sight of the stallion so as not to interfere with the subject's response. After the two minutes of silence, the vocalization played twice with ten seconds of silence between iterations (Proops et al., 2009). To capture the stallion's response, we conducted 15 minute focal samples (Altmann, 1974) starting immediately after the first vocalization played and recorded the following: whether stallions responded in any way to the stimulus, the latency to respond, whether stallions approached the speaker, length of vigilance behavior (characterized by ears erect and directed forward, head and neck held high, and eyes alert (Feist and McCullough, 1976)), and the latency to return to normal behaviors (measured as the time between the initiation of any response and the return to normal behaviors (e.g. grazing, standing)). A total of 40 trials were conducted among six horses in the East, eight in the Mideast, and six in the West receiving one squeal and one control vocalization. All playbacks were conducted when the stallion of interest was out of sight of other bands and when the weather was dry and winds were relatively calm.

2.5. Female group changing data

Study bands were located twice per week from late May to early August, and GPS location and group composition were noted. As witnessing group changing behavior by females was rare

Journal Pre-proof

(n = 1), presence and absence of females in the band were noted to monitor this behavior. These data were used to calculate the number of group changes experienced by males (the number of times females entered or left a male's band). The number and rate of group changes experienced by all males is detailed in Table 1. For most males that experienced group changes (100% in 2016; 92% in 2017), at least one of the females that left their band returned for some period of time.

2.6. Assessing visibility on Shackleford Banks

Habitat visibility can affect a stallion's ability to protect his band from intruders because increased visibility allows males to defend territory boundaries and track band member activity more easily (Rubenstein 1981). Therefore, we included visibility as a potentially important environmental factor that could influence male responses to rival stallions. We quantitatively assessed visibility across the island by conducting a viewshed analysis in ArcMap 10.4.1 (Alonso et al., 2012; Aben et al., 2017). Digital surface models were created using USGS LiDAR point cloud data to take both bare earth elevation and vegetation structure into account (U.S. Geological Survey, 2015). GPS locations collected at every band sighting using Garmin eTrex 10 units were used as observer points, and an observer offset of 1.2 m (the average height of Shackleford horses) was added to each observation point to account for the height at which a horse would be able to see across the landscape at eye level (Stuska, personal communication). The Visibility tool in ArcMap was then used to predict the number of 10 m x 10 m cells visible from each point, and the number of visible cells was averaged across all points for each stallion and converted to km^2 to produce an average visibility score.

2.7. Statistical analysis

We used generalized linear mixed-effects models with the lmerTest package (Kuznetsova et al., 2017) in R (version 3.4.1) to examine how female group changing behavior influenced male responses to playbacks (R Development Core Team, 2017). Playback type (squeal or control),

Journal Pre-proof

female turnover rate, and the timing of playback trials with regard to group changes were used as explanatory variables. Female turnover rate was calculated as the total number of group changes each male experienced divided by the total time that male was surveyed (expressed as observation days, which were defined as 12 hour periods (the approximate length of daylight during our study period)). Playback timing was determined by classifying each trial as occurring in the one to two weeks before the stallion experienced a female group change (weeks 1-2), during the week of and the week following a group change (weeks 3-4), or in the five weeks following a group change (weeks 5-10) (Figure 2). Interactions between playback type and female turnover rate as well as playback type and playback timing were included to assess whether experience with female group changes altered male responses to all stimuli or only relevant cues from potential rivals.

All response variables were analyzed independently due to small sample size. Binary response variables (whether stallions responded to the stimulus and whether they approached the speaker) were analyzed using models with binomial distributions, while models with normal distributions were used for continuous variables (response latency, length of vigilance behavior, and latency to normal).

The models also included male age, average female age (within bands), and the average number of adult females present as fixed effects as these factors are also likely to affect male behavior (Berger, 1977; Vervaecke et al., 2007; Nuñez et al., 2017). Visibility was included in the models to determine whether habitat openness affects how males respond to the stimuli. All models included stallion identity as a random effect to control for pseudo-replication. Best fit models were simplified using backwards elimination, removing terms with *P*-values > 0.1. In the final models, predictor variables were considered significant if $P \leq 0.05$. For these generalized linear mixed-effects models, parameter estimates, standard errors (SE), t- or z-values, and *P*-values are

Journal Pre-proof

presented.

3. Results

Males were more likely to approach the speaker (Figure 3; estimate = 2.325, SE = 1.13, z = 2.06, P = 0.039) and spent more time vigilant (Figure 4; estimate = 12.431, SE = 4.56, t_{13} = 2.73, P = 0.016) following squeal playbacks than control trials. The probability of showing any response and the response latency did not differ based on the type of playback trial (all P-values > 0.2).

Main effects of the number of group changes males experienced per day and interactions between this variable and playback type were dropped from all final models (all P-values > 0.4), indicating that the rate of female turnover did not affect male responses to either stimulus.

However, there was a significant interaction between playback type and playback timing with regard to female group changes (before, during, or after a male experienced a group change) in the final model for latency to return to normal behaviors (Figure 5; P = 0.025). Tukey post-hoc pairwise tests revealed that males took significantly longer to return to normal following squeal trials than control trials after a group change (estimate = -53.380, SE = 16.77, t_{25} = -3.18, P = 0.040), and there was a strong trend showing the same pattern for trials conducted during a group change (estimate = -23.232, SE = 7.68, t_{19} = -3.03, P = 0.065). However, there was no difference in males' latency to return to normal between squeal and control trials conducted before a group change (estimate = 0.738, SE = 9.44, t_{20} = 0.08, P > 0.9).

With regard to the additional covariates, the average visibility score across all samples was 0.73 km^2 (range = 0.06—3.97 km^2); however, visibility had no effect on male responses. The number of adult females was the only factor retained in the final model predicting the probability of any response. While the effect was not significant, there was a trend by which males with more females in their bands were more likely to respond to all playbacks (estimate = 1.118, SE = 0.62, Z = 1.80, P = 0.072). Additionally, average female age and male age were retained in the final

Journal Pre-proof

model predicting response latency. Males with younger females in their bands took longer to respond to playbacks than males with older females (estimate = -0.185, SE = 0.09, t_{15} = -2.15, P = 0.048). Finally, older males tended to take longer to respond than younger males (estimate = 0.035, SE = 0.01, t_9 = 2.13, P = 0.062).

4. Discussion

Here we show that males exhibit heightened responses to squeal playbacks compared to controls, and while the overall rate of female turnover does not affect those responses, responses to squeals are stronger during periods of group instability. These context-dependent responses suggest that female group changing events can influence how males respond to rivals. On Shackleford Banks, females previously treated with PZP change bands more often than untreated females, interfering with the population's social stability (Nuñez et al., 2009; Madosky, 2011). This playback experiment provides a more controlled assessment of how this altered social context affects stallion response to rivals than can observation alone. While the impacts of fertility control on the behavior of treated animals have been studied in a variety of species and populations (Hayes et al., 1996; McShea et al., 1997; Heilmann et al., 1998; Powell, 1999; Ramsey, 2007; Nuñez et al., 2009; Ransom et al., 2010; Madosky, 2011), its consequences for non-target individuals have received considerably less attention (Ji et al., 2000; Poiani et al., 2002; Gray and Cameron, 2010; Ransom et al., 2010; Druce et al., 2013). Here we provide evidence that immunocontraception management can have indirect consequences for non-target males.

Among the response variables measured, males were more likely to approach the speaker and spent more time vigilant following squeal playbacks than control stimuli (Figure 3, Figure 4). Rubenstein and Hack (1992) found similar responses in stallion vigilance and likelihood of approach in their playback experiment investigating agonistic encounters among stallions. However, contrary to our expectations, the likelihood of any type of response and response latency

Journal Pre-proof

did not differ between squeal and control trials. The fact that playback type did not affect response likelihood may be attributed to a ceiling effect. Stallions responded in 80% of playback trials, suggesting that this measure may not be useful when examining response variation and that differences between playback types are more likely reflected in specific behaviors exhibited during responses. As horses are prey animals that respond to novel auditory stimuli as well as signals from conspecifics, it is important to consider which specific behaviors are relevant to the social context of interest when conducting playback experiments (Christensen et al., 2005). Vigilance and approaches are commonly demonstrated during male-male conflicts or when an intrusion by a rival is suspected, indicating that our playbacks served their intended purpose; males did engage, at least to some extent, in more typical contest behaviors following squeals than following control playbacks (Feist and McCullough, 1976; Miller, 1981; Hynes, 1998).

The rate of female group changes experienced by males did not explain variation in any of the measured response variables following squeal or control playbacks. Similarly, the likelihood of response, response latency, vigilance, and likelihood of approach did not differ depending on whether the trial was conducted before, during, or after a group change by a female. These findings contradict our prediction that males experiencing more group changes would exhibit more heightened responses to squeal playbacks than those experiencing fewer group changes. Low variation in male behavior may have been due to strong stabilizing selection on stallions' responses to potential threats in the environment. More responsive males are likely better able to monopolize and protect their females and offspring from rivals, thus increasing their own reproductive success, than are less responsive males (Rubenstein 1981, Asa 1999). It may be then that in feral horses, males respond strongly to potential threats, regardless of the social circumstances.

Alternatively, limitations of the experiment may have contributed to the insignificant

Journal Pre-proof

findings. This study was conducted over the course of a single season with each male receiving only one squeal and one control playback. In addition, we could not control for the behavioral context at the time of testing; therefore, unknown external factors could have affected stallions' responses (Tyack, 2009). Furthermore, we presented only auditory stimuli in this experiment, while a typical encounter between rival males would also include visual and olfactory stimuli that play a significant role in determining responses (Feist and McCullough, 1976; Miller, 1981; Rubenstein and Hack, 1992). The limitation of the auditory stimuli used here likely restrained stallions' responses, potentially masking variation in the most aggressive behaviors that stallions would exhibit in response to visible intruders.

Moreover, our response measurements may not have been precise enough to capture subtle variations in stallions' responses to squeals. Transcribing responses as they occurred restricted our ability to note nuances such as laterality, subtle changes in ear positions, and nostril lifts, all of which have been noted as relevant responses to conspecifics in domestic horses (Austin and Rogers, 2014; Wathan et al., 2015; Smith et al., 2016; Wathan et al., 2016). In future playback studies, video recordings that allow for more nuanced measurements of responses may be an important tool to reveal variation missed in the measurements reported here (McComb et al., 2000; Proops et al., 2009; Austin and Rogers, 2014).

It is of interest that the short-term context of female group changes did influence males' latency to return to normal after playbacks. Males took longer to return to normal behaviors following squeals than controls but only when the playback was conducted during or after a group change by a female (Figure 5). This indicates that at least some responses are context-dependent, with males exhibiting prolonged responses to signals from perceived rivals compared to random stimuli in periods of social instability. Similar context-dependent changes in male behavior during

Journal Pre-proof

periods of social instability have been observed in other systems. For instance, male ring-tailed lemurs were more aggressive toward rival males throughout the relatively unstable mating period (during female estrus) than they were during the more stable premating period (Cavigelli and Pereira, 2000). As in our study, this short-term period of social instability altered male-male interactions during that specific time-frame only. Because previously contracepted females change groups more often than other females (Nuñez et al., 2017; Jones and Nuñez, 2019), males associated with such females are likely to exhibit this increased responsiveness more often than other males. Admittedly, the sample size for trials conducted following a group change is low in our study (n = 5); as such these results should be interpreted cautiously. Additional playback trials would help to more clearly assess such patterns in stallions' latency to return to normal as well as other responses. Further, more nuanced exploration of these responses, perhaps in a more controlled setting, could reveal additional insights into the consequences of immunocontraception management for non-target animals.

More generally, our results support the use of auditory playbacks to experimentally investigate behavior in free-living populations (Reby et al., 2005; Fischer et al., 2013). Our data reinforce the importance of carefully considering the context of both stimuli and response measurements to ensure playback designs truly focus on behaviors relevant to the question of interest (Sayigh et al., 1999; McGregor, 2000). While playback experiments have been used extensively to assess domestic horse behavior (Lemasson et al., 2009; Proops et al., 2009; Lemasson et al., 2015; Smith et al., 2016; Wathan et al., 2016; Briefer et al., 2017), we posit that they are also a useful tool for feral horse behavior. They allow researchers to more precisely pinpoint causative relationships than do interpretations of correlative data and may be especially valuable when the behaviors of interest are rarely observed in the wild (Rubenstein and Hack,

Journal Pre-proof

1992; McComb et al., unpublished data).

ABSTRACT

Despite more than 40 years of research into zona pellucida (ZP)–based vaccines, relatively little is known about their mechanism of action. Early research demonstrated precipitation of ZP glycoproteins by antiovarian antiserum, rendering oocytes resistant to sperm binding *in vitro*. Subsequent work showed significantly decreased fertilization rates following passive immunization, sparking interest in anti-ZP immunocontraception for human and animal use. The primary mechanism of action of ZP vaccines is generally considered to be an antibody-mediated interference with sperm–oocyte binding and/or fertilization. However, this mechanism of action excludes the potential for ovarian dysfunction associated with anti-ZP treatment in some species. A review of relevant literature in pertinent model, domestic and wildlife species reveals a variety of previous and current hypotheses for ovarian effects following ZP-based immunization. Ovarian dysfunction has been suggested to be a species-specific response. In addition, cytotoxic T-lymphocytes and the use of Freund's adjuvants have been suggested to play a role. Finally, the type and extent of glycosylation of ZP antigens have been proposed to influence ovarian effects. The validity of these hypotheses is re-examined in the light of current knowledge. Further investigation of ovarian function in species believed to be resistant to the ovarian effects of anti-ZP vaccines is warranted. To this end, anti-Müllerian hormone may provide a novel tool for the assessment of ovarian function during ZP-based immunocontraception, particularly in wildlife species not amenable to frequent clinical examination.

1. Introduction

The zona pellucida (ZP) is a complex glycoprotein matrix surrounding the mammalian oocyte and early conceptus. Comprised of either three or four glycoproteins, the ZP plays a pivotal role in the union of oocyte and spermatozoon during mammalian fertilization, arguably the most important joining event in biology. In addition, the ZP functions in the induction of the acrosome reaction, the prevention of polyspermy, and protection of the early embryo [1]. Furthermore, the ZP is intimately involved in communication between the oocyte and its surrounding granulosa cells in the developing follicle [2]. These critical functions of the ZP in reproduction and its tissue-specific nature have encouraged research into its role as an immunocontraceptive for over 40 years [3].

Porcine zona pellucida (pZP) with added adjuvant remains the most common native form of the vaccine due both to the homology between the ZP proteins of many mammalian species and its availability in relatively large quantities [4,5]. Approximately 80 zoo and wildlife species have been successfully contracepted using pZP [6]. Despite this widespread application, relatively little is reported describing the vaccine's mechanism of action. In research

aimed at humans, initial enthusiasm for ZP-based immunocontraception waned sharply following reports of ovarian dysfunction in rabbits and nonhuman primates [7,8]. A number of hypotheses regarding the causes of ovarian dysfunction during ZP-based immunocontraception have since evolved.

This review revisits initial studies describing ovarian tissue, oocytes, or ZP as immunological agents, on which our current understanding of pZP's mechanism of action is based. In addition, several hypotheses advanced to explain ovarian dysfunction observed during ZP-based immunocontraception are re-evaluated based on relevant literature reporting on common laboratory and domestic animal species, as well as the feral horse, deer, and African elephant.

2. Early work on ZP antigens and antisera: a journey down the memory lane

Interest in immunological methods of fertility control dates back to the late 1890's with an initial focus aimed primarily at testes and spermatozoa as immunizing agents, reviewed by Tyler [9]. Reports of antisera to ovarian homogenates blocking fertilization processes in the sea urchin [10] and frog [11] encouraged interest in the mammalian oocyte and ovary as putative antifertility antigens. Initial studies demonstrated the existence of organ-specific antigens in the guinea pig ovary and testis [12,13]. Early immunofluorescence studies further localized common antigens to the ZP, atretic follicles, and the acrosome of spermatozoa [14].

Ownby et al. [15] injected golden hamster ovarian homogenates combined with Freund's complete adjuvant (FCA) into rabbits. Boosters, consisting of ovary homogenates with Freund's incomplete adjuvant, were followed by weekly serum sampling. The antisera produced included antibodies to at least one antigen unique to the ovary, demonstrated using agar-gel diffusion plates. Superovulated hamster eggs exposed to rabbit antiovary antisera formed a precipitate in the ZP that was visible under light- and phase-contrast microscopy. The precipitated ZP was found to be resistant to digestion by trypsin. Similar findings were reported by Sacco et al. [16].

Antiovarian antiserum, added to hamster ova before exposure to homologous spermatozoa *in vitro*, interfered with sperm–oocyte binding. None of 170 pretreated oocytes was penetrated by spermatozoa, in comparison to nearly half of 58 control oocytes [17]. The use of homogenized oocytes rather than the whole ovary as an immunogen produced similar results [18]. Despite ZP-based immunocontraception being in its infancy, researchers noted the potential advantages of this method of fertility control, including reversibility and the absence of somatic side effects because of the specificity of anti-ZP antibodies [17].

Jilek et al. [3], using mice passively preimmunized with rabbit anti-mouse ovary antisera, demonstrated via immunofluorescence the presence of anti-ZP antibodies bound to oocytes aspirated from antral follicles, as well as ovulated oocytes. This showed that anti-ZP antibodies were capable of reaching the ZP *in situ* within the follicle. In addition, passive immunization was found to decrease fertilization rates from over 91% to below 1%. The authors concluded that the effect on fertility *in vivo* "seems to be a block to sperm penetration through the ZP, on which antibodies were actually detected within the follicles".

Further study of aspirated oocytes and early embryos flushed from the uterus or uterine tubes of untreated hamsters showed that antihamster ovary antiserum precipitated the ZP of preovulatory oocytes as well as early embryonic stages *in vitro*. In addition, precipitation of the ZP following fertilization was thought to inhibit the attachment of transferred embryos to the endometrium [19], possibly as a result of interference with embryonic hatching [20]. In a similar study in mice, antioocyte and anti-ZP antisera had no effect on the development of early embryos to the blastocyst stage *in vitro*, although a small effect on zona shedding was noted [21]. A later study in the same species found that preincubation with anti-ZP antiserum had no effect on early embryonic development and zona hatching *in vitro*, nor implantation and further development of pretreated embryos transferred to pseudopregnant recipients, despite visible precipitation of the zonae [22]. Similarly, mice passively immunized with anti-ZP antiserum 2 days after mating showed no adverse effects on fertility or fecundity, and anti-ZP antisera had no effect on early embryonic development *in vitro* [23].

From these initial studies and those that followed, hypotheses regarding ZP vaccines' mechanism of action evolved as a primarily antibody-based interference with one or more of the following processes: sperm–oocyte binding, the acrosome reaction, sperm movement through the ZP, oocyte activation and/or the zona block; thus, at the level of the periovulatory oocyte. If so, estrous cyclicity and reproductive behaviors should remain unaffected following vaccination. This feature of pZP immunocontraception has been an important, although occasionally controversial, rationale supporting its application in species with complex social hierarchies, such as the African elephant and feral horse [24–28]. The detection, however, of ovarian dysfunction subsequent to treatment with ZP-based vaccines in some species has provided a challenge to researchers hoping to overcome this potentially undesirable outcome. During this process, a number of hypotheses regarding the cause of ovarian dysfunction have developed.

3. Hypotheses explaining ovarian dysfunction during ZP-based immunocontraception

3.1. Glycosylation causes oophoritis

Glycosylation refers to the pattern of binding of distinct carbohydrate moieties to amino acids, giving rise to the glycoprotein structure of the ZP. The diverse nature of ZP glycosylation across species may play a role in the species-specificity of sperm-zona binding [29]. Chemical deglycosylation of pZP3 was found to decrease its antigenicity and immunogenicity; precipitation of ZP *in vitro* by the relevant antisera was more superficial than precipitation produced using antisera to glycosylated pZP3 [30]. Consequently, early workers in the field considered the deglycosylation of ZP antigens to negate pZP's oophoritogenic effects. In rabbits, the degree of glycosylation of pZP was found to correlate directly with the degree of interference with

folliculogenesis, ovulation, and estrous cyclicity [31,32]. Researchers hoped that qualitative, rather than purely quantitative, differences in the immune response to deglycosylated versus glycosylated ZP antigens were responsible for the differences in oophoritogenic effect [32]. Subsequent trials in marmoset monkeys [33] and baboons [34] found that immunization with deglycosylated pZP3 did indeed result in lower levels of ovarian dysfunction compared with glycosylated pZP3; a result that correlated to poorer antibody responses. In addition, antisera to deglycosylated ZP antigens provided poorer contraceptive efficacy *in vitro* [33]. Although now abandoned as a possible means of preventing oophoritis, glycosylation remains a factor to consider when designing synthetic vaccines. For example, Hardy et al. [35] investigated the use of mammalian versus insect expression systems in the production of a recombinant murine ZP3 antigen. Recombinant ZP3 produced in a mammalian expression system caused a transient antifertility effect. However, recombinant ZP3 produced in an insect expression system had no antifertility effect despite evidence of an antibody response, possibly as a result of differences in glycosylation of the protein product. Furthermore, differences in glycosylation may contribute to the reduced immunogenicity associated with some synthetic vaccines, where multiple boosters have been required to maintain adequate antibody titers [36–38].

3.2. Contamination with non-ZP ovarian proteins causes ovarian dysfunction

An early study investigating pZP immunocontraception in cynomolgus monkeys suggested that contamination may have been responsible for the ovarian dysfunction detected, as a result of immune responses directed toward extra-ZP ovarian epitopes [8]. This hypothesis currently remains a commonly advanced argument [39].

Specific binding of anti-ZP antibodies within the developing ovarian follicle, primarily within the ZP, occasionally involving adjacent oolemma or granulosa cells, has been demonstrated in the rabbit [40], cat, dog, horse, and African elephant [41,42]. Similar findings have been demonstrated using immunofluorescence in both primates [43,44] and rabbits [45].

In addition, recombinant and synthetic peptide ZP antigens exclude the possibility of contamination by non-ZP ovarian proteins [46]. A review of the literature describing the use of these vaccines across a number of species includes multiple studies in which synthetic vaccines, including antigens delivered within a virus or as a DNA plasmid vaccine, are nevertheless associated with abnormalities on ovarian histology, including cellular inflammatory infiltration, and/or decreased follicle numbers [38,40,45,47–57]. Although these findings do not completely exclude the possibility of contamination of pZP vaccines as a cause of ovarian dysfunction, these reports suggest that oophoritis or interference with folliculogenesis may be an inherent feature of ZP-based vaccines.

In addition, attempts at purification of pZP to avert ovarian dysfunction have shown limited success in primates [34,58,59]. In the bitch, purified pZP failed to prevent ovarian pathology, although the observed pathology was milder and seen in association with lower antibody titers than that induced by a crude pZP preparation [60,61].

3.3. Freund's adjuvants are linked to ovarian dysfunction

Freund's complete adjuvant consists of a water-in-oil emulsion, incorporating nonmetabolizable oils (paraffin oil and mannide monooleate) and heat-killed *Mycobacterium tuberculosis* cells. Freund's incomplete adjuvant, generally preferred for booster vaccinations, consists of a similar water-in-oil emulsion without mycobacterial cells. Since its initial description nearly 80 years ago, initially incorporating only paraffin oil and mycobacteria (reviewed in [62]), FCA has enjoyed widespread application in immunological research due to its marked efficacy as an adjuvant. However, side effects associated with FCA, particularly granulomatous injection site reactions, have discouraged its commercial use [63].

Concerns regarding false positive results to tuberculosis testing following the use of FCA led to the development of Freund's modified complete adjuvant (FMCA), incorporating *M butyricum* instead of *M tuberculosis*. Although most ZP-based research involving Freund's adjuvants has employed FCA, recent research in horses and African elephants has made use of FMCA. In horses, pZP with FMCA was found to induce antibody titers consistently higher than, although statistically no different to pZP with FCA [64]. Although most researchers likely refer to FCA when discussing Freund's adjuvants, the following discussion encompasses both FCA and FMCA.

A third hypothesis within ZP-based immunocontraceptive research implicates the use of Freund's adjuvants in the pathogenesis of ovarian dysfunction. Early studies in primates detected disturbances of ovarian function in control groups administered Freund's adjuvant alone [59,65]. These findings were later contradicted by investigators who reported an absence of ovarian pathology in adjuvant control groups [33,66]. A similar lack of ovarian effects was found in rabbits administered Freund's adjuvant only, in comparison to saline-treated controls [31,32,67].

In two studies reporting a direct comparison between Freund's and alternative adjuvants in combination with pZP, only the inclusion of Freund's adjuvant was associated with ovarian pathology in two monkey species [66,68]. However, the alternative adjuvants induced antibody titers that were lower, and/or diminished faster than antibody titers induced by Freund's adjuvants.

Furthermore, ovarian dysfunction or oophoritis is clearly not limited to the use of Freund's adjuvants, having been reported in association with a number of non-Freund's adjuvants, including alum [8,61]; muramyl dipeptide (MDP) [34,49,69]; MDP with Morris adjuvant [36,70]; squalene with Arlacel-A (and SPLS; primary vaccination) [38,71]; MDP with squalene and Arlacel-A [52]; and CP20,961 [60,72].

3.4. Cytotoxic T-cells cause oophoritis and ovarian dysfunction

The adaptive immune system is mediated largely by T-helper and T-cytotoxic lymphocytes. T-helper ($CD4^+$)

cells recognize soluble and particulate antigens presented by professional antigen presenting cells, in association with major histocompatibility class (MHC) II molecules. In the classical endogenous pathway, intracellular-derived antigens presented in association with MHC class I molecules are recognized by cytotoxic T-lymphocytes ($CD8^+$; CTL). An alternative pathway has been suggested, whereby dendritic cells present extracellular antigens, which could include ZP antigens, via MHC I [73]. Although T-helper cells play a role in the production of antibody by B-lymphocytes, CTL produce a direct cytotoxic effect. Other cells capable of cytotoxicity include members of the innate immune system such as macrophages and natural killer cells.

Various authors have suggested that a CTL response may be involved in the development of oophoritis during pZP immunocontraception [1,74–77], often citing Rhim et al. [47], Lou et al. [78], and Lou et al. [79] despite no reference to CTL within the cited studies. Few studies have actively attempted to identify CTL responses during ZP-based immunocontraception. In mice, the infiltration of $CD4^+$ and $CD8^+$ T-lymphocytes was demonstrated in ovarian sections using immunohistochemistry, following infection by a murine cytomegalovirus expressing mZP3 [56]. However, the presentation of the antigen by a virus provides a direct link to the classical MHC I T-cell pathway, likely contributing to the $CD8^+$ response. Further work classifying the immune response to ZP vaccines, including the potential role of CTL in the pathogenesis of ovarian dysfunction, is warranted.

What does seem clear is the link between ovarian pathology, a helper ($CD4^+$) T-cell–mediated immune response and an antibody response. Rhim et al. [47] showed that the adoptive transfer of $CD4^+$ T-cells induced an oophoritis despite the absence of any detectable antibody response. This oophoritis was described as interstitial, excluding developing follicles, and did not appear to interfere with ovarian function in mice [50]. In a subsequent study, Lou et al. [51] reported that the presence of anti-ZP antibodies redirected the cell-mediated inflammatory response from the ovarian interstitium to the developing follicles, resulting in profound interference with ovarian function [51].

Furthermore, Lloyd et al. [57] found that immunoglobulin-deficient mice, incapable of mounting an antibody response but otherwise capable of normal adaptive immune responses, showed neither decreased fertility nor abnormalities on electron microscopy of ovarian sections following infection by a recombinant murine cytomegalovirus expressing murine ZP3 [57].

Immunocompetent mice infected with the same virus showed decreased fertility and fecundity, and evidence of abnormal ZP formation and vacuolization of oocytes on electron microscopy of ovarian sections. Although it could be argued that a recombinant ZP-expressing virus would be expected to show differences in immune response mechanisms to the conventional pZP vaccine, this study suggested a pivotal role for antibodies in the development of oophoritis during anti-ZP immunocontraception.

Taken together, these studies demonstrate the roles of both $CD4^+$ T-lymphocytes and antibodies, in unison, in ZP vaccine-induced interference with ovarian function in mice. Whether or not a similar dynamic plays a role in ovarian dysfunction in other species warrants further research.

3.5. Ovarian dysfunction is species-specific

Finally, ovarian dysfunction during ZP-based immunocontraception, characterized as a cellular oophoritis and/or interference with folliculogenesis has been described as a species-specific complication. Antibody responses to ZP-based vaccines show some variation between individuals within a species, and likely represent variation in the overall immune response to vaccination. Reasons for individual variation in immune response include factors influencing the physiological status of the individual during or after vaccine administration, including physiological stress, nutritional status, and the presence of concurrent systemic conditions. In addition, genetic differences in immune response to immunocontraceptive vaccines have been suggested to play a role [80].

Significant species differences in terms of the endurance of antibody titers have also been well documented. To illustrate this, Dall sheep maintained significant antibody titers for over 3 years following an initial pZP vaccination regime (primary plus booster) [81], whereas Muntjac deer required biannual boosters to maintain antibody levels [82].

A review of nine species groups (mice, rabbits, nonhuman primates, dogs, cats, sheep, deer, horses, and African elephants), arguably the most studied species to date in terms of ZP-based immunocontraception, revealed evidence of abnormal cyclicity in each one of these species following treatment, with the notable exception of the cat and African elephant (Table 1). Cats are refractory to pZP, showing neither cyclic disturbances nor any effect on fertility [92,93]. One study examining estrous cyclicity during pZP immunocontraception (2–3 years after the start of treatment) in African elephants included evidence of anestrus in a proportion of treated cows [106]. Although this effect was possibly ascribable to seasonal effects, the lack of controls complicates any definitive conclusions.

In horses, ovarian inactivity following pZP treatment, certainly in the short term, appears to have been undetected for over 20 years. An initial study of pZP in horses found no significant evidence of abnormal ovarian function following short-term treatment [101]. Similarly, Powell et al. [102] found no differences in estrous cycle characteristics between pZP-treated and untreated mares. Although researchers noted depressed excretory steroid levels and slower reversal of infertility following prolonged ($\geq$3 years) treatment [103,104], the mechanism of action of pZP immunocontraception in mares as an antibody-based interference with conception at the level of the oocyte remained until recently the generally accepted dogma in this species. Bechert et al. [105] compared two long-acting pZP vaccine formulations in mares. Treated mares demonstrated lower serum progesterone levels, smaller ovaries, and fewer follicles than control mares; 93% of treated mares ceased estrous cyclicity within 4 months of treatment. Similarly, six of seven mares treated with two doses of the conventional pZP vaccine demonstrated

Table 1
Overview of the literature reporting on ovarian dysfunction during zona pellucida–based immunocontraception.

Species	No evidence of ovarian dysfunction detected[a]	Evidence of ovarian dysfunction detected[a]	Inconclusive evidence of ovarian dysfunction detected	Fertility rates[b] reported for the relevant vaccine formulation, within the cited studies
Mice	[74,83–85]			9%–100%
		[48,50,53,55–57,86,87]		0%–100%
Rabbits	[7,54]			100%
		[7,31,32,40,45,54,88]		0%–30%
Nonhuman primates	[36,37,49,68,70,89–91]			25%–100%
		[8,33,34,36,49,52,58,59,68–71,89]		0%–50%
Cats	[92–94]			16%[c]–100%
Dogs	[38,60,72]			100%
		[60,61,72]		0%–34%
Sheep	[95]			100%
		[95]		0%
White-tailed deer	[96–99]			0%–95%
			[100]	11%
Horses	[39,101,102]			0%–57%
		[39,103–105]		0%–8%
African elephants			[106]	0%

[a] Evidence of ovarian dysfunction includes histological evidence of oophoritis or decreased follicle numbers, or behavioral or hormonal evidence of abnormal estrous or menstrual cyclicity.
[b] Expressed as a proportion of the control group, where control groups are available.
[c] Not statistically different to control group.

periods of anestrus posttreatment, characterized by baseline serum progesterone levels and a lack of follicular development [39]. In part, the discrepancy between the latter two studies and other, earlier studies might be explained by differences in antigen dose rates (100 μg [39] and 200 μg of a single administered formulation [105], compared with 65 μg [107]). In addition, most trials observed feral horses with associated constraints on clinical monitoring [27].

In white-tailed deer, ongoing estrous behaviors during pZP immunocontraception have been reported by a number of studies [96–98]. Yet, a study showing depressed progesterone levels following pZP treatment suggests that ovarian inactivity may nevertheless be a feature of pZP immunocontraception in this species [100]. The dose of pZP administered in the latter study (300–500 μg) was higher than that reported in other deer studies (65 μg; [96,97,108]). This, however, suggests that ovarian suppression is dose-dependent, rather than species-dependent. In a later study, fewer normal secondary follicles were detected in recently revaccinated does in comparison to controls and does vaccinated 2 years previously, although sample sizes were low [99]. A third study anticipated observing increased mating behavior in pZP-treated does but found no differences in behaviors, including estrus and dominance behaviors, between treated and untreated groups of fallow deer [109]. Given the similar difficulties in estrus detection between feral horses and deer, further study of the ovarian effects of pZP in deer is warranted.

In summary, ovarian suppression may be an inherent feature of effective ZP-based immunocontraception, associated with the generation of elevated antibody titers over a prolonged period of time and contributing to the vaccine's contraceptive effect, rather than a species-specific response. However, further research to confirm this hypothesis is indicated.

4. The link between antibody titers, contraceptive efficacy, and ovarian dysfunction

Although not an absolute rule, a recurring theme throughout the literature is the apparent link between the immunogenicity of a ZP vaccine with the antifertility capabilities of the vaccine and the presence of ovarian dysfunction. In the dog [60], sheep [95], and rabbit [7,32,67], ovarian pathology and contraceptive efficacy showed a direct correlation when comparing two or more alternative formulations. Similarly, in primates, significant antifertility efficacy is associated with evidence of ovarian dysfunction [70,71,89]; with the converse also demonstrated (poor antifertility effect with no evidence of ovarian effects) [90,91]. Finally, in the cat, the absence of contraceptive efficacy accompanies a consistent lack of ovarian effects [92–94].

These observations support the hypothesis that ovarian dysfunction is an inherent feature, or at least a component, of the mechanism of action of ZP-based vaccines [46,60]. To the best of the authors' knowledge, no vaccine formulation, whether native or synthetic, has yet achieved near complete contraceptive efficacy without some evidence of ovarian effects following further study. Attempts at vaccine design, aimed at the inclusion of B-cell epitopes while excluding putative oophoritogenic T-cell epitopes, have indeed shown decreased ovarian effects but, again, limited contraceptive success [70,79,83–85]. To further complicate matters, ovarian effects may inadvertently be missed. Periods of ovarian dysfunction may be transient and their detection consequently dependant on the timing of sampling interventions for ovarian histology in relation to vaccine administration [61]. In addition, the difficulty associated with the detection of cellular inflammatory infiltrates in ovarian tissue sections under light microscopy has been demonstrated. In an initial study, no

inflammatory infiltrate was detected in ovaries observed under light microscopy [86]. However, in a follow-up study using the same population and methodology, lymphocytic infiltration of the ovary was detected using immunohistochemistry [56]. The value of immunohistochemistry over conventional histopathology in detecting oophoritis was confirmed by Bagavant et al. [52].

Possible causes of interrupted folliculogenesis, leading to ovarian atrophy and anestrous, include immune-mediated follicular destruction and interference with normal follicle development [60]. Destruction of oocytes and follicles could occur as a result of antibody-mediated complement activation. Few studies have investigated the role of complement in ZP-based immunocontraception. In an early study, mice were treated with solubilized hamster ZP followed by superovulation and the flushing of oocytes from the oviducts. Antibody and complement binding to oocytes was assessed using fluorescein-conjugated rabbit anti-mouse IgG, and rabbit anti-mouse complement C3 followed by fluorescein-conjugated goat anti-rabbit IgG, respectively. In both tests, bright immunofluorescence was detected on oocytes from immunized animals, with no immunofluorescence detected on control oocytes [110]. In contrast, no complement binding was visualized in ovarian sections from immunocontracepted dogs; however, the small sample size and the lack of a positive control for the complement-binding assay were major limitations to the study [61].

Alternatively, or additionally, the immune response might alter ZP structure and function in developing follicles, affecting communication between the growing oocyte and its surrounding granulosa cells [88]. This scenario is mimicked in mice lacking the functional gene for connexin 37, one of a family of proteins involved in intercellular communication between oocytes and granulosa cells. Folliculogenesis is inhibited in connexion 37-deficient mice. In addition, ovaries show abnormal accumulations of luteinized tissue [111], possibly resembling that described in ZP-treated mice [87], rabbits [40,45,67], and primates [8,36]. This mechanism may be particularly plausible in the dog, where pZP treatment caused the formation of ovarian cysts associated with prolonged estrogen secretion [61].

4.1. Conclusions

The advantages of ZP-based immunocontraception include its efficacy as a contraceptive agent in many species, safety during pregnancy, reversibility (at least in the short term), and freedom from major side effects [112]. Apart from ovarian senescence, extensive macroscopic and microscopic postmortem examinations of the major organ systems in pZP-treated mares failed to reveal any pathology that could be linked solely to pZP [105]. The vaccine can be remotely delivered, important for use in feral species [113]. Furthermore, the protein nature of the vaccine precludes its entry into the food chain [29]. Permanent sterility, if indeed this could be induced by pZP vaccination with a degree of reliability, may be a desirable side effect in certain so-called pest species [46]. Importantly, pZP vaccination appears to show minimal adverse effects on animal welfare, particularly when compared to alternative means of population control such as culling [28]. No adverse behavioral or social effects were detected in a long-term study of pZP immunocontraception in elephants [114]. In the feral horse, pZP immunocontraception has been associated with both enhanced longevity and body condition [115]. Furthermore, the vaccine showed few significant effects on social behaviors and time budgets in horses [116,117]; one study reported an increased frequency of reproductive behaviors and a lengthening of the breeding season, which should be considered during the management of immunocontracepted herds [118]. Furthermore, studies to confirm the lack of effects on behavior and welfare are warranted.

In most species studied, annual and sometimes biennial boosters are required if the contraceptive effect is to be maintained. From a practical point of view, particularly in free-ranging species like the African elephant, this requires considerable time and resource investment. A long-acting pZP formulation which induces antibodies titers that are maintained for 2 years or longer after a single treatment would be a major advantage. A series of studies investigated the use of lactide-glycolide polymers to form pellets incorporating pZP. The release delay, depending on the ratios of lactide and glycolide in the pellets, was either 1, 3 or 12 months. Hand-injected pellets in combination with a conventional primary dose of pZP resulted in antibody titers that were sustained at contraceptive levels for 21 to 22 months. The contraceptive effect was evident for 2 years; a result which was promising [119]. An entirely different approach to achieve long-lasting antibody titers and thus contraception has been the use of a liposomal formulation consisting of lecithin and cholesterol and emulsified with FMCA or lyophilized and then reconstituted with FMCA [105]. Both formulations produced sustained antibody titers in mares (monitored for 22 weeks) and induced cyclic changes alluded to earlier. Moreover, the latter formulation maintained antibody titers for at least 7 years in African elephant cows [120]. The emulsified formulation has previously been tested in gray seals [121] and deer [122], both producing infertility that was maintained over 3 years or longer. Bechert et al. [105] proposed a number of possible mechanisms that may be responsible individually or, more likely, collectively for the sustained antibody titers. These were the sustained release of antigen from the injection site, increased production of long-lived plasma cells in the bone marrow, and mobilization of follicular dendritic cells within draining lymph nodes. Self-boosting by zona capsules in developing follicles was also mentioned but, in the absence of local adjuvant, seemed unlikely and would also apply to other pZP formulations. Although these results are extremely encouraging, the longer term effects on ovarian function have not been investigated satisfactorily. Reversibility and thus lack of long-term ovarian effects in species like the African elephant are an extremely important feature of this treatment.

The commercial availability of serum anti-Müllerian hormone (AMH) assays may provide access to a novel method of monitoring the ovarian effects of immunocontraception in females. This hormone, secreted by the

granulosa cells of, primarily, preantral, and early antral follicles, has been correlated to antral follicle counts and ovarian reserve in mice [123], cattle [124], and women [125]. Recently, AMH levels measured in mares during the course of 1 year of their immunocontraception with either pZP or GnRH vaccines were compared. Although the GnRH vaccine had little effect on AMH levels, pZP suppressed serum AMH in the short term (Joonè et. al., in preparation). Given the proposed link between low AMH levels and ovarian suppression in these mares, AMH may prove useful in species not amenable to direct clinical examinations of their reproductive organs. Likewise, pZP vaccination may provide an exciting tool for the study of AMH and its relationship to follicular dynamics and the ovarian reserve.

In conclusion, this review suggests a re-evaluation of dogmas that have emerged within the field of ZP-based immunocontraception, regarding these vaccines' ovarian effects. The suggestion that ovarian suppression could be an inherent feature of effective ZP-based immunocontraception, across all species, requires further investigation. Nevertheless, pZP remains a valuable, practical, and humane means of population management with application in a number of mammalian species.

Summary

Reasons for performing study: Few studies have investigated ovarian function in the mare undergoing porcine zona pellucida (pZP) immunocontraception despite reported ovarian dysfunction in other species.
Objectives: This study aimed to describe ovarian function and oestrous cyclicity in pony mares following treatment with either the conventional pZP vaccine or a novel recombinant form of the vaccine derived from porcine ZP3 and ZP4 (reZP). In addition, the contraceptive efficacy of pZP vs. reZP was assessed.
Study design: Blinded, randomised, prospective clinical trial.
Methods: Mares (n = 21) were randomised into 3 groups of 7: *Group I* received the pZP vaccine, with a booster 5 weeks later; *Group II* received the reZP vaccine, with a booster 5 weeks later; and *Group III* (controls) received 2 treatments, 5 weeks apart, of saline and adjuvant alone. Mares underwent weekly monitoring via transrectal palpation and ultrasound examination of the reproductive tract, with daily monitoring during oestrus. Data were collected over a 24 week period coinciding with the physiological breeding season; treatments commenced in Week 4. Serum samples were obtained for antibody titres and ovarian steroid level analyses at 7 day intervals. Cycling mares were bred via fresh semen artificial inseminations over a maximum of 2 consecutive oestrous cycles, commencing 5 weeks post booster vaccination.
Results: Control mares cycled throughout the trial. After treatment, 6 of 7 pZP mares (86%) and one reZP mare (14%) had an extended anoestrus that correlated with basal serum oestradiol and progesterone levels. All mares resumed cyclicity by 10 months post treatment. Pregnancies were diagnosed in all controls, 4 reZP- (57%) and none of the pZP-immunised mares.
Conclusions: The current study demonstrates the reversible suppression of ovarian function in pony mares following treatment with pZP. The effect of the reZP vaccine on pregnancy outcome requires further investigation.

Keywords: horse; ovarian function; anoestrus; progesterone; oestradiol; artificial insemination

Introduction

Investigation of porcine zona pellucida (pZP) as an immunocontraceptive in the mare began over 20 years ago [1]. In contrast to immunocontraceptive vaccines targeting gonadotrophin releasing hormone (GnRH), which causes reproductive quiescence [2], pZP has traditionally been associated with continued oestrous cyclicity [3]. The maintenance of reproductive behaviours has made the pZP vaccine the preferred immunological method of population control in species with complex social structures, such as the feral horse (*Equus caballus*) and the African elephant (*Loxodonta africana*) [4,5].

Research on pZP as a human antifertility vaccine waned following evidence of ovarian dysfunction in nonhuman primates [6]. Similar effects are reported in the rabbit, dog and sheep [7–9]. In contrast, little evidence for interference with ovarian function has been reported in the mare. In a previous study, 1 year of pZP treatment was found to have no effect on ovarian function [1]; however, longer periods of contraception, specifically ≥3 years, were associated with declining oestradiol levels and ovulation rates in feral horses of the USA [10,11]. A subsequent study in the same population reported no association between the incidence of ovulatory failure in mares and their duration of treatment [12]. Recently, investigators demonstrated ovarian inactivity in 13 of 14 mares within 4 months of treatment with single-dose pZP vaccine formulations [13].

A recombinant zona pellucida vaccine may provide potential advantages compared with native pZP vaccines that include production efficiency and the avoidance of contamination with non-ZP proteins [14]. Recently, recombinant vaccines based on the expression of porcine ZP3 and ZP4 in *Escherichia coli*, hereafter referred to as reZP, were developed [15].

The current study aimed to describe ovarian function and oestrous cyclicity in pony mares following treatment with either native pZP or reZP vaccines. In addition, the contraceptive efficacy of reZP in the mare was investigated.

Materials and methods

Mare management

Twenty-one Nooitgedacht pony mares, aged between 3 and 14 years and of variable parity, were studied from October 2013 to March 2014, coinciding with the physiological breeding season in the southern hemisphere [16]. Inclusion criteria were nonpregnant status, good physical and reproductive health and no previous immunocontraceptive exposure. Ponies were housed in outdoor grass paddocks, with free access to water and *Eragrostis tef* grass hay. Clinical examinations were performed weekly and mares were weighed using an electronic scale during Weeks 1, 8 and 24 (Table 1).

Vaccines

Native pZP vaccine was prepared according to standard methods [1,11][a]. Aliquots of 1 mg purified pZP in phosphate buffered saline (PBS) were

TABLE 1: Mare distribution according to parity, age (median (range)), and body weight (median (range)) for each study group

Mare information	*Group I*: pZP (n = 7)	*Group II*: reZP (n = 7)	*Group III*: controls (n = 7)	P value
Nulliparous	4	3	5	0.6
Foaled within last 3 years	3	2	1	0.5
Foaled >3 years ago	0	2	1	0.3
Age (years)	7 (4, 10)	8 (3, 13)	6 (3, 14)	0.8
Body weight (kg) at Week 1	416 (360, 503)	396 (329, 433)	436 (360, 473)	0.2
Body weight (kg) at Week 8	396 (352, 495)	405 (333, 433)	405 (361, 433)	0.6
Body weight (kg) at Week 24	435 (382, 515)	439 (359, 467)	445 (369, 472)	0.7

pZP, porcine zona pellucida vaccine; reZP, recombinant zona pellucida vaccine.

transferred to glass vials and lyophilised, sealed and stored at 4°C. Before vaccination, each vial was reconstituted with 5 ml sterile injection water with a final protein concentration of 200 μg/ml.

The reZP vaccines, TT-KK-ZP3 and bRNase-KK-ZP4, were supplied by Dr Satish Kumar Gupta (Reproductive Cell Biology Laboratory)[b]. Porcine ZP3 (amino acid (aa) residues 20–344) was expressed as a chimeric fusion protein encompassing a promiscuous T-cell epitope of tetanus toxoid (TT; aa residues 830–844) at its N-terminus and separated from ZP3 by a dilysine linker (TT-KK-ZP3) in *E. coli* [15]. Similarly, porcine ZP4 (aa residues 22–462) was expressed in *E. coli* as a chimeric fusion protein incorporating a promiscuous T-cell epitope of bovine RNase (bRNase; aa residues 94–104; bRNase-KK-ZP4) [15]. Recombinant proteins were purified from inclusion bodies followed by refolding, as described previously [17]. Recombinant TT-KK-ZP3 and bRNase-KK-ZP4 were dialysed separately in 20 mmol/l Tris pH 6.0 and the respective protein concentration estimated using a BCA Protein Estimation Kit[c] and adjusted to 500 μg/ml.

Study design

Mares were stratified by age and randomly assigned to one of 3 treatment groups; the primary investigator was blinded to treatment assignment. Treatments were administered into the gluteal muscles, commencing in Week 4, as follows.

Group I (n = 7) received a primary vaccination (V1) consisting of 100 μg (0.5 ml) pZP emulsified with 0.5 ml Freund's modified complete adjuvant (FMCA). Five weeks later, a booster (V2) consisting of 100 μg pZP emulsified with 0.5 ml Freund's incomplete adjuvant (FIA) was administered into the contralateral hindquarter.

Group II (n = 7) received 2 primary vaccinations (V1), one on each side of the hindquarters, consisting of 250 μg (0.5 ml) recombinant ZP3 and ZP4 proteins, respectively, each emulsified with 0.5 ml FMCA. Five weeks later, 2 boosters (V2) consisting of the same doses of recombinant ZP3 and ZP4 emulsified with 0.5 ml FIA, were similarly administered.

Group III (n = 7, control group) received an initial treatment (V1) consisting of 0.5 ml sterile saline emulsified with 0.5 ml FMCA. Five weeks later, a second treatment (V2) consisting of 0.5 ml sterile saline emulsified with 0.5 ml FIA was administered into the contralateral hindquarter.

Transrectal monitoring of the reproductive tract

Mares underwent examination by transrectal palpation and ultrasonography of the reproductive tract at 7 day intervals. In cycling mares, examinations coincided with Days 7 and 14 of consecutive oestrous cycles, with daily monitoring from Day 14 until ovulation (Day 0). Day 0 was defined by the ultrasonographic detection of a *corpus luteum*, correlated with the absence of a dominant follicle identified on the previous day. Ultrasound examinations were performed using a portable ultrasound machine (A6V)[d] and a 3–8 MHz linear array rectal probe.

Ovarian dimensions were estimated digitally and recorded in 3 perpendicular planes. Ovarian volumes were calculated using the prolate ellipsoid formula (length × height × width × 0.523) [18]. Identifiable structures on each ovary were recorded and follicles ranked according to approximate diameter (<15 , 15–20 and 20–25 mm). Follicles ≥25 mm in diameter were individually measured from the ultrasonographic image of the follicle at its maximum using the electronic calliper function of the ultrasound machine. The average of 2 perpendicular diameter measurements, one of which represented the widest diameter of the follicle, was recorded as the follicle diameter [19]. Anoestrus was defined as bilaterally small ovaries (both ≤25 cm^3), scant follicular development and the absence of any follicles ≥15 mm in diameter [20].

Artificial inseminations

All cycling mares were bred by artificial insemination over a maximum of 2 consecutive oestrous cycles using fresh semen collected from a single stallion of proven fertility, commencing ≥5 weeks post V2. Inseminations were performed according to standard practices once a mare's ovulation was adjudged imminent, i.e. a preovulatory follicle ≥35 mm together with maximal or decreasing endometrial oedema [21]. Semen doses consisted of ≥1 × 10^9 progressively motile spermatozoa, extended 1:1 in a prewarmed skim milk (MCT) medium[e]. Semen motility was evaluated subjectively under light microscopy. Semen concentration was quantified using a photometer calibrated for use with equine semen (Spermacue)[f]. Inseminations were repeated if a mare failed to ovulate within 72 h. Pregnancy diagnoses by transrectal ultrasound examination were performed 14 days post ovulation. If pregnant, mares were excluded from further breeding and sampling.

Blood samples for hormonal assays and antibody titre determination

Blood samples from all mares were collected by jugular venipuncture at 7 day intervals. In cycling mares, sampling coincided with Days 0, 7 and 14 of the mares' oestrous cycles. Samples were centrifuged and serum stored at -20°C until required.

Serum progesterone and oestradiol assays

Serum progesterone and oestradiol levels were determined by means of radioimmunoassay (Coat-A-Count progesterone and oestradiol kits)[g] [22]. Assay sensitivities for progesterone and oestradiol were 0.06 nmol/l and 29 pmol/l, respectively. For progesterone, intra- and interassay coefficients of variation were 6.1%, 3.5% and 4.7% and 10.3%, 4.3% and 5.2% for low, medium and high concentrations, respectively. For oestradiol, intra- and interassay coefficients of variation were 7.0%, 4.3% and 4.0%, and 8.1%, 6.8% and 4.2% for low, medium and high concentrations, respectively.

Antibody response

Anti-ZP antibody response was measured by enzyme immunoassay (EIA), using a modification of a method previously described [2]. Briefly, 96-well plates (MaxiSorp, cat. no. NUN430341)[h] were incubated at 2–8°C for 16 h with 1 μg purified pZP in 100 μl coating buffer (2.94% $NaHCO_3$, 1.59% Na_2CO_3, pH 9.6) per well. Plates were washed with PBS containing 0.05% Tween 20 and then blocked with 0.03% BSA in PBS for 16 h at 2–8°C. Plates were then incubated with serial dilutions (1:1000 to 1:8000 for test samples and 1:1000 to 1:64,000 for positive reference serum) of standard and test serum samples at 37°C for 1 h. The positive reference serum consisted of pooled sera from all 7 individuals in *Group I* at expected maximal antibody titre (4 weeks post V2). Blank wells were used as negative controls. After washing, antibodies were detected by incubating plates with recombinant protein G-horseradish peroxidase[i] at 37°C for 1 h. After further washing, plates were developed with trimethylene blue (SureBlue™; cat. no. 52-00-03)[j]. The reaction was stopped by adding 50 μl of 2 mol/l H_2SO_4 per well. Absorbance at 450 nm was measured using a microplate photometer (Multiskan™ FC)[k].

Antibody response was measured as the mean sample absorbance (minus blank) expressed as a proportion of the mean absorbance (minus blank) of the positive reference sample at the same dilution for each plate (1:2000; 1:4000; 1:8000). The overall proportion positive (PP) was calculated as the average value over the 3 dilutions.

Monitoring injection sites

All mares were monitored daily for visible lesions, including heat and swelling, and weekly by palpation of the approximate injection sites. Transcutaneous ultrasonography of the injection site area was performed when indicated by clinical findings. Monitoring continued following completion of the study as part of the routine care of experimental animals.

Reversibility

All mares underwent examinations at 3 and 6 months following the trial's completion to monitor reproductive activity. Teasing of mares continued after the study period as part of their routine management.

Data analysis

Data were assessed for normality through the plotting of histograms, calculation of descriptive statistics, and the Anderson–Darling test for normality, which was performed in commercially available software (MINITAB Statistical Software, Release 13.32)[l]. Categorical data were compared among treatment groups using Chi-square or Fisher exact tests in available freeware (Epi Info, version 6.04)[m]. The maximum oestradiol values and mean progesterone values before and after V2 were extracted for each mare and used for the statistical comparison among groups. Quantitative data satisfying the normality assumption were subsequently compared among groups using one-way ANOVA. Non-normal data were compared using Kruskal–Wallis tests followed by pairwise Mann–Whitney *U* tests with correction of P values for multiple *post hoc* tests. A linear mixed model was used to estimate the effect of treatment group and time on antibody responses measured as proportion of the positive control. 'Horse' was included as a random effect to account for the repeated sampling design. Mixed effects models were analysed in commercially available statistical software (IBM SPSS Statistics Version 22)[n]. Bonferroni adjustment was used to adjust for multiple *post hoc* testing and significance was set at $P \leq 0.05$.

Results

Transrectal monitoring of the reproductive tract

All mares demonstrated cyclic ovarian activity prior to V2, although one mare in *Group II* showed a period of anoestrus between normal oestrous periods prior to commencing treatment.

In *Group I* (pZP), one mare cycled regularly throughout the study period. Four mares demonstrated anoestrus within 5 weeks of V2 that persisted until the end of the study. One showed anoestrus from 12 weeks post V2 until study completion, while another cycled erratically, characterised by one brief period of oestrus between prolonged periods of anoestrus.

In *Group II* (reZP), one mare entered anoestrus within 5 weeks of V2, persisting until study completion. The remaining 6 mares cycled regularly throughout the study period.

In *Group III* (controls), 6 mares demonstrated regular cyclic activity throughout the study. One developed a persistent *corpus luteum* of unknown cause, which resolved spontaneously.

By Week 16 (7 weeks post V2, prior to any positive pregnancy diagnoses), left and right ovary follicle counts and maximum follicle diameters in *Group I* were significantly lower than in *Group III*. There were no significant differences in *Group II* between either *Group I* or *Group III* for these data points, suggesting an intermediate effect (Table 2).

Serum progesterone and oestradiol profiles

Mean progesterone profiles of *Groups I*, *II* and *III* mares prior to, and more than 5 weeks following, booster vaccination (V2) are shown in Figures 1 and 2, respectively. The mean progesterone concentrations before and after V2 for the 3 groups were: 20.4 vs. 6.4 nmol/l (*Group I*), 20.8 vs. 19.0 nmol/l (*Group II*) and 24.8 vs. 25.3 nmol/l (*Group III*). There were no significant differences in average progesterone concentrations between groups prior to V2 ($P = 0.6$); thereafter the change in average concentrations was significantly different among groups ($P = 0.05$). *Group I* had the largest average difference in progesterone values but *post hoc* pairwise comparisons did not indicate significant differences compared with *Groups II* and *III* ($P = 0.2$ and $P = 0.07$, respectively).

The mean for the maximum oestradiol concentrations measured before and after V2 for the 3 groups were: 42.0 vs. 6.8 pmol/l (*Group I*), 37.1 vs. 19.8 pmol/l (*Group II*) and 51.5 vs. 27.1 pmol/l (*Group III*). There were no significant differences in maximum oestradiol concentrations between groups prior to V2 ($P = 0.6$); thereafter the change in maximum concentrations in *Group I* was significantly different to that in *Group III* ($P = 0.01$), with no significant differences, in terms of the change in maximum oestradiol concentrations, between either between either *Groups I* and *II* ($P = 0.2$) or *Groups II* and *III* ($P = 0.8$).

Antibody response

Samples from *Group I* and *II* mares prior to the first vaccination and *Group III* mares at all 4 sampling times (pre-V1, four weeks post V1, four weeks post V2 and ten weeks post V2), effectively negative serum controls, showed a mean (± s.d.) optical density (OD) of 0.0841 (± 0.0218). This mean was statistically no different from the mean of all blank wells ($P = 0.2$; independent *t* test). All samples following immunisation with pZP (*Group I*) or reZP (*Group II*) rendered ODs that were greater than this mean plus 2 standard deviations.

Anti-ZP antibody response, expressed as proportion positive values as described in materials and methods, varied by treatment group ($P<0.001$) and time ($P<0.001$), with the time effect also varying by treatment ($P<0.001$). Proportion positive values for *Group I* were significantly higher than those of *Group II* ($P<0.001$), and those of *Group II* were significantly higher than those of *Group III* ($P = 0.006$; Fig 3) post V2.

Pregnancy outcome

In *Group I*, only 4 inseminations were performed owing to the paucity of oestrous cycles available. In *Group II*, one mare showed anoestrus throughout and could not be bred. A total of 11 and 9 inseminations were performed in *Groups II* and *III*, respectively. The proportion of pregnancies achieved in *Groups I*, *II* and *III* were 0%, 57% and 100%, respectively. Comparison of these proportions for *Groups I* and *III* was significant ($P<0.001$), with no significant difference detected between *Groups I* and *II*, nor between *Groups II* and *III* ($P = 0.07$ and 0.2, respectively).

Injection site reactions

No lameness or pyrexias were recorded. Swelling and/or palpable changes in muscular density at injection sites was detected in 20/21 mares post treatment. Overt, sterile abscessation occurred in 3 mares, all from *Group II*. Ultrasonography performed at the end of the study showed lesions affecting ≥one hindquarter in 17 of the 18 remaining mares. Lesions varied from mild changes in muscular architecture to poorly marginated areas of complex echogenic pattern ≤8 cm in width. A follow-up ultrasonographic examination 3 months later showed a distinct improvement in the appearance of lesions in 11 of these mares.

Reversibility

All mares that had demonstrated anoestrus following treatment had resumed oestrous cyclicity by 10 months post V2, based on follow-up oestrous monitoring or teasing records.

Discussion

The traditionally accepted mechanism of action of pZP in the equid involves, primarily, the interference of anti-ZP antibodies in sperm–zona binding, leading to contraception with continued oestrous cyclicity [1,23]. The current study, however, demonstrated suppression of ovarian function in 6 of 7 pony mares following pZP treatment, characterised by small,

*All data are reported as median (range). †If more than one data point for a mare existed during a particular week, the data point exhibiting the greatest follicle diameter was included. ‡For data points with superscripts, medians without superscripts in common are statistically different at P≤0.05 after adjustment for multiple *post hoc* testing.

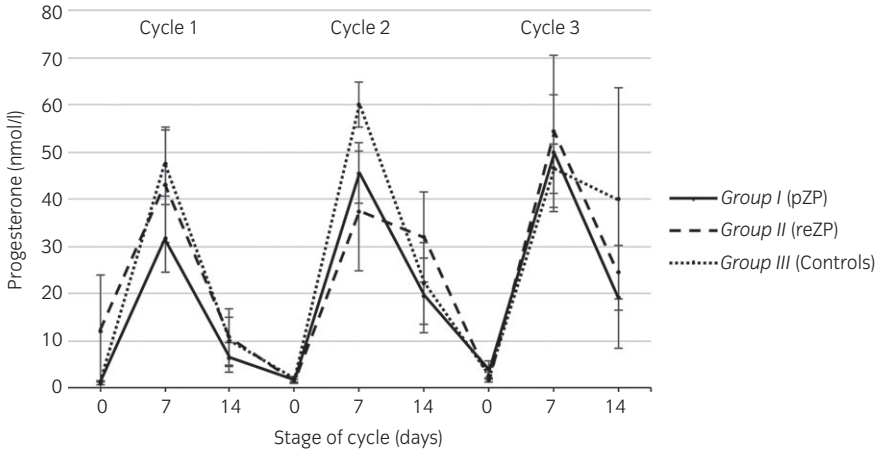

Fig 1: Graph showing mean weekly serum progesterone levels (s.e. bars) for each study group over 3 consecutive oestrous cycles prior to V2, where Days 0, 7 and 14 of each cycle have been synchronised in time.

inactive ovaries and basal ovarian hormone levels. The discrepancy between our findings and that of an earlier report of unaltered oestrous cyclicity during short-term treatment of mares with conventional pZP vaccine [1] may be due to the higher pZP dose administered in our study (100 μg vs. 65 μg pZP), selected to reflect the current dose administered to feral horses [24–26]. Our findings confirm recently reported ovarian quiescence in mares treated with long-acting pZP vaccines [13], suggesting that suppressed ovarian function is not unique to long-acting formulations.

Previous studies on the effects of pZP on behaviour and social structure in feral horse populations, at the same dose of pZP, suggested that treated

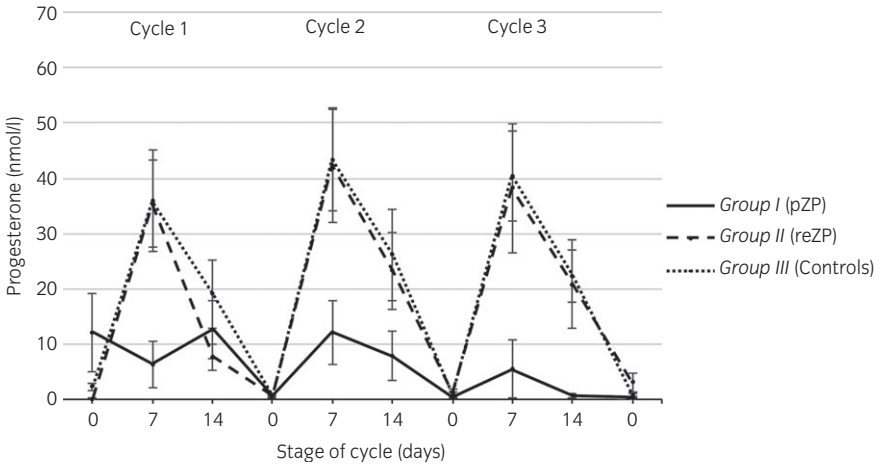

Fig 2: Graph showing mean weekly serum progesterone levels (s.e. bars) for cycling mares in each study group over 3 consecutive oestrous cycles ≥5 weeks post V2, where Days 0, 7 and 14 of each cycle have been synchronised in time. Weekly data are depicted for noncycling mares.

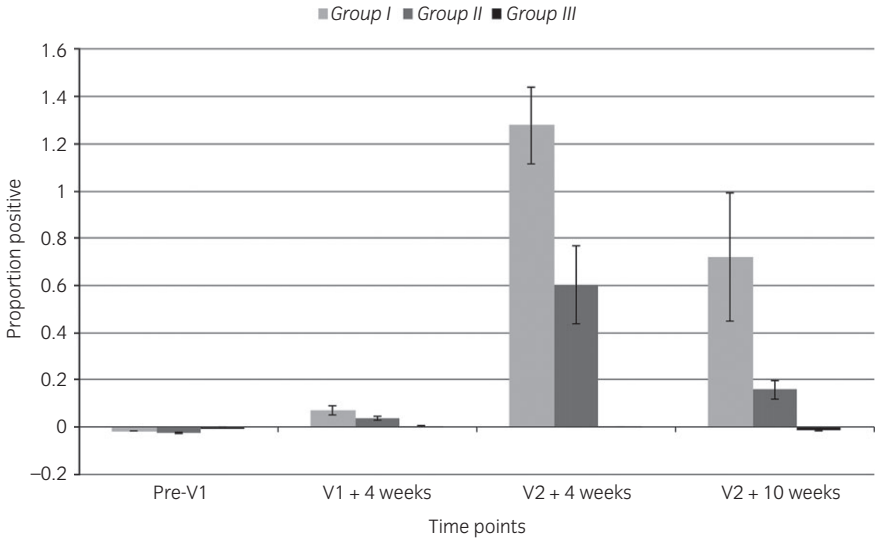

Fig 3: Mean anti-ZP antibody response expressed as a proportion of the positive control (with s.e.) for each treatment group at 4 successive time points.

mares show decreased harem fidelity and increased reproductive behaviours [27,28]. These findings are inconsistent with the current study, in which the majority of mares showed anoestrus following treatment, implying that there would be an opposite change (albeit transiently) in reproductive behaviours. The absence of these behaviours can be attributed to the significant decrease in follicular number and sizes, associated with decreased oestradiol concentrations.

Follicle counts and maximum follicle diameters for *Group II* showed no statistically significant differences from either *Group I* or *Group III* in Week 16, despite significant differences between the latter 2 groups. This partial effect parallels *Group II*'s intermediate antibody titres post V2. The pZP vaccine comprises all 3 native porcine zona glycoproteins (ZP2, ZP3 and ZP4), whereas reZP comprises only ZP3 and ZP4. The lower antibody titres post V2 in *Group II* compared with *Group I* may be due to the fact that the pZP vaccine will elicit an antibody response against ZP2 as well as ZP3 and ZP4, and the EIA read-outs using pZP antigen will reflect the summation of antibody titres against ZP2, ZP3 and ZP4. Ideally, antibody titres against purified ZP3 and ZP4 should be assessed to determine whether antibody titres are responsible for the intermediate ovarian response observed in *Group II*.

Further studies, involving either the administration of higher doses of the recombinant vaccine or using native pZP as the primary injection followed by reZP booster injections, are warranted. A third possibility would be to increase the number of booster vaccinations. Recently, it was shown that 2 boosters of recombinant dog ZP3, instead of one, showed better contraceptive efficacy in female mice [31].

An unexpected finding was the prevalence of injection site reactions, supporting Bechert *et al.* [13] who reported injection site reactions in 43% of treated mares. Our findings failed to support anecdotal reports of injection site reactions occurring less frequently when administered into the gluteal rather than the neck musculature [32,33]. The current findings, including the sterility of overt abscesses, also contradict previous reports linking abscessation to remote vaccine delivery, presumed to result from darts transferring dirt and bacteria into the subcutaneous tissues [34]. Reports of injection site reactions in feral populations, described as abscessation, varied from 0 to 11.5% and were associated with either Freund's complete adjuvant (FCA), (FMCA) or (FIA) [1,33,35–37]. Our use of domestic mares enabled closer inspection than can be achieved in a feral horse population. Although individuals from all groups showed lesions, *Group II* was particularly over-represented. This may be a result of either or both the double volume of FMCA and FIA in their vaccination protocol or the tetanus toxoid and bovine RNase linked to the ZP3 and ZP4 recombinant proteins, respectively.

The contraceptive efficacy of the pZP vaccine was confirmed in this study; however, the absence of oestrous cyclicity appears to be responsible for infertility to a larger extent than interference with sperm–zona binding. In addition to species differences in response, contamination with non-zona pellucida ovarian proteins has been proposed as a possible cause of ovarian malfunction in other species [29]. The latter cannot be completely ruled out for the pZP vaccine, although such contamination is impossible with the use of recombinant vaccines. Apart from oophoritis, a possible mechanism of ovarian suppression could be an interference with cellular communications between the developing oocyte and its surrounding granulosa cells, as a result of immune-mediated alterations to the zona pellucida. A family of proteins known as connexins is involved in oocyte–granulosa cell communication. Connexin gene-knockout mice were found to demonstrate suppressed ovarian activity with a lack of tertiary follicular development, reminiscent of the findings of the current study in mares [30].

All mares exhibiting anoestrus following treatment showed evidence of cyclic activity within 10 months of V2, which confirms the reported reversibility of pZP vaccines [38]. In the current study, follow-up examinations coincided partially with winter, thus the effect of seasonal anoestrus in biasing resumption of cyclicity remains undefined.

Conclusion

The current study demonstrates the reversible suppression of ovarian function in 6 of 7 (86%) pony mares following treatment with the native pZP vaccine. No significant contraceptive effect was produced by the (reZP) vaccine; however, further investigation of recombinant ZP vaccines, as an alternative contraceptive in the mare, is warranted.

Authors' declaration of interests

No competing interests to declare.

Ethical animal research

The study was approved by the University of Pretoria's Animal Ethics Committee (V051-13).

Sources of funding

This study was funded by the Technology Innovation Agency, Pretoria, South Africa.

Acknowledgements

The authors would like to thank Professor I. Liu for the provision of native zona pellucida vaccine and the Onderstepoort Training Animal Unit for assistance with animal handling during this project.

Authorship

C.J. Joonè, H.J. Bertschinger and M.L. Schulman contributed to the study design, study execution, data analysis and interpretation, preparation and final approval of the manuscript. S.K. Gupta contributed to study design and preparation of the manuscript. A.P. Arukha and V. Minhas prepared the recombinant vaccines and were involved in final approval of the manuscript. E. Dieterman contributed to the acquisition of data. G.T. Fosgate is an epidemiologist who contributed to study design, data analysis and interpretation, and preparation of the manuscript.

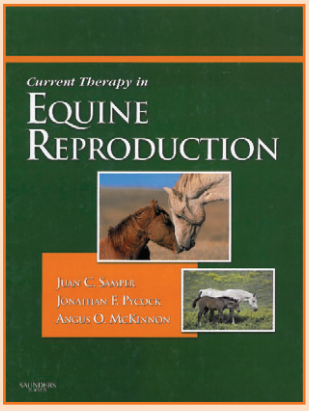
EQUINE VETERINARY JOURNAL BOOKSHOP



Current Therapy in Equine Reproduction

Editors: J.C. Samper, J.F. Pycock and A.O. McKinnon

Publisher: Saunders, 2007 • Hardback, 672 pages

Current Therapy in Equine Reproduction provides practicing veterinarians with a concise and up-to-date source of information regarding the equine reproductive process. Coverage of the mare includes the reproductive system, normal and abnormal physiology, and reproductive problems. It also discusses advanced reproductive techniques in the mare such as assisted fertilisation techniques and embryo transfer. Coverage of the stallion includes reproductive problems and advanced reproductive techniques.

Features the most current information available on equine reproduction, including the latest therapies and treatments for breeding dysfunction, as well as advances in reproductive techniques. Focuses on therapy and treatment to provide practitioners with quick access to key information. Features the shared experience and valuable advice of world-renowned experts who have first-hand knowledge of which treatments and therapies are most effective.

Immunocontraceptive vaccines target one or more selected proteins essential to a critical step in fertility. Examples include anti-gonadotrophin release hormone (GnRH) and native porcine zona pellucida (PZP) vaccines. The successful application of PZP vaccines over several decades for population management in feral horse populations in the USA is well described. The currently hypothesised mechanism responsible for this vaccine's contraceptive effect is the prevention of sperm-zona binding, sperm penetration of the zona and thus fertilisation of the oocyte, which is prevented for as long as antibody titres are sufficiently high whilst treated females continue to cycle normally. Our group's recent research projects investigated PZP vaccination of pony mares in South Africa and donkey jennies in the Caribbean. These trials included intensive clinical and laboratory monitoring and clearly showed that the majority (85.7%) of both mares and jennies treated with the vaccine formulated with either Freund's complete modified (primary) or Freund's incomplete (booster) adjuvants developed small inactive ovaries. This was accompanied by baseline serum progesterone concentrations typical of anoestrus. All mares resumed normal cyclic activity after approximately 7-8 months during the following physiological breeding season. We additionally measured the concentrations of anti-Müllerian hormone (AMH) at strategic times during the mare study to better define the mechanism of ovarian shut-down. Notably, AMH, which is reportedly well correlated with small antral follicle counts in the mare, was not detectable during the intervals of ovarian suppression. Of further interest was an AMH rebound observed coincident with the recovery of ovarian cyclicity. As normal ovarian function was re-established in all mares, an inflammatory process (with or without cellular invasion) seems an unlikely explanation for this ovarian response. These results showed vaccination was followed by a period of ovarian suppression related to the loss or malfunction of small antral follicles and suggested that prevention of fertilisation was not the only potential mechanism responsible for infertility in PZP-immunocontracepted mares.

Serum anti-Müllerian hormone dynamics in mares following immunocontraception with anti-zona pellucida or -GnRH vaccines

Abstract

Circulating anti-Müllerian hormone concentration (AMH) is positively correlated to the number of small growing follicles in the mare and may reflect ovarian function. Dynamics of AMH during immunocontraception have not previously been investigated. This study aimed to compare serum AMH in mares following treatment with native porcine zona pellucida (pZP), recombinant pZP3 and pZP4 (reZP) or gonadotrophin releasing hormone (GnRH) vaccines, and saline-treated controls. Stored sera collected during two previous studies examining ovarian activity in mares during zona pellucida (ZP) or GnRH immunocontraception were analysed for serum AMH. Data were compared among treatment groups using mixed-effects linear regression and one-way ANOVA with post hoc testing. Correlations between AMH and previously reported clinical variables were estimated using Spearman's rho. Mares immunized against GnRH showed variable but detectable AMH throughout successive breeding and non-breeding seasons that were not significantly different to unvaccinated control mares. Mares treated with pZP demonstrated marked, reversible suppression of AMH. Mares immunized using reZP showed an intermediate effect. In the ZP study, AMH was positively correlated to serum progesterone concentrations, mean ovarian volumes and antral follicle counts, whereas no correlations between AMH and serum progesterone concentrations, mean ovarian volumes, or the presence of one or more follicles $\geq$ 20 mm in diameter were detected in the GnRH study. In conclusion, marked suppression of AMH during pZP immunocontraception, but not during GnRH immunocontraception, suggested enhanced suppression of ovarian follicular development

ACCEPTED MANUSCRIPT

and, or follicular function during pZP immunocontraception. Serum AMH concentrations may provide a novel tool for the assessment of ovarian function during ZP-based immunocontraception.

1. Introduction

The porcine zona pellucida (pZP) and gonadotrophin releasing hormone (GnRH) vaccines are effective forms of immunocontraception in the mare [1]. The pZP vaccine induces an immune response to endogenous zona pellucida (ZP) glycoproteins surrounding the mammalian oocyte. This has been the preferred vaccine for population control in species with complex social structures, such as the feral horse (*Equus caballus*), due to pZP's association with the maintenance of reproductive cyclicity [2]. In contrast, GnRH antibodies deplete effective GnRH within the hypothalamic-pituitary portal blood vessels, inhibiting GnRH-induced release of LH and FSH from the anterior pituitary and culminating in reproductive quiescence. This vaccine, therefore, shows promise as a means of preventing unwanted reproductive behaviours in the domestic horse [3].

The ovarian effects of pZP immunocontraception in the mare have been assessed clinically (transrectal palpation and ultrasonography), histologically (ovarian histology) and endocrinologically (measurements of ovarian steroids or their metabolites) [4-8]. Initial reports observed no ovarian effects following short-term pZP treatment [4]. Longer intervals (up to 7 years) of anti-pZP immunization resulted in decreased ovarian oestrogen production and ovulation rates [5, 9]. More recently, ovarian inactivity was detected in $\geq$ 86% of mares within four months of treatment with both the conventional pZP vaccine [8] and a single-dose formulation of pZP [7]. The latter two studies highlighted a need for further study of the mechanism of action of ZP-based vaccines in the mare.

The ovarian effects of GnRH-based immunocontraception in the mare have similarly been assessed both clinically and endocrinologically [10-14]. Immunisation against GnRH was significantly associated with decreased ovarian weight [10], length [12] and volume [10, 14]; decreased ovarian activity (the absence of corpora lutea and follicles $\geq$ 10 mm) [10-15]; suppressed or variable oestrus expression [10, 12, 13, 15, 16]; and suppressed progesterone [10, 12-15], oestradiol-17β [13, 15], LH [10, 11, 13] and FSH secretion [10].

Measurement of serum anti-Müllerian hormone concentration (AMH) may represent a novel method for the assessment of ovarian function during immunocontraception in mares and other species. This homodimeric glycoprotein hormone, a member of the TGFβ family of growth and differentiation factors, is expressed by granulosa cells of developing follicles in the post-natal ovary [17]. In the mare, follicles between 6 and 20 mm in diameter have the greatest influence on AMH [18]. Positive correlations between AMH, antral follicle count (AFC) and primordial follicle count are reported in mice [19], cattle [20] and women [21]. Similarly, AMH is positively correlated with AFC in mares over eight years of age and this correlation strengthens with increasing age [18].

This study aimed to investigate AMH in mares following their active immunisation against one of GnRH, native pZP or a combination of recombinant pZP3 and pZP4 (reZP; [22]) vaccines. Measured AMH was then compared to previously-published clinical variables, including mare age, serum progesterone concentrations, mean ovarian volumes and AFC or the presence of follicles $\geq$ 20 mm in diameter [8, 14, 23].

2. Materials and methods

2.1 Experimental design

Specimens were obtained from two previously-reported controlled studies in the mare that described the ovarian effects and reversibility of native pZP, recombinant porcine ZP3 and ZP4 [8] and GnRH vaccines [14, 23]. Briefly, native pZP (Trumpeter Farms and Veterinary Services, Winters, California, USA) was prepared according to standard methods [4]. The reZP vaccine (Dr. Satish Gupta; Reproductive Cell Biology Laboratory, National Institute of Immunology, New Delhi, India) consisted of pZP3 and pZP4 expressed by *Eschirichia coli* as chimeric fusion proteins linked to promiscuous T-cell epitopes of tetanus toxoid (TT-KK-ZP3) or bovine RNase (bRNase-KK-ZP4), respectively [22]. The GnRH vaccine is commercially available (Improvac; Pfizer Animal Health, Sandton, South Africa).

For the ZP vaccine study, mares were stratified according to age and randomly assigned to one of three study groups: pZP, reZP and saline-treated controls (n = 7 per group) [8]. All treatments commenced during the southern hemisphere summer, consisting of a primary vaccination incorporating Freund's modified complete adjuvant (V1) and a single booster with Freund's incomplete adjuvant (V2) 35 days later. Mares were monitored by transrectal palpation and ultrasound examinations of their internal reproductive tracts. Recorded variables included ovarian volumes, AFC (grouped according to size) and the presence of corpora lutea. Blood samples were collected weekly, centrifuged and sera stored at – 20°C until analysed. Follow-up gynaecological examinations and blood sampling occurred during the following winter and again at the start of the subsequent breeding season. Seven and four mares became pregnant in the control and reZP groups respectively.

For the GnRH study, mares were stratified according to age and randomly assigned to either GnRH vaccine (n = 9) or saline-treated control (n = 3) groups [14, 23]. Treatments similarly commenced during the southern hemisphere summer and consisted of a primary vaccination (V1) followed by a

booster (V2) 35 days later. Mares underwent three similar gynaecological examinations (to the ZP vaccine study) at V1, V2 and five weeks post-V2. Recorded variables included ovarian volumes and the presence of corpora lutea and follicles $\geq$ 20 mm in diameter. Blood samples were similarly acquired individually until resumption of cyclic ovarian activity, with sera being stored at – 20°C until analysed.

2.2 Data comparison between ZP and GnRH studies

Treatments for both ZP and GnRH studies commenced within a similar 6-week period of the year (12 November - 22 December). In order to compare data across studies while minimising temporal effects, data were normalised according to vaccination status within the following periods: period I correlated to pre-V1 to within one month post V1 (3 - 22 December), period II correlated to between V2 and within one month post-V2 (2 - 29 January), period III correlated to between one and two months post-V2 (12 February - 6 March), period IV correlated to the first winter post-treatment with a vaccination status of four to six months post-V2 (3 May - 26 June). Period V correlated to the approximate commencement of the following breeding season (29 Sep 2007, GnRH study; 6 October 2014, ZP study), or later, depending on the date of resumption of cyclicity (up to 3 October 2008, GnRH study) [12]. Anoestrus was defined as the period when mares had small ovaries (<45 cm^3) with follicles $\leq$20 mm in diameter and a progesterone concentration below 6 nmol/l. For the ZP study, anoestrus was further qualified by the absence of an ultrasonographically visible corpus luteum.

2.3 Anti-Müllerian hormone assay

Anti-Müllerian hormone concentrations were determined by means of a commercially available ELISA according to the manufacturer's instructions (AMH Gen II ELISA; Beckman Coulter, Brea, CA, USA). This assay has been previously validated for use in mares [24]. Briefly, standard dilutions, controls and samples were incubated in an anti-AMH antibody coated microtitration plate. Samples were sequentially incubated with biotin-labelled anti-AMH antibody, streptavidin-horseradish peroxidase and tetramethylbenzidine. An acidic stop solution halted further colour development. Absorbance was measured at 450 nm using a microplate photometer (Multiskan™ FCd, Thermo Fisher Scientific, Waltham, Massachusetts, USA), and AMH concentrations determined by comparison to a calibration curve. The detection limit of the assay was 0.08 ng/ml. Intra- and inter-assay coefficients of variation were 3.7% and 4.4% respectively, for a low AMH concentration (3.82 ng/ml), and 3.4% and 4.0% respectively, for a high AMH concentration (16.45 ng/ml).

2.4 Statistical analysis

AMH concentrations below the assay detection limit of 0.08 ng/ml were assigned values of 0.07 ng/ml for statistical modelling. The normality assumption was assessed by calculating descriptive statistics, creating histograms, and performing the Anderson-Darling test for normality in commercial software (MINITAB Statistical Software, Release 13.32; Minitab Inc, State College, Pennsylvania, USA). Measured AMH values violated the normality assumption and were transformed using the natural logarithm prior to statistical analysis. The AMH values were compared among treatment groups using mixed-effects linear regression. Regression models included fixed effect terms for treatment group, sampling time (periods I to V), the interaction between treatment group and sampling time, and age categorized as <5, 5- 9, and >9 years of age to adjust for potential confounding. Horse identity was included as a random effect to account for the repeated measures sampling design. The complete model was followed by independent models for each treatment

group to evaluate changes in AMH over time using a linear mixed model incorporating a random effect for horse to account for the repeated sampling. One-way ANOVA was used to compare AMH among treatment groups within each sampling time. Post-hoc testing was adjusted for multiple comparisons using Bonferroni correction of P values. Correlations between AMH and previously reported variables, including mare age, serum progesterone concentrations, mean ovarian volumes, AFC (ZP study) or the presence of one or more follicles $\geq$20 mm in diameter (GnRH study), were estimated using Spearman's rho, across all time periods. Statistical testing was performed using commercially available software (IBM SPSS Statistics Version 23; International Business Machines Corp., Armonk, NY, USA) and results were interpreted at the 5% level of significance.

3. Results

According to the linear mixed model, measured AMH differed among treatment groups ($P < 0.001$) and there was a significant treatment by time interaction ($P < 0.001$). The pZP group was lower than all other groups ($P < 0.04$). The reZP group had lower AMH values than the GnRH-treated group ($P = 0.004$) but neither of the control groups ($P > 0.73$). The AMH values of the GnRH-treated group showed no difference to either control group ($P > 0.63$).

Data were further analysed within each time period (Table 1). Median AMH in the pZP group was below the detection limit of the assay, and significantly lower than that of control mares, at time periods II, III and IV. The reZP group demonstrated an intermediate effect between the pZP and control groups at time periods II, III and IV.

At time period V, AMH differed between the four groups ($P = 0.02$). Descriptively, the pZP and GnRH groups had similar concentrations that appeared different from the reZP and control groups, which

158 also appeared similar to one another. However, no pairwise differences were significant after
159 adjusting P values for the multiple post hoc testing.

160 Finally, data were analysed over time, within treatment groups (Table 1). Anti-Müllerian hormone
161 concentration in the control group changed significantly over time (P = 0.04). Although no pairwise
162 comparisons to time period I were significant, AMH tended to be lower at time period II (P = 0.07;
163 Figure 1a). In the pZP group, AMH showed a marked change over time (P < 0.001), characterised by
164 marked suppression of AMH at time periods II to IV. Furthermore, AMH increased significantly at
165 time period V in this group, with AMH exceeding 6 ng/ml in two mares (Figure 1b). In contrast, the
166 GnRH group showed a gradual increase in AMH over time (P = 0.001; Figure 1c). The reZP group
167 showed no significant change in AMH over time.

168 No correlation between AMH and age was detected in either vaccine study alone or in combination
169 (P > 0.2). In the ZP study (pZP and reZP), AMH was positively correlated to serum progesterone
170 concentrations (Spearman's rho = 0.244, P = 0.03; Figure 2) and mean ovarian volumes (Spearman's
171 rho = 0.391, P < 0.001; Figure 3). Moreover, AMH had a strong positive correlation to AFC
172 (Spearman's rho = 0.713, P < 0.001; Figure 4). In the GnRH study, AMH showed no correlation to
173 previously reported serum progesterone concentrations (P = 0.9), mean ovarian volumes (P = 0.2), or
174 the presence of one or more follicles $\geq$ 20 mm in diameter (P = 0.7).

175

176 **4. Discussion**

177 This is the first report describing variations in AMH in mares following their immunocontraception
178 with either pZP, reZP or GnRH vaccines. Marked differences in AMH of ZP-immunocontracepted
179 mares, particularly pZP, in comparison to GnRH vaccine-treated mares, were observed.

Post-treatment, AMH in pZP-treated mares was markedly suppressed and significantly lower than GnRH-treated and control mares. Clinically, six of seven pZP-treated mares demonstrated intermittent to persistent anoestrus during this time, characterised by bilaterally small ovaries, baseline serum progesterone concentrations and low AFC [8]. Decreased AMH during pZP-immunocontraception may be due to decreased AFC and, or downregulation of AMH expression by granulosa cells. The strong correlation between AMH and AFC in the ZP study supported the hypothesis that decreased AFC is a component of suppressed AMH.

Ovarian suppression following anti-pZP vaccination in the mare has been ascribed to immune-mediated destruction of developing follicles or inhibited folliculogenesis following antibody-mediated interference with oocyte-granulosa cell communication [7]. In the latter hypothesis, aberrant communication between the oocyte and its surrounding granulosa cells may lead to compromised competence of the developing follicle and diminished AMH expression. Expression of genes involved in steroidogenesis and follicular development, in relation to AMH, has been investigated in equine follicles. Mares with low AFC or circulating AMH were found to show decreased granulosa cell expression of AMH and AMH- and FSH-receptors [25]. A further study to examine molecular and hormonal changes within follicles during pZP immunocontraception is warranted.

In the mare, contraception as an outcome of anti-pZP vaccination has been shown to be reversible in the short term, associated with decreased antibody titres below a threshold level [4]. In feral populations however, prolonged treatment (up to 7 years) has been associated with prolonged intervals to reversal [5, 26]. Interestingly in the current study, in pZP-treated mares, AMH was markedly elevated in two mares at time period V, suggestive of a rebound effect of heightened folliculogenesis approximately concurrent with their reversal. Whether a similar resurgence in AMH occurred in the remaining five pZP-treated mares before or after the date of sampling is unknown. In

other species, particularly women, AMH has shown promise as an indicator of ovarian reserve, defined as the pool of primordial follicles [21, 27]. Assuming that a similar correlation between AMH and ovarian reserve exists in the mare, pZP immunocontraception may represent one instance where this correlation is rendered invalid.

The reZP-treated group showed an effect intermediate between the pZP-treated and control mares in terms of antibody titres, AFC and maximum follicle diameters [8]. Similarly, their AMH values were intermediate between pZP and control groups between one and 6 months post-V2. This finding encourages further research aimed at improved efficacy of reZP in mares, such as the administration of additional booster vaccinations [28] or alternative formulations such as the incorporation of liposomes [7].

Anoestrus during GnRH immunocontraception has previously been compared to winter anoestrus in the mare [10, 15]. Both are characterised by low bioavailability of GnRH associated with near-complete suppression of LH secretion. In contrast to LH, serum FSH levels are suppressed but detectable during both anti-GnRH vaccination [10] and winter anoestrus [29, 30], suggesting a non-GnRH dependent component of FSH secretion. Moreover, the ongoing presence of small antral follicles has been reported during anoestrus, whether induced via season [30] or anti-GnRH vaccination [11, 12]. In the current study, AMH values in GnRH-treated mares were similar to those in controls at each successive time period, likely due to continued AMH secretion by small antral follicles. However, AMH in GnRH-treated mares increased gradually over time, a pattern not detected in control mares. Increased AMH in anti-GnRH treated mares over time could be due to increased AFC or more efficient AMH production by granulosa cells. Increased AFC could result from either decreased atresia of growing follicles or increased recruitment of growing follicles from the ovarian reserve. Anti-Müllerian hormone was shown to play an important inhibitory role in primordial follicle recruitment, demonstrated using AMH *null* mice in which depletion of the

228 primordial follicle pool occurred at a faster rate than wild type mice [31]. Increased primordial
229 follicle recruitment as a hypothesis for increased circulating AMH concentrations in anti-GnRH-
230 treated mares is therefore unlikely. In goats [32] and women [33], transient decreases in AMH
231 following exogenous FSH administration was suggested in association with FSH-induced
232 development of large antral and preovulatory follicles, temporarily decreasing the number of smaller
233 follicles. A reversal of this process possibly occurs during anti-GnRH vaccination in the mare, where
234 anoestrous periods are characterised by the absence of follicular development to preovulatory
235 stages, resulting in decreased depletion of the population of preantral and small antral follicles.
236 Unfortunately, clinical data regarding AFC within the GnRH study included only the presence or
237 absence of follicles $\geq$ 20 mm in diameter. Since populations of follicles smaller than 20 mm in
238 diameter appear to correlate better to circulating AMH concentrations [18], limited conclusions can
239 be drawn. More detailed and frequent AFC assessments during GnRH immunocontraception are
240 required. Interestingly, a novel role for AMH as a stimulator of GnRH secretion was recently
241 demonstrated in mice [34]. Whether or not lowered GnRH levels during anti-GnRH vaccination
242 affects AMH over time due to a disrupted feedback mechanism between AMH and GnRH warrants
243 further research.

244 Mares show great individual variation in AMH [18, 35]. However, AMH values are repeatable within
245 mares, showing minimal changes throughout the oestrous cycle and gestation [35]. In the current
246 study, AMH in the control group were similarly variable and comparable to previously reported AMH
247 values in cycling and, or pregnant mares [18, 35]. Moreover, AMH in control mares, including four
248 mares pregnant at time periods IV and V, did not change significantly over time. The non-significant
249 decrease in AMH at time period II is of uncertain significance. Anti-Müllerian hormone
250 concentrations during the non-breeding season in the mare have not previously been reported. In
251 goats, a similarly seasonal breeder, AMH remains stable across seasons [32]. Although the findings

252 of the current study suggested minimal variation in AMH throughout the breeding and non-breeding
253 seasons in mares, both the unavailability of clinical data in controls from the GnRH study and
254 pregnancies in several mares from the ZP study at time periods IV and V resulted in a small sample
255 of relevant mares at these time periods, limiting valid conclusions. An important limitation of the
256 results presented here is the relatively small number of horses studied and the potential for low
257 power for the statistical tests to identify clinically important differences in AMH concentrations.

258

259 **5. Conclusion**

260 In mares, pZP immunocontraception caused a profound, temporary suppression of AMH. In contrast,
261 AMH values were maintained and rose gradually during GnRH immunocontraception. Maintenance
262 of AMH during seasonally-induced anoestrus, although suggested by current findings, requires
263 further study. The analysis of AMH provided a novel modality for the assessment of ovarian function
264 during ZP-based immunocontraception of domestic mares, potentially valuable in wildlife and feral
265 species where repeated gynaecological examinations are not feasible.

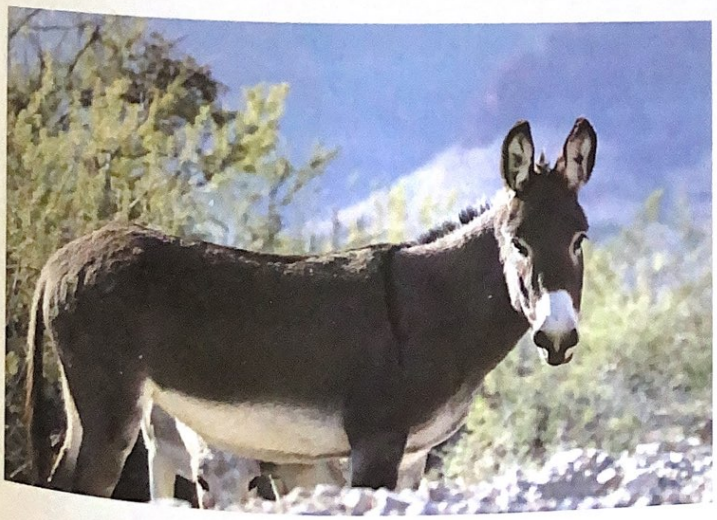
HIGHLIGHTS: Serum anti-Müllerian hormone dynamics in mares following immunocontraception with anti-zona pellucida or -GnRH vaccines

- Anti-Müllerian hormone (AMH) concentration has not previously been assessed during immunocontraception in the mare, or any other species, to the best of the authors' knowledge
- Measurement of circulating AMH provides novel data that contributes to our understanding of these contraceptive vaccines' mechanisms of action
- Mares immunized with native pZP vaccine showed profound suppression of AMH, followed by an apparent rebound effect in two of seven mares at the approximate time of reversal of the vaccine's contraceptive effect
- In contrast, mares immunized against GnRH showed little change in AMH over time
- Measurement of circulating AMH may provide an alternative method for monitoring of ovarian function during zona pellucida-based immunocontraception

ACCEPTED MANUSCRIPT

nicarbazin-treated bait for at least 3 consecutive years led to a visible and documented reduction of the number of pigeons. In turn, the number of public complaints and accidents had a documented reduction.

The talk will also discuss potential issues encountered by practitioners in delivering nicarbazin-treated bait, illustrate evidence-based solutions to overcome these issues and compare advantages and disadvantages of different methods to resolve human-pigeon conflicts. Combined with other pigeon population management methods, fertility control represents a modern, integrated solution to mitigate this man-made wildlife problem.



Field approaches to wild burro (*equus asinus*) identification and remote-delivery of ZonaStat-H in an American western landscape

Contact: Grace Kahler, gkahler@humanesociety.org

The use of immunocontraceptive vaccines is a well-established and viable approach for managing wild horse (*Equus caballus*) populations in western U.S. landscapes. Until recently, wild burro (*Equus asinus*) contraceptive research has not been a priority for the Bureau of Land Management (BLM) due to fewer populations of burros on public lands, slightly lower population growth rates, and historically higher adoption demand compared to wild horses. In 2017, the Humane Society of the United States (HSUS) partnered with the BLM to begin a four year pilot study to examine the efficacy and impacts of using the immunocontraceptive vaccine ZonaStat-H on wild burros in a western landscape. Since the project's inception, we have collected data associated with the treatment, observation, and management of the 109 wild female burros recruited from the Black Mountain Herd Management Area (HMA). The overarching goal of the project is to help build a scientific foundation for incorporating immunocontraception into the BLM's wild burro management programs. Although data collection for efficacy is ongoing, preliminary findings yield an opportunity to share the unique field experiences associated with identifying wild female burros and treating them with ZonaStat-H.

The Black Mountain HMA is the largest in Arizona and has field conditions applicable to other regions. Limited accessibility, diverse landscapes, windy and dry conditions, varying elevations, human activity, and extreme temperatures are factors that may impact efforts to successfully administer immunocontraceptive vaccines remotely to wild female burros. In addition, because wild horse identification and behavior has been the predominant focus of previous research, most available wild equid management resources exclude burro-specific attributes. Although similar to wild horses in many ways, wild burros exhibit different behaviors, social dynamics, and physical distinctions, making many horse-based identification strategies insufficient for field use. For a management program utilizing immunocontraceptive vaccines to be successful, the accurate identification of individual burros is essential. This presentation will focus on comparing different approaches to identifying burros and will summarize techniques used for effectively monitoring and administering ZonaStat-H to wild female burros in Arizona.

Commentary

A review of contemporary contraceptives and sterilization techniques for feral horses

Albert J. Kane, USDA, APHIS, Veterinary Services, 2150 Centre Ave., Building B MS2E6, Ft. Collins, CO 80526-8117, USA *albert.j.kane@aphis.usda.gov*

Abstract: This commentary provides a brief review of the history of contraceptive research efforts for feral horses (*Equus ferus caballus*) as well as the contraceptives and sterilization techniques currently available for feral horses. Porcine zona pellucida (PZP) immunocontraceptives have received the most attention and use over the past 40 years, but other treatments such as the GnRH vaccine Gonacon™-Equine are also available. Optimization of these treatments as well as the development of other molecular approaches, intrauterine devices, and surgical techniques is ongoing.

Key words: contraceptive, *Equus ferus caballus*, feral horse, fertility control, sterilization

Since the late 1970s, researchers have sought a safe and effective equine contraceptive to help reduce population growth rates of feral horses (*Equus ferus caballus*) and burros (*E. asinus*). A good treatment that is safe, practical, effective, and long lasting has not yet been developed. Even after a treatment is developed that is effective for individual animals, there remain significant hurdles at the population level that must be overcome to reduce population growth rates (Garrott 2018).

Early fertility control efforts focused on both male and female contraception. However, as early as 1980, scientists with the National Research Council (NRC), part of the National Academies of Science, recommended that wild horse contraceptive efforts focus on reducing fertility in mares (NRC 1982). They recognized the polygynandrous nature of feral horses where multiple males may breed the same or multiple females. While it is true that wild horses live in harems that include a dominant stallion, much of the breeding may also be done by other stallions, and harem structures are fluid over time. It has been demonstrated that up to one third of foals may be sired by stallions that are not affiliated with a mare's band (Bowling and Touchberry 1990).

Steroid hormones to vaccines

Early contraceptive studies in stallions and mares used steroid hormones to alter fertility. While there was some success in mares, the treatments were cumbersome to administer, and there were concerns about the potential for persistence of the hormones in the food chain and the environment. About this same time, studies were done with surgical vasectomies applied to harem stallions. There was a small effect noted in 1 of the 2 groups studied, but it was short lived. The researchers concluded that, while it may be effective at the individual horse level, the efficacy of vasectomizing males for population growth suppression over time was doubtful.

As attention turned away from using steroid hormones to alter fertility, porcine zona pellucida (PZP) vaccines were developed in laboratory rodents and later applied to horses (Liu et al. 1989, Kirkpatrick et al. 1992). The PZP vaccine contains a glycoprotein antigen harvested from pig (*Sus scrofa domesticus*) ovaries. When mixed with a powerful adjuvant (in most cases it is emulsified with Freund's adjuvant), it stimulates the mare's immune system to make antibodies to ZP proteins. These antibodies block fertilization of the egg and over time bind to zona proteins in the ovary causing it to shrink and become nonfunctional. The most widely used PZP vaccine is Zonastat-H®. This liquid immunocontraceptive can be hand injected or darted into mares. When a booster shot is also administered about 30 days later and about 1–2 months prior to the breeding

season, it is highly effective at preventing conception for 1 year, with only about 10–20% of treated mares foaling each year. In smaller herds where the number of animals is at or very close to the appropriate management level (AML), Zonastat-H can successfully reduce or even eliminate the need to gather and remove animals over time.

The Bureau of Land Management (BLM) is currently using this approach in several herds (BLM 2017). The biggest limitation to this treatment is that it must be administered every year. Most animals on BLM ranges cannot be approached closely enough to allow darting, and repeated annual roundups to allow hand injecting the treatment get more difficult with each repetition, usually becoming impractical and ineffective after 2 or 3 iterations. Another limitation of this approach is how long it takes to achieve desired population numbers, called the appropriate management level (AML) by the BLM, when herds are even modestly above the desired numbers. The so-called Assateague prescription, where the vast majority of mares was darted every year (Kirkpatrick and Turner 2008), was eventually effective at achieving population targets on a small barrier island, but it took 13 years before a decline in numbers was achieved and several additional years before AML was achieved. That population of 156 horses started in 1993 only 30% over the desired AML of 120 horses, had 143 horses after 13 years, and today has about 90 horses. For comparison, many wild horse herds managed by the BLM in the west are currently at levels >100% greater than AML.

The quest for a longer-lasting PZP treatment began about the same time that Zonastat-H was being developed. An early study of the pelleted "PZP-22" treatment was most promising with only 6–18% of mares reported foaling in the first 2 years of the Clan Alpine study (Turner et al. 2007) and 30–40% foaling in years 3 and 4. Unfortunately, this level of success has never been repeated, with several captive and free-ranging trials reporting 25, 30, or even 70% foaling in the first 2 years following treatment. The reasons for this poor performance mostly remain a mystery. Recently, success of 15–40% foaling over a 3-year period was reported with reformulated PZP-22 after additional booster treatments (Rutberg et al. 2017), but whether or not this can be repeated remains to be seen. Currently, PZP-22 is the treatment used most frequently by the BLM; at the very least, it usually provides 1 year of good efficacy without requiring a 30-day booster shot, and when boostered 1–2 years later, efficacy should improve.

Spay Vac®, another formulation of PZP developed to offer longer-lasting efficacy, uses similar PZP antigens with a unique liposome technology expected to provide several years of efficacy. As with PZP-22, an initial study of the treatment was promising (Killian et al. 2008). However, subsequent trials aimed at demonstrating long-term efficacy in a captive pasture breeding setting could not duplicate the same results and in fact showed reasonable efficacy in 1 year (15% foaling) but poor efficacy over time with up to 70% of treated mares foaling (Roelle et al. 2017). Although this vaccine is not commercially available at this time, the proponents of the product have regrouped and hope to conduct testing of a new formulation of Spay Vac in the future (Bechert and Fraker 2018). Although this product shares the same limitations inherent to the PZP antigen as Zonastat-H and PZP-22, in some species including occasionally horses, it seems like it could be long-lasting or even permanent. The reliability of the newly formulated product will need to be established in captive breeding trials with horses before one might have the confidence needed for field applications.

Gonacon

At this time, there is only 1 other contraceptive product available for use in horses. Gonacon™-Equine is a vaccine that acts against gonadotropin releasing hormone (GnRH), a hormone critical to fertility. The vaccine was formulated and registered with the Environmental Protection Agency as a 1-shot treatment that was thought to provide good multiyear efficacy. Captive pen trials resulted in good efficacy (6% foaling) the first year (Killian et al. 2008), but again the efficacy of a single treatment in field trials conducted with feral horses at Theodore Roosevelt National Park never reached that level of effectiveness, with about 50% of animals foaling the first and second years (Baker et al. 2017). Fortunately, with a booster treatment as much as 3 years

following the initial shot, efficacy improved dramatically with 0% of mares foaling a year later and around 15% foaling in the following 2 years. Like PZP vaccines, Gonacon can be hand injected or darted. It has 2 advantages in that it does not require mixing in the field and is more stable when stored. The longer-term efficacy of Gonacon seems more promising than the PZP vaccines at this time; however, optimal booster schedules are still being investigated. The BLM has used Gonacon in a small pilot project on the range, and the early results are encouraging. Gonacon treatment that includes a booster may be among the best options currently available for the contraception of feral horses.

Intrauterine devices

After many years of focusing primarily on PZP and GnRH technologies, other contraceptive approaches are now being investigated for feral horses with support from the BLM (BLM 2017). In addition to injectable treatments, new intrauterine devices (IUDs) are being tested. Early studies of IUDs were promising, with reports of >80% retention and efficacy with no negative effects on mare health (Daels and Hughes 1995). However, once again, when additional captive breeding trials were done with the same design (as well as other more sophisticated designs promoted as effective with 100% retention), the results were disappointing with 60–100% of the devices falling out soon after stallions were allowed to breed the mares. A current BLM-supported study of a new IUD has had some success with a redesigned product that seems to offer good retention in the presence of stallions. Data are still being obtained at this time to demonstrate retention, efficacy, and safety over a period of years. The IUDs have the advantage of being almost 100% effective as long as they are retained. They appear to have no long-term negative effects on the mare's health or the uterus, and they could be 100% reversible if removed. They do have the distinct disadvantage that they can only be inserted into non-pregnant mares, and most feral horse mares of breeding age are pregnant for most of the year.

Surgical sterilization

Surgical sterilization, once considered taboo for feral horses because it is permanent, is also again being considered as a means of reducing population growth rates. For stallions, the same limitations of polygynandry that became apparent back in the 1980s are still present. It seems unlikely that castrating or vasectomizing only some portion of the more dominant males in a herd will significantly slow population growth over a period of several years, because enough stallions will still be present to eventually breed all the mares present. However, a saturation approach where some high percentage (e.g., 80–95%) of stallions are sterilized remains untested.

In their most recent review of the science behind feral horse contraception, the National Academy of Sciences recommended chemical vasectomy as a promising technique (NRC 2013). Despite acknowledging that it was not yet proven, they felt that it should not be difficult to adapt to feral horses. Unfortunately, this doesn't seem to be the case. When chemically vasectomized horses were reexamined after a recent study performed on the Sheldon Wildlife Refuge (Collins and Kasbohm 2016), it was revealed that the chemical vasectomies failed to block sperm transport in any of the dozens of animals treated (Scully et al. 2015). While it should be possible to develop and use a technique for chemical vasectomy, it seems to offer little advantage over the surgical procedure, which has been done with individual horses but remains unproven at the population level. The fact that a small number of fertile stallions can impregnate many mares suggests that any form of vasectomy is unlikely to be an effective means of long-term population growth suppression.

The consideration of surgical sterilization is not limited to stallions but also extends to spaying and tubal ligation procedures for mares. There is no established procedure for tubal ligation in mares. It just is not something that is called for among domestic horses and has not been developed or tested for feral horses. Spaying, while not as common as castration, is done in domestic horses and has been done with feral horses. The procedure in horses is much more difficult than it is in cattle and not as routinely practiced as spaying dogs and cats, for example. It is almost never done to pregnant domestic horses, so the safety and practicality of spaying feral horses on a large

scale, particularly while pregnant, remains mostly untested.

Feral mares were spayed on the Sheldon Wildlife Refuge with a report of fewer foals born to harems that included spayed mares and vasectomized stallions (Collins and Kasbohm 2016), but it remains to be seen if similar results could be obtained in other places when spaying is done on a large scale in the context of typical BLM roundups. Yes, individual mares can be spayed, but can practitioners do it safely on a large scale with pregnant mares, and will it help achieve the goal of controlling population growth rates? The BLM has attempted to answer some of these questions with applied research, but these questions remain unanswered largely due to litigation that prevented the projects from getting started.

What is the ideal contraceptive?

We are often asked, why hasn't anyone developed the ideal contraceptive for feral horses when the BLM has been supporting this research for >40 years? The answer is perhaps that an ideal contraceptive is an unreasonable expectation for any species. Safety for mares, unborn colts, and the environment are paramount, but is it really reasonable to expect a 1-shot, long-lasting, predictably reversible contraceptive that has no behavioral effects for horses when modern science has never even developed such a treatment for dogs, cats, or people? The emphasis for reproductive research in the domestic horse world has always been getting mares pregnant, not trying to prevent pregnancy. Until the last few years, there has been very limited funding for contraceptive research for horses with more funding obligated by the BLM to research projects in the last few years than the previous 40 years combined. From where we started in the 1970s, researchers have made significant discoveries and improvements in contraceptives for feral horses.

The desperate need for results in the field and the limited funding available have meant that several treatments were advanced to field trials or management use in the field after only 1 test under more limited conditions. It is not uncommon for treatments that work in controlled laboratory or clinical settings not to work as well when applied on a larger scale in the field. Unfortunately, we have seen this with feral horse contraception on several occasions. Were the early studies flawed by unblinded, biased outcome assessments? What about the blinded (Spay Vac) studies that also could not be replicated? Was it the biological variation in the PZP itself, changes in the adjuvants or preparation of the vaccines? All of these factors are the reason that research science prefers to look for replication of results by different investigators under expanded conditions before taking treatments to management application in the field. However, these are luxuries that feral horse contraceptive research didn't have.

The pressure and the push have been to take treatments to the field as soon as they offer some legitimate promise of success. The upside would have been faster results where they were needed most. The downside was several treatments didn't work as well as expected when applied on a large scale. These challenges were added to the practical limitations and expectations of trying to apply darting programs to the typically vast western rangelands that span not thousands of acres but hundreds of thousands of acres. Darting programs can work on a small scale where 100 or so named animals can be approached to within 30 or 40 yards. However, where 10 times as many horses might roam on land areas 30 times larger and the horses can't be recognized as individuals because they mostly look alike, this approach is not practicable. Most often these animals can't be approached to less than hundreds of yards. Under these more typical conditions, darting programs aren't likely to succeed. Despite all this, there have been small-scale successes on some BLM lands: the Pryor Mountains Wild Horse Range and the Little Book Cliffs, McCullough Peaks, and Spring Creek Basin Herd Management Areas come to mind.

Conclusion

The history of feral horse contraception research is one of desperate need, ambitious (perhaps sometimes unreasonable) goals, and the passionate pursuit of a solution by a handful of investigators challenged by limited resources as well as the biology of the endeavor. Unfortunately, today, despite the many advances that have been made, a contraceptive solution that is safe, practical, and effective for most

herds on typical western herds is not in hand. Right now, feral horse contraception research has better levels of funding than ever before, with major universities more engaged than ever and new, never previously conceived molecular techniques being investigated. Nevertheless, progress will likely be slow. For every idea that advances to the next level of investigation 2 or 3 others will fail. Despite the desperate need, if we can maintain current research funding levels, we are years or likely more than a decade away from a contraceptive solution to the challenge of significantly reducing feral horse population growth rates on western rangelands. The good news is that it is still conceivable, and there are still some very bright and passionate scientists working on solutions that will make a difference.

Acknowledgments

The rapidly increasing global population has bowed the attention of family planning and associated reproductive health programmes in the direction of providing a safe and reliable method which can be used to limit family size. The world population is estimated to exceed a phenomenal 10 billion by the year 2050 A.D., thus presenting a real jeopardy of overpopulation with severe implications for the future. Despite the availability of contraceptive methods, there are over one million elective abortions globally each year due to unintended pregnancies, having devastating impact on reproductive health of women worldwide. This highlights the need for the development of newer and improved contraceptive methods. A novel contraceptive approach that is gaining substantial attention is "immunocontraception" targeting gamete production, gamete outcome, or gamete function. Amongst these, use of sperm antigens (gamete function) seems to be an exciting and feasible approach. However, the variability of immune response and time lag to attain titer among vaccinated individuals after active immunization has highlighted the potential relevance of preformed antibodies in this league. This review is an attempt to analyze the current status and progress of immunocontraceptive approaches with respect to their establishment as a future fertility control agent.

1. Introduction

The world population has exceeded 6.43×10^9 and is increasing by 1×10^9 every 12 years [1]. Besides population explosion, unintended pregnancies and elective abortions are a major public health issue. This overgrowth will also worsen the impact of many social, ecological, economical, and medical trends [2]. With the serious global issue of overpopulation, especially in developing countries, it becomes a necessity to find an effective way to control the rapid growth of population.

Contraception is an accepted route for the control of population explosion in the world [2]. The need for contraception varies for different couples from postponing child bearing, spacing childbirth and limiting family size to absolute no child bearing which is highly personal decision based on their individual preferences, medical history, life style and other factors [3]. The characteristics of an ideal contraceptive include acceptability of user, no loss of natural feeling, no side effects, relatively inexpensive, effective, easy to use and reversible. Contraceptive choices are accessible in case of both men and women. Currently practiced contraceptive options available for men include condoms, withdrawal and vasectomy [4, 5]. In case of females, the contraceptive methods available worldwide include oral contraceptive (OC) pills, injectable contraceptives, contraceptive implants, intrauterine devices, contraceptive vaginal ring, barrier methods, surgical sterilization, spermicides and natural family planning methods.

A novel contraceptive approach that is gaining substantial attention is immunocontraception, which is the use of contraceptive vaccines (CVs) or preformed antibodies to prevent fertilization. As with the conventional vaccines, CVs utilise the body's defense system to wedge an essential step in the reproductive process [6]. A successful contraceptive vaccine must meet a number of criteria; it must be reliable, easy to administer, safe, affordable, widely acceptable, and capable of evoking homogeneous response and must bestow a high level of contraceptive efficacy. There are three major categories involved in the development of CVs including gamete production, namely, gonadotropin releasing hormone (GnRH), follicle stimulating hormone (FSH), and luteinizing hormone (LH); gamete outcome, namely, human chorionic gonadotropin (hCG), or gamete function, namely, zona

pellucida (ZP) and sperm antigens [7]. Of all, validation and practicability for the development of antisperm vaccines targeting prefertilization events seem to be much more encouraging and promising. In this article we have tried to review the current status of the immunocontraceptive approaches and discussed their relative merits as a future contraceptive.

2. Immunocontraception

The advent of "immunocontraception" represents the first truly novel approach to the development of family planning methods. It involves the administration of a vaccine that induces an adaptive immune response which causes an animal to become temporarily infertile [8]. Immunocontraception promises many advantages over the methods of contraception currently available for human use which include high target specificity, long term action but not permanent, relatively inexpensive, lack of endocrine or metabolic side effects, and easy to use and does not require insertion of an implant or device and does not require surgical intervention [9].

Currently, there are three major categories involved in the development of immunocontraception including gamete production, gamete outcome, or gamete function [7] (Figure 1).

2.1. Gamete Production. Gamete production includes the synthesis of reproductive cells from gonads, that is, sperm from testes and ovum from ovaries. The first hormone in the chain is GnRH. It regulates the release of two peptide hormones from anterior pituitary, namely, FSH and LH, collectively called gonadotropins. Immunoneutralization of any of these hormones can prevent the binding of respective hormone with their receptor which may result in failure of conception.

2.1.1. Gonadotropin Releasing Hormone (GnRH). The decapeptide GnRH stimulates the release of the gonadotropins and is present both in males and females; thereby a vaccine against GnRH is feasible in both sexes. The hypothalamic GnRH-I (also referred to as GnRH or luteinizing hormone releasing hormone (LHRH)) is clearly the main hormone in the hypothalamic-pituitary-gonadal axis, besides a possible direct role of this decapeptide in extrapituitary organs, such as testis, prostate, and placenta [10]. The gene coding for GnRH-I is located on chromosome 8p21-p11.2.

When GnRH vaccine was tested on human subjects, including breastfeeding women by The National Institute of Immunology, India, and the Population Control Council, USA, the vaccine essentially resulted in castration and halted testosterone production [11]. However, these results were accompanied with impotence and loss of body hair in case of men and affected menopause in women [12]. Hence, an analogue of GnRH was prepared by linking with different carriers in an attempt to make improved vaccine [7]. Different carriers, namely, diphtheria toxoid (DT), tetanus toxoid (TT), *Mycobacterium tuberculosis* hsp 70 [13], thioredoxin [14], keyhole limpet hemocyanin [15], and ovalbumin, were employed. It was observed that the conjugation with any of the carriers induced specific antibody response. However, even after multiple injections, low titer antibodies were generated. It is well known that conjugation of protein/peptide with appropriate adjuvant can augment the immune response. Therefore, different adjuvants namely, Quil A, aluminium hydroxide, or polylactide co glycolide acid (PLGA), were employed. Among all these adjuvants, PLGA was found to be the most effective adjuvant [16]. Further, encapsulation of GnRH-TT in PLGA microspheres induced an effective antibody response within 15 days of administration, thus negating the need of repeated injections [17]. Use of any of the combinations in different animals (rats, monkeys, and pig) was effective in reducing testosterone levels to castration levels thus inducing infertility. However, decrease in testosterone levels was accompanied with concomitant atrophy of prostate.

Therefore, vaccines targeting GnRH were developed primarily as immunocontraceptive and immunocastration agents in animals [18]. Few GnRH vaccines are already available for veterinary use such as Vaxstrate and Improvac whilst research is still under development to obtain potentially improved vaccines [19–21]. In humans, they can be used for the treatment of prostate cancer and various sex hormone-dependent disorders [22]. However, the inability of vaccine to induce azoospermia in all the cases, loss of body hair, atrophy of prostate, and impotency after chronic exposure hinders its application as a safe vaccine. Also, as the vaccine affects sex steroids, consumers are unlikely to find this approach acceptable. Therefore, this may be suggested that enough data needs to be accumulated before the vaccines against GnRH can be employed in humans without side effects.

2.1.2. Follicle Stimulating Hormone (FSH). Follicle stimulating hormone (FSH) plays an essential role in the initiation and maintenance of spermatogenesis in primates [23]. FSH has two subunits alpha (α) and beta (β). The α subunit of FSH, LH, thyroid stimulating hormone (TSH), and human chorionic gonadotropin (hCG) is identical. FSH-β is responsible for its binding with FSH receptor.

The use of FSH appears to be an attractive contraceptive candidate for application in males. Most of the research has been carried out using ovine FSH rather than human FSH. The rationale for this is associated with the fact that specific antibodies raised to ovarian FSH cross reacted and neutralized the activity of FSH of variety of species including humans. Also, the use of ovine FSH in place of human FSH lowers the chances of producing cross reactive antibodies with human LH and TSH (due to structural similarity with α-subunit) [24]. Immunization of male bonnet monkeys with ovine FSH resulted in testicular dysfunction, oligozoospermia, and subsequent infertility [25]. It was noteworthy that infertility was not associated with any change in testosterone levels thus adding an additional advantage of using FSH based vaccine. Following successful studies by ovine FSH, a phase 1 clinical trial was carried out using two different versions either ovine FSH $\alpha\beta$ heterodimer or isolated ovine β-chain. In both the cases alum was used as an adjuvant [26]. Immunization by any of these resulted in generation of FSH-specific antibodies in all immunised individuals. But, as the

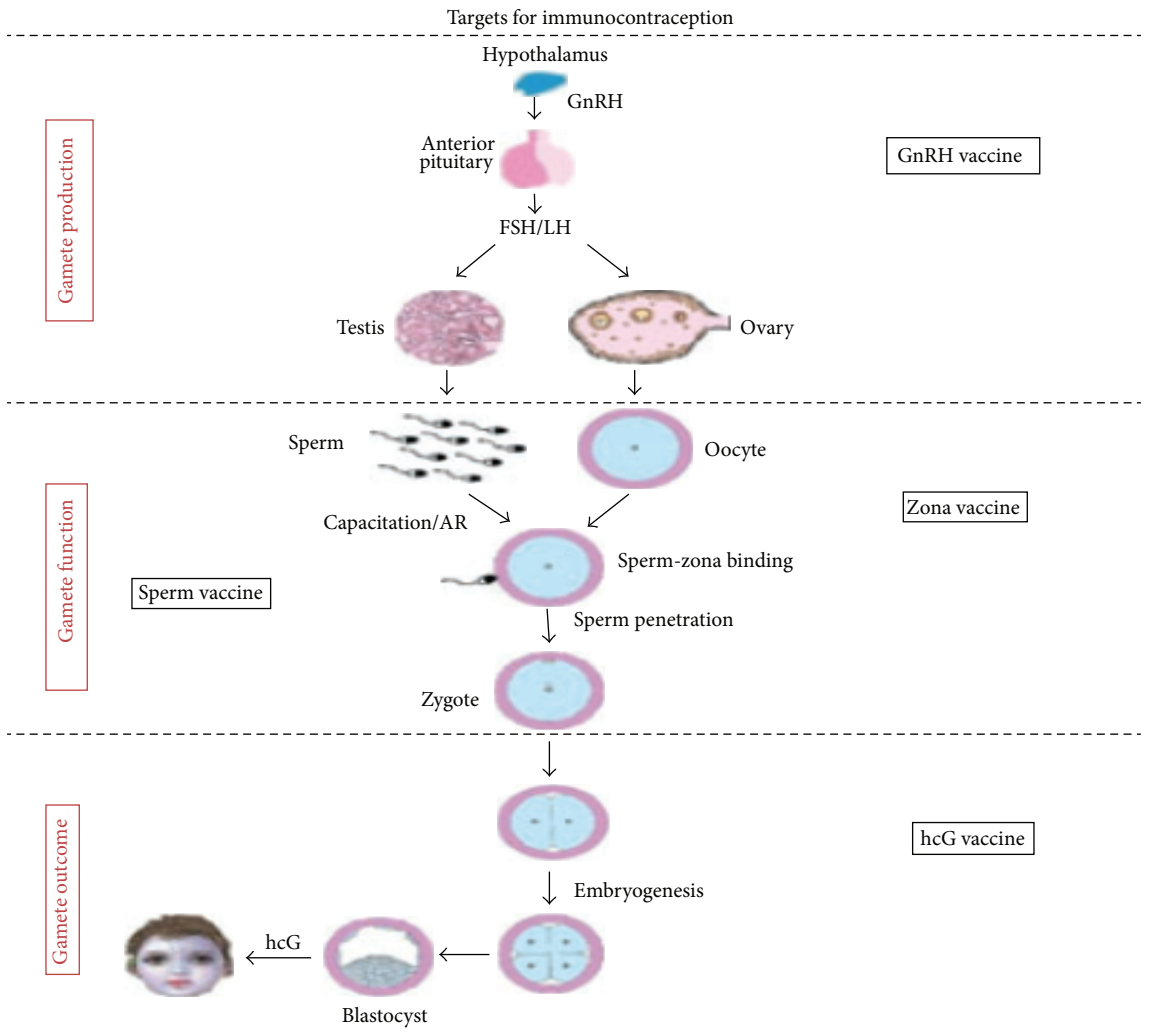

Figure 1: Schematic model indicating various targets that are being explored for the contraceptive vaccine development. These include targeting gamete production [gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH)], gamete function [zona pellucida (ZP) proteins of the oocytes and sperm antigens], and gamete outcome (human chorionic gonadotropin [hCG]) (adapted from [9]).

antibodies being generated were of fairly low titer, there was no reduction in the sperm count in the volunteers.

Further, an attempt was made by using FSH coding peptides instead of native protein form. Two peptides considered contained the sequences of β 33–53 and β 81–95 aa. Both the peptides were used in monomeric as well as dimeric form (tandem) and were subsequently used to immunize male rabbits, respectively. Immunization with β 33–53 tandem inhibited FSH bioactivity specifically and hence it was considered an attractive candidate to be used as the antigen of choice in a male contraceptive vaccine [27]. However, incidence of spermatogenesis in FSH-β knockout mice and considerable fertility in men homozygous for an inactivating mutation of FSH receptor [28] suggested that FSH suppression might not be a feasible alternative for the development of male contraceptive vaccine.

2.1.3. Luteinizing Hormone (LH). Luteinizing hormone (LH, also known as lutropin and sometimes lutrophin) is a heterodimeric glycoprotein hormone produced by gonadotroph cells in the anterior pituitary gland. An acute rise of LH triggers ovulation and development of the corpus luteum in females. It stimulates leydig cells to produce testosterone in males and also termed as interstitial cell-stimulating hormone (ICSH) in males. Similar to FSH, LH is also made up of one α and one β subunit which make the full, functional protein. Immunization of adult female sheep (ewe) with LH prohibited pregnancy in all the animals during two breeding seasons. The mode of action was assumed as prevention of ovulation presumably by inhibition of the preovulatory surge of LH [29]. Though immunization with LH has potential application as contraceptive agent, it is not widely accepted since it potentially affects sex steroids.

2.2. Gamete Outcome. The fusion of sperm and ovum is followed by gamete outcome, that is, the formation of fertilized egg which is maintained under the control of pregnancy specific enzyme, human chorionic gonadotropin (hCG). Soon after the conception, hCG is secreted during luteal phase and prepares endometrium to receive fertilized egg. Generation of antibodies against hCG can provide an immunocontraceptive agent which will target the establishment of fertilized egg.

Human chorionic gonadotropin is the only well-defined protein playing an essential role in the maintenance of pregnancy. The hormone is formed by the trophoblast and acts on the corpus luteum for stimulating progesterone production. If progesterone level drops, uterine endometrium will shed; thus preventing implantation [30]. As the substantial amounts of hCG are secreted only during pregnancy, its neutralization should have no other effects than on fertility. It also plays a critical role in implantation of the embryo onto the uterus.

Anti-hCG vaccine was the first and only birth control vaccine to go through Phase II efficacy trials successfully. The use of vaccine in sexually active women prevented them from becoming pregnant [31]. The vaccine was highly effective as long as the antibody titers remained >50 ng/mL. Action of the vaccine was fully reversible as women conceived readily when the antibody titers declined (<35 ng/mL). No side effects were observed during Phase I and Phase II trials as women showed normal ovulation and normal synthesis of their own sex hormones along with regular menstrual cycles. Also, no irregularity of bleeding in terms of spotting, amenorrhoea, or extra bleeding occurred [32].

Despite the encouraging results of phase I and phase II trials, major shortcoming of vaccine still existed which included the variation in generation of protective threshold titers. Only 60–80% women showed the presence of high titer protective antibodies. This percentage would have been satisfactory in case of infectious diseases but in case of a birth control vaccine, it has to be effective in >90–95% of recipients in order to be acceptable.

Therefore, in order to enhance the titers, recombinant approaches were tried using different carriers. Use of both diphtheria toxin (DT) and tetanus toxin (TT) evokes good antibody response but the repeated immunization with β-hCG-TT vaccine causes a carrier induced epitope suppression in some women. Various studies showed that conjugation of β-hCG to cocktail of peptides resulted in enhanced immune response as compared to single peptide [33].

Later, another study was carried out using heat labile enterotoxin subunit B (LTB) genetically linked with hCG-β chain. It was cloned and expressed in yeast *Pichia pastoris* and was purified using standard purification techniques [34]. Intramuscular immunization in Balb/c mice fortnightly resulted in generation of bioeffective anti-hCG antibodies. The titers when tested were several folds higher than 50 ng/mL/mouse. Similar results were obtained when this vaccine was used in different inbred mice of varying genetic background. The action of the vaccine was reversible and it received approval from the Indian National Review committee on Genetic Manipulation. The vaccine is being produced under GMP conditions for the preclinical toxicological studies. After passing these tests, next plan is to conduct clinical trials with the vaccine for preventing pregnancy, as well as for its possible therapeutic action on cancers expressing hCG or its subunits [35].

2.3. Gamete Function. The term gamete function is associated with the two main cells participating in gamete formation, that is, sperm and ovum. This approach targets the zona antigens of egg and surface antigens of sperm. The targets being nonhormonal provide much better safety upon other approaches. Exploiting ZP antigens as immunocontraceptive may interfere with the normal production of egg in female while sperm-based vaccine will be used in female reproductive tract to block fertilization by interfering with sperm movement or function.

2.3.1. Zona Pellucida (ZP). ZP is an extra cellular matrix, composed of glycoproteins, which surround the mammalian oocyte. This matrix serves multiple functions which play important role during fertilization. It is responsible for binding of spermatozoa to the oocyte due to presence of specific glycoproteins on its surface which acts as a receptor for spermatozoa. This interaction is followed by induction of acrosome reaction in the sperm bound to ZP which results in successful fusion between the two. ZP is composed of 3-4 glycoproteins named ZP1, ZP2, ZP3, and ZP4 [36].

The ZP glycoproteins have emerged as potential candidate for immunocontraception due to their essential role in the fertilization and tissue specificity (Figure 2). Immunization against ZP might result in generation of antibodies against themselves which go and bind to ZP. Thus, when a sperm encounters ovum in case of immunized animals, the binding is inhibited because ZP is already occupied by the antibodies. Immunization of female rabbits with porcine ZP proteins results in generation of antibodies against porcine ZP proteins which showed immunological cross reactivity with ZP from various other species including humans. Further, immunized female rabbits failed to conceive even after mating with fertile male rabbits [37]. This homology allowed the use of heterologous immunization in case of ZP [7].

Further studies revealed that the infertility induced in immunized female rabbits was irreversible which could not be restored even after the administration of exogenous gonadotropins. Histological examination of ovaries showed the destruction of oocytes in all the growing follicles along with the depletion of resting follicles [38]. This observation indicated that the infertility was a consequence of ovarian dystrophy rather than inhibition of sperm-oocyte interaction.

The irreversibility associated with immunization using ZP posed a major hurdle in the development of ZP based contraceptive. While irreversibility is not a major concern in case of wildlife management where long term infertility is often desirable. Therefore further development in this area resulted in production of various marketed products playing an imperative role in wildlife management.

The immunization of female bonnet monkeys was carried out using purified porcine ZP3. High antiporcine ZP3 antibody titers were formed and all the animals were rendered

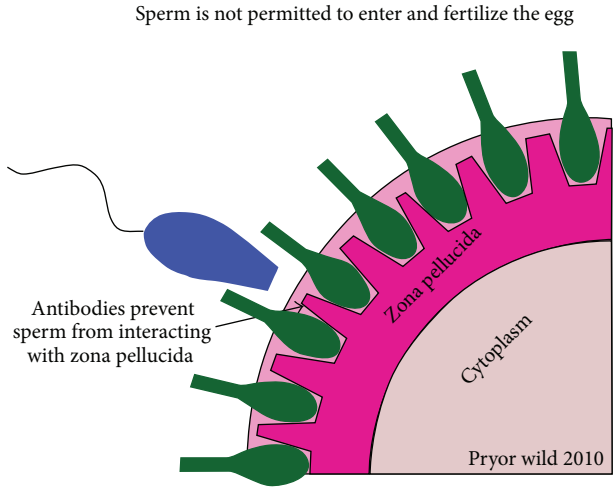

Figure 2: Immunocontraception using an immune response to zona pellucida (ZP). The immune response to the ZP antigen can inhibit sperm-egg binding or disrupt ovarian function (Source: http://www.newmalecontraception.org/risug/).

infertile [39]. Only 50% of the animals could regain fertility after the decline in antibody titers.

Ovarian histology of the animals that failed to regain fertility did not reveal any signs of inflammation or lymphocytic infiltration. The observed variations in the extent of ovarian dysfunction may be linked with differences in susceptibility among various species, purity of the ZP glycoproteins, and use of different adjuvants such as alum and synthetic muramyl dipeptide (MDP) [40–42]. It was suggested that these problems such as limited production of ZP glycoproteins from native source, batch to batch variation, and contamination with ovarian-associated proteins might be solved using recombinant form of ZP.

For this, the three glycoproteins, namely, ZP1, ZP2, and ZP3, were separately expressed in Chinese hamster ovarian (CHO) cells. A comparative analysis was carried out in two nonhuman primate species, namely, cynomolgus monkeys (*Macaca fascicularis*) and baboons (*Papio cynocephalus*) [43]. Animals immunized with any of the recombinant proteins remained infertile for some period of time but the animals immunized with recombinant ZP1 conceived later in contrast to control animals and animals immunized with remaining two proteins. Hence, another study was carried out in female baboons (*Papio anubis*) and immunization was done using *E. coli*-expressed recombinant bonnet monkey (*Macaca radiata*) ZP1 (bmZP1) conjugated to diphtheria toxoid (DT) [44]. After mating with males of proven fertility, immunized animals failed to conceive till the antibody titers were $> 2\times10^3$ antibody units. All the immunized animals became pregnant upon mating once the levels were less than the 2×10^3 antibody units. Significant curtailment of fertility was also observed by using recombinant possum ZP3 in grey kangaroos [45, 46]. Though the results were quite exciting, histological examination of ovaries of immunized animals revealed the presence of atretic follicles with degenerating oocytes.

These observations raised the hope of generation of ZP based CV for human use except for the histopathological damage. Thus, series of experiments were conducted to overcome these problems. It was found out that "oophoritogenic" T-cell epitopes existing in zona proteins might be responsible for ovarian dysfunction [47]. Hence, efforts were made to delineate B-cell epitopes which were devoid of "oophoritogenic" T-cell epitopes. As a result various synthetic peptides corresponding to ZP glycoproteins (ZP1, ZP2, and ZP3) were prepared and tested for immunocontraceptive potential *in vivo*. Female bonnet monkeys immunized with synthetic peptides remained infertile. Histopathological examination showed absence of any ovarian pathology in case of immunized animals. Similar results were obtained in case of mice immunized with ZP3 [48, 49].

Recently, murine ZP3 and sperm specific (YLP-12) epitope were expressed with Johnson grass mosaic virus coat protein to present antigens as virus like particles (VLPs) [50]. Immunization of animals resulted in significant infertility. The results were quite encouraging and suggestive of the possibility of using above mentioned approaches for immunocontraception. However, long term studies showed that immunization with zona antigens might induce immunological attack on many eggs in the ovary which might lead to premature ovarian failure [51]. Hence, enough data needs to be gathered before zona antigens are given any place in the market as immunocontraceptive measure [52].

2.3.2. Sperm Antigens. Development of CV based on sperm is a promising approach towards contraception [53]. The feasibility of employing sperm as a target is well documented. Sperm has both auto- and isoantigens and hence immunization of several species of animals and humans with sperm results in generation of antisperm antibodies (ASA), leading to infertility [54]. In a classic study carried out in 1932, fertile women (had at least one pregnancy) were injected with their husbands semen [55]. The women developed ASA which resulted in block of conception for up to 1 year of observation. More than 70% of the vasectomised men produce ASA after

vasectomy which interferes with regain of fertility even after successful surgical reanastomosis [56]. In addition, approximately 30% infertility may be attributed to the presence of ASA in either male or female partner. Disappearance of ASA from these males and females results in the recuperation of fertility. These findings provide evidence that sperm is an attractive candidate that can be exploited in case of both men and women.

Exploitation of whole spermatozoon/poorly characterized/crude sperm extracts is not a practical and feasible approach for the CV development as it has several antigens that are likely to be shared with various somatic cells due to molecular mimicry [6, 57]. Immunization with whole sperm can lead to immunopathological consequences with other tissues and organs. Thus, only sperm specific antigens can be regarded as a promising and attractive candidate for CV. The utility of an antigen is contingent upon its immunogenicity, expression on sperm surface (except from the acrosomal antigens that appear after the acrosome reaction) and involvement in fertility/fertilization. Fertilizing capacity of spermatozoa is dependent upon wide range of biological properties, namely, motility, ability to capacitate, undergoing acrosome reaction, penetrating ZP, and finally fusion with egg [58]. Antibodies generated against any of the antigens involved in above said phenomenon can result in suitable candidate.

Various approaches of genomics, proteomics, and vaccinology are being used to isolate sperm-specific antigens. In addition, several novel technologies such as subtractive hybridization, hybridoma technology, differential display technique, and gene knockout technology have also been employed. In addition to these approaches, sperm-bacteria interactions can also be targeted for the delineation of sperm antigens. Among various microorganisms that directly interact with spermatozoa leading to sperm immobilization/agglutination are well known causative pathogens of genitourinary infections such as *Chlamydia trachomatis*, *Mycoplasma genitalium*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Pseudomonas aeruginosa*, *Neisseria gonorrhoeae*, *Escherichia coli*, and *Staphylococcus aureus* [59]. These interactions use specific host cell-surface molecules known as receptors and such receptors provide a mechanism for intimate interaction with the ligand on bacteria. Harvey et al. [60] while studying the mechanism of interaction in case of *N. gonorrhoeae* with sperm showed that *N. gonorrhoeae* lipooligosaccharide (ligand) can bind to the asialoglycoprotein receptor (ASGP-R) on human sperm. Sulphoglycolipids have been confirmed as the only receptor molecule for the 70 kDa heat shock protein ligand on *M. hominis* [61]. Earlier studies have shown that sperm-*E. coli* adherence is mediated by mannose residues present on the sperm surface and mannose binding structures present on *E. coli* [62]. Addition of receptor antagonist resulted in inhibition of sperm-bacteria interactions. Therefore, it can be concluded that interaction of bacterium with spermatozoa is receptor mediated and involves interplay of multiple factors which cumulatively lead to sperm damage.

Amongst these microorganisms, *E. coli* is perhaps the most extensively studied microorganism in relation to infertility [63]. *E. coli* rapidly adheres to and agglutinates human sperm which results in significant decrease of motile sperm count. On the basis of this chemistry involved, the possibility arises that bacteria can also be exploited to identify these proteins on spermatozoa.

Various antigens that are being isolated from spermatozoa include sperm adhesion molecule 1 (SPAM 1), metalloprotease disintegrin cysteine (MDC), sperm protein (SP-10), fertilization antigen (FA-1), SP-17, NZ-1, NZ-2, lactate dehydrogenase (LDH-C_4), sperm agglutination antigen (SAGA-1), YLP-12 peptide, human equatorial segment protein (hESP), BS-17, rabbit sperm membrane protein-B (rSMP-B), sperm acrosomal membrane-associated protein (SAMP-32), and 80 kDa human sperm antigen (HSA). In addition few glycoproteins on the surface of spermatozoa were acquired from epididymal secretions during transit through epididymis, namely, dorsal head and equatorial (DE), epididymal protease inhibitor (Eppin), and sperm flagella protein (SFP-2). Izumo and AKAP are also being isolated.

Following antigens are being tried as CV. The antigens so obtained were tried in purified/semipurified forms for immunization. However, to achieve Food and Drug Administration (FDA) approval and to perform appropriate multicenter fecundity trials in a quality-controlled manner, recombinant or synthetic peptide molecules are required. Hence in addition to the use of native form, alternative forms of protein/antigens, namely, recombinant proteins and synthetic peptides, have also been tried. Among these two forms, synthetic form possesses advantage of being well-defined which can be synthesized and purified in large quantities at a relatively lower cost in contrast to recombinant proteins.

(1) The Sperm Adhesion Molecule 1 (SPAM1). The sperm adhesion molecule 1, a 64 kDa glycosyl-phosphatidylinositol (GPI)-linked protein, is expressed in testis, epididymis, sperm, and luminal fluid of the epididymis [64, 65]. SPAM1, a hyaluronidase enzyme, carries out three main functions during fertilization. These include penetration of cumulus [66], binding with ZP, and Ca^{2+} signalling in acrosomal exocytosis [67]. The protein is widely conserved among various mammals, hence it has been cloned from many species including fox [68], guinea pig [69], pig [70], rat [71], rabbit [72], monkey, and man [73].

In vitro incubation of sperm with antibodies generated against SPAM1 resulted in reduced sperm-ZP binding. Immunization of either male or female guinea pigs with purified SPAM1 from guinea pigs induced 100% infertility [74]. Infertility was associated with loss of normal sperm in epididymis and autoimmune disorders in case of immunized males [75]. In females, prevention of sperm-egg binding by antibodies resulted in infertility. However, the infertility induced by immunization was found to be reversible in both the cases as fertility was regained within 6–15 months.

Though the results were quite encouraging, but in order to produce an effective CV, it is necessary to generate protein in sufficient quantities. This shortcoming has been undertaken by the use of recombinant antigen. The cDNA encoding for the SPAM1 antigen has been cloned and sequenced. However immunization of both male and female rabbits carried out using recombinant SPAM 1 (rSPAM-1) did not result in

infertility in any of the immunized animal. These differences between native and recombinant form may be due to lack of sufficient quantities of anti-rSPAM1 antibodies which were required to block conception [72, 76].

(2) Metalloprotease/Disintegrin/Cysteine-Rich (MDC). The MDC proteins are a rapidly growing family of integral membrane proteins, expressed predominantly in mammalian testis. All the proteins have distinct conserved features such as a metalloproteinase-like domain, a disintegrin-like domain, a cysteine-rich domain, a prodomain, and a transmembrane domain (also known as ADAM family) [77]. Among these proteins, few are known to be expressed on male germ cells and/or mature sperm. Notable among them are fertilin α, fertilin β (collectively called fertilin), and cyritestin (tMDC I).

Fertilin, previously designated PH30, is a sperm-associated protein. It was originally isolated from detergent extracts of guinea pig caudal epididymal sperm. In guinea pig, it is composed of two related subunits, α and β, with molecular masses of 60 kDa (Fertilin α) and 44 kDa (Fertilin β), respectively, as observed on reducing sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS PAGE). Role of fertilin α is associated with sperm-egg adhesion, but whether it has some part to play in membrane fusion or not is still not very clear [78]. Its role in adhesion is justified by the presence of cysteine-rich domain that appears to participate in cell adhesion. The use of recombinant form of fertilin α inhibits sperm-egg binding more effectively than does a shorter form with a truncated disintegrin-like domain. But the fact that the sperm lacking fertilin α are still capable of sperm-egg fusion has hindered the use of fertilin α [79].

Fertilin β was one of the first "cellular disintegrins" identified. It is one of the subunits of dimeric sperm antigen "fertilin" and the antibodies generated against fertilin cross reacts with fertilin α. The function of fertilin β is well known; it mediates sperm-egg binding and membrane fusion [80]. Inhibition in the presence of antidisintegrin loop antibodies pointed that fertilin β appears to utilize its disintegrin loop sequence to interact with the egg membrane. Although antibodies to fertilin β inhibit fertilization *in vitro* [81], but immunization with the same does not affect fertility *in vivo*, it is not suitable as a contraceptive agent [82, 83].

Cyritestin is the product of *Cyrn* gene and has an apparent molecular weight of 110 kDa but is subjected to processing during epididymal sperm transport, thus having an approximate weight of 55 kDa. It is involved in sperm-oocyte membrane adhesion and is similar to fertilin; it also uses its disintegrin loop for adhesion. Cyritestin gene knockout mice did not show any defect in sperm-oocyte membrane fusion, but they did show impairment in sperm-zona binding [84]. However, as human cyritestin gene is nonfunctional illustrating the risk of using rodents as models of human/primate fertility.

(3) Sperm Protein-10 (SP-10). Sperm-specific acrosomal protein, SP-10, was first identified in humans [85]. It was observed that SP-10 is a testis but not species-specific protein as antibody against SP-10 recognized sperm from baboon, macaque, and pig, but not from rabbit, bull, rat, guinea-pig, and cat [86]. The cDNA encoding SP-10 protein has been cloned and sequenced from a human cDNA expression library and was found to contain 1117 bp sequence encoding for 256 aa [87]. *In vitro* incubation of anti-SP-10 antibodies inhibited bovine fertilisation by reducing sperm-zona binding.

In vivo potential of SP-10 as an immunogen was tested using attenuated strain of *Salmonella* sp. expressing human SP-10. Immunization was carried out using oral route in mice and intramuscular route in monkeys. Presence of anti-SP-10 specific antibodies was seen in both cases [88]. However, antibody levels in the oviduct are of particular relevance in case of SP-10 since it is localised within the acrosomal compartment and the outer acrosomal membrane complex and is therefore only accessible to antibody after the acrosome reaction has been initiated.

(4) Fertilization Antigen-1 (FA-1). Fertilization antigen-1 (FA-1) is a 47 kDa glycoprotein which develops in testis during later stages of spermatogenesis and has autophosphorylating activity [89]. This tyrosine phosphorylation occurs during human sperm capacitation/acrosome reaction [90]. Thus, it was suggested that FA-1 has important role in capacitation/acrosome reaction which might also have effect on sperm-ZP binding. To check the specificity of FA-1 towards ZP, *in vitro* incubation of FA-1 antigen was performed with major components of ZP, that is, ZP1, ZP2, or ZP3. Results showed the specificity of FA-1 antigen towards ZP3, thus suggesting the presence of complementary sequence of FA-1 antigen on the murine oocyte.

Further, monoclonal antibodies raised against FA-1 antigen were used to ascertain the phenomenon involved in reduction of fertilization [91]. It was observed that antibodies to FA-1 block fertilization by affecting both capacitation/acrosome reactions as well as reducing sperm-zona binding. This blockage was not limited to humans as similar results were obtained in case of mice, cattle, and monkeys.

Active immunization of mice with rFA-1 resulted in an overall 64–70% reduction in fertility compared to that of controls [92]. The effect induced by antibodies was reversible and long lasting as animals delivered healthy babies when the titers reached control levels with no effect on litter size. Thus, involvement of rFA-1 antigen makes it attractive candidate for CV development. However, further studies in higher animal models are still awaited.

(5) Sperm Protein 17 (SP-17). Three sperm specific low molecular weight (~13 ± 2 kDa) proteins have been isolated from rabbit sperm and named rabbit sperm antigen-1 (RSA-1), RSA-2, and RSA-3/SP17 [93]. Monoclonal antibodies to RSA antigens showed cross reaction with human, baboon, and mice sperm. These antibodies also inhibited penetration of zona-free hamster oocyte by human spermatozoa [94]. Among these, SP-17 is the most important antigen which is exposed on the surface of mouse sperm after acrosome reaction. The localization of SP-17 was seen throughout the equatorial segment and this segment binds to ZP. *In vitro* studies revealed the specificity of SP-17 towards ZP3. When male and female mice were immunized with a chimeric peptide containing SP-17 and T-cell epitope, there was rise

in antibody titers. This rise in antibody titer confirmed the immunogenic nature of the peptide. Interestingly, the increase was pertinent in both sexes.

(6) NZ-1. The isolation of NZ-1 was carried out using polyclonal sera which was obtained from mice after immunization with human sperm antigens. The antigens so obtained had bands belonging to the molecular weight of 14–18 kDa on SDS-PAGE. Screening of the mouse λgt11 library using these antibodies recognized a cDNA clone coding for an antigen, designated as NZ-1. Neither the sequence of amino acid nor cDNA had matching with any known cDNA/amino acid sequence present in database. Recombinant form of NZ-1 antigen was used to immunize mice which resulted in reduced fertility rates [95].

(7) NZ-2. Another cDNA encoding for a sperm antigen, designated NZ-2, was also cloned and sequenced from human testis cDNA-lgt11 expression library by using polyclonal antibodies to human sperm surface antigens belonging to 14–18 kDa molecular regions. These sperm antigens are involved in binding to ZP of the human oocyte. The NZ-2 cDNA has 335-bp 58 and 139-bp 38 noncoding regions. The translated protein has a calculated molecular weight of 19 kDa. Extensive computer search in the Gen-Bank, National Biomedical Research Foundation (NBRF), and Swiss database indicates it to be a novel protein, having 99.5% nt sequence similarity, except for the first 40-bp, only with the human bacterial artificial chromosome (BAC) containing cloned human sperm DNA. The 20 kDa protein was recognized specifically by the antisperm IgG, not by the control IgG in the western blot procedure [92]. The recombinant human sperm NZ-2 antigen may find applications in the development of a contraceptive vaccine and diagnosis and treatment of infertility in humans.

(8) Lactate Dehydrogenase (LDH-C_4). The isozyme lactate dehydrogenase (LDH) plays important role in lactate metabolism and glycolysis of developing and mature spermatozoa. It has different subunits LDH-A, LDH-B, and LDH-C. Among these, LDH-C subunit is independent gene product which is expressed only in spermatogenic cells and is immunologically different from the other two subunits. Homotetrameric LDH-C_4 is perhaps the most extensively characterized sperm antigen which plays chief role in lactate metabolism and glycolysis. *In vitro* incubation of anti-LDH-C_4 antibodies resulted in sperm agglutination and cytotoxic effects on sperm cells. Active immunization using LDH-C_4 in variety of mammalian species including primates did affect fertility. Immunization of fertile baboons with synthetic form of LDH-C_4 conjugated to DT resulted in 75% reduction in fertility rates [96].

(9) Sperm Agglutination Antigen-1 (SAGA-1). Sperm agglutination antigen-1 was isolated from human spermatozoa using a monoclonal antibody generated against human sperm, designated as S19. Molecular weight of SAGA-1 ranges between 15 and 25 kDa. Immunolocalization by electron microscopy revealed the reactivity of S19 monoclonal antibody to the entire human sperm surface indicating the presence of SAGA-1 on whole sperm surface [97]. *In vitro* incubation of antibody generated against SAGA-1 resulted in agglutination/immobilization of sperm as well as inhibition of penetration of zona-free hamster ova [98].

(10) Human Equatorial Segment Protein (hESP). Human equatorial segment protein (hESP) is a sperm specific protein, first reported in the year 2003 [99]. Mouse ESP (mESP) has 81% homology with hESP. It is localized to the equatorial segment of acrosome and is associated with acrosome biogenesis. Interaction of hESP with sera of infertile male and female patients showed positive reaction. The use of antiserum raised against recombinant hESP inhibited the binding and fusion of human sperm in the hamster egg penetration assay [100]. These results suggested that ESP might be an interesting target for designing contraception vaccine.

When immunization of mice was carried out with polyepitope antigens, results showed that fertility of mice was significantly reduced. Further, an attempt was made to isolate the important part of mESP playing vital role in infertility. For achieving this, full mESP was divided in 3 fragments, namely, P1, P2, and P3. Inhibition of sperm-egg binding was seen only in the presence of anti-P1 or anti-P2 antibodies, while no inhibition was seen in case of anti-P3 antibodies. These results indicated that additional studies are needed to better characterize these peptides [100].

(11) YLP-12. A dodecamer sequence (YLPVGGLRRIGG), designated as YLP-12, was identified on human sperm using phage display technology [101]. This technology is an innovative tool which was first reported by George Smith in which the peptide sequences are presented on the surface of filamentous phage to examine their interaction with specific antibodies [102]. The peptide sequence of YLP-12 is primarily localized on acrosome and tail in case of humans and murine sperm. Extensive computer search in the database did not result in homology or identity with any known sequence indicating the novelty of the peptide. Immunoblotting analysis suggested that antibodies resulting from vaccination with YLP-12 recognized a specific protein band of 72 kDa in testis.

In vitro incubation of spermatozoa with YLP-12 Fab significantly reduced acrosome reaction (AR) [101]. Prevalence of antibodies against YLP-12 in sera of immunoinfertile patients highlighted its potential to be used as CV. Thus *in vivo* studies were carried out in mouse model using synthetic YLP-12 peptide conjugated with the binding domain of recombinant cholera toxin subunit B (rCTB). Immunization of female mice was done using two different routes, namely, intranasal and intramuscular. Both the routes resulted in overall reduction of 70.3% (intranasal) and 61.4% (intramuscular) in fertility, respectively. Though, further studies need to be carried out in higher animal models.

(12) Rabbit Sperm Membrane Protein-B (rSMP-B). One of the components with a molecular weight of 20.1 kDa was identified from the tail of rabbit sperm and designated as rSMP-B [103]. Immunolocalization of rSMP-B on spermatozoa and somatic cells was tested using polyclonal antibodies to rSMP-B. The results suggested that this antigen was

produced by germ cells during spermatogenesis. Monoclonal antibodies raised against rSMP-B were demonstrated for their ability to block the penetration and fertilization of zona-free hamster eggs by human sperm *in vitro*. Immunization of male rabbits with rSMP-B protein resulted in blockage of spermatogenesis resulting in azoospermia. Further it was found that immunization by rSMP-B 230 peptide resulted in 83.3% infertility which was observed in case of immunized female rats after mating.

(13) Sperm Acrosomal Membrane-Associated Protein (SAMP-32). A novel human sperm membrane antigen, SAMP32 (sperm acrosomal membrane-associated protein 32), was discovered from human sperm extracts [104]. When the experiments were carried out to reveal the expression of SAMP-32, results showed that the expression was testis-specific and subsequent stages of acrosome biogenesis. Before acrosome formation, SAMP32 expression did not occur. *In vitro* incubation of anti-SAMP antibodies significantly suppressed the binding and the fusion of capacitated human spermatozoa with zona-free hamster eggs in comparison to preimmune serum. The reason that serum from an ASA positive infertile man strongly reacted with the recombinant SAMP32 antigen suggested that it might be one of the antigens related to immune infertility which can be exploited as a target for CV [105].

(14) 80 kDa Human Sperm Antigen (80 kDa HSA). 80 kDa HSA was identified from human sperm extract by western blot analysis using serum of an immunoinfertile healthy woman. It was found to be a conserved glycoprotein localized only in testis and epididymis and not localized in other somatic tissues. The pI of the protein was found to be 4.5 [106]. Active immunization of both male and female rats was carried out using native protein and it induced infertility in both sexes. Use of synthetic form of 80 kDa HSA was also tried in order to augment the immunogenicity. Maximum inhibition in fertility was seen in case of male rabbits immunized with peptide-1 followed by peptide-NT and remaining peptides. Active immunization of male marmosets with synthetic peptide-1 induced antibody response in 7 out of 9 marmosets and 6 out of 7 became infertile. Semen samples of the animals from treated group showed complete loss of progressive motility. The effect was found to be reversible as antibody titer declined 8–10 weeks after last booster injection and the animals regained their fertility. Thereafter, no apparent effect on normal physiological processes was observed [107].

(15) BS-17. BS-17 is one of the antigens being identified using ASA from serum of infertile woman. When the human testis λgt11 cDNA expression library was probed with polyclonal anti-BS-17 antibodies, the positive clone yielded a cDNA fragment consisting of 758 bp. Polyclonal antibodies to the BS-17 antigen inhibited human sperm from penetrating and fertilizing zona-free hamster oocytes [108]. Due to 99.7% homology of BS-17 with calpastatin, it was suggested that this inhibition involved destabilization of the calpastatin-calpain complex by the anti-BS-17 antibodies. After this destabilization, calpain could trigger the premature sperm acrosome reaction before sperm would reach the ovum, thus resulting in deterioration of the sperm fertilizing capability. However, till now none of the *in vivo* experiments have been carried out.

(16) Contraceptive Vaccinogen. Complementary DNAs encoding few sperm antigens have been cloned and sequenced [92]. Subtractive cDNA hybridization technology was used to isolate novel human testis specific antigen which was designated as contraceptive vaccinogen [109]. The molecular mass of the deduced aa sequence of contraceptive vaccinogen protein was calculated to be 35.3 kDa. Contraceptive vaccinogen cDNA had no homology with existing sequences in database.

The recombinant contraceptive vaccinogen protein recognized ZP3 component of ZP of human oocytes rather than ZP1/ZP2. The specificity of this interaction was further confirmed when human sperm binding to ZP of human oocytes was significantly inhibited in the presence of antirecombinant contraceptive vaccinogen antibodies. In addition, immunobead binding technique (IBT), using live sperm, highlighted the predominant presence of recombinant contraceptive vaccinogen on surface, thus accessible to antibody binding. Though antibodies produced against recombinant contraceptive vaccinogen did neither agglutinate nor cause immobilization, they could block capacitation of human sperm as deduced by sperm penetration assay (SPA). Presence of contraceptive vaccinogen antigen on murine sperm raises the feasibility of exploitation of animal model for studying its immunocontraceptive potential and it may find application in CV development.

(17) Epididymal Protein-20 (EP-20). A 20 kDa glycoprotein designated as epididymal protein (EP-20) was isolated from rabbit cauda epididymal fluid. Immunolocalization of EP-20 protein was carried out using polyclonal antibodies to EP-20 which showed the presence of the protein in testis and epididymis. Interestingly, intense staining was also observed in case of human testes, whereas germ cells, interstitial cells, and nine other tissues remained unstained. This observation highlighted the conserved nature of the protein. Polyclonal antibodies raised against EP-20 not only immobilized and agglutinated human sperm but also blocked the penetration of zona-free hamster eggs by human sperm *in vitro* [110]. However, potential of EP-20 as an immunocontraceptive needs to be examined in *in vivo* model.

(18) Dorsal Head and Equatorial Segment (DE) Protein. Dorsal head and equatorial segment protein, also known as acidic epididymal glycoprotein (AEG), has a molecular weight of 37 kDa. It is associated with the dorsal region of the sperm head during epididymal maturation with binding characteristic of a receptor-type mechanism [111]. During acrosome reaction both *in vitro* and *in vivo*, the protein migrates from epididymal region to the equatorial segment of sperm [112]. The protein plays an important role in sperm-egg binding. Incubation of sperm with antibodies against the protein significantly inhibited the penetration of zona-free eggs *in vitro* [113]. This binding was significantly reduced when

sperm formerly exposed to anti-DE antibodies were used for artificial insemination *in vivo* [111]. Decreased fertilization rates were observed in male rats, after immunization with purified DE.

Further an attempt was made to evaluate the immunocontraceptive potential of recombinant DE in rats. Animals immunized with recombinant form showed statistically significant reduction in fertility in contrast to native DE. This observation supports the evidence of exploiting epididymal proteins as a target for CV development.

(19) Epididymal Protease Inhibitor (Eppin). An epididymal protein designated as epididymal protease inhibitor (Eppin) has a molecular weight of 26 kDa [114]. Immunizationof male monkeys was carried out using Eppin. After immunization, 78% of monkeys who developed high anti-Eppin antibody titers became infertile and 71% of those monkeys recovered fertility after immunization was stopped. Later, another study was carried out wherein active immunization with Eppin gave maximum reduction of 90% in animals [115]. These results highlighted the potential of Eppin as a very attractive candidate in contraception because none of the proteins isolated so far resulted in >75% of infertility. To enhance the sensitivity of eppin, recombinant form of Eppin was tried. However, immunization with recombinant protein resulted in only 70% of reduction in contrast to native protein. Therefore, further studies need to be employed using Eppin as a potential target for immunocontraception.

(20) Sperm Flagella Protein (SFP2). Several novel epididymis-specific proteins have been identified using the combinatorial approach [116]. SFP2 is localized on the surface of sperm and showed epididymis specificity. Antibodies to SFP2 peptide 1 recognized a doublet at 220–230 kDa only in epididymal extract. Antibody to peptide 1 recognized the cognate protein on mouse, rat, and human spermatozoa. Immunization of male mice with peptide1 resulted in production of specific antibodies.

In vitro incubation of immune sera from immunized male mice with sperm caused significant reduction in motility and viability but did not agglutinate sperm. Mating of immunized male mice was allowed with female mice. A reduced fertility rate of 20% was observed in female mice mated with immunized male when compared with control animals (100%). The antibody levels in the immunized males declined by 22 weeks after immunization, resulting in 100% reinstatement of fertility. Histological examination of reproductive organs of the immunized mice and control mice caput, corpus, and cauda region of epididymis was carried out. No gross histological difference was found between immunized group and control group. No sign of leucocyte infiltration was seen in any tissue thereby; data provide an experimental basis for the development of an effective contraceptive vaccine based on new epididymal target. Still, the research is at its infancy stage and has miles to go.

(21) Izumo. *Izumo* is named after a Japanese shrine dedicated to marriage. It is a typical type I membrane glycoprotein consisting of one immunoglobulin, like domain and putative N-glycoside link motif. It is expressed on both mouse and human sperm with a molecular weight of 56.4 kDa and 37.2 kDa, respectively. cDNA encoding for mouse and human Izumo protein has been sequenced. It is not detectable on ejaculated sperm but becomes recognizable once the sperm cell undergoes AR. Among all gene knockouts, Izumo has gained highest insight because gene knockout male mice for Izumo resulted in 100% block of conception. It was observed that even after mating of Izumo−/− male mice with proven females, none of the female delivered pups [117].

Thus to evaluate the immunocontraceptive potential of Izumo, three peptides of Izumo, namely, IZ1/IZ2/IZ3, were generated [118]. High titer specific antibodies were generated against all the peptides in three groups in contrast to control group (nonimmunized). Mating of immunized female mice with proven breeder male mice was allowed, and results showed block of conception leading to infertility. However, none of the peptides resulted in 100% contraceptive effect and maximum contraceptive effect was found to be only 53.4%. Regain of fertility was seen few months subsequent to the last booster. Thus, it may be stated that Izumo antigen holds potential for becoming CV. Also, as it is not exposed until the sperm cell undergoes AR; hence antibodies against the protein should be present at a particular space and time.

(22) A-kinase Anchoring Protein (AKAP). Phosphorylation of sperm proteins is regulated by a synchronized balance between kinase and phosphatase activities. It was demonstrated that two proteins, namely, A-kinase anchoring protein 3 (AKAP 3) and AKAP 4, are the most abundant proteins present in fibrous sheath of sperm. AKAP 3 is the basic organized structure of the sheath while AKAP 4 plays an imperative role in completing the assembly of fibrous sheath [119]. Relation of partial deletions of Akap3 and Akap4 gene sequences may therefore be linked to defective assembly and failure of compartmentalization of AKAP3 and AKAP4 proteins in the tail. These gene deletions may result in sperm immotility [119, 120]. However, the hypothesis needs to be verified using animal models.

(23) Testis Specific Antigen-1 (TSA-1). A 24 kDa testis specific antigen-1 (TSA-1) is expressed in murine sperm and human sperm. Northern blot procedure revealed the expression of TSA-1 on testis. TSA-1 cDNA did not have any sequence similarity with known nucleotide/amino acid sequence in the databases. Antibody recognized acrosomal, equatorial, mid piece, and tail regions of human sperm [121]. Antirecombinant TSA-1 antibodies inhibited the acrosome reaction and sperm egg binding in *in vitro* assays [122]. These findings indicated that the testis/sperm specific protein has role in human sperm function and may find clinical application in the contraceptive vaccine development.

Various sperm antigens have been delineated and characterized. Active immunization using most of these antigens resulted in generation of high titer specific antibodies; even then none of the antigens have resulted in 100% infertility. The reasons associated include variability in immune response at individual level, maintenance of high antibody titers, time lag to achieve reasonably good titers, that is, approximately

3 months, and uncertainty that for how long the required level of antibody will remain in circulation. All these concerns may be taken care by the use of preformed antibodies, that is, passive immunization approach. The success of application of passive immunization in case of various infectious diseases indicated the feasibility and viability of such an approach [123]. Furthermore, local application of preformed antibodies will not interfere with endocrine system of the individual and is independent of host's immune status, thus providing additional advantages over the use of active immunization.

2.4. Passive Immunization: An Effective Approach. Passive immunization includes two basic approaches, that is, use of polyclonal or monoclonal antibodies. In comparison to polyclonal antibody, use of monoclonal antibody is particularly appealing and feasible. Being specific, monoclonal will avoid any cross reaction with somatic cells and there will also be lesser chances of allergic reactions. Due to this reason, they have been heralded as "magic bullets." The term "magic bullet" was coined in the end of 19th century to describe a theoretical agent that could specifically target pathogens while leaving a healthy tissue intact [124]. As a further consequence of their high specificity, monoclonal antibodies are more potent; for example, use of monoclonal (Synagsis) against RSV infection in high risk infants is approximately 50 times effective than polyclonal preparation (RespiGam). Similar results were obtained in case of *Streptococcus* infection in neonates. Also, recent advances in hybridoma technology used for generation of monoclonal antibody have revitalized interest in passive immunization.

The guiding concept which led to the idea of using passive immunization for immunocontraception was based on the clinical reports of infertile men whose semen contains antibodies that immobilize sperm usually by agglutination. The data from previous studies indicated that sperm agglutinating/immobilizing antibodies must be present in the reproductive tract specifically vagina to provide significant immunoprotective effect from pregnancy. Earlier reports have examined the stability of antibodies in mucus secretions and found that antibodies whether polyclonal/monoclonal are stable in seminal fluid and cervical mucus at 37°C. The antibodies can provide protection for one to several days depending on their half-life [125] and the use of gels for the delivery of antibodies will result in sustained release.

Very few antigens have been explored to date via passive immunization approach. Polyclonal antibodies have been raised against three proteins, namely, 16 kDa sperm protein, HSA, and Eppin. Singh et al. [126] observed that polyclonal antibody raised against a 16 kDa human sperm protein when administered passively in female mice resulted in reduction of fertility. It was likely that the antifertility effect was due to agglutinating nature of the antibody which inhibited the motility of spermatozoa. In another study, passive administration of antibodies to 80 kDa HSA in male and female rats resulted in agglutination of the spermatozoa with the loss of motility and impaired fertility [127]. Though still detailed toxicological evaluation needs to be conducted using nonhuman primate model (bonnet monkey). Also, passive immunization in mice with antibodies to a 26 kDa epididymal protein showed 89% reduction in fertility [128].

Further, monoclonal antibodies have been raised against human sperm and rabbit sperm, namely, MA-24 and mouse anti-rabbit sperm (MARS), respectively. Naz et al. [129] found that systemic intraperitoneal injection of MA-24 ascites fluid in mouse models reduced the percentage of fertilized ova (from 69% in untreated to 29% in treated), thereby reducing the fertility *in vivo* [130]. For determining the *in vivo* contraceptive efficacy of MARS, the antibodies were incubated *in vitro* with a defined volume of semen, followed by insemination of females. All the mAbs were found contraceptively effective [131].

3. Conclusion

In conclusion, it may be suggested that better understanding of the mechanisms of immunocontraception will lead to large scale applications of these methods in future. The review highlights that use of passive immunization approach is more feasible when compared with the concerns associated with the active immunization since data from antibody therapies including clinical trials in infectious diseases indicate that it is an exciting, practical, viable, and durable proposition ready for experimentation. Further, among all exploitation of sperm antigens as an immunocontraceptive agent after evaluating its feasibility and effectiveness can result in potent immunocontraception. Moreover, the generation of monoclonal antibodies in this league will act as "cherry" on top of the cake.

Conflict of Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.

ABSTRACT Leghorn lines had been selected for an immunocompetence index based on four traits: antibody production to *Mycoplasma gallisepticum* (MG) and *Pasteurella multocida* (PM) vaccines, reticuloendothelial clearance of colloidal carbon (CCA), and cell-mediated, wing web response to phytohemagglutinin (PHA). The purpose of this study was to produce replicated lines of chickens with divergent levels of multitrait immunocompetence by index selection. The objectives of analyses of Generations 5 to 7 of this study was to characterize these lines with respect to immune-response traits, correlations among these traits, and correlated responses in other important production traits.

Differences ($P < .05$) existed between the lines selected for high or low immune response and between the two replicates in mean breeding values and in individual immune-response traits. Averages of heritability estimates, weighted by number of offspring and pooled across three generations (two cycles of selection), estimated by using sire variance components and parent-offspring correlations were, respectively, .16 and .09 for the index, .31 and .08 for MG, .21 and –.02 for PM, .06 and .05 for CCA, and .08 and .12 for PHA. Realized heritabilities (response divided by effective selection differential) pooled across the two selection cycles, were .19 and .11 for the index, .06 and –.01 for MG, .44 and .32 for PM, 1.52 and –1.21 for CCA, and .48 and .15 for PHA, for Replicates 1 and 2, respectively. Phenotypic correlations among traits were generally small, and several estimates were negative. Estimates of genetic correlation varied widely. Juvenile and adult body weights, age of first egg, 32-wk egg weight, and rate of egg production were analyzed to evaluate effects of selection on these traits of direct economic importance. Very few differences were noted.

of immune response, selection for immunocompetence has been suggested as an indirect method of improving disease resistance (Gavora and Spencer, 1983; van der Zijpp, 1983; Warner *et al.*, 1987). Selection experiments using a variety of agents to elicit an immune response have been conducted (Bacon, 1992). Biozzi *et al.* (1979) reported selection experiments to several antigens in mice. The results of these experiments suggested that, in some instances, selection for increased antibody production to one antigen (for example SRBC) improved the responses to several other antigens. Antibody production against SRBC has also been used in selection experiments in chickens (Siegel and Gross, 1980; van der Zijpp *et al.*, 1983; Martin *et al.*, 1990; Pinard *et al.*, 1992). Pevzner *et al.* (1981a) reported on selection for antibody response to the synthetic amino acid polymer, GAT and also for antibodies against *Salmonella pullorum* (Pevzner *et al.*, 1981b). Antibody production against Newcastle disease virus and *Escherichia coli* (Pitcovski *et al.*, 1987) and against *E. coli* alone (Leitner *et al.*, 1992) have also been used in selection experiments. Karakoz *et al.* (1974) selected for cell-mediated immune response by using purified protein derivative of tuberculin.

Although these and other experiments have been conducted by selecting for immune response to some specific agent (or specific facet of immune response), selection for general immunocompetency, combining multiple facets of immune response, might be more desirable (Gavora and Spencer, 1978; van der Zijpp, 1983). Successful selection for different components of immune response simultaneously requires a knowledge of each individual trait and the interactions between the different facets of immune response and associations with disease resistance and other important biological traits. Biozzi *et al.* (1979) reported a negative correlation between antibody production and phagocytic ability in lines of mice divergently selected for SRBC response. Most of the other correlations found by Biozzi *et al.* (1979) between different measures of different facets of immune response were relatively small. Gross *et al.* (1980) found positive association between resistance to viral and protozoal diseases in lines selected for antibody production to SRBC but found negative correlation between anti-SRBC antibody production and resistance to bacterial diseases.

Mallard *et al.* (1992) characterized the immune-responsiveness of a random-bred population of Yorkshire pigs by using 14 indicator traits. Five traits [antibody production against hen egg white lysozyme (HEWL), total serum IgG, delayed-type hypersensitivity to a purified protein derivative of Bacillus (PPD), blastogenic response to concanavalin A (ConA), and monocyte killing of *Salmonella typhimurium*] were then chosen for multitrait selection. After one generation of selection based on a combined estimated breeding value (EBV), high and low lines differed significantly with respect to HEWL, PPD, and ConA, and also with respect to total EBV. Heritability estimates ranged from 0 to .25. The ConA and HEWL were positively correlated in the base population and no other significant correlations among these five traits were reported.

Experiments with selection for immune response have yielded varied results with respect to correlations with other important economic traits. In pigs, Meeker *et al.* (1987) found a negative correlation between growth traits and immune responses to both *Bordetella bronchiseptica* and pseudorabies virus vaccines but found no correlation between the two antigens and backfat thickness. Researchers working with dairy cattle (Detilleux *et al.*, 1991; Kehrli *et al.*, 1991; Weigel *et al.*, 1992) have used a somewhat reversed approach by selecting lines divergent in milk production and then comparing the lines' immune responsiveness. Several negative correlations with milk production have been found in these studies. In chickens, Siegel and Gross (1980) and Siegel *et al.* (1982) reported a negative correlation between body weight and antibody production in lines divergently selected for antibody production to SRBC. Van der Zijpp (1983) also reported negative correlation between antibody production to SRBC and body weight, and no other significant correlations with produc-

COLORADO STATE UNIVERSITY

tion traits were found. Although antagonistic correlations with important economic traits could diminish selection pressure and, therefore, slow improvements in immune response traits, simultaneous selection for negatively correlated traits is still possible (Falconer, 1989).

The overall purpose of this selection project was to develop replicated lines of chickens divergent in levels of multitrait immunocompetence and to characterize the genetic parameters of the traits involved. Cheng *et al.* (1991) reported parameters from the base population and the first two selected generations of chickens in this project. This report presents results from the fifth, sixth, and seventh generations of these lines. Genetic parameters of the selection index and the four individual traits that are used in that index, as well as associations between the immune response traits and production traits, are presented.

MATERIALS AND METHODS

Chickens

Divergent selection for multitrait immunocompetence has been conducted in a group of White Leghorn chickens derived from the Ottawa Control Strain 7 (Gowe and Fairfull, 1980). High-responding half-siblings from 10 sires and 36 dams were used to produce a high-immune-response line (1H) and corresponding low-responding half-siblings from the same 10 sires and 36 dams were used to produce a low-immune-response line (1L) in Replicate 1. Similarly, half-sib offspring from another 10 sires and 37 dams were used to produce a high-immune-response line (2H) and a low-immune-response line (2L) in Replicate 2. Matings for future generations were within lines, based upon breeding values (estimated by using the index described below), and sibling matings were avoided.

All progeny (approximately 500) were tested in each generation. In each generation, chickens with the highest ranking breeding values within each sire family within each high-immune-response line and chickens with the lowest ranking breeding values within each sire family within each low-immune-response line were chosen as breeders for the next generation. Ten sires and 40 dams were used as breeders in each of the four lines in each generation. Immunocompetence parameters of the base generation and first two selected generations have been reported previously (Cheng *et al.*, 1991).

All chickens in each generation were raised in floor pens until 20 wk of age and in individual cages after 20 wk of age. They were provided *ad libitum* access to feed meeting all NRC (1984) requirements and water at all times.

Immunocompetence Measures

The immunocompetence measures used in this project have been described in detail (Cheng *et al.*, 1991). Brief descriptions follow. Humoral immune response was measured as antibody production to two vaccines. Vaccines against *Mycoplasma gallisepticum* (MG bacterin)[3] (MG) and *Pasteurella multocida* (FC bacterin)[3] (PM) were injected at 6 wk of age. Serum samples, collected at 9 wk of age, were analyzed for specific antibodies by using commercial ELISA[4] kits according to the manufacturer's directions. Antibody production was calculated as a corrected ratio of the individual's sample and a positive control $(S - N)/(P - N)$, where S = sample; N = negative control; and P = positive control; per kit instructions. The positive and negative controls were chicken sera included in the commercial kits and were tested in duplicate on each plate of samples. The MG and PM responses are expressed as a ratio of sample to the positive serum. Sera collected before initial injection were also tested to evaluate any possible previous exposure and response to these antigens.

Cell-mediated immune response was measured by using wing web response to phytohemagglutinin (PHA-P)[5] (van der Zijpp, 1983; Lamont and Smyth, 1984) when the chickens were 10 to 12 wk of age. Wing web response (PHA), in millimeters, was

[3]Solvay Animal Health, Charles City, IA 50616.

[5]Fisher Scientific, Itasca, IL 60143.

calculated as

$$PHA = (postINJ - preINJ) - (postPBS - prePBS), \quad [1]$$

where postINJ = thickness of test wing 24 h after injection of PHA; preINJ = thickness of test wing before injection; postPBS = thickness of control wing 24 h after injection of physiological saline (PBS); and prePBS = thickness of control wing before injection (van der Zijpp, 1983).

Reticuloendothelial clearance, a measure of phagocytic ability, was measured by using intravenous injection of colloidal carbon (Glick *et al.*, 1964; Lamont, 1986) as modified by Cheng *et al.* (1991). The CCA was calculated as in Equation 2

$$CCA = -\frac{\ln(5 \text{ min O.D.}) - \ln(1 \text{ min O.D.})}{5 - 1} \quad [2]$$

where 5 min O.D. was the optical density of the sample drawn 5 min after injection of carbon; 1 min O.D. was the optical density of the sample drawn 1 min after injection, and the denominator reflected the time between collection of samples (Lamont, 1986; Cheng *et al.*, 1991). The CCA values are reported as ln of absorbance values (at 675 nm) relative to the individual's normal serum.

Index

A selection index based on the four described traits was used to rank the chickens in each generation. Index weights were calculated by solving

$$[P] [b] = [G] [a] \quad [3]$$

for [b], a vector of unknown index weights, where [P] was the phenotypic variance-covariance matrix of the four traits (MG, PM, CCA, and PHA), [G] was the genotypic variance-covariance matrix of the four traits, and [a] was a vector of "economic" weights (Hazel, 1943). Some modifications were made to the index. Because no estimates of economic values of these traits were available, [a] was calculated as the inverse of the heritability of each trait in an effort to balance selection pressure on all four traits. With no estimates of relative economic worth for each trait, balanced gains in all three facets of immune response were deemed desirable. Cheng (1990) used parameter estimates from the base population and compared different weights for the four traits. He determined that the inverses of the traits' estimated heritabilities equalized gains better than did the inverses of the traits' variances or setting each trait's weight to unity. Also, for selection in the sixth and seventh generations, for breeders of the seventh and eighth generations, respectively, the weights for each measure of antibody production (MG and PM) were divided in half in an effort to increase selection emphasis for cellular immune response and reticuloendothelial clearance relative to humoral immune response. In addition, all genetic covariances in [G] were set to zero because no previous estimates of covariances for these traits in chickens were available in the literature, and estimates for similar traits in other species were relatively small (Biozzi *et al.*, 1979). Another important feature in this selection experiment was that the parameters used to calculate index weights were adjusted in each generation to reflect added information. Heritabilities, genetic variances, and phenotypic variances and covariances were estimated in each generation by using records from all previous generations and the present generation combined. Methods used to estimate these parameters are described below.

Production Records

Body Weights. Body weights were recorded on all individuals at 2, 6, 12, and 20 wk of age and on selected individuals (those chosen to be future breeders) at 32 and 51 wk of age in Generations 5 and 6. Body weights at 32 and 51 wk of age were not yet available for Generation 7 at the time of this study's analyses.

Egg Production. Egg production records were collected for hens in Generations 5 and 6 selected as breeders. Age at first egg (AFE), average egg weight at 32 wk of age (EGGWT), and egg production in periods 1, 2, 3, 4, and Total (P1, P2, P3, P4, and PT, respectively) were recorded. Each production period was 8 wk, and eggs were

COLORADO STATE UNIVERSITY

recorded for 4 d/wk, for a total of 32 d per period. Production was measured on a hen-housed basis from 20 wk of age. Egg production records were analyzed by number of eggs produced within each period and then converted to percentages for presentation.

Mortality. Mortality was recorded on all chickens to 20 wk of age. The number of accidental deaths was subtracted before analysis. After 20 wk of age, only those chickens selected as breeders 40 males and 160 females) were kept and mortality is, therefore, recorded only on these chickens.

Statistical Analyses

The General Linear Models (GLM) Procedure of SAS® (SAS Institute, 1985) was used to estimate least squares means of breeding values and the four individual traits of immune response in each generation. The model (Model [4]) used for these analyses was

$$Y_{ijkl} = \mu + R_i + D_j + R \times D_{ij} + s_{ijk} + e_{ijkl}, \quad [4]$$

where Y is the phenotypic trait (Index, MG, PM, CCA, PHA) of an individual; μ is the population mean; R is the fixed effect of the ith replicate (1, 2), D is the fixed effect of the jth selection direction (H, L), s is the random effect of the kth sire within the ij^{th} replicate and direction, and e is a random residual term. Differences between replicates and between selection directions, and the interaction, were tested for significance by using the mean square for sire as the error term.

Variance and covariance components were computed by using the restricted maximum likelihood (REML) method of the VARCOMP Procedure of SAS® (SAS Institute, 1985). Phenotypic variance and covariance components and sire variance components were used to calculate the index weights (by using Equation [3]) and were also used to estimate heritabilities in these lines. Heritabilities were estimated by using three methods. "Narrow sense" heritability ($\hat{h}^2_s$) was estimated by:

$$\hat{h}^2_s = \frac{4\,(\hat{\sigma}^2_s)}{\hat{\sigma}^2_s + \hat{\sigma}^2_e} \quad [5]$$

where $\hat{\sigma}^2_s$ = sire variance component and $\hat{\sigma}^2_e$ = error variance component (Falconer, 1989). The same model, Model 4, was used for this analysis.

Heritabilities were also estimated by using correlations between offspring values and their midparent values. The NESTED Procedure of SAS® (SAS Institute, 1985) was used to estimate within-line correlations. Estimates of correlations ($\hat{t}_{OP}$) were weighted by number of offspring for each parent. Heritability ($\hat{h}^2_P$) was calculated as

$$\hat{h}^2_P = \hat{t}_{OP}. \quad [6]$$

Realized heritabilities were also estimated for each replicate in the two selection cycles analyzed here. Because no control lines were measured, it was necessary to assume that response was symmetric in the high and low selected lines within each replicate (Hill, 1972). Response to selection (ΔR) was calculated as

$$\Delta R = (H_k - L_k) - (H_{k-1} - L_{k-1}) \quad [7]$$

where H = high line mean (within a replicate); L = low line mean (within a replicate); and k = generation.

Selection differentials (ΔS) were calculated as

$$\Delta S = (sH_k - sL_k) - (H_{k-1} - L_{k-1}) \quad [8]$$

where sH = mean (weighted by number of progeny) of effective breeders in the high line (within a replicate); sL = mean (weighted by number of progeny) of effective breeders in the low line (within a replicate); H = high line mean (within a replicate); L = low line mean (within a replicate); and k = generation. Selection differentials were calculated separately for sires and dams, and the mean of these differentials was used for the final analysis. Realized heritability ($\hat{h}^2_r$) was calculated as $\Delta R/\Delta S$ for each replicate in each selection cycle. The index weights from Generation 6 were used for chickens in all three generations to calculate realized heritabilities.

Phenotypic and genetic correlations between the index and the four traits were calculated from variance and covariance components. The variance components were estimated by using the REML method of the VARCOMP Procedure of SAS® (SAS Institute, 1985). Again, Model [4] was used. Covariance components ($\hat{\sigma}_{xy}$) of two traits, x and y, for example, were calculated by using Equation 9

$$\hat{\sigma}_{xy} = \frac{\hat{\sigma}^2_{x+y} - \hat{\sigma}^2_x - \hat{\sigma}^2_y}{2}, \quad [9]$$

where $\hat{\sigma}^2_{x+y}$ is the variance of the individual sums of the two traits, and $\hat{\sigma}^2_x$ and $\hat{\sigma}^2_y$ are the variances of x and y, respectively. Genetic covariances were calculated by using sire components of variance, multiplied by 4, in Equation [9]. Phenotypic correlations ($\hat{r}_{xy}$) were calculated by

$$\hat{r}_{xy} = \frac{\hat{\sigma}_{xy}}{\hat{\sigma}_x \hat{\sigma}_y}, \quad [10]$$

where $\hat{\sigma}_x$ and $\hat{\sigma}_y$ were phenotypic standard deviations of x and y, respectively. Genetic correlations were calculated by using sire standard deviations of x and y, multiplied by 4, in Equation [10].

Genetic correlations were also estimated by using parent-offspring correlations and were calculated as

$$\hat{r}_{xy} = \frac{\hat{r}_{o_x p_y} + \hat{r}_{o_y p_x}}{2\sqrt{\hat{r}_{o_x p_x} \hat{r}_{o_y p_y}}} \quad [11]$$

Some parent-offspring correlations were negative and therefore resulted in unestimable genetic correlations. Again, index weights used in Generation 6 were used for Generations 5, 6, and 7 for parent-offspring analyses.

The General Linear Models program of SAS® (SAS Institute, 1985) was used to estimate least squares means for body weights and egg production records. Again, Model [4] was used for this analysis. Standard errors were computed by using the mean square for sire as the error term, and these were used to calculate probabilities of significant differences between replicates, between high- and low-response-selected groups, and interactions.

Incidence of mortality within replicates and selection directions are reported (in percentages). Differences between replicates, between high- and low-selected groups, and the interaction were tested for significance by using 2 × 2 contingency tables (Snedecor and Cochran, 1989).

RESULTS

Least squares means for pools of lines by selection direction, Replicates 1 and 2, and their interactions are reported in Table 1. Comparing high lines and low lines, significant differences ($P < .05$) were present with respect to the overall index in Generation 7. Responses to MG differed by selection direction in Generations 5 and 7 but not in Generation 6. Differences were also seen between high-response lines and low-response lines in PM in Generation 7 and in PHA in Generation 5. Significant differences were present between replicates in antibody response to MG in Generations 5, 6, and 7, the overall index in Generations 5 and 6, in PHA in Generations 6 and 7, and in PM in Generation 6. Of the four instances of significant interactions, two (index in Generation 5 and CCA in Generation 6) were due to differences in direction and two (index in Generation 7 and MG in Generation 5) were due only to differences in magnitude.

Parameters used to calculate index weights were modified after each generation, with the assumption that additional records improved the accuracy of these estimates. As an example, the parameters used to calculate index weights in Generation 7 are reported below.

$$\mathbf{P} = \begin{bmatrix} & \text{MG} & \text{PM} & \text{CCA} & \text{PHA} \\ \text{MG} & 2.053 & .126 & -.027 & -.037 \\ \text{PM} & .126 & .420 & -.0001 & -.019 \\ \text{CCA} & -.027 & -.0001 & .053 & -.004 \\ \text{PHA} & -.037 & -.019 & -.004 & .230 \end{bmatrix},$$

$$\mathbf{G} = \begin{bmatrix} & \text{MG} & \text{PM} & \text{CCA} & \text{PHA} \\ \text{MG} & .737 & 0 & 0 & 0 \\ \text{PM} & 0 & .097 & 0 & 0 \\ \text{CCA} & 0 & 0 & .003 & 0 \\ \text{PHA} & 0 & 0 & 0 & .022 \end{bmatrix},$$

COLORADO STATE UNIVERSITY

$$\mathbf{a} = \begin{bmatrix} \text{MG} & 1.39 \\ \text{PM} & 2.17 \\ \text{CCA} & 16.13 \\ \text{PHA} & 10.64 \end{bmatrix}.$$

Index weights used for the fifth, sixth, and seventh generations, respectively, were: .379, .522, and .512 for MG; .335, .546, and .398 for PM; .335, 1.52, and 1.36 for CCA; and .409, 1.14, and 1.14 for PHA.

Heritability estimates of the four individual traits, MG, PM, CCA, and PHA and of the index were estimated by using three different methods. Table 2 presents Restricted Maximum Likelihood (REML) estimates of heritabilities from sire variance components of Generations 5, 6, and 7 and a mean (weighted by number of birds per generation) of the three generation means. Heritabilities ranged from 0 to .43 in individual generations and from .06 to .31 when averaged across generations. Estimates of heritabilities obtained by using parent-offspring correlations in the two cycles of selection and the weighted means of these estimates and from chickens pooled by selection direction are presented in Table 3. Heritability estimates ranged from –.13 to .16 in individual cycles of selection and from 0 to .12 when averaged across selection cycles. Estimates of realized heritabilities of the four traits and of the index are in Table 4. Again, estimates from each cycle of selection and a weighted mean are shown. These estimates ranged from –2.42 to 2.18 in individual cycles and from –1.21 to 1.52 when averaged across cycles.

Correlations, both genetic and phenotypic, between the four traits and between the individual traits and the index were estimated by using two different methods. Phenotypic and genetic correlations from REML estimates of variance and covariance are reported in Table 2. Phenotypic correlations among individual immune-response traits ranged from –.15 to .31 in individual generations and from –.06 to .12 when pooled across generations. Phenotypic correlations pooled across generations between the index and individual traits ranged from .21 between the index and CCA to .60 between MG and the index. Estimates of genetic correlations among immune response traits ranged from –.34 to .61. When pooled across generations, estimates were from –.34 to .58.

[2]$\bar{x}$ = mean of two cycles, weighted by number per cycle.

Parent-offspring correlations are reported separately for trait x in parents with trait y in offspring and trait y in parents with trait x in offspring (Table 5). These correlations ranged from −.11 to .06 between traits and from −.10 to .12 between the index and individual traits.

Estimates of genetic correlations, estimated from parent-offspring correlations (Table 6), ranged from −.66 to .21 for individual traits in a single cycle and from −.66 to .05 when the two cycles were pooled. Genetic correlations between the index and individual traits ranged from −.42 to .96 when the two cycles were pooled.

Some differences were noted between high-response lines and low-response lines and between Replicates 1 and 2 with respect to juvenile body weights (Table 7). In Generation 5, chicks in the low lines were heavier than chicks in the high lines at 2 wk of age. In Generation 6, the low lines were heavier at 6 wk and at 12 wk of

[1]Traits are: AFE, age in days at first egg; EGGWT, average egg weight in grams at 32 wk of age; P1, egg production frequency from 20 to 28 wk; P2, egg production from 29 to 36 wk; P3, egg production from 37 to 44 wk; P4, egg production from 45 to 52 wk; PT, egg production from 20 to 52 wk.

replicates or between high- and low-response lines for the egg production traits measured, which included age at first egg, average egg weight at 32 wk of age, four 8-wk production periods starting at 20 wk of age, and total egg production in the 32-wk period from 20 to 52 wk of age.

Percentage mortality in each generation is shown in Table 9. Significant interactions were present because Line 1L had significantly ($P < .05$) lower juvenile mortality (0 to 20 wk) than did Line 1H in Generations 5 and 6 (data not shown). No significant differences were noted in adult mortality in Generations 5 or 6 or in Generation 7 up to 20 wk of age.

DISCUSSION

Divergent selection for multitrait immune response has produced phenotypic differences in immune response among the lines in this study. In Generation 7, lines selected for high immune-response had greater humoral immune response and greater index values than did lines selected for low immune-response. Because the selection has been on an index composed of all four traits, intensity of selection for each individual trait has been decreased. It may require several more generations before significant differences are realized among these lines for all of the immune-response traits. Estimates of

heritabilities, although low, predict that successful long-term selection is feasible.

Several of the estimates of heritability (ranging from 0 to .43 as estimated by using variance components or parent-offspring correlation) are similar to those found in other experiments involving traits of immune response. Biozzi *et al.* (1979) reported a heritability of .18 for antibody response to SRBC in mice. Eide *et al.* (1991) reported realized heritability of .19 for antibody response to diphtheria toxoid in goats. After one generation of selection, Mallard *et al.* (1992) characterized several immune response traits in swine and estimated heritabilities ranging from 0 to .25. In chickens, van der Zijpp *et al.* (1983) found realized heritability of .20 when selecting for increased antibody titer to SRBC and .52 when selecting for decreased titers. Martin *et al.* (1990) reported realized heritabilities of .23 and .25 in Generations 10 to 14 of selection for high and low antibody production to SRBC, respectively. Realized heritabilities of Leitner *et al.* (1992) for antibody response to *Escherichia coli* were similar, with estimates of .23 for high response and .32 for low response.

The estimates of realized heritabilities varied widely in the generations evaluated in the present study. These fluctuations may be influenced by many factors. Because the selection was conducted on the index, the actual selection differentials for individual traits were very small in some instances (data not shown). Additionally, because no control group was kept, responses in each direction of selection were assumed to be equal. This has not been confirmed and, based upon recent studies by Pinard *et al.* (1992), may possibly be unequal. Additionally, incidence of nonresponders, as has been noted in other immune response selection experiments (e.g., Pitcovski *et al.*, 1987), has been low (data not shown). This implies that the low-immune-response line has not been selected to a point below which no response can be measured.

The estimates of heritability may also have been biased because selection has occurred (Falconer, 1989). The selection pressure on each individual trait has not been overly intense, however, and because of the low selection pressure and small changes among lines, correction for bias was not included in this analysis.

Phenotypic correlations among the four traits of immunoresponsiveness were generally small (Tables 2 and 5), with the exception of the correlation between MG and PM. Positive, but often small, correlations between measures of antibody production have been found in other experiments conducted with pigs (Buschmann *et al.*, 1985) and with chickens (Cheng and Lamont, 1988; Heller *et al.*, 1992). Mallard *et al.* (1992) reported a very small positive and nonsignificant correlation of .01 in males and .05 in females. After one generation of selection, using EBVs that included response to HEWL but did not include response to TGAL, the high line exhibited a significantly greater response to TGAL than did the low line. Antibody response to SRBC, another unselected trait, was also greater in the high line than in the low line. Several of the other phenotypic correlations in this study, although small, were negative. Biozzi *et al.* (1979) also reported some negative correlations between measures of different facets of immune response, especially between phagocytic ability and antibody production, but found no significant correlation between either of these two traits and measures of cellular immune response. Mallard *et al.* (1992) reported a greater delayed-type hypersensitivity response to dinitrochlorobenzene (DNCB), an unselected trait, in the line of pigs selected for low multitrait immune responsiveness than in the corresponding line selected for high response.

Estimates of genetic correlation between immune response traits (Tables 2 and 6) from the present study were generally negative. These may slow further progress in this selection experiment. Improved accuracy, obtained by testing more generations, would seem to be necessary before these estimates should be included in index calculations.

More information concerning the true economic values of these immune-response traits is needed as well. Hazel and Lush (1942) point out that the first important part of using a selection index is to have the proper economic weights.

COLORADO STATE UNIVERSITY

Although this index was designed with the expectation that the weights (the relative amount of value given to responses to each of the four measures of immunocompetence) used would balance selection pressure evenly across the four traits, the correlations between the index and individual traits calculated from Generations 5 to 7 suggest that this may not have been effective. The correlations, both genetic and phenotypic, between the index and MG are consistently larger than those between the index and any of the other three traits (Tables 2 and 5). Gains in selection have also been more striking in MG, although this gain is probably also due to a higher heritability. In Generations 6 and 7, the economic weights (as in Equation 1) for MG and PM were divided in half to increase pressure on CCA and PHA. Index values still were more strongly correlated with MG (Tables 2 and 5) than with CCA or PHA but improvements were made in correlations between the index and CCA and the index and PHA in Generations 6 and 7.

The minimal differences among lines in measures of production traits may be a result of a lack of correlation between these traits and the immune-response traits included in this study or of low selection intensity. Negative correlations have been reported between body weight and antibody production to SRBC in other selection experiments (Siegel *et al.*, 1982; van der Zijpp, 1983). In another study, van der Zijpp (1984) found a small, positive correlation between antibody production to Newcastle's disease vaccine and body weight gain.

In Generations 5 and 6 in this experiment, Line 1L had lower mortality from 0 to 20 wk than did Lines 1H or 2L, causing a significant interaction. In recent studies (Nelson and Lamont, unpublished data) low-immune-response lines show greater resistance to Marek's disease than do high-immune-response lines, suggesting that specific resistance differences may contribute to observed differences in general mortality.

In summary, the results of this long-term, multitrait selection for immune response in poultry demonstrate that, with simultaneous selection, one can successfully alter humoral immune response without compromising cell-mediated immunity, reticuloendothelial clearance, and growth and egg production traits. Further tests, including direct challenge with specific pathogens to determine effects of altered immunophysiology on resistance traits, will elucidate the effects of multitrait immune-response selection on disease resistance.

ACKNOWLEDGMENTS

The authors thank the workers at the Iowa State University Poultry Research Center for excellent animal care and record collection, numerous students and staff for assistance in conducting the assays as well as for expert advice, and Agriculture Canada, Centre for Food and Animal Research, Ottawa, ON, Canada K1A 0C6 (R. W. Fairfull), for generously donating eggs to produce the base population.

ABSTRACT: Overabundant populations of elk (*Cervus elaphus*) are a significant concern in some areas of the western United States because of potential ecologic damage and spread of brucellosis to domestic livestock. *Brucella abortus* is transmitted among elk through direct contact with aborted fetuses, placentas and associated fluids, or postpartum discharge of infected animals. Because transmission of brucellosis is dependent on pregnancy, contraception of cows could be used for both disease and population management. The objective of this study was to evaluate the contraceptive efficacy of a gonadotropin-releasing hormone vaccine (GonaCon™) in female elk. In September 2004, cows were given a single immunization of either 1,000 μg ($n=12$) or 2,000 μg ($n=10$) of GonaCon™ and compared with a group of adjuvant-treated controls ($n=15$). In November 2004, 2005, and 2006, cows were grouped with bulls for the breeding season. Blood samples were taken in February 2005 and March 2006 and 2007 for pregnancy testing, progesterone assays, and antibody titers. For cows given 1,000 μg GonaCon™ the percentages that were infertile for 2005, 2006, and 2007 were 86%, 90%, and 100%, respectively, compared with 90%, 100%, and 100% for cows given 2,000 μg GonaCon™. Rates of infertility for control cows were 23%, 28%, and 0% ($P<0.0001$). The results indicated that either dose of GonaCon™ prevented pregnancy of elk cows for at least 3 yr. We concluded that GonaCon™ use for population management of elk warrants consideration as part of a strategy to control brucellosis.

Key words: Elk, *Cervus elaphus*, GnRH vaccine, GonaCon™, immunocontraception.

INTRODUCTION

In previous studies, we have demonstrated that the gonadotropin-releasing hormone (GnRH) vaccine, GonaCon™, is highly effective for preventing pregnancy in white-tailed deer (*Odocoileus virginianus*; Miller et al., 2000, 2007), feral horses (*Equus caballus*; Killian et al., 2004, 2006a), domestic and feral swine (*Sus scrofa*; Miller et al., 2003; Killian et al., 2006c), bison (*Bison bison*; Miller and Drew, 2004), as well as several other species (Levy et al., 2004; Miller and Killian, 2004; Nash et al., 2004). In female deer and horses, a single intramuscular injection of GonaCon™ was effective for up to 5 yr (Killian et al., 2006b; Miller et al. 2007). GonaCon™ stimulates the immune system to produce antibodies against GnRH, a small peptide protein produced by the hypothalamus. When sufficient antibody is present, the antibody complexes with, and inactivates, GnRH and prevents it from stimulating reproductive hormone and gamete production. The result is an infertile animal that remains in this state until the concentration of antibody declines to an ineffective level. In safety and toxicity studies with white-tailed deer, GonaCon™ had no adverse effects based on blood chemistry, postmortem, and histopathology evaluations (Killian et al., 2006a).

Contraceptive vaccines can be used as a tool to manage overabundant wildlife populations where lethal means of management are not feasible (Fagerstone et al., 2002), such as in national parks or urban or suburban areas. The contraceptive management strategy works best when populations have been reduced to the desired level before the use of contraceptive vaccines.

Overabundant wildlife populations also

increase the potential for disease transmission. Brucellosis is a zoonotic disease transmitted among elk, bison, and domestic livestock by direct contact with aborted fetuses, placentas, and associated fluids of infected animals. The disease is present in free-ranging elk and bison in the Greater Yellowstone Area (GYA; Cheville et al., 1998). Because the ranges of elk and bison may overlap with grazing cattle, there is considerable concern the disease will be spread to livestock. Although elk cows, under natural conditions, typically seek isolation during calving, winter feeding of elk and livestock has increased congregation and commingling, resulting in increased opportunities for disease transmission.

Miller and Drew (2004) and Killian et al. (2006c) introduced the concept that brucellosis transmission could be limited by preventing pregnancy in conjunction with a *Brucella* vaccination campaign in bison and feral swine. Reversible contraception could prevent pregnancy, and thus abortion, of *Brucella*-infected elk until they cleared the bacteria. We undertook the present study to evaluate the contraceptive efficacy of two doses of GonaCon™, given as a single injection to captive female elk.

The study was conducted at the Sybille Wildlife Research Unit of the Wyoming Game and Fish Department (Wheatland, Wyoming, USA; 41°45′47″N, 105°22′36″W) from 2004–2007. In February 2002, female elk calves were captured in corral traps at the National Elk Refuge (Jackson, Wyoming, USA) and transported to Sybille. There elk were housed in 0.4-ha corrals and fed alfalfa hay supplemented with a pelleted ration. Water and a trace mineral block were provided ad libitum. Chronic wasting disease has existed in the Sybille facility for more than 15 yr and captive cervids often contract the disease, probably from a contaminated environment (Miller et al., 2004) Chronic wasting disease has not been found where the calves were captured (Kreeger, unpubl. data).

The GonaCon™ vaccine consisted of GnRH peptide conjugated to Keyhole Limpet Hemocyanin (KLH; Miller et al., 2000) made into an emulsion with Adju-Vac™ adjuvant (Pocatello Supply Depot, Pocatello, Idaho, USA). In September 2004, 12 cows received a 1-ml injection of 1,000 μg of GonaCon™, 10 cows received a 1-ml injection of 2,000 μg of GonaCon™, 13 control cows received a 1-ml injection of the adjuvant-buffer emulsion, and two control cows were untreated. Treatment groups were housed in individual pens. Intramuscular injections were delivered remotely by darts equipped with biodegradable barbs (Pneu-Dart, Inc., Williamsport, Pennsylvania, USA).

At the beginning of November 2004, 2005, and 2006, cows were grouped with bulls for breeding. Bulls were exchanged among the cow groups every other week for 3 mo to maximize conception. Blood samples were collected in February or March of 2005, 2006, and 2007 from the jugular vein while cows were restrained in a chute. After clotting, the serum was harvested by centrifugation and kept stored frozen at −20 C until assay. Serum was used to determine antibody titers to GnRH and progesterone concentration using methods described elsewhere (Miller et al., 2000). Assays for pregnancy-specific protein B were performed by BioTracking (Moscow, Idaho, USA).

Significant differences among treatments and controls for percentages of infertility and mortality were determined by chi-square. Differences between treatments for antibody titers and serum progesterone concentrations were determined by Student's *t*-test.

Antibody titers for cows treated with 1,000 μg of GonaCon™ averaged 1.04×10^5 at 5 mo after the immunization. Average titers were maintained for the 1,000 μg group at 7.8 and 8.5×10^4 in 2006 and 2007, respectively (Fig. 1). Cows receiving the 2,000-μg dose of GonaCon™ had an average titer of 1.29×10^5 in 2005, which compared with average titers of 1.48 and 1.44×10^5 ($P=0.016$) in

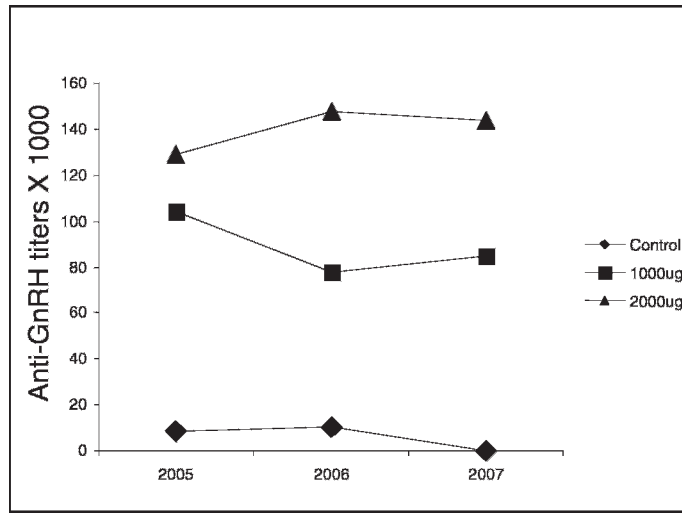

FIGURE 1. Average anti-GnRH titers for serum samples taken from control elk cows and from 1,000-μg, and 2,000-μg treated elk cows in February or March of 2005, 2006, and 2007, following a single vaccination with GonaCon™ or a control vehicle in September of 2004.

2006 and 2007 (Fig 1). These data suggested that there may be an advantage to using the 2,000-μg dose of GonaCon™ over the 1,000-μg dose to provide significantly greater titers.

Compared with the control animals, both doses of the GonaCon™ vaccine were highly effective in preventing pregnancy in elk cows throughout the entire study ($P<0.0001$). Annual infertility rates were lowest in the control animals where 27% (4/15), 25% (2/8), and 0% (0/6) were infertile in 2005, 2006, and 2007, respectively (Fig. 2). In contrast, 92% (11/12), 90% (9/10), and 100% (8/8) were infertile in the group receiving 1,000 μg of Gona-

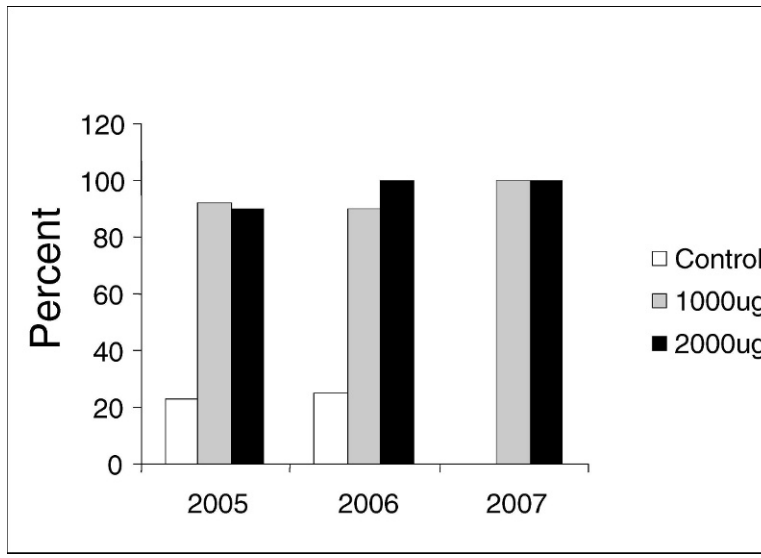

FIGURE 2. Average rates of infertility for control elk cows and for 1,000-μg and 2,000-μg treated elk cows for breeding seasons in 2005, 2006, and 2007, following a single vaccination with GonaCon™ in September of 2004.

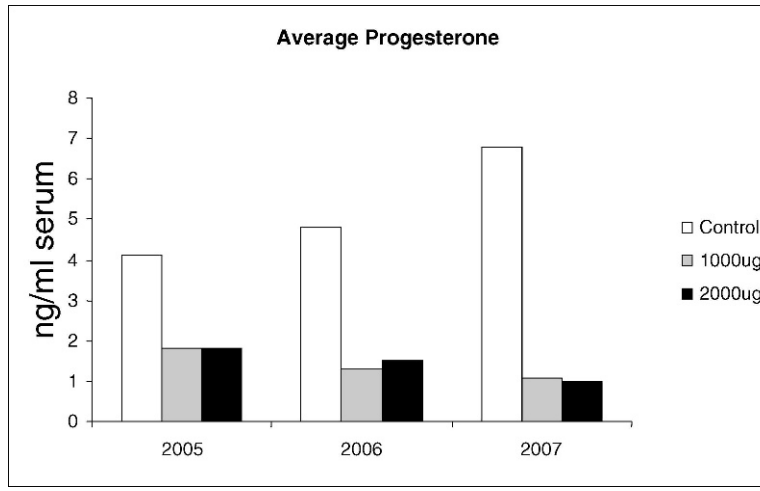

FIGURE 3. Average serum progesterone concentrations for control elk cows and for 1,000-μg and 2,000-μg treated elk cows for breeding seasons in 2005, 2006, and 2007, following a single vaccination with GonaCon™ in September of 2004.

Con™, and 90% (9/10), 100% (8/8), and 100% (6/6) were infertile in the group receiving the 2,000-μg dose of GonaCon™ (Fig. 2).

Although antibody titers were greater in cows treated with the 2,000-μg dose of GonaCon™, there were no differences in rates of infertility between the 1,000 μg and 2,000 μg GonaCon™ groups ($P = 0.697$) over the three breeding seasons studied. This outcome could change in future years if there is a greater decline in titers for the 1,000 μg group compared with the 2,000 μg group. Taken together, these results suggested that a single injection of either dose of GonaCon™ could be used for elk herds where population management by nonlethal means is desired.

Although some progesterone is secreted during the luteal phase of the estrous cycle, maximal serum concentrations of progesterone are produced by the corpus luteum during pregnancy. Control animals, most of which were pregnant when the blood samples were taken in February or March, had greater average concentrations of serum progesterone ($P<0.0001$) than cows treated with GonaCon™ (Fig. 3).

Because GonaCon™ was a highly effective immunocontraceptive vaccine for three breeding seasons, we suggest that it may prove useful in controlling brucellosis in infected elk herds' winter feed grounds in the GYA-concentrated elk, where the likelihood of disease transmission is increased. This is supported by the increased prevalence of *Brucella* antibodies in feedground elk, which is an order of magnitude higher than rates in elk not wintering on feed grounds (Kreeger, 2002). However, elk concentrated on feed grounds lend themselves to a large-scale vaccination program (Kreeger and Olsen, 2002). A challenge in managing elk in the GYA is that most herd sizes are higher than desired management levels, and hunting has been unable to reduce elk numbers. Thus, a single-dose, highly effective immunocontraceptive, like GonaCon™, would serve to reduce herd numbers while simultaneously preventing pregnancy and thus abortion, which would decrease transmission of brucellosis.

An unfortunate aspect of this study is that a large number of cows died. Of the cows that began the study in the fall of 2004, only 20 of the animals were alive when blood samples were taken in April of 2007. The cause of death in every instance

was CWD, diagnosed by immunohistochemistry. Exposure to the CWD prion was most likely environmental (Miller et al., 2004) because the facility has experienced continuous losses to CWD for more than 20 yr (Kreeger, unpubl. data).

Results of this study indicated that either dose of GonaCon™ prevented pregnancy of elk cows for at least 3 yr. We concluded that GonaCon™ use for population management of elk warrants consideration as part of a strategy to control brucellosis.

ABSTRACT: Controlling fertility of feral horses through the use of long-acting contraceptives or sterilization approaches has been championed as a reasonable and humane solution for addressing overpopulation problems in several western states. However, methods to accomplish long-term contraceptive efficacy of horses following a single treatment have been lacking. In fall 2002 and spring 2003, we initiated a study to compare the long-term efficacy of a single-shot contraceptive vaccine directed at gonadotropin releasing hormone (GonaCon™) to that of a single-shot vaccine directed at the zona pellucida (SpayVac) and to the use of intrauterine contraceptive devices (IUD). Both vaccines were administered with AdjuVac™, an adjuvant developed at the National Wildlife Research Center. The objectives of the study were to determine: 1) 3-year efficacy for preventing pregnancy, 2) whether the contraceptive effects are reversible, and 3) whether there are contraindications. The Nevada Department of Agriculture provided the feral mares, which were maintained at the Nevada State Penitentiary, Carson City, facility. Mares were dewormed and given health vaccinations annually. Eight untreated control mares were compared to 12 mares treated with SpayVac, 16 mares treated with GonaCon™, and 15 mares treated with copper-containing IUDs. Only 25% (2/8) of the control mares were not pregnant or infertile in the first year. All mares in the SpayVac group were infertile, and 94% (15/16) were infertile in the GonaCon™ group during the first breeding season. In Year 2, 80% (10/12) of the SpayVac-treated mares and 60% (9/15) of the GonaCon™-treated mares were infertile. In Year 3, 80% of the SpayVac mares and 53% (8/15) of the GonaCon™-treated mares were infertile. For IUD-treated mares, 80% (12/15) were infertile after Year 1, but only 29% (4/14) and 14% (2/14) were infertile after Years 2 and 3, respectively. For IUD mares that were infertile, it was possible to visualize the IUD by ultrasonography, leading us to conclude that mares that became pregnant had lost their IUDs. For mares given SpayVac, uterine edema was commonly observed. In Years 2 and 3, antibody titers for SpayVac were progressively lower compared to titers observed in Year 1.

INTRODUCTION

Contraception of wildlife and feral species has been considered a desirable option for addressing concerns of over population for many years. Ideally, the contraceptive approach should be easily administered, be effective for multiple years, and have few if any contraindications in the target species. Immuncontraceptive vaccines are believed to fulfill many of the attributes desired for population control. Data reported previously for several species, including horses (*Equus caballus*), support the notion that immunocontraceptive vaccines are safe and effective in the short term (reviewed in Killian *et al*. 2004). One injectable immunocontraceptive vaccine that has been extensively researched for use in wildlife and feral species is the porcine zona pellucida (PZP) vaccine. This vaccine presumably works by stimulating antibody production against the zona pellucida, the non-cellular outer covering of the egg. Consequently, the normal interaction between sperm and egg is prevented by the presence of antibodies on the surface of the ovum. One of the shortcomings of most formulations of PZP vaccines previously reported, however, is that a single vaccination is effective for only 1-2 years at most (Fagerstone *et al*. 2002). Although less extensively evaluated than the PZP vaccine for wildlife contraception, the gonadotropin releasing hormone (GnRH) vaccine is also of interest as an immunocontraceptive approach, since it provides a means of non-surgical sterilization by compromising reproductive hormone and gamete production of both males and females.

Considering the needs of population control of western, free-ranging mustangs, annual vaccination by injection is not a practical means to maintain infertility. Annual capture is inefficient, costly, and involves added risks of injury to horses and handlers. Although oral forms of contraceptive vaccines may make it practical to annually vaccinate free-roaming species with minimal difficulty, they are not now available and their development will probably take many years. Given the status quo, it was our belief that if the PZP and GnRH vaccines were modified or shown to act longer, they would eliminate the need for annual vaccination and provide a reasonable short-tem solution for controlling fertility in wild mustang populations.

In fall 2002 and spring 2003, we initiated a study to compare the long-term efficacy of a single-shot contraceptive vaccine directed at gonadotropin releasing hormone (GonaCon™) with that of a single-shot vaccine

directed at the zona pellucida of the ovum (SpayVac). Both vaccines were administered with AdjuVac™, an adjuvant developed at the USDA National Wildlife Research Center (NWRC). In addition, we evaluated the use of an intrauterine contraceptive device (IUD), the 380 copper "T", since in humans it has been shown to be effective for maintaining infertility for up to 12 years (Killian *et al*. 2004).

The objectives of the study for these contraceptive approaches were to determine: 1) rates of contraception for up to 3 years, 2) whether the contraceptive effects were reversible, and 3) whether there were contraindications. We now report the results following 3 years of study.

MATERIALS AND METHODS

The details pertaining to the horses used in the study and the treatments they received were previously reported (Killian *et al*. 2004). They are briefly summarized below.

Animals

The Nevada Department of Agriculture provided 53 mares and 3 stallions for use in the project. The mares weighed 225-360 kg and ranged in age from 18 months to 12 years at treatment. The horses were previously gathered from state lands and brought to the Nevada State Penitentiary, Carson City facility, where the study was conducted. All horses were given annual health vaccinations and dewormed routinely.

To handle feral mares for jugular blood sampling and vaccinations, they were run into a hydraulic chute and haltered. Contraceptive vaccines were given intramuscularly in the left lateral neck. For pregnancy evaluations by ultrasound or palpation, or IUD placement, the mares were chemically restrained.

Treatments

The studies were approved by the Institutional Animal Care and Use Committee of Pennsylvania State University. Eight mares were assigned to be untreated controls, 12 mares received a single shot of 400µg SpayVac PZP vaccine, 15 mares received a single shot of 1800µg GonaCon™ vaccine, and 3 mares received a single shot of 2800µg GonaCon™ vaccine. Fifteen mares received copper-containing IUDs placed into the uterus, trans-cervically. Doses of the SpayVac PZP vaccine were kindly provided by the vaccine's developer, Dr. Robert Brown (Brown *et al*. 1997). The single-shot GonaCon™ vaccine was developed at and provided by the NWRC. Both SpayVac and GonaCon™ were used in combination with AdjuVac™ adjuvant (Miller *et al*. 2004). The human copper 380 "T" intrauterine devices were purchased from Family Planning Sales Ltd., Littlemore, Oxford, UK. Mares were penned with a fertile stallion for a breeding trial lasting from June to September of each year. If mares failed to breed or become pregnant during the breeding season, they were considered infertile.

Observations

Nevada mares were routinely observed for breeding activity by staff and prisoner caretakers, and they were checked once or twice annually by ultrasonography for pregnancy, IUD retention, and uterine inflammation. Blood samples were assayed for estradiol, progesterone, and antibody titers to the contraceptive vaccines at the NWRC (Miller *et al*. 2000, 2001). Contraindications evaluated included general health and body condition, and uterine edema, which may be associated with hormonal changes or presence of IUDs. One mare receiving the GonaCon™ vaccine died after the first breeding season of causes not related to the treatment.

RESULTS AND DISCUSSION

Contraceptive Efficacy

All mares in the SpayVac group were infertile and 94% (15 /16) were infertile in the GonaCon™ group during the first breeding season (Figure 1). In Year 2, 80% (10/12) of the SpayVac-treated mares and 60% (9/15) of the GonaCon™-treated mares were infertile. In Year 3, 80% (10/12) of the SpayVac mares and 53% (8/15) of the GonaCon™-treated mares were infertile. For IUD-treated mares, 80% (12/15) were infertile after Year 1, but only 25% and 14% were infertile and after Years 2 and 3.

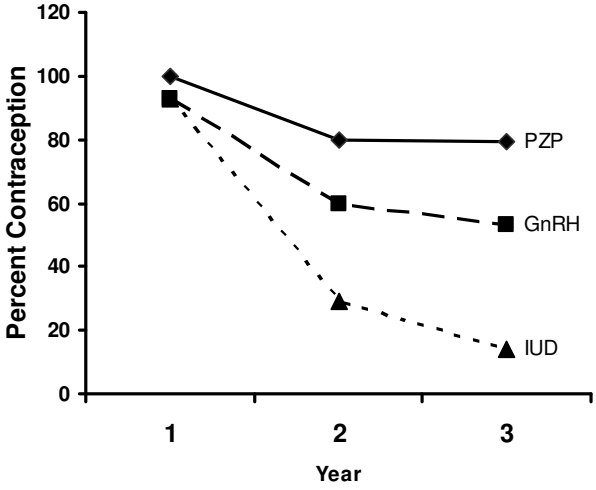

Figure 1. Percent mares contracepted in years following treatment with SpayVac (PZP), GonaCon™ (GnRH), or the 380 copper "T" human intrauterine device (IUD).

SpayVac

Mares receiving a single vaccination of SpayVac maintained a high level of contraception throughout the 3-year study. This rate of efficacy exceeds any previously reported rate for use of PZP vaccines in mustang mares or burros (Liu *et al*. 1989, Kirkpatrck *et al*. 1996, Turner *et al*. 2002). In previous studies with mares given a primary and booster vaccination, infertility was achieved in 80-90% of animals for 1 year and further sustained at this level by annual vaccination. Although Kirkpatrick, Turner, and colleagues have used annual vaccination with a PZP vaccine to effectively manage reproduction in some feral horse populations (Turner *et al*. 2002), annual recapture and vaccination of mares is not a practical approach for most field applications.

Various preparations of injectable PZP vaccines have

been used for contraception of a long list of species (Fagerstone *et al*. 2002), including deer (Turner *et al*. 1997, Miller *et al*. 2001, Fraker *et al*. 2002), elephants (Fayer-Hosken *et al*. 1999), dogs (Mahi-Brown *et al*. 1985), baboons (Dunbar 1989), and seals (Brown *et al*. 1997). However, the only formulation of single-shot PZP vaccine that appears to consistently produce a high degree of contraception lasting multiple years is the form known as SpayVac, developed by Dr. Robert Brown. Our findings confirm, in a controlled study, the multi-year efficacy for mares that has been reported for grey seals (*Halichoerus grypus*, Brown *et al*. 1997) and fallow deer (*Dama dama*, Fraker *et al*. 2002) using this formulation of PZP vaccine.

We observed that SpayVac-treated mares were more likely to have elevated serum concentrations of estradiol and show evidence of estrus at sampling than GonaCon™- or IUD-treated mares. These observations were correlated with a high incidence of uterine edema (>80%) in PZP-treated mares (Table 1). Uterine edema associated with estrus would normally be expected to be seen in ~25% of a population of randomly sampled mares during the breeding season. This prediction is based on the assumption that the normal mare estrous cycle is 22-24 days, and for approximately 6 days or 25% of that cycle she will be in estrus. From our observations, it is evident that uterine edema was present in a much higher percentage of PZP-treated mares. Although repeated estrous cycles during the breeding season have been reported for PZP-treated mares (Turner and Kirkpatrick 2002), it was generally concluded that the repeated estrous cycles were of normal length. However, we suggest that the high incidence of uterine edema and behavioral estrus observed for the Nevada mares during sampling in this study indicates abnormal estrous cycles. These abnormal estrous cycles are likely characterized by a prolonged follicular phase and a brief, if not absent, luteal phase. To better characterize the estrous cycle of mares treated with the PZP vaccine, it would be necessary to draw daily blood samples for hormone assay. Unfortunately, mustangs do not lend themselves to frequent handling regimens. Such studies would need to be done on domestic mares.

Table 1. Percentage of reproductive tracts with edema revealed by ultrasonography of mares for each of the treatments compared to the predicted number of mares expected to be in estrus.

	Year 1	Year 2	Year 3
Predicted %	25%	25%	25%
GonCon™ actual %	23% (3/13)	25% (2/8)	25% (2/8)
SpayVac actual %	82% (9/11)	91% (10/11)	100% (10/10)

GonaCon™

The single-shot GonaCon™ vaccine performed quite well during the first year, but the contraception rate decreased to 60% in Year 2 and 53% in Year 3. Although GonaCon™ did not perform as well as SpayVac, the multi-year results achieved with a single vaccination of GonaCon™ far exceed published results for contraception studies with wild horses using PZP vaccines (Turner *et al*. 2002, Kirkpatrick and Turner 2002). In addition, mares did not display evidence of frequent estrus or abnormally high incidence of uterine edema. It is noteworthy that the drop in contraception rate was greatest between Years 1 and 2, with only minimal decrease from Year 2 to Year 3 (Figure 1). A similar trend was seen with SpayVac, although to a lesser degree. This suggests that considering the immunological response, there are two sub-populations of mares: one population responded with antibody titers adequate for contraception that were maintained over several years, while in the other population contraception lasted no more than 1 year. Given the limited data we were able to collect from mustang mares, it is not possible to provide an explanation for the immunological differences between the multi-year and single-year responders.

Vaccine Antibody Titers

Contraceptive efficacy of both SpayVac and GonaCon™ was clearly related to antibody titer (Figures 2 and 3). Average titers for contracepted mares in each of the 3 years of study were considerably greater than those mares that became pregnant. The average titer for contracepted mares receiving SpayVac progressively declined during each year of study. However, the average titer in Year 3 for contracepted SpayVac mares was still nearly 8-fold greater than the average "breakthrough" titer for all SpayVac-treated mares that became pregnant. There was a 37% decline in titer between Years 1 and 2 and a 33% decline between Years 2 and 3. If we assume an average annual rate of decline in titer of 35%, this suggests that, on average, the majority of SpayVac-treated mares will remain contracepted for 4 additional years before the breakthrough titer is reached. This projection of a total of 7 years of contraception for SpayVac-treated mares is supported by the literature report of long-term efficacy of SpayVac use in grey seals (Brown *et al*. 1997).

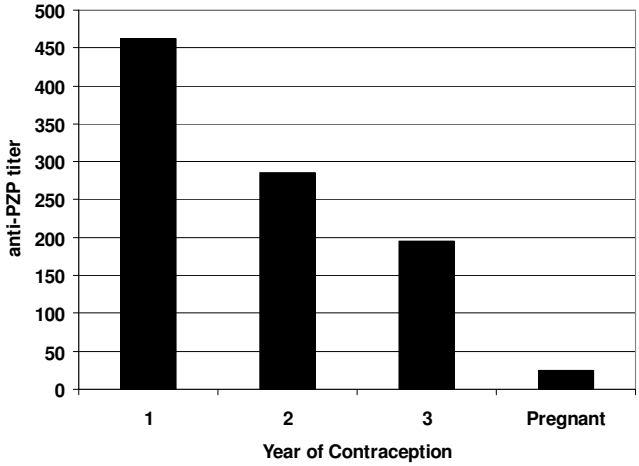

Figure 2. Average antibody titers for contracepted mares treated with SpayVac in years following treatment compared to the average titer of all pregnant mares.

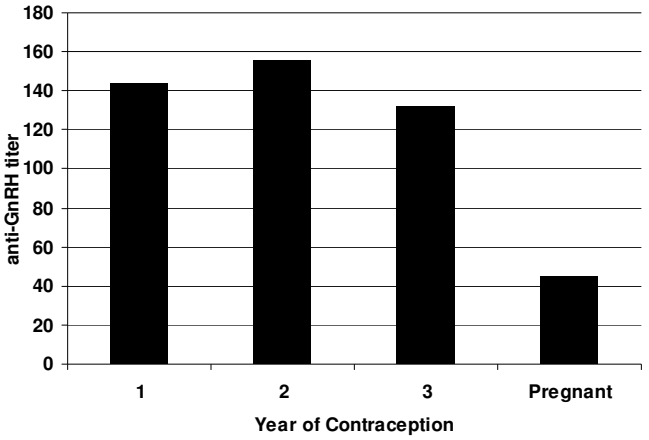

Figure 3. Average antibody titers for contracepted mares treated with GonaCon™ in years following treatment compared to the average titer of all pregnant mares.

Average titers for contracepted GonaCon™-treated mares did not show the same rate of decline in annual titer as seen with SpayVac. However, this observation is somewhat misleading, since in Year 2, 40% of the GonaCon™-treated mares became pregnant. The lower titers for these mares were averaged in the pregnant group, favoring a higher average titer for the mares in the GonaCon™-contracepted group. The fact that pregnant mares with lower titers were no longer included in the contracepted group explains the small artifactual rise in titer in Year 2. The 15% decline in GonaCon™ titer for the contracepted mares between Years 2 and 3 may more accurately reflect the annual rate of titer decline to expect for GonaCon™-treated mares following a single injection. The average titer for the 8 remaining GonaCon™-treated mares contracepted in Year 3 was 132×10^3, or nearly 3-fold greater than the 45×10^3 titer for the 5 mares that became pregnant. However, one of the mares that became pregnant had a titer of 128×10^3, while the average for the other 4 was only 24×10^3. This emphasizes the individual variability that can occur relative to titers and efficacy of a contraceptive vaccine.

IUDs

Although the 380 copper "T" IUD performed respectably during the first year of study with an 80% contraception rate (Figure 1), its performance as a contraceptive was poor during Years 2 and 3. Because we were able to visualize by ultrasonography the IUD in infertile mares, but in Years 2 and 3 we were not able to visualize the IUD in mares that were <50 days pregnant, we believe that the IUD was expelled from the reproductive tract. Daels and Hughes (1995) reported that 6 domestic mares implanted with a silastic ring IUD were infertile for 1 breeding season, and all mares returned to fertility after IUD removal the following breeding season. In unpublished studies we are conducting using the 380 copper "T" in domestic pony mares, 4 out of 5 mares have remained contracepted for 3-4 years. Given the difference in uterine size between the pony and mustang mare, it is likely that the human 380 cooper "T" is too small to be consistently retained in the uterus of the mustang mare. Retention of foreign objects in the uterus of the mare is clearly related to the size of the object. In studies using glass balls inserted into the uterus of mares to suppress estrous behavior, it was indicated that the size of the glass ball influenced its ability to be retained by the mare (Nie *et al.* 2001, Thomas 2002). Although the human 380 copper "T" did not perform for multiple years as we expected, based on studies with humans, further research to develop an IUD better suited to mustang mares could produce an effective means of long-term contraception.

Contraindications

We found no significant contraindications that would affect the well-being of mares given any of the treatments. All mares were in good body condition throughout the study. The presence of the copper-containing human IUD in the uterine lumen did not appear to cause a uterine inflammatory response, as reported for domestic mares equipped with silastic IUDs (Daels and Hughes 1995).

While a high incidence of uterine edema was observed in SpayVac-treated mares, which may have been due to irregularities in the estrous cycle, there was no indication that this naturally-occurring response to estrogen adversely affected the mares. There was no pattern of elevated estradiol or reduced progesterone in SpayVac-treated mares compared to GonaCon™- or IUD- treated mares. However, given the limited blood sampling we were able to do, it is not surprising. Frequent blood sampling is necessary to accurately characterize hormonal changes during the estrous cycle, a study better pursued with domestic mares.

Our results with the PZP vaccine agree with the report and general conclusion that mares treated with the PZP vaccine do not suffer from ill effects (Kirkpatrick *et al.* 1995, Turner and Kirkpatrick 2002). This conclusion is also supported by our study in white-tailed deer (*Odocoileus virginianus*) treated with PZP vaccine, which showed no significant adverse health effects (Miller *et al.* 2001). We also came to the same conclusion for white-tailed deer treated with GonaCon™, evaluated in a target safety study that is reported in a companion paper at this conference (Killian *et al.* 2006).

CONCLUSIONS

Three years of study on mustang mares treated with immunocontraceptive vaccines and an IUD suggest that they are safe and effective. Multiyear contraceptive efficacy was greatest for SpayVac, followed by GonaCon™ and the IUD. Given the number of mares becoming pregnant in Years 2 and 3, we conclude that the IUD and GonaCon™ approaches are reversible. Further study is needed to establish the rate of reversibility for the SpayVac vaccine, although the reversibility of other PZP immunocontraceptive vaccines has been reported (Kirkpatrick and Turner 2002).

Abstract. We evaluated the multiyear contraceptive efficacy of the gonadotrophin-releasing hormone (GnRH) vaccine GonaCon, the porcine zona pellucida (PZP) vaccine SpayVac and the human intrauterine device (IUD) 380 Copper 'T' in mustang mares provided by the State of Nevada. Eight untreated control mares were compared with 12 mares treated with SpayVac, 16 mares treated with GonaCon and 15 mares treated with the copper-containing IUD. Rates of contraception for Years 1, 2, 3 and 4 respectively for SpayVac were 100% (12 of 12), 83% (10 of 12), 83% (10 of 12) and 83% (10 of 12), rates for GonaCon were 94% (15 of 16), 60% (9 of 15), 60% (9 of 15) and 40% (6 of 15) and rates for IUD-treated mares were 80% (12 of 15), 29% (4 of 14),14% (2 of 14) and 0% (0 of 14). Antibody titres against PZP and GnRH declined over the four-year study. For mares given SpayVac, uterine oedema was commonly observed. IUDs were visible by ultrasonography in non-pregnant mustang mares, suggesting that pregnant mares did not retain their IUD. IUD retention may be a function of uterine size: pony mares with IUDs had high retention and contraception rates for 4–5 years. We conclude that long-term contraception of mustang mares with a single shot of either the SpayVac or GonaCon vaccine is possible.

Introduction

Overpopulation of wild horses is a significant concern in the western United States (Fisher 1983). In Nevada, where most of the wild horses are located, populations grow at a rate of 15–20% a year on State lands, while their range continues to shrink. Current management strategies of removal and adoption are expensive, logistically challenging, and minimally (if at all) effective in reducing and maintaining wild horse populations at a desired level. Conflicting interests associated with increased movement of people into wild horse ranges, sympathy to maintain wild horse populations because of their historic and cultural importance, competition among horses and indigenous plant and wildlife species, as well as ranching interests, are issues impacted by wild horse overpopulation. Controlling the fertility of free-ranging horses is considered a viable option for population control. However, this approach has many challenges for which solutions have been elusive. Ideally, methods for contraception of wild horses should be safe and potentially reversible, effective for several years, practical to administer and of reasonable cost and have minimal effect on reproductive or harem behaviour. Immunocontraceptive vaccines have garnered considerable attention in recent years as a means to address problems of overabundant wildlife and feral species (Fagerstone *et al*. 2002; Delves and Roitt 2005; Naz *et al*. 2005). Two immunocontraceptive vaccines that have been used in a variety of species and for which data exist on their safety and efficacy are porcine zona pellucida (PZP) vaccine (Kirkpatrick *et al*. 1992, 1995; Miller *et al*. 1999, 2001; Kirkpatrick and Turner 2002; Turner and Kirkpatrick 2002, 2003; Curtis *et al*. 2007) and gonadotrophin-releasing hormone (GnRH) vaccine (Miller *et al*. 2000, 2004; Killian *et al*. 2006*a*; Massei *et al*. 2008). Fertility control of mares using existing PZP vaccines has been shown to be safe and effective for up to 10 or more years. However, wild horses vaccinated with PZP preparations have required revaccination every year or two to maintain infertility (Turner *et al*. 2001, 2002). Limited data exist for the use of GnRH vaccines in mares to control fertility, ovarian function or behaviour (Dalin *et al*. 2002; Killian *et al*. 2004, 2006*b*; Imboden *et al*. 2006; Elhay *et al*. 2007). Information on multiyear efficacy and effects following a single injection of a GnRH vaccine in mares is lacking. Regardless of the contraceptive vaccine considered, most formulations that have been used do not appear to be effective for the long term without revaccination. Revaccination of mustangs involves considerable expense, manpower, and horse handling to maintain infertility. If a single-injection multiyear contraceptive were available it may be possible to achieve effective population reduction and reduce costs and risks associated with frequent horse handling.

We initiated a study in the autumn of 2002 and the spring of 2003 to compare the multiyear contraceptive efficacy of a single-shot contraceptive vaccine directed at GnRH with that of a single-shot vaccine directed at the zona pellucida of the ovum. We selected GonaCon to test as the GnRH vaccine on the basis of our positive experiences with it as a single-injection vaccine in deer and other species (Miller *et al*. 2000, 2004; Miller and Killian 2001; Killian *et al*. 2006*c*; Fagerstone *et al*. 2008). We selected SpayVac as the PZP vaccine to test in mares on the basis of our unpublished experiences with it as a single-injection vaccine in

white-tailed deer and the reports of multiyear efficacy in harbor seals (Brown *et al*. 1997) and fallow deer (Fraker *et al.* 2002). Both vaccines were administered with AdjuVac, an adjuvant developed at the National Wildlife Research Center. In addition, on the basis of preliminary studies with pony mares, we evaluated the use of an intrauterine contraceptive device (IUD), the 380 copper 'T', which has been shown to be safe and efficacious in humans for multiple years (Fortney *et al*. 1999; Wu *et al.* 2000). Preliminary results of these studies with Nevada mustangs have been reported earlier (Killian *et al.* 2004, 2006*b*). This paper reports results for these contraceptive approaches after four years of study with Nevada mustangs and five years of observation on the use of IUDs in pony mares.

Materials and methods

Animals

Horses for the study were provided by the State of Nevada and were maintained at the Nevada State Penitentiary, located at Carson City. The studies were approved by the Institutional Animal Care and Use Committee of the Pennsylvania State University. In total, 51 mares and three stallions were used. The mares weighed 225–360 kg and their ages were estimated to be between 18 months and 12 years of age at the time the treatments were given. All mares except the 18-month-old filly were observed in the wild to foal normal healthy foals.

For jugular blood sampling and vaccinations, the mares were run into a hydraulic chute and haltered. Vaccines were given intramuscularly in the left lateral neck. Mares were chemically restrained for IUD placement and for pregnancy evaluations by ultrasound or palpation. Chemical restraint was achieved with an initial intravenous injection of a mixture of 1 mL Dormosedan (detomidine hydrochloride) 10 mg, 2 mL xylazine 200 mg, and 2 mL acepromazine 20 mg to produce sedation, followed in 5 min with a second intravenous injection of one bottle of Telazol (250 mg Tiletamine base, 250 mg Zolazepam base) resuspended in 3 mL xylazine 300 mg for anaesthesia. This regimen typically gave 15–45 min of anaesthesia.

Ten pony mares and two pony stallions belonging to the Department of Dairy and Animal Science of the Pennsylvania State University were used to develop methods and evaluate the use of IUDs as a means to block fertility. The mares ranged in age from 18 months to 12 years when the treatments were administered. Seven of the mare ponies were pastured with a stallion during the entire five-year study, except when treatments were being administered or when data were collected. They weighed 204–306 kg, Three of the mares were on the study for only one year and were pastured with a stallion for two months during the breeding season. They weighed 281–391 kg.

Ponies were haltered and restrained in a chute for examination and data collection. If sedation was necessary, mares were given intravenous 0.5–1.5 mL xylazine (50–150 mg) and 0.2–0.5 mL butorphanol, or 0.1–0.25 mL Dormosedan (10–25 mg) and 0.2–0.5 mL butorphanol (20–50 mg).

Treatments

For the Nevada study vaccinations were given in March of 2003. Eleven mares were given a single-shot GnRH vaccine containing 1800 μg of GonaCon and four mares were given a single-shot GnRH vaccine containing 2800 μg GonaCon, 12 mares received a single-shot PZP vaccine containing 400 μg SpayVac and 8 mares were assigned to be untreated controls. Copper-containing 380 'T' IUDs were placed in the uterus of 15 mares transcervically in October of 2002. The SpayVac PZP vaccine was provided Dr Robert Brown (Brown *et al*. 1997), who developed the vaccine. The GonaCon vaccine was provided by the National Wildlife Research Center, USDA-APHIS-WS. Both SpayVac and GonaCon were made into an emulsion with AdjuVac adjuvant (Miller *et al.* 2004) and injected as a 1-mL dose. To evaluate reproductive capacity, treated and control mares were randomly assigned to two breeding groups. 'Band Stallions' that had been observed to sire multiple generations in the wild were selected to be pen stallions. Most mares were maintained in the same pen throughout the study, but if behavioural issues resulted in mares fighting, the less dominant mare was moved to the other pen. Mares were penned with a fertile stallion for a breeding trial typically lasting from June through September of each year. If mares failed to breed, or failed to become pregnant or foal during the breeding season, they were considered infertile.

Ponies were used to evaluate three different types of IUDs for ease of placement, retention and efficacy. The 380 Copper T and the GyneFix IUDs were purchased from Family Planning Sales Limited, Littlemore, Oxford, UK. The ring IUD was fabricated from Sialistic tubing (2.5 mm o.d.), which was used to create a ring size of ~2.5 cm. Prior to closing the ring with Silastic cement, five or six small copper cable clamps were threaded over the tubing for inclusion in the ring.

In preliminary studies we attempted direct finger insertion of the IUDs into the uterus of the mare after dilation of the cervix with two fingers. Because this approach was somewhat cumbersome, time consuming and did not easily ensure placement of the IUD deep within the uterine lumen we attempted to use the IUD insertion devices that were supplied with the IUDs that were intended for humans. However, both of these insertion devices were unsatisfactory for the mare uterus. The insertion device for the copper 'T' was too short to traverse the mare vagina and cervix. Likewise, the insertion device for the GyneFix IUD, which is intended to attach the IUD to the uterine endometrium with a monofilament, was also too small for the mare reproductive tract. Consequently, we modified disposable large animal uterine swabs to accommodate the IUDs. The modified swabs enable the successful deposit of the IUDs transcervically into the uterine lumen of sedated ponies or anesthetised Nevada mares. The insertion device containing the IUD was placed between the two fingers used to dilate the cervix and guided into the uterine lumen where the IUD was discharged. With minimal practice the time needed to clean the perineum, palpate the cervix by hand, and then insert the device was 2–5 min, with actual insertion of the rod and placement of the device requiring ~30–60 s.

For the research trial, all IUDs were placed into the uterus transcervically following dilation of the cervix with one or two fingers. As detailed in the Results, several animals received more than one type of IUD during the course of the study. If a mare became pregnant after receiving an IUD she was either allowed to go to term or, in the case of two mares in which the pregnancy was 60 days or less, the pregnancy was terminated with prostaglandin F2α. Within 2–3 weeks of termination of pregnancy or

parturition, mares were treated with another IUD. As a result, the GyneFix IUD was evaluated in four mares, the copper ring in four mares and the 380 Copper 'T' in seven mares. Two untreated mares served as a control for each breeding season.

Observations

Blood samples were collected from treated Nevada mares once or twice a year. However, the only observations consistently made on the eight control mares were general health, body condition and foaling. In mid- to late-October of each year treated mares were examined by rectal ultrasonography for pregnancy, IUD retention and uterine inflammation. Pregnancy was established by ultrasonography by observance of an embryonic vesicle, a fetus or in the case of later gestation, rectal palpation of a fetus. These observations were later confirmed by birth of a foal. In a few cases where the behaviour of the mare prevented ultrasonography or rectal palpation, pregnancy was determined later by the birth of a foal. General health and body condition, and uterine oedema that may be associated with oestrous cycle changes or presence of an IUD were noted. Uterine oedema in healthy mares is an indication that she is in heat and that she is under the influence of oestrogen produced by ovarian follicles (Sample 1997). All blood samples were assayed for oestradiol, progesterone and antibody titres to the contraceptive vaccines (Miller *et al*. 2000, 2001). One mare receiving the GonaCon vaccine and one mare with an IUD died after the first breeding season of causes not related to the treatments.

From April through November of 2002–05 ponies were gathered and examined by ultrasonography every 4–6 weeks. During the 2004 breeding season, daily observations were also made from April through August on the breeding and harem behaviour of a group of ponies consisting of one stallion, two control mares, one mare with a GyneFix IUD, two mares with the ring IUD and four mares with the 'T' IUD. For 2006, ponies were pastured for the entire year and the only observations made were for general health status and foaling rates. In April of 2007, ultrasonography was performed to check for IUD placement, pregnancy and any contraindications.

Statistical evaluation

Data from hormone assays were subjected to one-way analysis of variance by treatment. Differences between means were detected by two-sided *t*-test. Mean values are reported plus or minus standard error. Regression analyses were used to evaluate changes in antibody titres during the study.

Results

Nevada mustangs

Foaling data for the eight control mares for Years 1–4 were 75% (6 of 8 mares), 75% (6 of 8 mares) 88% (7 of 8 mares) 100% (8 of 8 mares), respectively. Rates of contraception for SpayVac-treated mares for Years 1, 2, 3 and 4 were 100%, 83%, 83% and 83%, respectively (Fig. 1). Average anti-PZP titres for the autumn bleed for mares that were contracepted were sustained considerably above the titers of mares that became pregnant (Fig. 2). Although regression analysis indicated a significant decline of anti-PZP titres for the first three years of the study ($P < 0.05$), average titres tended to increase in the fourth year. Compared with titres in the third year, individual titres increased in 8 of the 10 contracepted mares, with the remaining 2 mares having titres similar to the titres they had in the third year. For all years, serum progesterone values ($ng\,mL^{-1}$) averaged 1.3 ± 0.40 for non-pregnant mares during the October bleed compared with 17.5, the average for two pregnant mares. We were unable to obtain serum oestradiol

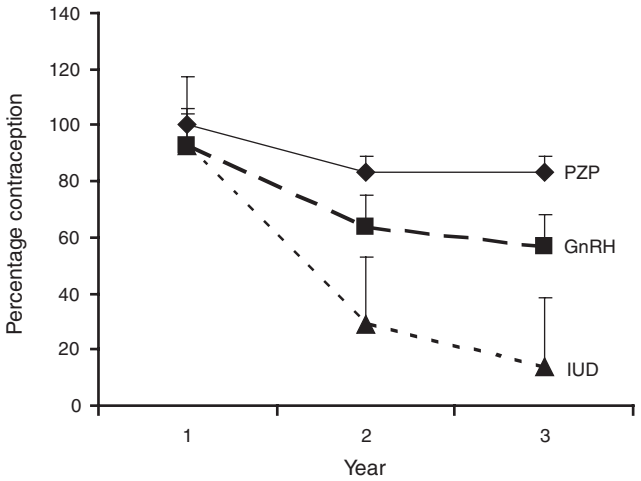

Fig. 1. Comparative rates of contraception for the three methods of contraception for each year of the four-year study. Rates of contraception for SpayVac-treated mares for Years 1, 2, 3 and 4 were 100% (12 of 12 mares), 83% (10 of 12), 83% (10 of 12) and 83% (10 of 12), respectively. Rates of contraception for GonaCon-treated mares were 93% (14 of 15 mares), 64% (9 of 14), 57% (8 of 14) and 43% (6 of 14) for Years 1–4, respectively. Contraception rates for intrauterine device (IUD)-treated mares were 80% (12 of 15 mares), 29% (4 of 14), 14% (2 of 14) and 0% (0 of 14), respectively in Years 1–4 of the study. In Year 2, one mare died in each of the GonaCon- and IUD-treatment groups of causes not related to the treatments.

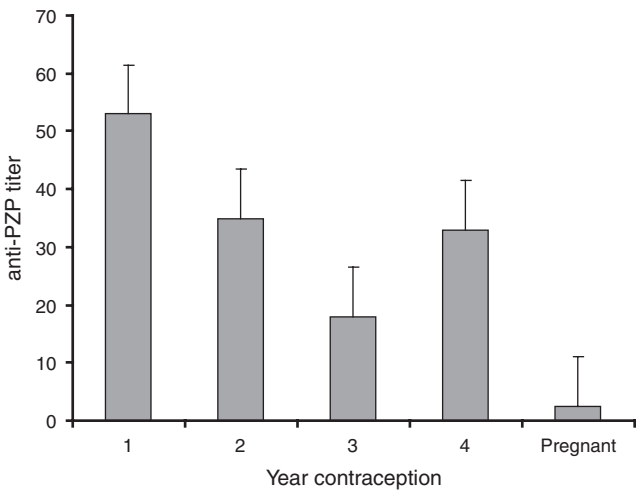

Fig. 2. Average anti-porcine zona pellucida (PZP) titres (±s.e.m.) for the autumn bleed for mares that were contracepted compared with titres of mares that became pregnant. The average titres for each of Years 1–4 were for the serum samples for the 10 mares that were infertile. The titre for the pregnant mares was the average for the 2 mares that became pregnant during the study.

values for the two SpayVac-treated mares that became pregnant, but the average serum oestradiol concentrations (ng mL^{-1}) for the cycling females at the autumn bleed was 25.9 ± 2.9.

Rates of contraception for GonaCon-treated mares were 93%, 64%, 57% and 43% for Years 1–4 (Fig. 1). For contracepted mares, regression analyses indicated that there was significant decline of average antibody titres over the last three years ($P < 0.01$). Nevertheless, anti-GnRH titres of non-fertile mares were significantly greater ($P < 0.01$) than average titres for mares that became pregnant during the study (Fig. 3). Serum progesterone concentrations (ng mL^{-1}) for non-pregnant GonaCon-treated mares at the autumn bleed averaged 0.3 ± 0.1, which was significantly lower ($P < 0.01$) than progesterone concentrations of pregnant mares treated with GonaCon (7.7 ± 1.5). Average serum oestradiol concentration (pg mL^{-1}) for the non-pregnant GonaCon-treated mares for all years was 32.6 ± 6.7, which was significantly less ($P < 0.001$) than concentrations detected in pregnant GonaCon-treated mares (1179 ± 225).

Contraception rates for IUD-treated mares were 80%, 29%, 14% and 0%, respectively in Years 1–4 of the study (Fig. 1). Average serum progesterone for all years at the autumn bleed was significantly lower ($P < 0.017$) for non-pregnant IUD-treated mares (4.3 ± 1.4 ng mL^{-1}) than for pregnant IUD-treated mares (11.3 ± 2.7 ng mL^{-1}). The average serum oestradiol concentration of 62.5 ± 34.2 ρg mL^{-1} for all years for non-pregnant IUD-treated mares was significantly less ($P < 0.001$) than the oestradiol serum concentrations of IUD-treated mares that became pregnant (1907 ± 505).

Comparing autumn serum progesterone values among treatments for non-pregnant mares, differences between GonaCon- and SpayVac-treated mares were not significant. However, progesterone values in non-pregnant GonaCon-treated mares and SpayVac-treated mares were significantly lower ($P < 0.02$) than values in non-pregnant IUD-treated mares (Fig. 4). In contrast, serum progesterone values at the autumn bleed were lower in pregnant GonaCon-treated mares than in pregnant SpayVac- or IUD-treated mares (Fig. 5). These differences were significant between IUD- and GonaCon-treated mares ($P < 0.025$), but because only two SpayVac-treated mares became pregnant, statistical comparisons could not be made with the other treatments. There were no significant differences in serum oestradiol concentrations in non-pregnant mares among treatments ($P = 0.13$) and differences between serum oestradiol concentrations of pregnant IUD-treated and pregnant GonaCon-treated mares were not significant ($P = 0.1$).

Observations made by ultrasonagraphy usually enabled visualisation of IUD location and the presence of uterine oedema or luminal fluid. In most instances IUDs were not observed in mares that were pregnant. When uterine oedema was observed it was recorded by treatment that the mare received (Table 1). These values were compared with the expected incidence of uterine oedema during oestrus based on a normal mare oestrous cycle. We assumed that within a normal 21-day oestrous cycle, 5–7 days of the cycle would be in oestrus, and the remaining 14–16 days the mare would be in dioestrus (Crowell-Davis 2007). Therefore, in a random sample of mares taken from a normal population, ~25–30% would be expected to be in oestrus

Fig. 3. Average anti-gonadotrophin-releasing hormone (GnRH) titres (±s.e.m.) for the autumn bleed for mares that were contracepted compared with titres of mares that became pregnant. The sample sizes for titres for Years 1, 2, 3 and 4 were 14, 9, 8 and 6 respectively. The average titre for the pregnant mares was for the 8 mares that became pregnant during the four-year study.

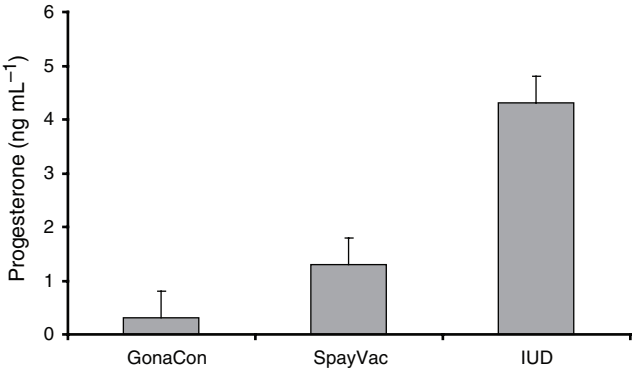

Fig. 4. Average progesterone values (ng mL^{-1}) (±s.e.m.) in non-pregnant GonaCon-treated mares ($n = 35$) and SpayVac-treated mares ($n = 46$) and non-pregnant intrauterine device (IUD)-treated mares ($n = 17$) for the autumn bleed for all years of the study. Values for GonaCon- and SpayVac-treated mares were significantly lower ($P < 0.02$) than values for IUD-treated mares.

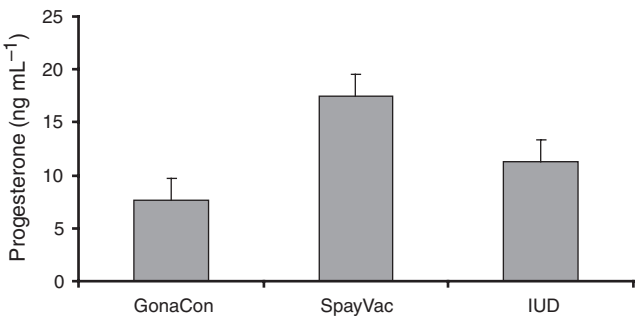

Fig. 5. Average serum progesterone (ng mL^{-1}) at the autumn bleed for pregnant GonaCon-treated-mares ($n = 8$), pregnant SpayVac-treated mares ($n = 2$) and pregnant intrauterine device (IUD)-treated mares ($n = 7$). Values were significantly different between IUD- and GonaCon-treated mares ($P < 0.025$); a comparison could not be run with the SpayVac-treated mares because of only two observations.

Table 1. Percentage of reproductive tracts with oedema revealed by ultrasonography of mares for each of the treatments compared with the predicted number of mares expected to be in oestrus

Numbers in parentheses indicate the number of mares showing uterine oedema out of the total number observed. Not all mares were observed at all time points. If a mare was found to be pregnant in a given year, she was dropped from the trial and not observed in subsequent years. Some mares on the trial could not be evaluated by ultrasonagraphy at a sampling date because their behaviour was unmanageable

Percentage	Year 1	Year 2	Year 3	Year 4
Predicted	25–30%	25–30%	25–30%	25–30%
IUD actual	20% (2 of 10)	0% (0 of 4)	0% (0 of 2)	–
GonCon actual	23% (3 of 13)	25% (2 of 8)	25% (2 of 8)	17% (1 of 6)
SpayVac actual	82% (9 of 11)	91% (10 of 11)	100% (10 of 10)	70% (7 of 10)

and to have oedematous uteri during the breeding season. Non-pregnant mares treated with GonaCon had rates of uterine oedema similar to the expected rate of 25–30% for normal non-pregnant cycling mares (Table 1). Likewise, IUD-treated mares in the first year had rates of uterine oedema similar to the expected rate, although in subsequent years too few non-pregnant mares remained in the IUD-treated group to obtain a reliable estimate. In contrast, SpayVac-treated mares had high rates of uterine oedema during all four years of the study (Table 1).

Ponies

A summary of the IUDs inserted into the pony mares is provided in Table 2. Only one of the four mares successfully retained the GyneFix IUD for a five-year period. Likewise, the copper-containing Sialistic ring was retained in only one mare for at least a year before she was sold. The copper 'T' device provided the greatest rates of contraception and retention, with several mares having the device in place for 3–5 years. We were able to observe only two of the mares (Table 2: Wanda, Remy) for one year before they were removed from the study.

Regardless of the type of IUD, the usual reason for failure was pregnancy. In most instances, we assumed that the pregnancy resulted from failed retention of the IUD, since we were unable to visualise the IUD by ultrasonography, or to identify it in the afterbirth when observed. In one case, we observed a 60-day pregnancy, but in a subsequent examination six weeks later the mare was not pregnant and the IUD was seen, suggesting that the pregnancy was aborted. In one case, a copper 'T' was removed because of pyometria. The recovery of that mare was unremarkable.

Two mares (Table 2: Libby, Maddie) were tested with all three IUD types. Both mares had the longest contraception rates with the copper 'T'. It is noteworthy that most mares given the copper 'T' IUD remained contracepted for multiple years. However, one mare (Libby) became pregnant within a year, regardless of the IUD type.

Observations made from April through August 2004 on the breeding behaviour of three non-pregnant mature mares equipped with a Copper 'T' IUD (Dewdrop, Maddie, Godiva) indicated that they had four or five oestrous cycles. The one mature mare equipped with a GyneFix IUD (Sprite) had six oestrous cycles and the one filly equipped with a 'T' IUD at 11 months of age had three oestrous cycles. These numbers were within the normal range of oestrous cycles for pony mares at the Penn State University facility.

Table 2. Summary of intrauterine device (IUD) types installed in pony mares, dates of installation, duration of contraception and reason for failure

n.a. = not applicable because the IUD is still intact

IUD type/ mare	Installation date	Date of last observation	Duration of contraception	Reason for failure
GyneFix				
Maddie	24.v.2002	25.vi.2002	30 days	Pregnant
Godiva	24.v.2002	23.vii.2002	60 days	Pregnant
Sprite	24.v.2002	28.iv.2007	5 years	n.a.
Libby (2)	23.ix.2005	23.iv.2006	7 months	Pregnant

Discussion

As with other species, population management of wild horses presents a specific set of challenges for a contraception method to meet in order for it to be of practical use. Assuming the contraception method does not pose serious problems to the health, behaviour or well being of the animal, two factors of considerable importance for contraceptive application in wild horses are long-term efficacy and whether the approach is easy to use. Wild horses need to be gathered from their range and managed under safe conditions for them to be hand injected with an immunocontraceptive vaccine. This approach has routinely been used for horses in the western United States. However, it is time consuming, expensive and, despite best efforts, not free of risk of injury to the horses or the human handlers. Although remotely darting individuals is possible (Kirkpatrick *et al*. 1990; Turner *et al*. 1996), it is not practical for vaccinating large numbers of horses in the western United States. For example, an internal cost–benefit analysis performed

by the Nevada Department of Agriculture (D. Thain, unpublished) for the Nevada Virginia Range horse-management area, consisting of over 145 000 ha of mountainous arid rangeland, concluded that equine bands did not aggregate in any one area to enable cost-effective darting. Because the Nevada Virginia Range is typical of many horse-management areas in the western United States, we believe that having a single-application contraceptive approach that is effective for multiple years would minimise or remove the need for additional gathers in these areas for revaccination in subsequent years. To date, a single-injection vaccine with multiple years of efficacy has not been available for horses despite considerable efforts of investigators working on the problem (Turner *et al*. 2001, 2002; Liu *et al.* 2005). The present study provides evidence that multiple years of contraceptive efficacy can be achieved with a single-shot immunocontraceptive vaccine in the mustang mare. SpayVac was shown to have the greatest contraception rate. For the four years of study, only two of the 12 SpayVac-treated animals had foals. This rate for a single vaccination far exceeds what has been reported by others for wild horses, although SpayVac has been shown to have long-term efficacy in other species (Brown *et al*. 1997; Fraker *et al.* 2002). Mare contraception with SpayVac was associated with antibody titre, since the two mares that became pregnant had titres much below the average titre of contracepted mares. Although the average titre for the non-pregnant SpayVac-treated mares declined in Years 2 and 3 relative to Year 1, the titres actually increased in the fourth year in most of the contracepted mares. This suggests that self boosting of the immune response may occur (Perry *et al.* 2006), perhaps as a result of the seasonality of mare reproduction. It is thought that self boosting occurs in the draining lymph node (Burton *et al*. 1994) as antigen is released from the follicular dendritic cell when the antibody flowing through the draining lymph node drops to a certain level. The released antigen then provides restimulation of antibody production. It is also possible that as the mare returns to breeding condition from a period of anoestrus, new zona pellucida proteins are produced with the initiation of follicle development which restimulate an immune response. If the titre at which mares became pregnant is assumed to be the set point for pregnancy to occur, we would predict that the mares currently contracepted with SpayVac will remain infertile for several more years. It is also possible that some of the mares may remain infertile indefinitely.

Compared with GonaCon and the IUD treatments, mares treated with SpayVac had a greater incidence of uterine oedema than would be predicted for normal cycling mares. Uterine oedema is associated with a predominance of oestradiol (Sample 1997), although there was no significant difference among treatments in oestradiol values for non-pregnant mares. However, expression of uterine oedema during the normal oestrous cycle is also influenced by the absence of serum progesterone (Crowell-Davis 2007). Relative to non-pregnant IUD-treated mares, which we found to have normal cycle lengths in the pony study, the serum progesterone values were significantly lower in SpayVac-treated mares than in IUD-treated mares. Although we were unable to make observations on the length of the oestrous cycle for the Nevada mares in this study, it has been reported that mares treated with PZP vaccine tended to have normal cycle length (Kirkpatrick *et al*. 1997; Powell 1999) although urinary oestrogen has been reported to be lower (Kirkpatrick *et al*. 1992), along with a short-term high incidence of persistent corpora lutea (Liu *et al*. 2005).

Serum oestradiol concentrations determined for SpayVac-treated mares suggest that some follicular development occurred. However, for SpayVac-treated mares showing some evidence of follicular development based on serum oestradiol, ovarian pathologies may be involved. Ovarian pathologies have been recorded for several species given PZP vaccines (Skinner *et al*. 1984; Mahi-Brown *et al*. 1988; Kirkpatrick *et al*. 1992; Lou *et al*. 1996; Stoops *et al*. 2006; Curtis *et al*. 2007), and are summarised as a disruption of folliculogenesis, depletion of primary oocytes and an infiltration of leucocytes. Given that serum progesterone was significantly lower in SpayVac-treated mares than in IUD-treated pony mares known to be having oestrous cycles of normal length, we suggest that SpayVac-treated mares may undergo some follicular development, but fail to ovulate and/or develop a normal corpus luteum.

Literature reports of circulating progesterone concentrations for untreated mares indicate considerable variation of values. Although concentrations of serum progesterone of $<1\ ng\ mL^{-1}$ are generally associated with oestrus, the concentrations progressively increase to high dioestrous values by Days 5–7 and are sustained there until Days 13–14. According to Ginther (1992, pp. 238–240), the range of means for 10 publications assaying serum progesterone during mare dioestrus was $4–22\ ng\ mL^{-1}$. Clearly, an average exceeding $4\ ng\ mL^{-1}$ for the IUD-treated mares suggests that most IUD-treated mares were in dioestrous when they were sampled. This is what would be expected when randomly sampling a population of mares. In contrast, an average of $1.3\ ng\ mL^{-1}$ for SpayVac-treated mares suggests that most of those mares were not in dioestrus. Whether they were in oestrus or transitioning into or out of dioestrus cannot be determined with only one sampling point for each mare. Nevertheless, we believe that the published values for average progesterone values during dioestrus, plus the reports of ovarian pathologies associated with PZP vaccines supports the notion that the lower progesterone values in SpayVac-treated mares may be due to a failure to form or maintain a normal corpus luteum. It is possible that antibodies to the zona pellucida prevent follicles from developing to normal ovulatory size and formation of the corpus luteum. Aside from these characteristics, there was no other evidence of contraindications associated with the SpayVac treatment.

Mares receiving a single vaccination of GonaCon showed a high degree of contraception during the first year, but this rate gradually declined to less than half after four years. This decline was associated with a gradual decline in antibody titre to GnRH over the same period. Unlike what was seen with SpayVac titres, there was no evidence for a self-boosting effect that occurs when the native protein is produced. The reason for this difference in response to the two immunogens is unknown, but it may relate to the fact that the PZP immunogen is a large glycoprotein compared with the GnRH decapeptide. Nevertheless, while the contraceptive efficacy of GonaCon was not as impressive as that of SpayVac, the GonCon results exceed rates of contraception reported by others for mares using other single-injection contraceptive vaccines (Turner *et al*. 2001, 2002).

The incidence of uterine oedema for GonaCon-treated mares was similar to what would be predicted in a population of normal cycling mares. This suggests that these mares may have some degree of oestrous cycle activity, although it is difficult to make firm conclusions. Theoretically, we would predict minimal steroid hormone production in GonaCon-treated mares if we assume that GnRH were inactivated by antibody to the vaccine. However, plasma oestradiol and progesterone concentrations in GonaCon-treated mares were similar to those in the other treatment groups. Because we have no direct observations on the reproductive behaviour of the GonaCon-treated mares, we cannot say whether these females expressed oestrus or showed evidence of an oestrous cycle. However, our unpublished data from white-tailed deer treated with GonaCon suggests that GonaCon does inhibit expression of oestrus at least in the first year or two following vaccination.

The presence of serum oestradiol in GonCon-treated mares is contrary to the notion that the GnRH is the sole regulator of follicle-stimulating hormone (FSH) secretion by the pituitary gland leading to stimulation of follicle development and oestrogen secretion. The GonaCon used in this study is prepared with the luteinising hormone-releasing hormone (LHRH) peptide (Levy *et al*. 2004) which has been shown to stimulate both luteinising hormone (LH) and FSH secretion. However, there is also evidence in several species for a follicle-stimulating hormone-releasing hormone (FSHRH) that specifically stimulates FSH secretion by the anterior pituitary gland (McCann *et al*. 1993, 1998; Yu *et al*. 1997; Padmanabhan and McNeilly 2001; McNeilly *et al*. 2003). If an FSHRH exists in the mare, it could explain the presence of serum oestradiol in infertile GonaCon-treated mares. Antibodies to LHRH in the serum would act to block some follicular development and the LH surge associated with ovulation, but some follicular development and oestrogen production would also occur in response to FSHRH and FSH secretion.

Contraception results for the Nevada mares treated with the IUD were encouraging in the first year of the study, but the performance was poor for the remainder of the study.

When IUDs were visualised, there was no evidence of uterine pathology as assessed by ultrasonography. It has been reported that mares implanted with a Sialistic ring IUDs were infertile for one year, but that device was associated with a uterine inflammatory response (Daels and Hughes 1995). In our study we did not see evidence of a uterine inflammatory response, and mares in the IUD-treatment group had the predicted number of occurrences of uterine oedema for the population size sampled. This, along with the serum progesterone and oestradiol data suggests that the IUD-treated mares were experiencing oestrous cycles.

Studies with ponies enabled more frequent observations of the IUDs and oestrous cycle events. From these observations we concluded that the 380 Copper ‘T’ IUD was superior to the other IUDs tested for long-term contraception. In addition, observations on oestrous cycle events for one breeding season led us to conclude that cycle length for mares with IUDs was within the normal range. The discrepancy in long-term rates of infertility between the mustang mares and pony mares equipped with a similar IUD is probably due to differences in uterine size. The retention of foreign objects in the mare uterus is related to the size of the object, relative to the size of the uterus. The ability of glass balls to be retained in the mare uterus has been shown to be related to the size of the glass ball (Nie *et al*. 2001; Thomas 2002). Although we have not found IUDs expelled by the uterus of an IUD-treated mare that became pregnant, we suspect the reason for the decline in efficacy of the Nevada mares was that the IUD was not retained in the uterus. This suggests that if larger ‘T’ IUDs were used, better rates of retention and contraceptive efficacy may be possible. On the basis of the pony studies, there is also evidence to suggest that shape of the IUD may also be a factor affecting retention, since neither the string GyneFix nor the ring IUDs were retained and performed as well as the ‘T’.

The mechanism preventing fertility in IUD-treated females has been argued to be either by interference with attachment of the early embryo to the uterus, or by induction of early abortion (Ortiz *et al*. 1996; Fortney *et al*. 1999). This mechanism may differ among species and no data have been published for the mechanism in the mare. Because the length of the oestrous cycle of pony mares in this study was within the normal range, we suggest that infertility in most instances was the result of the IUD interfering with events occurring between fertilisation and early embryo attachment. However, in one pony mare that was observed to be 50–60 days pregnant, in a subsequent examination she was not pregnant and the IUD was visualised. This indicated that abortion had occurred, but the IUD was retained. This observation raises the possibility that if pregnancy occurs followed by abortion, IUD expulsion may also occur. It is also possible that if pregnancy occurs but abortion does not, the IUD could be expelled with the placenta at parturition. This appears to have occurred with one Nevada mare that we observed to have the IUD when she was pregnant, and she went on to foal.

We believe that these studies provide evidence that long-term contraception of the mare is possible with the SpayVac PZP vaccine. Further improvements to the formulation of GonaCon that are now being tested in white-tailed deer suggest that rates of contraception similar to SpayVac are achievable with GonaCon. Development of larger IUDs that are better suited to the mustang mare may be possible. Regardless of the approach used, if a high rate of contraception is achievable for multiple years, population models suggest that contraception alone or used in conjunction with removal programs have the potential to stabilise and reduce population growth as well as reduce wild horse management costs (Garrott *et al*. 1992; Cameron *et al*. 2001; Bartholow 2004; Ballou *et al*. 2008; Kirkpatrick and Turner 2008). These observations lead us to conclude that population management of wild horses by single-application multiyear contraceptives will probably be possible in the near future for horse populations that can be gathered from their range for treatment and release.

Contributors

Jay F. Kirkpatrick, Ph.D. is Director of The Science and Conservation Center, Billings, Montana and holds a Ph.D. in reproductive physiology from the New York State College of Veterinary Medicine at Cornell University, Ithaca, New York.

Allen T. Rutberg, Ph.D. is a Research Assistant Professor, Center for Animals and Public Policy, Cummings School of Veterinary Medicine at Tufts University, North Grafton, Massachusetts; and Consultant and Senior Research Scientist for The Humane Society of the United States. Dr. Rutberg holds a Ph.D. in zoology from the University of Washington (1984) and an A.B. in biological anthropology from Harvard College (1976).

Linda Coates-Markle was, formerly, the Montana/Dakotas Wild Horse and Burro Specialist and the Wild Horse and Burro National Research Coordinator, Bureau of Land Management, Billings Field Office, Billings, Montana. She is now with the BLM's Division of Rangeland Resources as the Society of Range Management Liaison in Wheat Ridge, Colorado.

Compiler and Editor

Patricia M. Fazio, Ph.D. is an environmental writer and editor. Dr. Fazio holds a B.S. in animal husbandry/biology from Cornell University (1964); an M.S. in environmental history from the University of Wyoming, Laramie (1982); and a Ph.D. in environmental history from Texas A&M University, College Station (1995). Her dissertation was an establishment history of the Pryor Mountain Wild Horse Range (1968), in Montana/Wyoming.

Aknowledgements

The compiler and editor wishes to express heartfelt appreciation to Dr. Jay F. Kirkpatrick, Dr. Allen T. Rutberg, and Linda Coates-Markle for providing answers to complex scientific questions in a professional, obliging manner.

THE PZP VACCINE

Q. What is porcine zona pellucida (PZP), and how does it work to block pregnancy?…… 8
Q. How is it made, and who manufactures it?…… 8, 9
Q. How is the PZP vaccine obtained?…… 9
Q. Are any pigs killed, expressly to produce the vaccine?…… 9
Q. Is this drug FDA approved and patented? If so, who is making all the profit from its use?……. 10, 11
Q. What groups are on the PZP Contraceptive Research Team?……. 11
Q. Who Funds PZP Contraceptive Research and Applications?……. 11-13
Q. Who controls vaccine use in wild horse populations?…… 13, 14
Q. Does an agency have to do an environmental assessment (EA) or an environmental impact statement (EIS) prior to using PZP on a wild horse herd?…….. 14
Q. What wild horse populations, within the United States, are presently being managed with PZP?…… 14-16
Q. What herds do you propose to treat with contraceptives in the near future? Why did you choose these particular herds? Who decides? What are your long-term goals?…….. 16

DELIVERY, APPLICATION, AND BIOLOGICAL EFFECTS OF PZP

Q. How is the vaccine delivered?…… 16, 17
Q. How would you describe the new pelleted form of PZP-22, and how does it work? …….. 17, 18

Q. How does the liquid vaccine compare to the pelleted form?..... 18
Q. Isn't darting mares painful and potentially harmful or even lethal? Will it result in mares being shot in critical anatomical areas – abdomen or chest, causing inhumane deaths?…….. 18-20
Q. How do immune system depression issues affect the formation of abscesses and lameness in horses? ……. 20
Q. Will PZP harm mares or foals, physiologically? Have any negative pharmacological side effects been observed? Are any benefits derived from its use?……. 20, 21
Q. Does PZP application create late foaling in treated populations?.. 21, 22
Q. For how many years is a mare generally treated with PZP?…… 22
Q. How do you determine which mares within a herd will be treated?..23
Q. How effective is PZP? Won't some mares still become pregnant after treatment?……..23
Q. Why can't you block pregnancy with just one inoculation instead of the two shots you use now? …… 23, 24
Q. What do you mean by a one-year, two-year, or three-year vaccine?25, 26
Q. How long does it take for native PZP to stop population growth in a herd? ……. 26
Q. How long does it take for PZP to begin reducing a wild horse population? …… 26
Q. How can you tell if a wild mare is pregnant, so you don't treat her with PZP?…… 27
Q. Is the drug residual in urine or feces or in the dead carcasses of treated mares, where PZP could get into the food chain or cause adverse effects to wildlife, or even contaminate water?…….. 27
Q. What about compensatory reproduction in PZP-treated herds?…… 27

BEHAVIORAL EFFECTS OF PZP

Q. Is wild horse behavior affected by PZP use? Are there any effects on motivation or drive, general contentedness, and the emotional stability of mares treated with PZP? Is band social stability affected negatively? Has any aberrational behavior been seen in PZP-treated mares, band stallions, or bands where mares have been treated with a contraceptive? What behavioral studies have been conducted on wild horses, both in eastern and western wild horse herds? Do you plan additional behavioral studies?……. 27-29

Q. What about behavioral changes, recently observed in mares, attributed to native PZP? …… 29
Q. What about behavioral changes, recently observed in mares, attributed to native PZP? …… 29
Q. Won't mares just keep coming back into estrus (heat) if they don't get pregnant? Won't prolonged estrus cycling make stallions "edgy" and aggressive, creating continuous "unrest?" In the chaos, won't foals be harmed or even killed?…… 29-31
Q. I "live" with wild horses and feel that some of your behavioral studies (measuring PZP effects) are wrong or incomplete. …… 31
Q. I wish the BLM had used a bit of (its research) money or allocated new money to do a study regarding the effects of PZP on the social structure and health of wild horses in the west. …… 31
Q. Isn't the use of PZP "against nature?" Why can't you just leave these animals alone? ……31, 32

OPPOSITION TO PZP

Q. Why are some wild horse advocacy groups so vehemently opposed to PZP? It seems like the perfect solution. …… 32, 33
Q. Aren't you trying to bring wild horses to extinction (using PZP)?…. 33

MEMORANDUM OF UNDERSTANDING
between the Humane Society of the United States and the Bureau of Land Management

After a workshop held in Santa Fe, NM, November 29 and 30, 2005 on wild horse fertility control, the Humane Society of the United States and the Bureau of Land Management have agreed to develop a Memorandum of Understanding to co-operate on: -

1) The further development and wider use of contraception in wild horse populations,
2) Resolve some of the uncertainties being faced in producing the vaccine and ensuring a continuing supply of a safe and effective vaccine,
3) Assist in public outreach on the issues, and
4) Maintain healthy and viable herds in the existing BLM wild horse Herd Management Areas.

"The BLM sees this as a way to reduce horse removals, to place fewer horses in short- and long-term holding facilities, and to achieve budgetary savings," said Don Glenn, Acting Group Manager of the BLM Wild Horse and Burro Program, Washington, DC.

~~~~~~

~~~~~~

Introduction

Two fundamental questions exist…

1) Does PZP harm wild horses?
2) Will its use eliminate entire herds?

The quick answers are that the Food and Drug Administration (FDA), The Humane Society of the United States (HSUS), and animal care committees all carefully review protocols for PZP use, and more than 20 years of data, carried out under these set of rules, clearly show that wild horses are neither injured by this drug, nor do aberrational behaviors occur as a consequence of its application. Too, oversight by The Humane Society of the United States assures that the vaccine is used only to slow reproduction and may not be used for the extermination of entire herds. PZP is designed to bring about short-term infertility and is reversible, if not used beyond five consecutive years. It reduces the need for gathers and preserves the original gene pool in each herd.

Expanding on these central points, the contributors and editor of material presented within this document have aspired to answer, with scientific objectivity, common questions and concerns raised by actual individuals and groups about porcine zona pellucida (PZP) and to provide citations and references that may be accessed through interlibrary loan, or other sources, for further study. Updates and additional questions and answers (Q&A's) will be provided periodically, as research progresses or protocols change.

PZP use in wild horse herds has been studied extensively for more than two decades, with papers published in peer-reviewed scientific journals by experienced reproductive physiologists, equine scientists, wildlife biologists, geneticists, and animal behaviorists, providing a portrayal of safety, high efficacy, and absence of long-term behavioral, physical, or physiological effects from the vaccine. Those involved in the creation of this Q&A have endeavored to produce a factual document of scientific merit, supported by field data, with statistically adequate sample sizes. Data was collected by trained, unbiased individuals, who adhere to established research methodology within his or her respective field.

Questions & Answers

THE PZP VACCINE

Q. What is porcine zona pellucida (PZP), and how does it work to block pregnancy?

A. A non-cellular membrane known as the zona pellucida (ZP) surrounds all mammalian eggs. The ZP consists of several glycoproteins (proteins with some carbohydrate attached), one of which, ZP3, is thought to be the primary component of the sperm receptor (the molecule that permits attachment of the sperm to the egg during the process of fertilization). The PZP vaccine is derived from pig eggs. When this vaccine is injected into the muscle of the target female animal, it stimulates her immune system to produce antibodies against the vaccine. These antibodies also attach to the sperm receptors on the ZP of her own eggs and distort their shape, thereby blocking fertilization. [see Paterson and Aitkin 1990; Miller et al. 2001]

Thus far, PZP has been a promising form of contraception in wild horses and other wildlife for the following reasons:

1. Pregnancy is prevented approximately 9o% of the time in treated animals;
2. The vaccine can be delivered remotely by small darts;
3. Contraceptive effects are reversible (up to five years in wild horses);
4. PZP is effective across many species;
5. No debilitating health side effects have been observed, even after long-term use;
6. No effects on social behaviors have been observed;
7. The vaccine cannot pass through the food chain;
8. It is safe to administer the vaccine to pregnant animals.

Q. How is it made, and who manufactures it?

A. The porcine zona pellucida (PZP) vaccine, used on BLM, U.S. Forest Service, and NPS wild horse mares, as well as within several wild horse sanctuaries, is produced by The Science and Conservation Center (SCC) in Billings, Montana. Each batch is subjected to a qualitative and quantitative quality-control program and shipped under the authorization of an Investigational New Animal Drug (INAD) exemption for wild horses (FDA

8857-G0002) issued to The Humane Society of the United States (HSUS) by the Center for Veterinary Medicine of the Food and Drug Administration. In collaboration with other investigators, The SCC continues to conduct research with the contraceptive vaccine, focusing on the ability to produce larger quantities, and increasing the efficacy of long-term contraception through a single inoculation (see Turner et al. 2002, 2008).

Q. How is the PZP vaccine obtained?

A. Once all necessary authorizations and approvals have been obtained for use of the vaccine, it may be ordered from:

Kimberly M. Frank
The Science and Conservation Center (SCC)
ZooMontana
2100 S. Shiloh Road
Billings, MT 59106
(406) 652-9719 (phone)
(406) 652-9281 (fax)
e-mail: sccpzp@hotmail.com

The vaccine is not commercially available and is provided at 60% of the cost of production, which currently runs about $24/dose. This is the price of the standard, one-year, 100 microgram dose. The 2-3 year vaccine uses considerably more than 100 micrograms, as well as more adjuvant, and includes the added cost of pelleting. The 2-3 year PZP vaccine costs about $200 per dose, plus the personnel costs of administration, which are minor, if horses are being gathered anyway. Compared with the $1,100 - $1,600 it takes to gather, remove, transport, hold, and adopt a horse (or care for it indefinitely), PZP is a bargain.

Q. Are any pigs killed, expressly to produce the vaccine?

A. Pig ovaries are obtained from a slaughterhouse in Iowa, as a by-product of hogs already destined for slaughter. Therefore, no fewer hogs will be killed if the PZP vaccine were no longer made. Major competitors for pig ovaries include Chinese restaurants, and pharmaceutical companies, that use ovarian endocrine components for research and production of products.

_Q_. Is this drug FDA approved and patented? If so, who is making all the profit from its use?

A. In FDA language, “approval” refers to approval for commercial distribution and marketing, and PZP is not a commercial product. No one is profiteering from PZP. The Humane Society of the United States holds the Investigational New Animal Drug exemptions (INAD), which are the oversight process by which FDA compiles data to examine vaccine safety and effectiveness. Basic and applied research that generated most of the knowledge about the vaccine was carried out with public funds (from the National Science Foundation, National Institutes of Health, U.S. Department of Agriculture, Bureau of Land Management, etc.). The research team considers products developed with public monies to be in the domain of the public, and therefore has no intention of commercialization. Therefore, it will always be called "experimental,” under FDA rules, despite the fact that PZP has been studied and field-tested extensively, for safety and efficacy, and is currently being used with more frequency on federal wild horse mares.

However, at the same time, use of public monies for research and development ***does not legally prohibit*** the commercialization of a product. Some researchers are, nonetheless, offended (due to a personal sense of ethics) and will not move forward with commercialization of a product developed with public funds. The rational is that the public has already paid for the product, and commercialization only allows private companies and individuals to profit from sale without having contributed to the process of research, development, and testing.

Because of this, PZP cannot be used on wildlife without the Investigational New Animal Drug exemption, or INAD. Once the INAD from FDA (one for horses, one for deer and zoo animals) was obtained, the INAD was turned over to The HSUS, leaving that organization to deal with the ethical issues. This means that each project – even at the management level – must have a research question attached to it, and The HSUS must approve the project. An added note is that the Investigational New Animal Drug exemption (INAD) issued to HSUS by the FDA requires a sound safety base before it is issued and would never have been issued were there a significant (or even an insignificant) health or safety concern. Therefore, neither HSUS nor The SCC make money from the vaccine. The SCC provides PZP vaccine at cost of production. Coupled with the paperwork required, The SCC actually

loses money. That is why The SCC is a non-profit. Currently, The SCC's annual budget is about $120,000, and PZP income results in less than half of that, meaning that a great deal of vaccine is donated.

The patent issue is a different question, not to be confused with the FDA process. Merck patented PZP in the 1970s, but the patent lapsed, and the technology is no longer patentable. Organon International, a large drug company based in the Netherlands, holds the patent for PZP use in humans, but that application may never take place, as scientists have not yet been able to make an effective synthetic form. Also, the variability in time for infertility reversal is significant and could potentially result in litigation.

In recent years, the FDA has transferred authority for wildlife contraceptives (exclusive of captive zoo animals) over to the Environmental Protection Agency (EPA). In 2009, an application is pending for approval of native PZP for use in wild horses by the EPA.

Q. What groups are on the PZP Contraceptive Research Team?

A. Today, the team consists of The Science and Conservation Center, Billings; Toledo University Medical College, Ohio; University of California-Davis; Tufts University, Medford, Massachusetts; The Humane Society of the United States, Gaithersburg, Maryland and Washington, DC; and the University of Iowa, Ames. Many other individuals contribute to the effort in one form or another. Governmental agencies that can be considered team members include the National Park Service, U.S. Forest Service, U. S. Department of Commerce, and the Bureau of Land Management.

The entire PZP contraceptive effort involves many people, several institutions, and numerous funding agencies. This team works together, bringing many disparate disciplines and talents in concert to solve the problems at hand.

Q. Who Funds PZP Contraceptive Research and Applications?

A. Funding for application of the vaccine to wildlife has been provided by many individual communities, agencies, and organizations, including but not limited to:

- The Humane Society of the United States

- Elinor Patterson Baker Trust
- Geraldine R. Dodge Foundation
- Bernice Barbour Foundation
- Leuthold Family Foundation
- Panaphil Foundation
- Delta-Sonics
- PNC, Inc.
- U.S. Navy
- National Park Service
- Bureau of Land Management
- Rachel Carson National Estuarine Reserve
- U.S. Department of Commerce
- National Institutes of Health
- Fire Island Community Association
- Burkett-Plack Foundation
- Bosack-Kruger Foundation
- Annenberg Foundation
- Cargill Foundation
- THAW Charitable trust
- 112 different zoos in North America, Europe, New Zealand and Australia
- South African National Parks Board
- U.S. Fish and Wildlife Service – African Elephant Conservation Fund
- Fripp Island (SC) Property Owners Association

- Morris County (NJ) Parks Commission
- Franklin County/Columbus (OH) Metro Parks
- and several anonymous donors.

This list is not all-inclusive but provides a picture of the breadth of support for this approach to wildlife management.

Q. Who controls vaccine use in wild horse populations?

A. No agency or organization can use the vaccine without the assent of HSUS, which monitors management plans and the INAD. In fact, the BLM approached the FDA and tried to circumvent HSUS control over vaccine use but was turned down by the FDA. Therefore, oversight and approval by HSUS still exists. No agency or organization will have control of the PZP vaccine in the foreseeable future. Every μg of vaccine that is produced can only be used in projects where HSUS has reviewed and approved a wild horse herd management plan.

All projects in which the vaccine crosses state lines must be on record with the FDA. As explained previously, the authority to carry out these projects is issued by two separate Investigational New Animal Drug documents (INADs) issued by the FDA to HSUS. As each new project is identified, HSUS reviews the need for the project in the context of scientific, ethical, and moral issues, and, if approved, issues permission to proceed. Notification of each project is accomplished by means of a form, filed with the FDA by The Science and Conservation Center, which specifies how much vaccine is being shipped and what species are to be treated. The INAD also requires that data from each project be gathered in a systematic way and filed, and be made available to the FDA when the need arises. These files are maintained at The Science and Conservation Center. Additionally, the legal managers of the horses (NPS or BLM) or the animal care committee of each zoo must also provide permission to treat animals. This regulatory process is similar for any wildlife species not classified as a food animal by the FDA or as a game animal by a state fish and wildlife agency.

Precisely how procedures will change – or remain the same – after EPA assumes regulatory authority, remains to be seen, but the HSUS will hold the approval; thus, we see no major changes at this time (6/09).

Q. Does an agency have to do an environmental assessment (EA) or an environmental impact statement (EIS) prior to using PZP on a wild horse herd?

A. Yes. Environmental Assessments are mandatory for any use by federal agencies. One difference between agencies is that the NPS does a single management EA, that is in force for years, while the BLM does one every five years for application in each herd management area.

Q. What wild horse populations, within the United States, are presently being managed with PZP?

A. The vaccine has been used successfully to manage the wild horse population of Assateague Island National Seashore (ASIS), in Maryland, under the sponsorship and authority of the National Park Service (NPS). The population has been treated for 22 years, without health problems, and the population has decreased by almost 40%, since management-level application began in 1995. Wild horses are also being treated on Cape Lookout National Seashore (Shackleford Banks), North Carolina, for the NPS; on Carrot Island, North Carolina; on the Rachel Carson National Estuarine Reserve, North Carolina; and on many areas of Nevada, for the Bureau of Land Management (BLM). Other treated herds include Return To Freedom (American Wild Horse Sanctuary), Lompac, California; Pryor Mountain Wild Horse Range (Montana/Wyoming); Little Book Cliffs National Wild Horse Range, Colorado; McCullough Peaks Horse Management Area, Wyoming; and Little Cumberland Island, Georgia; International Society for the Protection of Mustangs and Burros Wild Horse Sanctuary, Lantry, SD; Black Hills Wild Horse Sanctuary, Hot Springs, SD, Carson National Forest, NM, and the Navaho and Pima/Maricopa Indian reservations. In Nevada and Wyoming, at least 12 different wild horse herds are being treated "experimentally" to evaluate population effects. For Nevada references, see (1) Turner et al. 2001; (2) Turner et al. 1997; (3) Kirkpatrick et al. 1997; and (4) Kirkpatrick et al. 1997. In March, 2009, The Washington Office of the BLM Wild Horse Program i/ssued a memorandum that directs local horse managers to treat all mares returned to the range.

In the case of the four barrier island herds, the Pryor Mountain Wild Horse Range, Little Book Cliffs Wild Horse Range, and Return To Freedom Wild Horse Sanctuary, horses are treated remotely, with dart guns. In Nevada, they are treated in conjunction with gathers, as most of these HMA's are too large, and the horses too wild to dart.

In addition to controlling the horse population on Assateague Island, treatment has extended the lives and improved the health condition of older mares, by removing the stresses of pregnancy and lactation [see Kirkpatrick 1995; Kirkpatrick and Turner 2002, 2003; Kirkpatrick et al. 1990, 1991, 1992, 1995a, 1996a,b, 1997; Liu et al. 1989; Turner and Kirkpatrick 2002, 2008; Turner et al. 1996a]. Horses on Assateague are doing well. About 125 total animals roamed the area in 2009 (27% less than the starting number of 173 in 1995), and their body conditions have improved significantly since 1990 [Turner and Kirkpatrick 2002]. Mortality almost disappeared for the first eight years of management, and the horses are generating new age classes (large numbers between 20-25 years of age, and a growing population between 25-30).

Thus, at the management level, horses are being treated with PZP for the NPS, Rachel Carson National Estuarine Reserve, the BLM, and at least five private sanctuaries. In addition, new forms of the vaccine are being tested for the BLM in western horses, but not on a management level.

The following HMAs are sites that have been treated with long-acting PZP:

Onaqui Mountain, UT - 56 mares
Sand Springs, OR - 31 mares
Fox-Hog, NV - 28 mares
Green Mountain, WY - 38 mares
Monte Cristo, NV - 53 mares
Blue Wing, NV - 136 mares
Antelope Hills, WY - 28 mares
Black Rock East, NV - 19 mares
Black Rock West, NV - 19 mares
Warm Springs, NV - 27 mares
Antelope Complex, NV - 29 mares
Calico, NV - 92 mares
Groshuite, NV - 44 mares

Granite Range, NV - 79 mares
Nellis Air Force Base Bombing Range, NV (Nevada Wild Horse Range) - 358 mares
McCullough Peaks, WY - 34 mares
Sand Springs, CO - 75 mares
Cedar Mountain, NV - 85 mares

Additionally, another form of the long-acting PZP has been tested in captive mares at Canon City, CO; a reduced dose of PZP was tested successfully in captive mares at Canon City, CO; and a lyophilized form of the vaccine was tested successfully in domestic mares in Clark, WY and Billings, MT.

Q. What herds do you propose to treat with contraceptives in the near future? Why did you choose these particular herds? Who decides? What are your long-term goals?

A. While the PZP vaccine is currently being used on at least 20 horse management areas for the National Park Service or the Bureau of Land Management, its use is appropriate for all free-ranging wild horse herds. Application to particular herds is at the invitation of the managing agency. The long-term goal is to reduce or eliminate the need for gathers and removals.

DELIVERY, APPLICATION, AND BIOLOGICAL EFFECTS OF PZP

Q. How is the vaccine delivered?

A. The PZP vaccine must be injected into the muscle of the target animal. This can be done by hand if the animal is restrained, or by dart, for remote delivery. There are many commercial dart systems available, but the thick viscosity of the vaccine requires a large needle and a quick injection. Thus far, Pneu-Dart® systems (Williamsport, Pennsylvania) seem to work the best. The Pneu-Dart® 1.0 cc barbless darts can be fired from Pneu-Dart® capture guns or from several other commercial dart guns [Pax-Arms® or Dan-Inject®, for instance]. The darts are disposable, and after hitting the animal in the rump or hip (the only acceptable location for darting), they inject by means of a small powder charge, and then pop out. Because of

their bright colors, the darts are usually retrieved in the field. Darts that have not been discharged cannot be discharged by stepping on them or by any other kind of casual contact. Over a six-year period on Fire Island National Seashore, and with more than 1,000 dartings of deer, only two darts have not been recovered.

Normally, each animal is darted twice the first year, with the first injection being given up to a year before a booster, just preceding the breeding season (March for wild horses or September for deer). Thereafter, a single annual booster inoculation will maintain contraception. The second inoculation of the first year requires that…

a. you are able to recognize the individual animals; or

b. you do the first inoculation with a special "marker dart," which leaves a dye mark on the animal at the same time it injects the vaccine; or

c. selected mares are treated to allow for both genetic diversity within a specific herd and for the promotion of health and improved body condition of an individual animal (through temporary infertility).

An alternative strategy is to give only a single inoculation the first year, from which there will be little contraception, and then a single annual inoculation thereafter, from which there will be significant contraception (see McShea et al. 1997; Turner and Kirkpatrick 2002.)

New approaches using small non-toxic, biodegradable lactide-glycolide pellets, that result in several years of contraception after a single application, are being tested. [Turner et al. 2002, 2008].

Q. How would you describe the new pelleted form of PZP-22, and how does it work?

A. PZP is incorporated into lactide-glycolide pellets, small enough to be injected intramuscularly. After injection, the lactide-glycolide erodes (It is biodegradable and non-toxic) and releases the PZP at varying rates, depending on the ratio of lactide to glycolide. It is an injectable version of a contact cold pill. The pellets are made at the School of Pharmacy, University of Iowa. There have been spotty results in horses. It works in some herds and not in others, and it has worked well in deer, but not in elephants. Not all, but much of the data associated with the pellets has

come from helicopter counts, and it is difficult to match foals with mares from a helicopter. After the summer of 2010, more data will be available. Two herds in the Annenberg Foundation project have been treated with pellets. People are on the ground, who are familiar with the horses; so more solid data should be forthcoming.

***Q*. How does the liquid vaccine compare to the pelleted form?**

A. Nothing works as well as a primer dose of native PZP, followed by a booster 2 to 6 weeks later**,** and then annual boosters after that. Efficacy with the pelleted form, even where it has appeared to work, is not as good. The issue, of course, is having to treat mares every few years versus only once.

***Q*. Isn't darting mares painful and potentially harmful or even lethal? Will it result in mares being shot in critical anatomical areas – abdomen or chest, causing inhumane deaths?**

A. As long as only 1.0 cc Pneu-Darts are used, there is almost no risk of injury to the animal. These are very small, light darts. Over a 22-year period, no horse has ever been injured on Assateague Island, the Shackleford Banks, Carrot Island, the Pryor Mountains, or the Little Book Cliffs (translating to well over 1,000 dartings, over the course of 20 years).

On the Pryors, PZP remote-darting operations typically take place in late summer/early fall, and any wild mares receiving the vaccine are individually-identified and tracked regularly with data, non-intrusively gathered on behavior, estrus, fertility, reproduction, survival, and any health concerns. The field studies are conducted by seasonal and term USGS-Biological Resources Division and BLM biological technicians under the supervision of BRD research biologists and the BLM Wild Horse and Burro Specialist.

Several studies of injection site reactions have been carried out. In one study it was shown that of 38 total treated mares, 55% exhibit no reaction to darting, 6% have some level of swelling around the injection site, 22% have a small nodule (granuloma) about the size of a marble, and no animals had abscesses. Only one mare of 38 has ended up with a medium-level swelling, about one year after treatment. In a larger study, data were generated from the records of 329 different horses on Assateague Island, darted over a 19-year period. 1,094 different dartings resulted in a 0.2% abscess rate. The

abscesses healed within two weeks. In another study of captive zoo animals, 1,185 dartings of 25 different species resulted in 16 abscesses (1.3%) (Lyda et al. 2005). In the Pryor Mountains, 151 dartings resulted in 1 abscess (0.7%). At Return To Freedom Wild Horse Sanctuary, in California, 451 dartings of 85 total horses over six years resulted in 15 abscesses (3.0%). At the Black Hills Wild Horse Sanctuary, in 2009, 140 dartings resulted in one abscess (0.7%).

Abscesses typically appear as 25 mm swellings which open and drain within two weeks without complications. More common are granulomas, or subcutaneous nodules, about the size of marbles. These nodules are most notable post-injection but typically disappear over time. Ultimately these nodules are very difficult to discern amongst other natural scars within the coats of these wild mares. Furthermore, there is no indication that the presence of these nodules has compromised the quality of life for these horses. Field technicians have never recorded the mares showing any indication that these nodules are causing any level of discomfort during daily activities and/or interfering with reproductive activities. The granuloma is the counterpart of the smallpox vaccination scar found on humans, but beneath the skin instead of on its surface.

These injection site reactions should be given some context and compared with the same events in domestic livestock. The 1995 Beef Council Quality Audit reported that 11% of cattle inoculated with USDA-approved vaccines produced injection site reactions, including lesions and abscesses. In another study, the Kentucky Beef Council reported that fed cattle had abscess/lesion rates of 3.2-21.6% after vaccinations with USDA-approved vaccines, and in non-fed cattle, the abscess/lesion rate ran from 28.9 to 40.9%.

The most recent study of injection site reactions (Roelle and Ranson 2009) provides some interesting data. In any herd studies, often there are a few horses where abscesses appear more frequently than in other animals. Thus, for some reason, some animals are more prone to abscesses than others, and this often skews the abscess rate within a single herd. For example, in one herd, of a total of six abscesses that appeared after darting, four occurred in the same mare. The other data suggest that vaccinations given by dart produced more abscesses than those given by hand injection. This makes sense, if you consider that hand injections are preceeded by antiseptic swabbing of the skin surface, while field darting simply drives dirt and hair

follicles in to the wound, along with the vaccine. Thus, this all suggests that abscesses may not have any relationshop to the vaccine or adjuvant, but to the delivery method instead.

Q. How do immune system depression issues affect the formation of abscesses and lameness in horses?

We have insufficient data regarding how mares will react if they are in poor condition versus good condition, at least not enough for statistical analysis. Then, we just have visual indexes for body condition scores, from which you can simply infer immune competency; thus, we can offer only anecdotal information. Classic immunology says that animals in poor condition (or stressed for any other reason, as well) will not mount as strong an immune response as unstressed animals. Whether or not this effect will cause poorer efficacy, more abscesses, or other issues, is not known. In zoo animals, where we often administer PZP because of health problems, there seems to be no problem. Next, lameness and abscesses may not be at all associated with the vaccine *per se*. Rather, there is some limited data, by the Science and Conservation Center, and by Jason Ransom, U.S. Geological Survey, Ft. Collins, Colorado, that darted horses will produce more abscesses than hand-injected horses. When you hand inject, you wash the surface of the skin with ETOH. However, when you dart, you drive any surface dirt into the dart puncture. The same problem exists when darting wildlife with anesthetics, rather than vaccine. This issue is not any different from differing efficacies among individuals getting flu shots. In general, about all you can say is that animals with compromised immune systems do not do as well as those with competent systems, and there are many variables associated with what causes immune incompetency.

Q. Will PZP harm mares or foals, physiologically? Have any negative pharmacological side effects been observed? Are any benefits derived from its use?

A. Safety data has been accumulated over 20 years. It essentially says there are no short- or long-term health problems of any kind, and that the vaccine is reversible, unless the mare is treated for more than five consecutive years (in which case you probably didn't want her to reproduce again anyway). The data make clear that pregnancies in progress are not affected in any way by the vaccine, nor is the health or fertility of the foals compromised, once

they are born. Treating mares carrying female fetuses does not affect the fertility of the offspring.

In fact, as mentioned previously, mares on Assateague Island are living longer than ever, and their mortality has decreased, they are achieving new age classes never before seen on the island, and all of this happened because their body condition scores have increased steadily since 1989, when PZP application started. Historically, a mare never survived to 20 years of age, but now a significant percentage have passed twenty, and about 29 animals (20% of the herd) are between 25 and 30 years old. Removal of the stresses of pregnancy and lactation gives them an immense health advantage, both at the younger and older stages of life.

Foal mortality has dropped significantly. This is probably because their mothers, when they finally do become pregnant, after several years of contraception and then withdrawal of PZP treatments, are much healthier. All of this data (derived not from casual observation) is published.

The other victory for horses is that every mare prevented from being removed, by virtue of contraception, is a mare that will only be delaying her reproduction rather than being eliminated permanently from the range. This preserves herd genetics, while gathers and adoption do not. (Kirkpatrick and Turner 2002, 2008; Turner and Kirkpatrick 2002, 2003; Willis et al. 1994.)

Q. Does PZP application create late foaling in treated populations?

A. No. Available data from 20 years of application to wild horses contradicts this claim (Kirkpatrick and Turner 2003). From 1990 to present, Assateague Island has records for 178 horses whose month of birth is known (and in some cases, day of birth known). An examination of the published data, from 1984, of Ron Keiper (retired Distinguished Professor of Biology at Pennsylvania State University and currently Chairman of the Department of Biology at Valencia Community College, Orlando, Florida) in which he looked at eight years of birth dates for the same herd, which at that time was much smaller than we have today (considerably less than 100 horses versus 155) indicates that approximately 85% of the foals were born in April, May and June. Among the 178 horses with known birth dates, 95 were born to mothers who were never treated with PZP, with 70 born in April, May and June (73.6%), and 25 born outside this window. Another 83 foals were born to mares that had at some point been treated with PZP

before their pregnancies, and 65 were born in April, May or June (78.3%), with 18 outside this window. Thus, with a database of 178 horses over an eleven-year period, there is no evidence of late foals being born among treated mothers.

That corroborates published work (Kirkpatrick and Turner 1983), where it was demonstrated that Pryor Mountain wild horses did not extend their season of ovulation even when placed on high planes of nutrition. Mares do not extend their breeding season if they do not get pregnant.

One interesting issue is that the percent of untreated mares giving birth on Assateague Island in the April, May and June window has decreased from 85% down to 74% since 1984. This suggests that as herd size increases, variability in birth dates also increases, but this may simply be a function of larger numbers (in this case a 100% increase in herd size). There is also a moderate pattern among some mares (the N9BF line in particular) with regard to producing foals outside this window. This genetic line was consistently producing foals in March. If that observation is correct (This is only an untested observation.), then it corroborates Eric Palmer's theory that seasonal ovulatory patterns in mares are genetically controlled. In any case, these data, at least, demonstrate that contraception with PZP does not cause early or late births. Once again the Assateague Island (ASIS) horses and the 22-year treatment history produced a wealth of information (Kirkpatrick and Turner 2003).

In the Pryor Mountain Wild Horse Range, the normal foaling period has been well documented (EA #BLM MT010 FY05 -16, figure 10) to primarily take place in May and June, with limited foaling known to happen outside this window, from February to September. Thus, later foaling dates are not considered abnormal.

Q. For how many years is a mare generally treated with PZP?

A: This depends on the management plan of the agency, for a particular herd. Perhaps the most effective plan is the one used on Assateague Island, where all two-year-old mares are put on treatment, and then boosted at three and four years of age. After this, they are removed from treatment until they foal, which might occur anywhere from one to five years later. Mares that have already made their genetic contribution to the herd, in the context of the management plan, are treated until extinction.

***Q*. How do you determine which mares within a herd will be treated?**

A. The question of which mares to treat with vaccine is an important one, and the answer is embodied in the management plan. The approach used on Assateague Island has proven very effective and safe, i.e., two, three and four year olds are all treated and then withdrawn from treatment until they produce a foal. Older mares with good genetic representation in the herd are treated to extinction. Dr. E. Gus Cothran, an equine geneticist from Texas A&M University, College Station, monitors the plan on Cape Lookout. Immunocontraceptive control is more logical (genetically) than removing animals before they have had a chance to reproduce. Genetic representation is the key element within the management plan.

The most important consideration is to ensure that all genetics are represented, whether or not they reflect "wildness" or band stability, phenotype, or whatever social hierarchy exists. The bottom line is that wild horses are native North American wildlife, and humans should not be selecting for anything other than complete genetic representation and kinship.

***Q*. How effective is PZP? Won't some mares still become pregnant after treatment?**

A. PZP treatment in wild horses is about 95+% effective (Turner and Kirkpatrick 2002, 2008). The failure of some horses to respond to the vaccine results from an immune system that either doesn't "recognize" the vaccine's antigen, or from a compromised immune system. This is true for human vaccines as well (consider the less than 100% efficiacy with flu vaccines). Regardless, 95% efficacy is enough to manage wild horse populations effectively. In other species, efficacy varies in a species-specific manner (Frank et al. 2005).

***Q*. Why can't you block pregnancy with just one inoculation instead of the two shots you use now?**

A. The issue of the "one-shot" is complicated. Currently there are tests with SEVERAL forms of a one-shot vaccine. Despite that, this matter clouds the real issue of putting the vaccine to work NOW.

The initial “primer” dose of PZP causes the immune system to “recognize” and type the antigen, not so much for immediate long-term response, but to prepare the animal’s immune system for future exposures to the vaccine. Thus, a booster inoculation is required the first year, and an annual booster thereafter (Liu et al. 1989).

There is a second reason for the need for booster inoculations. Many human and veterinary vaccines use attenuated (weakened) or killed viruses as the vaccine, and these are powerful stimulators of the immune system. Often a single inoculation lasts for years. The PZP, however, is a relatively small protein that is not especially immunogenic. It is also very close in structure to the native PZP on the target animal’s own ova; thus, the target animal has difficulty in “recognizing” the PZP as foreign to the body. This, in turn, means that multiple inoculations must be given, and with a more immunogenic compound, known as an adjuvant (Lyda et al. 2005).

The subject of the one-shot also clouds the bigger topic of management because it only provides an advantage in the first year. After that, the horses are "one-shot" animals anyway. In 1994, almost every mare on Assateague Island was treated with a single shot. That shot was not meant to cause contraception but to set the herd up as a "one-shot" herd in preparation for management a year later. It was done this way because the National Park Service had to do an environmental assessment (EA) before they were allowed to manage with contraception. Then in 1995, the whole herd was managed with only a single shot per animal. The concept is fairly simple, and a "one-shot" vaccine only aids in the first year. Of course, a single inoculation that lasts multiple years would have more utility. (Turner et al. 2002, 2008)

The present advice given to the BLM is plain. Not a single mare that is gathered, for any purpose, and returned to the range should get back on the range without an inoculation. That makes them "one-shot" animals, and the expense of developing "one-shot" vaccines becomes moot. Once they have had that first shot, they can be re-treated anytime with a single shot.

A One-Inoculation Vaccine

Because of the need to inoculate animals twice the first year, and the difficulty of doing this with wild species, research is proceeding toward a "one-inoculation" vaccine. Such a vaccine would permit a single darting to

cause one or more years of contraception. The approach under study incorporates the PZP into a non-toxic, biodegradable material, which can be formed into small pellets. The pellets can be designed to release the vaccine at predetermined times after injection (at one and three months, currently), much the same way time-release cold pills work. Initial trials were encouraging, and continued trials are underway (see Eldridge et al., 1989; Turner et al., 2002, 2008). The downside to this approach is the immense amount of vaccine needed for the production of the pellets and the associated cost. While this approach may have some limited use, the difficulty in producing large amounts of vaccine make it unsustainable. What is needed is either a synthetic form of the PZP antigen or a pellet making process that reduces wastage by at least 65%.

Q. What do you mean by a one-year, two-year, or three-year vaccine?

Response to the PZP antigen is variable among individual mares. Some mares appear to be naturally poor responders to the vaccine and probably never develop sufficient antibody titer levels to confer infertility (hence the 95% efficacy of the vaccine in horses). Research with the Pryor Mountain wild horse herd indicates that immune response in mares may be correlated with age and fitness. One six-year-old mare, contracepted due to poor physical condition in September 2003, responded poorly to the vaccine, conceived in 2004, and foaled in 2005. Similarly, two 16-year-old mares last boostered in 2003, also produced a foal in 2005. Conversely, younger mares in good condition may have a stronger than expected antibody titer response resulting in a longer period of infertility. This appears to be the case with the first young mares treated with PZP on the Pryor Mountain Wild Horse Range (PMWHR).

Immunocontraception is not an exact science. The vaccines are designed to offer an effective time period based on the average response for many numbers of animals. As the treated number of animals increases, then the known response time for a specific formulation of PZP and adjuvant (carrying-agent) becomes better known. There are many variables to consider, the largest factors being animal condition and related immune response. Young PMWHR mares were healthy when injected (though a small sample size), and it would appear the resulting immune response (to a 90% effective one-year agent) has resulted in 2 years of efficacy. Older Pryor mares are relatively worn-out, and immune response appears limited. As such, the vaccine was not effective in a couple of mares. This is also true

with a younger mare that was treated, due her poor condition, but she still produced a foal.

Perhaps animal condition on Assateague Island (ASIS) is such that one year of efficacy is all that results with the same formulation of PZP and adjuvant that has been used on the Pryors. These are questions that still need to be dealt with, which is why the need exists for continued research. These questions are addressed in individual-based study herds within the Wild Horse & Burro Fertility Control Field Trial program and a project funded by the Annenberg Foundation. This is one of the reasons why the efforts on the Pryors have been critical to knowledge of this vaccine for use on western herds.

Q. How long does it take for native PZP to stop population growth in a herd?

A. This depends on the percentage of adult mares treated. On Assateague Island (ASIS), growth was stopped almost immediately. A large number of mares were given the PZP vaccine on ASIS during the first three years (about 87%), and growth stopped quickly. On the Pryor Mountain Wild Horse Range, fewer mares were treated (< 30%), but growth was slowed, as well. So, it depends mostly on the percentage of adult mares treated. However, fertility rates and mortality rates enter into this answer as well. It is precarious to address this any other way than to point out that results are site-specific and cannot be generalized.

Q. How long does it take for PZP to begin reducing a wild horse population?

A. On ASIS, the first sign of population reduction took about eight years, but herd reduction has been moving more quickly since then. The following eight years, herd numbers went down from 175 to 116, without any removal of horses, treating anywhere from 48 % to 79% annually. The lag time between initiation of treatment and decline in numbers is largely a function of increased longevity in treated horses, but, as pointed out above, there are other variable factors involved (fertility rates, mortality rates, sex ratios, and so forth). Fertility rates are average on ASIS (45-60%), and mortality is low (<5%).

***Q*. How can you tell if a wild mare is pregnant, so you don't treat her with PZP?**

A. In some cases, a fecal or urine sample is collected off the ground, or from yellow snow following urination. Reproductive steroid hormone metabolites are measured that tell us, with almost 100% accuracy, which mares are pregnant and which are not. A pregnancy can be diagnosed from 40 days post-conception until the day of parturition, and the animal does not have to be touched. That said, there is no danger to either the mother or the *in utero* foal, if the mare is treated with PZP during pregnancy (Kirkpatrick and Turner 2003, 2007).

***Q*. Is the drug residual in urine or feces or in the dead carcasses of treated mares, where PZP could get into the food chain or cause adverse effects to wildlife, or even contaminate water?**

A. Because PZP is primarily protein, it is readily destroyed in digestion, reduced to amino acids, and therefore cannot pass through the food chain intact and with biological activity (Oser 1965).

***Q*. What about compensatory reproduction in PZP-treated herds?**

Thus far, after 22 years of PZP treatment, there is no evidence for compensatory reproduction in a PZP-treated wild horse herd. This might be an issue if a herd is treated for long periods of time and then all treatment withdrawn, but that flies in the face of an effective management plan (Kirkpatrick and Turner 1991b).

BEHAVIORAL EFFECTS OF PZP

***Q*. Is wild horse behavior affected by PZP use? Are there any effects on motivation or drive, general contentedness, and the emotional stability of mares treated with PZP? Is band social stability affected negatively? Has any aberrational behavior been seen in PZP-treated mares, band stallions, or bands where mares have been treated with a contraceptive? What behavioral studies have been conducted on wild horses, both in eastern and western wild horse herds? Do you plan additional behavioral studies?**

A. After 22 years of treating the ASIS mares, there is still no evidence of altering behaviors. The baseline behaviors of eastern wild horses were the same as western horses. In order to understand this, a great deal of information must be read, which examines wild horse behavior from a variety of sites around the world. A huge body of literature exists on this subject, and a few of the more salient publications include: Berger 1977; Feist and McCullough 1976; Keiper 1976, 1986; Klingel 1975; McCort 1984; Rubnestein 1981; Rutberg 1990; Rutberg and Greenberg 1990; Salter and Hudson 1982. An independent investigator from the National Zoological Park has confirmed earlier results that show no behavioral changes (Powell 2000). Thirty-years of observing wild horses in North America and Australia and New Zealand have revealed no difference in fundamental behavioral structures. On the other hand, the affects of gathers on social behaviors are obvious (Ashley and Holcombe 2001; Hansen and Mosley 2000).

A good start on this subject can be obtained by reading Powell (1999), which reports on a study done by researchers from the National Zoological Park/Smithsonian. They found no behavioral effects, at that time, after almost eight (8) years of PZP treatment. The same results were reported in several of the Assateague Island papers, including (1) Kirkpatrick 1995, and (2) Kirkpatrick et al. 1995. Also, other studies (Fayrer-Hosken et al. 2000; Delsink et al. 2002) showed a lack of behavioral effects of this same vaccine on free-roaming African elephants, which have an even more complex social order than wild horses.

One critic of PZP claims, “The horses [on Assateague Island] seem more listless than western wild horses...” However, this could only be determined by time budget studies, and, in fact, no evidence for this has been found (referenced above). Casual observation of wild horses proves nothing. For example, casual observation has reported that Pryor horses travel less than ASIS horses, but that has no scientific significance. If one understands the biology of PZP, one would never suggest there is a "psychological" impact of the vaccine.

The research has already shown that band structures do not change and neither do hierarchies. The only major change in hierarchies that occurs is when mares get pregnant, and then they drop down the ladder even more. Most wild horse behavioral researchers still don't know how to measure hierarchy rank.

A more recent study (Nunez et al. 2009) on Cape Lookout National Seashore indicated that treated mares change bands more often outside of the breeding season. However, the control group for this study is a group of mares that become pregnant and have their foals removed from them. One could just as easily conclude that removing foals from untreated mares causes the mares to stay with the band for longer durations.

Q. What about behavioral changes, recently observed in mares, attributed to native PZP?

A. After 23 years of experience in the field, using native PZP, researchers observing wild horse mares feel that fundamental wild horse social behavior is not changed by the vaccine. However, other researchers are looking at issues such as "time budgets" to find any potential changes. It is the opinion of long-term PZP researchers, however, that these changes are neither of significance, nor are these studies controlled properly. For example, do time budgets differ for horses on good range as opposed to poor range? No one has looked at this, but if there are differences (and logic tells you there should be differences in time budgets between horses living in knee-deep alfalfa and those scratching out a living in a place like the Pryor Mountain Wild Horse Range), then we might expect the time budget of a chronically treated horse to change from untreated horses because of the better body condition scores of the former. These studies have not been controlled for mares with foals (usually untreated) and those without (usually treated), but the important point is that if the fundamental social structure and behavior do not change, it is of no consequence if time budgets change.

Q. Won't mares just keep coming back into estrus (heat) if they don't get pregnant? Won't prolonged estrus cycling make stallions "edgy" and aggressive, creating continuous "unrest?" In the chaos, won't foals be harmed or even killed?

A. At the heart of this issue is the subjective nature of casual observation. Science is based on data, not informal surveillance. Systematically collected data, reviewed by other scientists, accepted as legitimate, treated appropriately statistically, and published in a recognized journal is the only acceptable means for arriving at generalizable, accurate behavioral information. A good start for understanding the rudiments of behavioral research in social animals can be found in Craig (1986).

In 1983, it was shown (Kirkpatrick and Turner 1983; 1986 a,b) that wild horses do not have the same ovulatory patterns as domestic horses, and that wild horses have well-defined breeding seasons (usually from about late March until July, but this will vary somewhat from herd to herd). Wild mares do not extend their breeding season if they do not become pregnant. Keiper and Houpt (1984) also showed this for Assateague horses. This DOES happen, however, in deer (McShea et al. 1997) but not with wild horses. In 27 years of data collection on Assateague Island, only a single documented incident of a stallion killing another stallion, because of fighting, has been observed. This occurred in the middle of breeding season (late May).

The PZP vaccine does not prevent ovulation in horses and there is some limited data that it might interfere with ovulation in deer, at least after the initial treatments. Wild horses do not come into estrus every month, whether or not they have been treated with a contraceptive. They have a breeding season that barely makes it from April through July. Many wild mares have but a single estrous cycle and some have none in a given year, but they are highly seasonal and do not ovulate year-round, or even half the year.

The implication of the question is that by treating wild horse mares with PZP, they will continue to cycle throughout the year, and that this will cause stallion "unrest," aggression, and potential injury. By contrast, documented evidence shows that mares will NOT continue to cycle if they do not conceive, at least beyond the normal 3-4 month breeding season.

If critics were correct, and PZP did cause “unrest” and continuous cycling, which, in turn, led to worked-up stallions and foals dying as a result of this behavioral turmoil, then any area using PZP would have greater foal mortality. However, after 15 years of management-level treatment on ASIS, foal mortality has decreased. That is a data-driven fact.

Granted… wild horse behaviors are subtle, and individual horses will show a wide range of variability in behavioral patterns. It takes a great deal of observational experience to pick them up. We do know that hierarchies and band fidelity, are not affected by PZP application. We also know that aggressiveness and aberrational behaviors are not caused by PZP use. Perhaps, however, there may be a subtle change in daily routine. However, the larger question is, even if subtle alterations in behavior may occur, this

is still far better than the alternative of wild horses being rounded up, bands broken apart, and all of the other negatives that go with traditional management. These issues need to be put into the perspective of risk-benefit by PZP opponents.

There may be some minor time budget changes, but this was addressed several quesitons above. In any case they are not significant in the world of wild horse behavior.

***Q.* I "live" with wild horses and feel that some of your behavioral studies (measuring PZP effects) are wrong or incomplete.**

A. Living with wild horses and seeing them every day is one thing, but while of interest, this doesn't necessarily hold noteworthy meaning, unless a parameter for study is identified, a hypothesis established, and a means of testing that hypothesis is conducted. Additionally, this still does not indicate a significant behavioral or other casually observed pattern for an individual animal or for a band or herd unless the data is analyzed properly.

***Q.* I wish the BLM had used a bit of its research money or allocated new money to do a study regarding the effects of PZP on the social structure and health of wild horses in the west.**

A. The effects of PZP on social structure and herd health have been studied on herds within the Pryor Mountain Wild Horse Range and Little Book Cliffs Wild Horse Range, and no behavioral changes have been noted, nor have any behavioral changes been noted on wild horses at Return To Freedom (American Wild Horse Sanctuary) in California, where animals are observed daily.

***Q.* Isn't the use of PZP "against nature?" Why can't you just leave these animals alone?**

A. Except in a small number of wild horse herds (such as in the Montgomery Pass herd (Turner et al. 1992), Bordo Atravasado in New Mexico, and a few others), mountain lions cannot predictably predate a sufficient number of wild horses to keep herd levels at population numbers in balance with the carrying capacity of their ecosystem. The potential for both wolf and grizzly bear predation of wild horses is in question, as well,

especially if grizzlies and wolves are delisted from the Endangered Species Act, making grizzlies, wolves, and mountain lions all open to hunting pressures.

OPPOSITION TO PZP

Q. Why are some wild horse advocacy groups so vehemently opposed to PZP? It seems like the perfect solution.

A. Opposition to the contraception arises for several reasons. Wild horse advocates do not trust the BLM with the PZP vaccine, despite assurances that the agency cannot use it without approval from The Humane Society of the United States (HSUS). BLM has inflamed the issue by asking FDA for their own INAD, so they could bypass The HSUS. FDA told the BLM that no more "use" INADs would be issued; so, currently, the agency has no choice but to work with HSUS, unless they are willing to change horses in the middle of the race. The HSUS will permit the use of PZP to manage, even reduce, but not to eliminate wild horses.

This has now led the BLM to seek as many other forms of wild horse contraception as possible, from other groups, but it will take significant time to match the safety data studies that have been generated on PZP over many years.

All wild horse advocates want horses to have a better life, but if this entails a choice between having 130 healthy horses versus 200 living on the nutritional edge (in the event of a drought or a severe winter), some would choose the 130 healthy-horse option, out of (what they see as) concern for the well being of the horses. The irony is that those who seek to control wild horse populations through immunocontraceptive measures often spar with other horse advocates who (in the opinion of PZP supporters) object to what pro-PZP factions perceive as the humane treatment of wild horses. The anti-PZP community, who often question factual information and historic success, distrust the morals of those who strongly profess they care (about the well being of the herds). Pro-PZP individuals and groups believe, with conviction, that the primary motivation behind wild horse contraception is keeping healthy wild horses in the wild, on the land forever, in as natural a state as possible, with minimal interference from humans.

Many of these opponents dislike PZP because they fear it will reduce the herd to lower numbers than they want. That has been the major contention with most gathers. After 22 years of contraception on ASIS, and 15 at the management level, contraception has only been able to reduce that herd from 173 to 116. Zero population growth was achieved, and, to date, there has been no need for gathers, but reduction has been slow. So, there is little danger of massive reductions happening anywhere. Even the event of a catastrophic winter has less danger inherent than most advocates might think. The Pryor Mountain herd in Montana/Wyoming went from about 140 horses to 70 in a tragic winter die-off of 1977-1978, but the population had recovered within three years. The only thing that would have changed, had there been 200 animals instead of 140 is that more animals would have had less to eat, and therefore more would have died. The severity of the winter determined that 70 horses would survive, and not the starting population number.

Q. Aren't you trying to bring wild horses to extinction (using PZP)?

A. The concerns of some anti-PZP wild horse groups over BLM use of the vaccine are justifiable, and the BLM's proposal to use PZP to cause an Oregon herd to approach extinction, and other proposals that have surfaced to use PZP to manipulate herd composition, prove this. These apprehensions are legitimate and acknowledged by PZP researchers. However, Assateague Island data have proven the safety and efficacy of the vaccine, and it is obvious that the BLM is not going to be able to treat 30,000 wild horses to extinction with contraception, especially with continued involvement from The HSUS. Vigilance is important in the continued utilization of the PZP vaccine and in monitoring questionable research studies by state and federal agencies not sanctioned by The HSUS or the BLM, some involving the use of contraceptives that may potentially cause complete sterilization or deleterious effects in mares. Despite the utter rejection of scientific data as a legitimate form of persuasion by some anti-PZP individuals and groups, their hearts are in the right place. They are not the natural enemies of those promoting PZP as a humane management tool. Affable cooperation is needed to resolve issues of wild horse over-population, when and where it legitimately exists, once other means of population reduction have failed or are found to be undesirable.

****

REFERENCES

References below are a sampling of the only known published reports, to date, on the subject of PZP use in wild or domestic horses, or in zebras, wild burros or Przewalski's (Mongolian) horses. However, additional peer-reviewed papers, not listed below, have been published on these topics. Those selected were chosen to support material included in answers to the questions above.

Wildlife, free-ranging and captive, poses and causes serious population problems not unlike those encountered with human overpopulation. Traditional lethal control programs, however, are not always legal, wise, safe, or publicly acceptable; thus, alternative approaches are necessary. Immunocontraception of free-ranging wildlife has reached the management level, with success across a large variety of species. Thus far, the immunocontraceptive research and management applications emphasis have been centered on porcine zona pellucida and gonadotropin-releasing hormone vaccines. Contraceptive success has been achieved in more than 85 different wildlife species, at the level of both the individual animal and the population. At the population management level with free-ranging species, the primary focus has been on wild horses, urban deer, bison, and African elephants. The challenges in the development and application of vaccine-based wildlife contraceptives are diverse and include differences in efficacy across species, safety of vaccines during pregnancy, the development of novel delivery systems for wild and wary free-ranging animals, and the constraints of certain non-contraceptive effects, such as effects on behavior. Beyond the constraints imposed by the public and a host of regulatory concerns, there exists a real limitation for funding of well-designed programs that apply this type of fertility control.

Introduction

While elective contraception of domestic animals can be traced back hundreds of years, more recent contraceptive research has been almost universally associated with human applications. However, in the past 40 years a new application has arisen, involving certain species of both domestic animals[1] and wildlife.[2] In the past decade, increased public concern over unrestrained dog and cat reproduction has stimulated a great deal of research in this area, and issues such as the prevention of pregnancies in feedlot cattle have even brought the commercial agricultural community into the world of contraceptive research.[3] A few of these activities, however, provide methods that are directly applicable to non-domesticated animals. Not surprisingly, wildlife contraception involves a number of diverse challenges not seen with either human contraception or domestic species.

With regard to wildlife contraception, four commonly referenced case studies include wild horses (*Equus caballus*), urban and park cervids such as white-tailed deer (*Odocoileus virginianus*) and wapiti (*Cervus elphus*), African elephants (*Loxodonta africana*) in game parks, and more recently bison (*Bison bison*). There are other examples but these stand out with regard to free-ranging wildlife. A growing number of non-domestic species housed in zoos and wild animal parks could also be included. With rare exception, all are medium to large mammals.

Efforts at controlling wildlife overpopulation by means of contraception began as early as the 1950s, and most research involved natural and synthetic steroids, or a variety of non-steroidal compounds.[4–6] Virtually all of these early attempts, while

© 2011 John Wiley & Sons A/S

pharmacologically successful, ended in failure, for a variety of reasons including toxicity, passage through the food chain, adverse effects on social behaviors, high cost of application, difficulty in delivering the compounds remotely, health risks in pregnant animals, and a host of regulatory issues. Of course, the constraints within these early approaches varied depending on the species. For example, remote delivery was not a requirement for captive exotic species, and behavioral changes were of less importance in urban deer, which were viewed as 'pests' in some quarters. Conversely, remote delivery is a virtual requirement for free-ranging wildlife, and behavioral changes would not be tolerated in social animals such as wild horses and African elephants. Thus, each species and setting brings with it specific needs and limitations. The cumulative effect of all these issues resulted in the realization that contraception with steroid hormones, the method of choice for humans and dogs, was not acceptable across the broader spectrum of wildlife. Steroids remain useful in some captive wildlife contraception efforts but have been abandoned for use in free-ranging wildlife.

It was only with the advent of practical immunocontraception that significant progress in free-ranging wildlife contraception occurred. Immunological approaches were considered for use in wildlife as early as 1987[7] and the earliest recorded attempts at wildlife immunocontraception included a gonadotropin-releasing hormone (GnRH) vaccine tested in wild horses on Cumberland Island National Seashore in 1986.[8] Shortly thereafter, a porcine zona pellucida (PZP) vaccine was tested in domestic and captive wild horses.[9] The results of the GnRH trial were not promising, while the PZP trial provided clear evidence that an immunocontraceptive could successfully inhibit fertility in equids. In relatively rapid succession, trials with PZP were successful in captive white-tailed deer[10–12] and a variety of zoo animals, including Przewalski's horse (*Equus przewalskii*) and Banteng (*Bos javanicus*)[13] Formosan sika deer (*Cervus nippon taiouanus*), axis deer (*Cervus axis*), Himalayan tahr (*Hemitragus jemlahicus*), Roosevelt elk (*Cervus elaphus roosevelti*), muntjac deer (*Muntiacus reevesi*), and sambar deer (*Cervus unicolor*)[14] and African elephants (*Loxodonta africana*) (J. F. Kirkpatrick, unpublished data).

Identifying an effective vaccine was only the initial step in developing a population management for wildlife. Very early it was recognized that the major challenges in wildlife contraception included (i) identifying successful contraceptive agents in captive animals, (ii) documenting safety associated with successful agents, (iii) developing a means of delivering these agents to free-ranging wildlife, and (iv) actually altering populations. With the success of PZP-induced fertility control in captive animals, which addressed the first of the four challenges, the next and more challenging step was the implementation of actual field trials with free-ranging animals. While the strategy remained the same, this represented a major change in tactics and one that is still underappreciated. Fortunately, one of the major advantages of immunocontraception became obvious during captive animal trials, which was the ability to deliver contraceptive doses in very small volumes, which could be delivered remotely. This is now recognized as a key requirement for practical wildlife contraception.

The first field trial of wildlife PZP immunocontraception occurred on Assateague Island National Seashore, a barrier island off the coast of Maryland 23 years ago. This trial proved successful in inhibiting fertility in wild horses.[15] Aside from demonstrating a high degree of contraceptive efficacy, this initial study proved beyond a doubt that the vaccine could be delivered remotely, without any handling of animals. It also demonstrated the safety of the vaccine in pregnant animals[15] and that fertility inhibition could be maintained with annual booster inoculations.[16]

The first field trial with white-tailed deer occurred at the Smithsonian Institute's Conservation and Research Center at Front Royal, VA.[17] Deer were captured, tagged, and given a primer dose of PZP and then released. Subsequent booster inoculations were given remotely via small 1.0 cc darts. As with earlier captive trials, the vaccine proved efficacious (85%) and remote delivery proved successful. In the case of both the wild horse and deer field trials, animals received a 65- to 100-μg primer dose emulsified with Freund's complete adjuvant (FCA) and a booster inoculation of 100-μg PZP emulsified with Freund's incomplete adjuvant (FIA). The first field trial with free-ranging African elephants occurred in 1996, in the Kruger Park, in South Africa. Animals were immobilized from a helicopter, given ultrasound examinations to determine pregnancy status, collared and hand injected with a 600-μg primer dose of PZP + a component of Ribi® adjuvant.[18] Subsequent booster inoculations occurred by remote

© 2011 John Wiley & Sons A/S

treatment. Results were positive but efficacy was lower (75%) than with horses and deer. A change of adjuvants, to Freund's modified adjuvant (FMA), increased efficacy to 100%.[19,20] Since the completion of these trials, management level application of the PZP vaccine has been successful in altering entire populations, stopping population growth and even decreasing populations, of wild horses,[21] urban deer,[22] wapiti,[23] and African elephants.[19,20]

Safety

At this point, attention turned to safety issues. The questions at hand were (i) did PZP alter ovarian function, (ii) were the contraceptive effects reversible, (iii) were there adverse behavioral effects of PZP immunocontraception, and (iv) were there any short- or long-term adverse physical side effects?

A major advantage of zona proteins as immunogens is the absolute lack of cross-reactivity with other tissues and protein hormones.[24–26] Additionally, the site and mechanism of action (see Clark and Dell[27] for an eloquent discussion of the mechanism of action supporting zona vaccines) is as far 'downstream' for most of the reproductive processes as possible, such that the sequelae of reproductive events that are disrupted are inconsequential. This is essential for wildlife species but may be considered a disadvantage if the target animals are domestic species, such as dogs and cats, where extinguishing undesirable behaviors is as much a goal as contraception.

The safety of PZP immunocontraception was confirmed for horses, deer, and elephants through a series of follow-up investigations. Ovarian endocrine function was monitored in treated wild mares via urinary steroid metabolites,[28] and it was shown that there were no permanent or significant changes in ovarian endocrine parameters and estrous cyclicity even after long-term treatment.[29–31] This is consistent with the accepted theory of the mechanism of action of zona proteins.[32] Later studies in wild horses confirmed the safety of PZP use in pregnant mares[33,34] and reversibility of contraceptive action, at least through five consecutive years of treatment,[33] demonstrated increased body condition[35] and increased longevity in mares treated chronically,[36] and no significant changes in fundamental social organization or behaviors.[37] Two more recent studies found that PZP treatment resulted in less band fidelity among treated mares outside the breeding season[38] and minor changes in time budgets among treated mares.[39] However, the former study was not controlled for pregnant animals or mares that had foals removed annually. The latter study found that most behavioral changes were associated with changes in body condition or the presence of foals. Considering that untreated mares have more foals than treated mares, and that treated mares develop better body condition than untreated mares, small changes in time budgets would be expected. Ultrasound examinations of ovaries and uteri from PZP-treated elephants also revealed a lack of negative effects.[18,20]

While no long-term negative health effects were detected in PZP-treated wild horses, there was some concern over injection site reactions. Because of the homology of the zona glycoproteins across many mammalian taxon groups, PZP is a poor immunogen. Thus, a powerful adjuvant is necessary and between 1988 and 1998, FCA was the adjuvant of choice for initial inoculations, followed by booster inoculations of PZP + FIA. In reality, as long as inoculations were given in the rump or hip, injection site reactions were uncommon; however, there was concern over causing false tuberculosis-positive tests among some species of animals treated with FCA (there is no TB test for equids; thus, this was not a problem in these species). As a result, for initial inoculations, a new adjuvant was utilized with PZP in wild horses, and later among other species as well. FMA, which utilizes the fractionated cell walls from *M. butyricum*, a common soil bacterium with no known pathologies associated with it was tested and proved to be as efficacious as FCA.[40] Thus, this is the adjuvant of choice since 1998. Rare injection site reactions still occur after inoculation, even with FMA or FIA, but seldom exceed 1%.[40] One study[41] demonstrated a higher incidence of injection site reactions in horses treated remotely, with darts, than those treated by hand-injection. This suggests that injection site reactions may be as much a function of delivery as the actual vaccine. Delivery by dart must result in surface bacteria and debris being pushed into the injection site. In the absence of either short-term or long-term health issues, PZP contraception is now common in free-ranging and sanctuary wild horses, urban deer, zoo animals, and African elephants. Other safety issues have been reviewed in more detail elsewhere.[42]

Other immunogens have been used in horses but thus far none have been applied to free-ranging wild

© 2011 John Wiley & Sons A/S

horses except in small-scale research trials. Several approaches targeted the stallion. GnRH vaccines have demonstrated that testicular function can be suppressed in the stallion.[43,44] However, the application of these vaccines to wild horses is contraindicated because of the suppression of testosterone-mediated reproductive behaviors, which are necessary for holding breeding bands together in the face of competition from other stallions. The entire social structure of wild horses is disrupted if the dominant stallion is chemically castrated. Further, studies have shown that control of dominant males, by means of vasectomy, in wild horses is not effective because this increases the reproductive success of bachelor stallions.[45] A second problem associated with targeting the male of the species, is that, if it is not a harem-based social structure, nearly every male in the population will need to be treated, and this is probably not logistically possible. Thirdly, the removal of functioning males from the breeding population may have far more serious genetic consequences that treating females[46,47] and certainly provides less management flexibility.

Three commercial GnRH vaccines have shown success in suppressing reproduction in mares. Both Equity® (Pfizer Animal Health, Sandton, South Africa) and Improvac® (CSL, West Ryde, NSW, Australia) suppressed cyclic activity in mares.[48,49] GonaCon®, a GnRH vaccine developed by USDA, primarily for use in deer, was tested in captive wild mares and also was successful in blocking cyclic activity and ovulation.[50] A fourth commercial GnRH vaccine, Repro-BLOC® (Amplicon Vaccine, Pullman, WA, USA) has been developed as an alternative to castration in cattle. This latter vaccine utilizes a series of GnRH genes, which were cloned into an ovalbumin carrier via an *Escherichia coli* expression vector. Aside from trials in cattle, Repro-BLOC® has been used to suppress estrus in captive Asian elephants and proposed as a contraceptive for this species;[51] however, five serial inoculations were required to achieve adequate anti-GnRH titers. Despite contraceptive success, and clear potential applications to several other species, the application of GnRH vaccines to wild horses brings to the fore issues that usually are not considered with human contraception. The complex evolutionary social organization of horses and other equids is driven to a large degree by reproductive steroids. In the case of GnRH vaccines, the result is, although temporary, a non-surgical castration. Public opinion, which directs so many aspects of contraception, human, or wildlife, requires in the case of wild horses an intact set of social behaviors. The same is true for elephants and most captive exotic species in zoos.

Other potential safety issues regarding GnRH vaccines remain. Safety for use in pregnant animals remains a species-specific issue. In those species that rely on pituitary Luteinizing hormone (LH) to maintain the corpus luteum of pregnancy throughout the entire gestation period, GnRH will cause abortion. This is not an issue in a species such as the horse, where placental hormones take over the task of supporting pregnancy, but use in bovids, for example, such as the bison, or during the first half of pregnancy in the goat family would interfere with pregnancies in progress. More troubling, however, are a variety of other issues associated with any vaccine that blocks GnRH. It has now been demonstrated that GnRH receptors exist in a variety of tissues throughout the mammalian body, including the cerebellum,[52] bladder,[53] and cerebrospinal fluid.[54] Now recognized as a form of neurotransmitter, GnRH has physiological effects throughout the central nervous system. GnRH activity in the hippocampus has been implicated in Alzheimers-like syndrome. GnRH activity can alter olfactory function, which is, of course, vital in the reproductive process for so many wildlife species. In the cerebral cortex, GnRH can cause depressed activity, and in the cerebellum GnRH has a correlative link to two genetically based disorders, including Gordon–Holmes Syndrome and Boucher–Neuhauser Syndrome. In the pituitary, it has also been demonstrated that GnRH affects more than just gonadotropic cells.[55] The action of GnRH in cardiac tissue, which is exceptionally rich in GnRH receptors, may also be an important safety issue. At least two studies have demonstrated a serious and negative effect on cardiac function and in men, blocking GnRH can place the patient at greater risk for coronary infarction.[56,57] Whether or not these particular safety issues have any clinical relevance to free-roaming or captive wildlife remains to be seen. However, it becomes intuitive that vaccines that exert their influence further 'upstream' in the reproductive process and which have interactions with non-reproductive tissues will be more problematic than those with target tissue specificity and that exert their effects further 'downstream' in the reproductive process.

In white-tailed deer, safety issues relating to PZP largely paralleled those of wild horses, but with

© 2011 John Wiley & Sons A/S

some exceptions. Reversibility of contraceptive action occurred after 1–3 years in captive PZP-treated deer[11] and after 1–4 years in another study with captive deer.[12] An earlier study demonstrated that there were no changes in ovarian histology, but that the breeding season was extended by one to 2 months in PZP-treated deer.[17] In one study, this resulted in a pulse of late births the first year, but in subsequent years, the late births did not occur.[58] Treated deer were more active than untreated deer but did not spend more time feeding. Despite the increased activity, treated deer gained significantly more weight by the summer following treatment than untreated deer, presumably because of avoidance of lactation, but by the following fall, all weight differences disappeared.[59,60]

Potential changes in ovarian histology were a concern. Prior to application of PZP vaccines to wildlife, some temporal changes in ovarian function were shown to occur in PZP-treated non-human primates[61] and mice,[62] but long-term effects did not occur. Early studies with PZP-treated dogs revealed significant changes in ovarian histology.[63] Another study[64] demonstrated similar effects in PZP-treated rabbits, along with a depletion of primordial follicles. Among PZP-treated sheep, significant changes in the ovarian histology were found.[65] The dog study was probably compromised by a rather impure PZP, and the rabbit and sheep studies revealed species differences in response to the PZP. Collectively, this research raised an issue of concern as wildlife contraception moved forward and into the realm of management.

In the first trial with PZP and horses,[9] no changes in ovarian histology were found, and other investigators had demonstrated ovarian weights and histology were unchanged after PZP treatment of white-tailed deer.[17] In another study[66] ovarian eosinophilic oophoritis was found in six of eight treated deer, but this rate was not significantly different from controls. This same study revealed that this condition is common in untreated deer at the time of ovulation. Despite the absence of any significant changes in ovarian histology in wildlife studied thus far, it is vital that each species be evaluated for potential changes. Blood chemistry studies in treated white-tailed deer revealed only a few significant changes after PZP treatment, but none was associated with any physiological abnormalities.[66,67] Ongoing studies with Dall sheep (*Ovis dalli*)) and domestic goats (*Capra hircus*) reveal the same lack of blood chemistry changes in these two species.[42] Injection site abscesses were found in only 2 of 353 deer (0.5%)[68] and 100% of PZP-treated deer revealed granuloma formation at the injection site[66] but without any complications.

Efficacy

A major challenge in the development of human immunocontraceptives is the variability in immune responses by individuals, similar to that which is evident in so many prophylactic vaccines, such as influenza. It is unlikely that humans will use contraceptives with efficacy as low as even 95%. There are individual differences within a species in reactions to contraceptive immunogens. For example, examining the anti-PZP antibody titers from several groups of horses,[40] wapiti[69], fallow deer (*Cervus dama*),[70] and white-tailed deer[11] treated with PZP reveals a significant difference in response to the same immunogen, the same dose, and the same adjuvant. However, for wildlife populations, a variety of modeling[71] and results from field trials[21] have demonstrated that contraceptive vaccines with less than 100% effectiveness will suffice.

Clearly there are species differences as well. For wild horses treated with native PZP, efficacy is approximately 95% over 23 years.[21] In the case of white-tailed deer, there is more variability,[11,22] with an efficacy of approximately 75%. Among PZP-treated wapiti, efficacy ranged from a low of 84% to a high of 90%.[23] African elephants in one population have responded with a 100% efficacy over 10 years of management.[20] Among captive exotic species, efficacies ranged from lows of 70% in Sambar deer (*Cervus uniciolor*) to highs of 100% in addax (*Addax nasomaculatus*), gerenuk (*Litrocranius walleri*) markhor (*Capra falconeri*) bighorn sheep (*Ovis canadensis*), mountain goats (*Oreamnos americanus*), and several other ungulates.[72] Thus, a major challenge to the development of wildlife immunocontraceptives is the ability to inhibit fertility across diverse species. GonaCon-B® and SpayVac® have both been associated with efficacies in the ranges of 39–64% and 27–48%, respectively, in wild horses[73] while SpayVac® was associated with 100% efficacy in fallow deer over 3 years.[74] The GnRH vaccine Improvac®, when given to domestic mares in two inoculations over 35 days provided 100% efficacy with cycling and ovulation as the endpoints.[48]

This latter issue reflects both a strength and weakness of PZP immunoconception, and for that matter

© 2011 John Wiley & Sons A/S

any immunocontraceptive targeting some reproductive tissue (ovum, sperm or pituitary cell) or protein hormone (GnRH). Unlike reproductive steroids, which have absolute homology across species, protein hormones reveal amino acid differences across species. In the case of PZP, there must be an immune response to an epitope of either or both the PZP-1 and the PZP-3 alpha glycoprotein for a successful antibody response and effective contraception. In the case of white-tailed deer, anti-porcine ZP antibodies recognized several epitopes of both the ZP-1 and ZP-3 glycoproteins[75,76] but in domestic cats, the same antibodies do not recognize any segment of the zona glycoproteins.[77,78] While a species-by-species analysis of cross-reactivity with PZP-induced antibodies has not occurred, it is clear that species-specific epitopes vary across taxonomic lines and will affect the contraceptive efficacy of the immunogen. Thus far, PZP-induced contraception has not failed in any of 64 members of Ungulata in which it has been attempted, whether members of Perissodactyla or Artiodactyla,[42] or bears[72,79] or pinnipeds.[72,80] This implies some evolutionary relationships among the epitopes of the zona sperm receptor. Although not directly related to contraceptive research, the application of zona proteins from, and directed toward, a variety of species across broad taxonomic lines will surely reveal interesting evolutionary pathways in the development of the sperm receptor.

Duration of contraceptive action

Vaccines generally, but not universally, employ killed or attenuated virulent organisms and the immune response by humans and domestic animals is very powerful, with lasting effects even after a single inoculation. In contrast, contraceptive vaccines generally target reproductive hormones or tissue receptors, and the ability to cause long-lasting elevations in antibodies, individual differences notwithstanding, is far more challenging, because of the relative homology of these protein molecules between species. It is intuitive that a single inoculation, long-lasting contraceptive vaccine is valuable and a worthy goal for free-ranging wildlife.

The current major shortcoming of the most widely used wildlife contraceptive, PZP, is that contraceptive duration is short-lived, at least during the first few years of treatment. An initial inoculation followed by a booster inoculation 2–6 weeks later generally provides a year of contraception. But then, an annual booster is required for a second year of contraception. At least for the first 2–3 years, this is a requirement for successful contraception. Following 3 years of treatment, the duration of high antibody titers is sufficient for successful contraception over several years and eliminates the need for annual booster inoculations. For example, in the wild mare, 3 years of treatment, from age 2 through 4, result in contraception that lasts for a mean of 3.7 years. However, the range is 1–8 years.[33]

This shortcoming of native PZP has stimulated a search for more lasting contraceptive vaccines. Several approaches to this challenge have occurred. The first approach has attempted to incorporate the PZP glycoprotein in biodegradable, non-toxic matrices, which can be injected and which then release the PZP molecule slowly in a sustained release or in pulsed releases. The matrix used thus far has incorporated various ratios of lactide-glycolide, either in the form of microcapsules[81] or in the form of small pellets that can be injected either by hand or by dart.[82–84] Results thus far have been encouraging, but not definitive, and a great deal of variability in both the manufacturing process and the results has resulted. Another difficulty with this approach is that it has not been possible to incorporate powerful oil-based adjuvants in the microcapsules and pellets.

A second approach has incorporated a novel 'packaging' of the PZP. In the case of a proprietary product, SpayVac®, native PZP is incorporated into a multilamellar liposome. This platform appears to provide a much longer duration of high antibody titers and contraception in seals,[80] fallow deer,[74] white-tailed deer[85,86] and horses.[71] Contraceptive duration appears to last for at least 3 years following a single treatment. The primary drawbacks to this approach appear to be the high viscosity of the preparation and the inability to deliver it remotely, and possible side effects on reproductive tissues,[50] at least in horses. The former is a technical problem and may be overcome, and the latter requires substantially more safety testing before this approach becomes practical. Nevertheless, an important point here is that native PZP vaccine must not be confused with more complex vaccines containing PZP.

A third approach that has shown promise is the GnRH vaccine GonaCon®. This vaccine targets the GnRH molecule and blocks ovulation and estrus by preventing endogenous GnRH from stimulating FSH and LH producing cells of the pituitary. In turn, the lack of gonadotrophs inhibits ovarian and testicular

© 2011 John Wiley & Sons A/S

function and gamete production. As with PZP, there are structural differences in the GnRH of various species, with varying degrees of homology. This means that the vaccine will work in some species but not as well or at all in others. GonaCon® was developed primarily for application to white-tailed deer,[12,87–90] but also works in wapiti,[91] swine,[92] and horses.[50] In the case of GonaCon® the longer lasting duration of antibodies has been accomplished by the addition of aromatic amino acids to the structure, which enhances immunogenicity but without interfering with binding to pituitary receptors. Puzzling, however, trials with free-ranging deer resulted in significantly lower efficacy than those with captive animals.

Alternatives to longer acting vaccines have examined delivery systems. As early as 1993, the idea was put forward to engineer the genes for immunogenic proteins into bacterial or viral vectors.[93–95] Known collectively as genetically modified organisms (GMO), the theory was that a gene for an immunogenic molecule that causes fertility inhibition, such as PZP, or GnRH, might be engineered in a non-pathogenic virus, which could then be used to infect the target species and express the gene. There are multiple questions associated with this technology. Can the vector persist for a long enough time to express the immunogen? Could the vector express the immunogen in sufficiently large quantities to elicit adequate antibodies? Will the vector reach a sufficiently large portion of the population to alter density?[96] Research followed that examined a number of possibilities. Cloned genes for PH-20, LDH-C4, and ZP3, all of which encode for gamete proteins were proposed for incorporation into GMO vectors,[97,98] but none ever reached the field test stage. Significant issues of regulation were raised for a contraceptive method that, once released into the environment, could never be called back.[99] The issue of mutation rates in viruses, and the potential for the vector to infect non-target species, was also an issue. For example, a vector that could successfully infect and cause contraception in non-native foxes in Australia would probably also bring about the same result with domestic dogs. One study concluded that the effort to assess risks of contraceptive GMOs would be greater than the effort to develop the technology.[99] These and many other concerns have led to a cessation of this line of research for wildlife immunocontraceptives and have been summarized elsewhere.[100–102]

Table I Comparison of Zona Protein and Anti-GnRH Contraceptive Vaccines

Parameter	ZP	Anti-GnRH
Efficacy	80–100%[a]	39–100%[a]
Male	–	+
Female	+	+
Reversibility	+[b]	+[c]
Remote delivery	+	+
Safety in pregnant animals	+	Species Dependent[d]
Passage through food chain	–	–
Target tissue specificity	+	–
Debilitating side effects	–	??[e]
Behavioral effects	Minor	Major
Available as a synthetic	–	+

[a]Values are for horses and deer; beyond those, efficacy is variable depending on the species.
[b]Reversible through five consecutive years of treatment; not reversible after 7 years of consecutive treatment.
[c]Long-term data not available.
[d]Species in which the corpus luteum of pregnancy is supported by pituitary LH will abort if treated with an anti-GnRh agent.
[e]Long-term data not available.
GnRH, gonadotropin-releasing hormone; LH, Luteinizing hormone.

One exception to this trend is a research effort in New Zealand.[103,104] Here, the vector is a nematode parasite *Parastrongyloides trichosuri* and the target species is the invasive brushtail possum (*Trichosurus vulpecula*). The parasite is species-specific and mutation into some form that might infect other species is unlikely. If a gene for a contraceptive protein can be engineered into this parasite, and can be expressed effectively, it may open the door to similar approaches in other species. Of course, there is no guarantee that this particular parasite could not find its way to Australia and infect native possums.

One final approach to the problem of long-term immunocontraception of wildlife remains. Oral delivery of a contraceptive vaccine would overcome the need for laborious delivery systems currently necessary for sustained antibody titers in target animals.[105] Currently, this approach is not a practical reality, but the challenges have been clearly delineated. First, either the contraceptive vaccine itself has to be species-specific or the oral delivery system must be species-specific. Approaches under consideration include transgenic plants[102] and bacterial ghosts,[106] both carrying genetic information for a contraceptive immunogen. The research challenges

© 2011 John Wiley & Sons A/S

are immense and the regulatory hurdles daunting, and it is unlikely that this approach will bear fruit for many years to come.

Conclusions

Immunocontraception for wildlife management has become a reality since its first application in 1988. Today, animals treated annually number in the thousands, and controlled alterations in population size are occurring in various settings at ever-increasing frequency. The most widely used wildlife contraceptive is native porcine zona protein, largely because of its ability to inhibit fertility in such a large breadth of species, its tissue-specific action, and because of its impressive safety record. Currently six different free-ranging wildlife species are being managed by means of PZP immunocontraception on 52 sites and 76 captive exotic species are being treated in 67 zoological gardens around the world. Several GnRH vaccines show promise, but widespread application will have to wait for more extensive safety testing. Table I summarizes and compares the major characteristics of PZP and anti-GnRH vaccines. The extraordinary success with actual field applications of wildlife immunocontraception over the past two decades has created a new paradigm. Only 23 years ago, the primary question was whether or not we could economically deliver, safely treat, and effectively regulate wildlife populations with vaccine-based contraception. Today, the new question is how we can achieve this goal easier, with less effort and cost and gain public approval at all levels. The remaining challenges now center on improving delivery systems, modifications of the vaccine components to enhance the duration of effectiveness, assuring comprehensive safety, developing a sustainable funding base for research, and achieving general acceptance.

Acknowledgments

The authors gratefully acknowledge the effort of Drs. Bill L. Lasley, Allen T. Rutberg, and Wolfgang Jochle, who reviewed the manuscript and offered helpful comments. We also offer special thanks to Dr. Donal Skinner for providing numerous helpful references.

Contributors

Jay F. Kirkpatrick, Ph.D. is Director of The Science and Conservation Center, Billings, Montana and holds a Ph.D. in reproductive physiology from the New York State College of Veterinary Medicine at Cornell University, Ithaca, New York.

Allen T. Rutberg, Ph.D. is a Research Assistant Professor, Center for Animals and Public Policy, Cummings School of Veterinary Medicine at Tufts University, North Grafton, Massachusetts; and Consultant and Senior Research Scientist for The Humane Society of the United States. Dr. Rutberg holds a Ph.D. in zoology from the University of Washington (1984) and an A.B. in biological anthropology from Harvard College (1976).

Linda Coates-Markle was, formerly, the Montana/Dakotas Wild Horse and Burro Specialist and the Wild Horse and Burro National Research Coordinator, Bureau of Land Management, Billings Field Office, Billings, Montana. She is now with the BLM's Division of Rangeland Resources as the Society of Range Management Liaison in Wheat Ridge, Colorado.

Compiler and Editor

Patricia M. Fazio, Ph.D. is an environmental writer and editor. Dr. Fazio holds a B.S. in animal husbandry/biology from Cornell University (1964); an M.S. in environmental history from the University of Wyoming, Laramie (1982); and a Ph.D. in environmental history from Texas A&M University, College Station (1995). Her dissertation was an establishment history of the Pryor Mountain Wild Horse Range (1968), in Montana/Wyoming.

Aknowledgements

The compiler and editor wishes to express heartfelt appreciation to Dr. Jay F. Kirkpatrick, Dr. Allen T. Rutberg, and Linda Coates-Markle for providing answers to complex scientific questions in a professional, obliging manner.

INTRODUCTION…… 7

THE PZP VACCINE

Q. What is porcine zona pellucida (PZP), and how does it work to block pregnancy?…… 8
Q. How is it made, and who manufactures it?…… 8, 9
Q. How is the PZP vaccine obtained?…… 9
Q. Are any pigs killed, expressly to produce the vaccine?…… 9
Q. Is this drug FDA approved and patented? If so, who is making all the profit from its use?……. 10, 11
Q. What groups are on the PZP Contraceptive Research Team?……. 11
Q. Who Funds PZP Contraceptive Research and Applications?……. 11-13
Q. Who controls vaccine use in wild horse populations?…… 13, 14
Q. Does an agency have to do an environmental assessment (EA) or an environmental impact statement (EIS) prior to using PZP on a wild horse herd?…….. 14
Q. What wild horse populations, within the United States, are presently being managed with PZP?…… 14-16
Q. What herds do you propose to treat with contraceptives in the near future? Why did you choose these particular herds? Who decides? What are your long-term goals?…….. 16

DELIVERY, APPLICATION, AND BIOLOGICAL EFFECTS OF PZP

Q. How is the vaccine delivered?…… 16, 17
Q. How would you describe the new pelleted form of PZP-22, and how does it work? …….. 17, 18

Q. How does the liquid vaccine compare to the pelleted form?..... 18
Q. Isn't darting mares painful and potentially harmful or even lethal? Will it result in mares being shot in critical anatomical areas – abdomen or chest, causing inhumane deaths?…….. 18-20
Q. How do immune system depression issues affect the formation of abscesses and lameness in horses? ……. 20
Q. Will PZP harm mares or foals, physiologically? Have any negative pharmacological side effects been observed? Are any benefits derived from its use?……. 20, 21
Q. Does PZP application create late foaling in treated populations?.. 21, 22

MEMORANDUM OF UNDERSTANDING
between the Humane Society of the United States and the Bureau of Land Management

After a workshop held in Santa Fe, NM, November 29 and 30, 2005 on wild horse fertility control, the Humane Society of the United States and the Bureau of Land Management have agreed to develop a Memorandum of Understanding to co-operate on: -

1) The further development and wider use of contraception in wild horse populations,
2) Resolve some of the uncertainties being faced in producing the vaccine and ensuring a continuing supply of a safe and effective vaccine,
3) Assist in public outreach on the issues, and
4) Maintain healthy and viable herds in the existing BLM wild horse Herd Management Areas.

"The BLM sees this as a way to reduce horse removals, to place fewer horses in short- and long-term holding facilities, and to achieve budgetary savings," said Don Glenn, Acting Group Manager of the BLM Wild Horse and Burro Program, Washington, DC.

~~~~~~

Introduction

Two fundamental questions exist…

1) Does PZP harm wild horses?
2) Will its use eliminate entire herds?

The quick answers are that the Food and Drug Administration (FDA), The Humane Society of the United States (HSUS), and animal care committees all carefully review protocols for PZP use, and more than 20 years of data, carried out under these set of rules, clearly show that wild horses are neither injured by this drug, nor do aberrational behaviors occur as a consequence of its application. Too, oversight by The Humane Society of the United States assures that the vaccine is used only to slow reproduction and may not be used for the extermination of entire herds. PZP is designed to bring about short-term infertility and is reversible, if not used beyond five consecutive years. It reduces the need for gathers and preserves the original gene pool in each herd.

Expanding on these central points, the contributors and editor of material presented within this document have aspired to answer, with scientific objectivity, common questions and concerns raised by actual individuals and groups about porcine zona pellucida (PZP) and to provide citations and references that may be accessed through interlibrary loan, or other sources, for further study. Updates and additional questions and answers (Q&A's) will be provided periodically, as research progresses or protocols change.

PZP use in wild horse herds has been studied extensively for more than two decades, with papers published in peer-reviewed scientific journals by experienced reproductive physiologists, equine scientists, wildlife biologists, geneticists, and animal behaviorists, providing a portrayal of safety, high efficacy, and absence of long-term behavioral, physical, or physiological effects from the vaccine. Those involved in the creation of this Q&A have endeavored to produce a factual document of scientific merit, supported by field data, with statistically adequate sample sizes. Data was collected by trained, unbiased individuals, who adhere to established research methodology within his or her respective field.

Questions & Answers

THE PZP VACCINE

Q. What is porcine zona pellucida (PZP), and how does it work to block pregnancy?

A. A non-cellular membrane known as the zona pellucida (ZP) surrounds all mammalian eggs. The ZP consists of several glycoproteins (proteins with some carbohydrate attached), one of which, ZP3, is thought to be the primary component of the sperm receptor (the molecule that permits attachment of the sperm to the egg during the process of fertilization). The PZP vaccine is derived from pig eggs. When this vaccine is injected into the muscle of the target female animal, it stimulates her immune system to produce antibodies against the vaccine. These antibodies also attach to the sperm receptors on the ZP of her own eggs and distort their shape, thereby blocking fertilization. [see Paterson and Aitkin 1990; Miller et al. 2001]

Thus far, PZP has been a promising form of contraception in wild horses and other wildlife for the following reasons:

1. Pregnancy is prevented approximately 9o% of the time in treated animals;
2. The vaccine can be delivered remotely by small darts;
3. Contraceptive effects are reversible (up to five years in wild horses);
4. PZP is effective across many species;
5. No debilitating health side effects have been observed, even after long-term use;
6. No effects on social behaviors have been observed;
7. The vaccine cannot pass through the food chain;
8. It is safe to administer the vaccine to pregnant animals.

Q. How is it made, and who manufactures it?

A. The porcine zona pellucida (PZP) vaccine, used on BLM, U.S. Forest Service, and NPS wild horse mares, as well as within several wild horse sanctuaries, is produced by The Science and Conservation Center (SCC) in Billings, Montana. Each batch is subjected to a qualitative and quantitative quality-control program and shipped under the authorization of an Investigational New Animal Drug (INAD) exemption for wild horses (FDA

8857-G0002) issued to The Humane Society of the United States (HSUS) by the Center for Veterinary Medicine of the Food and Drug Administration. In collaboration with other investigators, The SCC continues to conduct research with the contraceptive vaccine, focusing on the ability to produce larger quantities, and increasing the efficacy of long-term contraception through a single inoculation (see Turner et al. 2002, 2008).

Q. How is the PZP vaccine obtained?

A. Once all necessary authorizations and approvals have been obtained for use of the vaccine, it may be ordered from:

Kimberly M. Frank
The Science and Conservation Center (SCC)
ZooMontana
2100 S. Shiloh Road
Billings, MT 59106
(406) 652-9719 (phone)
(406) 652-9281 (fax)
e-mail: sccpzp@hotmail.com

The vaccine is not commercially available and is provided at 60% of the cost of production, which currently runs about $24/dose. This is the price of the standard, one-year, 100 microgram dose. The 2-3 year vaccine uses considerably more than 100 micrograms, as well as more adjuvant, and includes the added cost of pelleting. The 2-3 year PZP vaccine costs about $200 per dose, plus the personnel costs of administration, which are minor, if horses are being gathered anyway. Compared with the $1,100 - $1,600 it takes to gather, remove, transport, hold, and adopt a horse (or care for it indefinitely), PZP is a bargain.

Q. Are any pigs killed, expressly to produce the vaccine?

A. Pig ovaries are obtained from a slaughterhouse in Iowa, as a by-product of hogs already destined for slaughter. Therefore, no fewer hogs will be killed if the PZP vaccine were no longer made. Major competitors for pig ovaries include Chinese restaurants, and pharmaceutical companies, that use ovarian endocrine components for research and production of products.

_Q_. Is this drug FDA approved and patented? If so, who is making all the profit from its use?

A. In FDA language, “approval” refers to approval for commercial distribution and marketing, and PZP is not a commercial product. No one is profiteering from PZP. The Humane Society of the United States holds the Investigational New Animal Drug exemptions (INAD), which are the oversight process by which FDA compiles data to examine vaccine safety and effectiveness. Basic and applied research that generated most of the knowledge about the vaccine was carried out with public funds (from the National Science Foundation, National Institutes of Health, U.S. Department of Agriculture, Bureau of Land Management, etc.). The research team considers products developed with public monies to be in the domain of the public, and therefore has no intention of commercialization. Therefore, it will always be called "experimental,” under FDA rules, despite the fact that PZP has been studied and field-tested extensively, for safety and efficacy, and is currently being used with more frequency on federal wild horse mares.

However, at the same time, use of public monies for research and development ***does not legally prohibit*** the commercialization of a product. Some researchers are, nonetheless, offended (due to a personal sense of ethics) and will not move forward with commercialization of a product developed with public funds. The rational is that the public has already paid for the product, and commercialization only allows private companies and individuals to profit from sale without having contributed to the process of research, development, and testing.

Because of this, PZP cannot be used on wildlife without the Investigational New Animal Drug exemption, or INAD. Once the INAD from FDA (one for horses, one for deer and zoo animals) was obtained, the INAD was turned over to The HSUS, leaving that organization to deal with the ethical issues. This means that each project – even at the management level – must have a research question attached to it, and The HSUS must approve the project. An added note is that the Investigational New Animal Drug exemption (INAD) issued to HSUS by the FDA requires a sound safety base before it is issued and would never have been issued were there a significant (or even an insignificant) health or safety concern. Therefore, neither HSUS nor The SCC make money from the vaccine. The SCC provides PZP vaccine at cost of production. Coupled with the paperwork required, The SCC actually

loses money. That is why The SCC is a non-profit. Currently, The SCC's annual budget is about $120,000, and PZP income results in less than half of that, meaning that a great deal of vaccine is donated.

The patent issue is a different question, not to be confused with the FDA process. Merck patented PZP in the 1970s, but the patent lapsed, and the technology is no longer patentable. Organon International, a large drug company based in the Netherlands, holds the patent for PZP use in humans, but that application may never take place, as scientists have not yet been able to make an effective synthetic form. Also, the variability in time for infertility reversal is significant and could potentially result in litigation.

In recent years, the FDA has transferred authority for wildlife contraceptives (exclusive of captive zoo animals) over to the Environmental Protection Agency (EPA). In 2009, an application is pending for approval of native PZP for use in wild horses by the EPA.

Q. What groups are on the PZP Contraceptive Research Team?

A. Today, the team consists of The Science and Conservation Center, Billings; Toledo University Medical College, Ohio; University of California-Davis; Tufts University, Medford, Massachusetts; The Humane Society of the United States, Gaithersburg, Maryland and Washington, DC; and the University of Iowa, Ames. Many other individuals contribute to the effort in one form or another. Governmental agencies that can be considered team members include the National Park Service, U.S. Forest Service, U. S. Department of Commerce, and the Bureau of Land Management.

The entire PZP contraceptive effort involves many people, several institutions, and numerous funding agencies. This team works together, bringing many disparate disciplines and talents in concert to solve the problems at hand.

Q. Who Funds PZP Contraceptive Research and Applications?

A. Funding for application of the vaccine to wildlife has been provided by many individual communities, agencies, and organizations, including but not limited to:

- The Humane Society of the United States

- Elinor Patterson Baker Trust
- Geraldine R. Dodge Foundation
- Bernice Barbour Foundation
- Leuthold Family Foundation
- Panaphil Foundation
- Delta-Sonics
- PNC, Inc.
- U.S. Navy
- National Park Service
- Bureau of Land Management
- Rachel Carson National Estuarine Reserve
- U.S. Department of Commerce
- National Institutes of Health
- Fire Island Community Association
- Burkett-Plack Foundation
- Bosack-Kruger Foundation
- Annenberg Foundation
- Cargill Foundation
- THAW Charitable trust
- 112 different zoos in North America, Europe, New Zealand and Australia
- South African National Parks Board
- U.S. Fish and Wildlife Service – African Elephant Conservation Fund
- Fripp Island (SC) Property Owners Association

- Morris County (NJ) Parks Commission
- Franklin County/Columbus (OH) Metro Parks
- and several anonymous donors.

This list is not all-inclusive but provides a picture of the breadth of support for this approach to wildlife management.

Q. Who controls vaccine use in wild horse populations?

A. No agency or organization can use the vaccine without the assent of HSUS, which monitors management plans and the INAD. In fact, the BLM approached the FDA and tried to circumvent HSUS control over vaccine use but was turned down by the FDA. Therefore, oversight and approval by HSUS still exists. No agency or organization will have control of the PZP vaccine in the foreseeable future. Every μg of vaccine that is produced can only be used in projects where HSUS has reviewed and approved a wild horse herd management plan.

All projects in which the vaccine crosses state lines must be on record with the FDA. As explained previously, the authority to carry out these projects is issued by two separate Investigational New Animal Drug documents (INADs) issued by the FDA to HSUS. As each new project is identified, HSUS reviews the need for the project in the context of scientific, ethical, and moral issues, and, if approved, issues permission to proceed. Notification of each project is accomplished by means of a form, filed with the FDA by The Science and Conservation Center, which specifies how much vaccine is being shipped and what species are to be treated. The INAD also requires that data from each project be gathered in a systematic way and filed, and be made available to the FDA when the need arises. These files are maintained at The Science and Conservation Center. Additionally, the legal managers of the horses (NPS or BLM) or the animal care committee of each zoo must also provide permission to treat animals. This regulatory process is similar for any wildlife species not classified as a food animal by the FDA or as a game animal by a state fish and wildlife agency.

Precisely how procedures will change – or remain the same – after EPA assumes regulatory authority, remains to be seen, but the HSUS will hold the approval; thus, we see no major changes at this time (6/09).

Q. Does an agency have to do an environmental assessment (EA) or an environmental impact statement (EIS) prior to using PZP on a wild horse herd?

A. Yes. Environmental Assessments are mandatory for any use by federal agencies. One difference between agencies is that the NPS does a single management EA, that is in force for years, while the BLM does one every five years for application in each herd management area.

Q. What wild horse populations, within the United States, are presently being managed with PZP?

A. The vaccine has been used successfully to manage the wild horse population of Assateague Island National Seashore (ASIS), in Maryland, under the sponsorship and authority of the National Park Service (NPS). The population has been treated for 22 years, without health problems, and the population has decreased by almost 40%, since management-level application began in 1995. Wild horses are also being treated on Cape Lookout National Seashore (Shackleford Banks), North Carolina, for the NPS; on Carrot Island, North Carolina; on the Rachel Carson National Estuarine Reserve, North Carolina; and on many areas of Nevada, for the Bureau of Land Management (BLM). Other treated herds include Return To Freedom (American Wild Horse Sanctuary), Lompac, California; Pryor Mountain Wild Horse Range (Montana/Wyoming); Little Book Cliffs National Wild Horse Range, Colorado; McCullough Peaks Horse Management Area, Wyoming; and Little Cumberland Island, Georgia; International Society for the Protection of Mustangs and Burros Wild Horse Sanctuary, Lantry, SD; Black Hills Wild Horse Sanctuary, Hot Springs, SD, Carson National Forest, NM, and the Navaho and Pima/Maricopa Indian reservations. In Nevada and Wyoming, at least 12 different wild horse herds are being treated "experimentally" to evaluate population effects. For Nevada references, see (1) Turner et al. 2001; (2) Turner et al. 1997; (3) Kirkpatrick et al. 1997; and (4) Kirkpatrick et al. 1997. In March, 2009, The Washington Office of the BLM Wild Horse Program i/ssued a memorandum that directs local horse managers to treat all mares returned to the range.

In the case of the four barrier island herds, the Pryor Mountain Wild Horse Range, Little Book Cliffs Wild Horse Range, and Return To Freedom Wild Horse Sanctuary, horses are treated remotely, with dart guns. In Nevada, they are treated in conjunction with gathers, as most of these HMA's are too large, and the horses too wild to dart.

In addition to controlling the horse population on Assateague Island, treatment has extended the lives and improved the health condition of older mares, by removing the stresses of pregnancy and lactation [see Kirkpatrick 1995; Kirkpatrick and Turner 2002, 2003; Kirkpatrick et al. 1990, 1991, 1992, 1995a, 1996a,b, 1997; Liu et al. 1989; Turner and Kirkpatrick 2002, 2008; Turner et al. 1996a]. Horses on Assateague are doing well. About 125 total animals roamed the area in 2009 (27% less than the starting number of 173 in 1995), and their body conditions have improved significantly since 1990 [Turner and Kirkpatrick 2002]. Mortality almost disappeared for the first eight years of management, and the horses are generating new age classes (large numbers between 20-25 years of age, and a growing population between 25-30).

Thus, at the management level, horses are being treated with PZP for the NPS, Rachel Carson National Estuarine Reserve, the BLM, and at least five private sanctuaries. In addition, new forms of the vaccine are being tested for the BLM in western horses, but not on a management level.

The following HMAs are sites that have been treated with long-acting PZP:

Onaqui Mountain, UT - 56 mares
Sand Springs, OR - 31 mares
Fox-Hog, NV - 28 mares
Green Mountain, WY - 38 mares
Monte Cristo, NV - 53 mares
Blue Wing, NV - 136 mares
Antelope Hills, WY - 28 mares
Black Rock East, NV - 19 mares
Black Rock West, NV - 19 mares
Warm Springs, NV - 27 mares
Antelope Complex, NV - 29 mares
Calico, NV - 92 mares
Groshuite, NV - 44 mares

Granite Range, NV - 79 mares
Nellis Air Force Base Bombing Range, NV (Nevada Wild Horse Range) - 358 mares
McCullough Peaks, WY - 34 mares
Sand Springs, CO - 75 mares
Cedar Mountain, NV - 85 mares

Additionally, another form of the long-acting PZP has been tested in captive mares at Canon City, CO; a reduced dose of PZP was tested successfully in captive mares at Canon City, CO; and a lyophilized form of the vaccine was tested successfully in domestic mares in Clark, WY and Billings, MT.

Q. What herds do you propose to treat with contraceptives in the near future? Why did you choose these particular herds? Who decides? What are your long-term goals?

A. While the PZP vaccine is currently being used on at least 20 horse management areas for the National Park Service or the Bureau of Land Management, its use is appropriate for all free-ranging wild horse herds. Application to particular herds is at the invitation of the managing agency. The long-term goal is to reduce or eliminate the need for gathers and removals.

DELIVERY, APPLICATION, AND BIOLOGICAL EFFECTS OF PZP

Q. How is the vaccine delivered?

A. The PZP vaccine must be injected into the muscle of the target animal. This can be done by hand if the animal is restrained, or by dart, for remote delivery. There are many commercial dart systems available, but the thick viscosity of the vaccine requires a large needle and a quick injection. Thus far, Pneu-Dart® systems (Williamsport, Pennsylvania) seem to work the best. The Pneu-Dart® 1.0 cc barbless darts can be fired from Pneu-Dart® capture guns or from several other commercial dart guns [Pax-Arms® or Dan-Inject®, for instance]. The darts are disposable, and after hitting the animal in the rump or hip (the only acceptable location for darting), they inject by means of a small powder charge, and then pop out. Because of

their bright colors, the darts are usually retrieved in the field. Darts that have not been discharged cannot be discharged by stepping on them or by any other kind of casual contact. Over a six-year period on Fire Island National Seashore, and with more than 1,000 dartings of deer, only two darts have not been recovered.

Normally, each animal is darted twice the first year, with the first injection being given up to a year before a booster, just preceding the breeding season (March for wild horses or September for deer). Thereafter, a single annual booster inoculation will maintain contraception. The second inoculation of the first year requires that…

a. you are able to recognize the individual animals; or

b. you do the first inoculation with a special "marker dart," which leaves a dye mark on the animal at the same time it injects the vaccine; or

c. selected mares are treated to allow for both genetic diversity within a specific herd and for the promotion of health and improved body condition of an individual animal (through temporary infertility).

An alternative strategy is to give only a single inoculation the first year, from which there will be little contraception, and then a single annual inoculation thereafter, from which there will be significant contraception (see McShea et al. 1997; Turner and Kirkpatrick 2002.)

New approaches using small non-toxic, biodegradable lactide-glycolide pellets, that result in several years of contraception after a single application, are being tested. [Turner et al. 2002, 2008].

Q. How would you describe the new pelleted form of PZP-22, and how does it work?

A. PZP is incorporated into lactide-glycolide pellets, small enough to be injected intramuscularly. After injection, the lactide-glycolide erodes (It is biodegradable and non-toxic) and releases the PZP at varying rates, depending on the ratio of lactide to glycolide. It is an injectable version of a contact cold pill. The pellets are made at the School of Pharmacy, University of Iowa. There have been spotty results in horses. It works in some herds and not in others, and it has worked well in deer, but not in elephants. Not all, but much of the data associated with the pellets has

come from helicopter counts, and it is difficult to match foals with mares from a helicopter. After the summer of 2010, more data will be available. Two herds in the Annenberg Foundation project have been treated with pellets. People are on the ground, who are familiar with the horses; so more solid data should be forthcoming.

***Q*. How does the liquid vaccine compare to the pelleted form?**

A. Nothing works as well as a primer dose of native PZP, followed by a booster 2 to 6 weeks later**,** and then annual boosters after that. Efficacy with the pelleted form, even where it has appeared to work, is not as good. The issue, of course, is having to treat mares every few years versus only once.

***Q*. Isn't darting mares painful and potentially harmful or even lethal? Will it result in mares being shot in critical anatomical areas – abdomen or chest, causing inhumane deaths?**

A. As long as only 1.0 cc Pneu-Darts are used, there is almost no risk of injury to the animal. These are very small, light darts. Over a 22-year period, no horse has ever been injured on Assateague Island, the Shackleford Banks, Carrot Island, the Pryor Mountains, or the Little Book Cliffs (translating to well over 1,000 dartings, over the course of 20 years).

On the Pryors, PZP remote-darting operations typically take place in late summer/early fall, and any wild mares receiving the vaccine are individually-identified and tracked regularly with data, non-intrusively gathered on behavior, estrus, fertility, reproduction, survival, and any health concerns. The field studies are conducted by seasonal and term USGS-Biological Resources Division and BLM biological technicians under the supervision of BRD research biologists and the BLM Wild Horse and Burro Specialist.

Several studies of injection site reactions have been carried out. In one study it was shown that of 38 total treated mares, 55% exhibit no reaction to darting, 6% have some level of swelling around the injection site, 22% have a small nodule (granuloma) about the size of a marble, and no animals had abscesses. Only one mare of 38 has ended up with a medium-level swelling, about one year after treatment. In a larger study, data were generated from the records of 329 different horses on Assateague Island, darted over a 19-year period. 1,094 different dartings resulted in a 0.2% abscess rate. The

abscesses healed within two weeks. In another study of captive zoo animals, 1,185 dartings of 25 different species resulted in 16 abscesses (1.3%) (Lyda et al. 2005). In the Pryor Mountains, 151 dartings resulted in 1 abscess (0.7%). At Return To Freedom Wild Horse Sanctuary, in California, 451 dartings of 85 total horses over six years resulted in 15 abscesses (3.0%). At the Black Hills Wild Horse Sanctuary, in 2009, 140 dartings resulted in one abscess (0.7%).

Abscesses typically appear as 25 mm swellings which open and drain within two weeks without complications. More common are granulomas, or subcutaneous nodules, about the size of marbles. These nodules are most notable post-injection but typically disappear over time. Ultimately these nodules are very difficult to discern amongst other natural scars within the coats of these wild mares. Furthermore, there is no indication that the presence of these nodules has compromised the quality of life for these horses. Field technicians have never recorded the mares showing any indication that these nodules are causing any level of discomfort during daily activities and/or interfering with reproductive activities. The granuloma is the counterpart of the smallpox vaccination scar found on humans, but beneath the skin instead of on its surface.

These injection site reactions should be given some context and compared with the same events in domestic livestock. The 1995 Beef Council Quality Audit reported that 11% of cattle inoculated with USDA-approved vaccines produced injection site reactions, including lesions and abscesses. In another study, the Kentucky Beef Council reported that fed cattle had abscess/lesion rates of 3.2-21.6% after vaccinations with USDA-approved vaccines, and in non-fed cattle, the abscess/lesion rate ran from 28.9 to 40.9%.

The most recent study of injection site reactions (Roelle and Ranson 2009) provides some interesting data. In any herd studies, often there are a few horses where abscesses appear more frequently than in other animals. Thus, for some reason, some animals are more prone to abscesses than others, and this often skews the abscess rate within a single herd. For example, in one herd, of a total of six abscesses that appeared after darting, four occurred in the same mare. The other data suggest that vaccinations given by dart produced more abscesses than those given by hand injection. This makes sense, if you consider that hand injections are preceeded by antiseptic swabbing of the skin surface, while field darting simply drives dirt and hair

follicles in to the wound, along with the vaccine. Thus, this all suggests that abscesses may not have any relationshop to the vaccine or adjuvant, but to the delivery method instead.

Q. How do immune system depression issues affect the formation of abscesses and lameness in horses?

We have insufficient data regarding how mares will react if they are in poor condition versus good condition, at least not enough for statistical analysis. Then, we just have visual indexes for body condition scores, from which you can simply infer immune competency; thus, we can offer only anecdotal information. Classic immunology says that animals in poor condition (or stressed for any other reason, as well) will not mount as strong an immune response as unstressed animals. Whether or not this effect will cause poorer efficacy, more abscesses, or other issues, is not known. In zoo animals, where we often administer PZP because of health problems, there seems to be no problem. Next, lameness and abscesses may not be at all associated with the vaccine *per se*. Rather, there is some limited data, by the Science and Conservation Center, and by Jason Ransom, U.S. Geological Survey, Ft. Collins, Colorado, that darted horses will produce more abscesses than hand-injected horses. When you hand inject, you wash the surface of the skin with ETOH. However, when you dart, you drive any surface dirt into the dart puncture. The same problem exists when darting wildlife with anesthetics, rather than vaccine. This issue is not any different from differing efficacies among individuals getting flu shots. In general, about all you can say is that animals with compromised immune systems do not do as well as those with competent systems, and there are many variables associated with what causes immune incompetency.

Q. Will PZP harm mares or foals, physiologically? Have any negative pharmacological side effects been observed? Are any benefits derived from its use?

A. Safety data has been accumulated over 20 years. It essentially says there are no short- or long-term health problems of any kind, and that the vaccine is reversible, unless the mare is treated for more than five consecutive years (in which case you probably didn't want her to reproduce again anyway). The data make clear that pregnancies in progress are not affected in any way by the vaccine, nor is the health or fertility of the foals compromised, once

they are born. Treating mares carrying female fetuses does not affect the fertility of the offspring.

In fact, as mentioned previously, mares on Assateague Island are living longer than ever, and their mortality has decreased, they are achieving new age classes never before seen on the island, and all of this happened because their body condition scores have increased steadily since 1989, when PZP application started. Historically, a mare never survived to 20 years of age, but now a significant percentage have passed twenty, and about 29 animals (20% of the herd) are between 25 and 30 years old. Removal of the stresses of pregnancy and lactation gives them an immense health advantage, both at the younger and older stages of life.

Foal mortality has dropped significantly. This is probably because their mothers, when they finally do become pregnant, after several years of contraception and then withdrawal of PZP treatments, are much healthier. All of this data (derived not from casual observation) is published.

The other victory for horses is that every mare prevented from being removed, by virtue of contraception, is a mare that will only be delaying her reproduction rather than being eliminated permanently from the range. This preserves herd genetics, while gathers and adoption do not. (Kirkpatrick and Turner 2002, 2008; Turner and Kirkpatrick 2002, 2003; Willis et al. 1994.)

Q. Does PZP application create late foaling in treated populations?

A. No. Available data from 20 years of application to wild horses contradicts this claim (Kirkpatrick and Turner 2003). From 1990 to present, Assateague Island has records for 178 horses whose month of birth is known (and in some cases, day of birth known). An examination of the published data, from 1984, of Ron Keiper (retired Distinguished Professor of Biology at Pennsylvania State University and currently Chairman of the Department of Biology at Valencia Community College, Orlando, Florida) in which he looked at eight years of birth dates for the same herd, which at that time was much smaller than we have today (considerably less than 100 horses versus 155) indicates that approximately 85% of the foals were born in April, May and June. Among the 178 horses with known birth dates, 95 were born to mothers who were never treated with PZP, with 70 born in April, May and June (73.6%), and 25 born outside this window. Another 83 foals were born to mares that had at some point been treated with PZP

before their pregnancies, and 65 were born in April, May or June (78.3%), with 18 outside this window. Thus, with a database of 178 horses over an eleven-year period, there is no evidence of late foals being born among treated mothers.

That corroborates published work (Kirkpatrick and Turner 1983), where it was demonstrated that Pryor Mountain wild horses did not extend their season of ovulation even when placed on high planes of nutrition. Mares do not extend their breeding season if they do not get pregnant.

One interesting issue is that the percent of untreated mares giving birth on Assateague Island in the April, May and June window has decreased from 85% down to 74% since 1984. This suggests that as herd size increases, variability in birth dates also increases, but this may simply be a function of larger numbers (in this case a 100% increase in herd size). There is also a moderate pattern among some mares (the N9BF line in particular) with regard to producing foals outside this window. This genetic line was consistently producing foals in March. If that observation is correct (This is only an untested observation.), then it corroborates Eric Palmer's theory that seasonal ovulatory patterns in mares are genetically controlled. In any case, these data, at least, demonstrate that contraception with PZP does not cause early or late births. Once again the Assateague Island (ASIS) horses and the 22-year treatment history produced a wealth of information (Kirkpatrick and Turner 2003).

In the Pryor Mountain Wild Horse Range, the normal foaling period has been well documented (EA #BLM MT010 FY05 -16, figure 10) to primarily take place in May and June, with limited foaling known to happen outside this window, from February to September. Thus, later foaling dates are not considered abnormal.

Q. For how many years is a mare generally treated with PZP?

A: This depends on the management plan of the agency, for a particular herd. Perhaps the most effective plan is the one used on Assateague Island, where all two-year-old mares are put on treatment, and then boosted at three and four years of age. After this, they are removed from treatment until they foal, which might occur anywhere from one to five years later. Mares that have already made their genetic contribution to the herd, in the context of the management plan, are treated until extinction.

***Q*. How do you determine which mares within a herd will be treated?**

A. The question of which mares to treat with vaccine is an important one, and the answer is embodied in the management plan. The approach used on Assateague Island has proven very effective and safe, i.e., two, three and four year olds are all treated and then withdrawn from treatment until they produce a foal. Older mares with good genetic representation in the herd are treated to extinction. Dr. E. Gus Cothran, an equine geneticist from Texas A&M University, College Station, monitors the plan on Cape Lookout. Immunocontraceptive control is more logical (genetically) than removing animals before they have had a chance to reproduce. Genetic representation is the key element within the management plan.

The most important consideration is to ensure that all genetics are represented, whether or not they reflect "wildness" or band stability, phenotype, or whatever social hierarchy exists. The bottom line is that wild horses are native North American wildlife, and humans should not be selecting for anything other than complete genetic representation and kinship.

***Q*. How effective is PZP? Won't some mares still become pregnant after treatment?**

A. PZP treatment in wild horses is about 95+% effective (Turner and Kirkpatrick 2002, 2008). The failure of some horses to respond to the vaccine results from an immune system that either doesn't "recognize" the vaccine's antigen, or from a compromised immune system. This is true for human vaccines as well (consider the less than 100% efficiacy with flu vaccines). Regardless, 95% efficacy is enough to manage wild horse populations effectively. In other species, efficacy varies in a species-specific manner (Frank et al. 2005).

***Q*. Why can't you block pregnancy with just one inoculation instead of the two shots you use now?**

A. The issue of the "one-shot" is complicated. Currently there are tests with SEVERAL forms of a one-shot vaccine. Despite that, this matter clouds the real issue of putting the vaccine to work NOW.

The initial “primer” dose of PZP causes the immune system to “recognize” and type the antigen, not so much for immediate long-term response, but to prepare the animal’s immune system for future exposures to the vaccine. Thus, a booster inoculation is required the first year, and an annual booster thereafter (Liu et al. 1989).

There is a second reason for the need for booster inoculations. Many human and veterinary vaccines use attenuated (weakened) or killed viruses as the vaccine, and these are powerful stimulators of the immune system. Often a single inoculation lasts for years. The PZP, however, is a relatively small protein that is not especially immunogenic. It is also very close in structure to the native PZP on the target animal’s own ova; thus, the target animal has difficulty in “recognizing” the PZP as foreign to the body. This, in turn, means that multiple inoculations must be given, and with a more immunogenic compound, known as an adjuvant (Lyda et al. 2005).

The subject of the one-shot also clouds the bigger topic of management because it only provides an advantage in the first year. After that, the horses are "one-shot" animals anyway. In 1994, almost every mare on Assateague Island was treated with a single shot. That shot was not meant to cause contraception but to set the herd up as a "one-shot" herd in preparation for management a year later. It was done this way because the National Park Service had to do an environmental assessment (EA) before they were allowed to manage with contraception. Then in 1995, the whole herd was managed with only a single shot per animal. The concept is fairly simple, and a "one-shot" vaccine only aids in the first year. Of course, a single inoculation that lasts multiple years would have more utility. (Turner et al. 2002, 2008)

The present advice given to the BLM is plain. Not a single mare that is gathered, for any purpose, and returned to the range should get back on the range without an inoculation. That makes them "one-shot" animals, and the expense of developing "one-shot" vaccines becomes moot. Once they have had that first shot, they can be re-treated anytime with a single shot.

A One-Inoculation Vaccine

Because of the need to inoculate animals twice the first year, and the difficulty of doing this with wild species, research is proceeding toward a "one-inoculation" vaccine. Such a vaccine would permit a single darting to

cause one or more years of contraception. The approach under study incorporates the PZP into a non-toxic, biodegradable material, which can be formed into small pellets. The pellets can be designed to release the vaccine at predetermined times after injection (at one and three months, currently), much the same way time-release cold pills work. Initial trials were encouraging, and continued trials are underway (see Eldridge et al., 1989; Turner et al., 2002, 2008). The downside to this approach is the immense amount of vaccine needed for the production of the pellets and the associated cost. While this approach may have some limited use, the difficulty in producing large amounts of vaccine make it unsustainable. What is needed is either a synthetic form of the PZP antigen or a pellet making process that reduces wastage by at least 65%.

Q. What do you mean by a one-year, two-year, or three-year vaccine?

Response to the PZP antigen is variable among individual mares. Some mares appear to be naturally poor responders to the vaccine and probably never develop sufficient antibody titer levels to confer infertility (hence the 95% efficacy of the vaccine in horses). Research with the Pryor Mountain wild horse herd indicates that immune response in mares may be correlated with age and fitness. One six-year-old mare, contracepted due to poor physical condition in September 2003, responded poorly to the vaccine, conceived in 2004, and foaled in 2005. Similarly, two 16-year-old mares last boostered in 2003, also produced a foal in 2005. Conversely, younger mares in good condition may have a stronger than expected antibody titer response resulting in a longer period of infertility. This appears to be the case with the first young mares treated with PZP on the Pryor Mountain Wild Horse Range (PMWHR).

Immunocontraception is not an exact science. The vaccines are designed to offer an effective time period based on the average response for many numbers of animals. As the treated number of animals increases, then the known response time for a specific formulation of PZP and adjuvant (carrying-agent) becomes better known. There are many variables to consider, the largest factors being animal condition and related immune response. Young PMWHR mares were healthy when injected (though a small sample size), and it would appear the resulting immune response (to a 90% effective one-year agent) has resulted in 2 years of efficacy. Older Pryor mares are relatively worn-out, and immune response appears limited. As such, the vaccine was not effective in a couple of mares. This is also true

with a younger mare that was treated, due her poor condition, but she still produced a foal.

Perhaps animal condition on Assateague Island (ASIS) is such that one year of efficacy is all that results with the same formulation of PZP and adjuvant that has been used on the Pryors. These are questions that still need to be dealt with, which is why the need exists for continued research. These questions are addressed in individual-based study herds within the Wild Horse & Burro Fertility Control Field Trial program and a project funded by the Annenberg Foundation. This is one of the reasons why the efforts on the Pryors have been critical to knowledge of this vaccine for use on western herds.

Q. How long does it take for native PZP to stop population growth in a herd?

A. This depends on the percentage of adult mares treated. On Assateague Island (ASIS), growth was stopped almost immediately. A large number of mares were given the PZP vaccine on ASIS during the first three years (about 87%), and growth stopped quickly. On the Pryor Mountain Wild Horse Range, fewer mares were treated (< 30%), but growth was slowed, as well. So, it depends mostly on the percentage of adult mares treated. However, fertility rates and mortality rates enter into this answer as well. It is precarious to address this any other way than to point out that results are site-specific and cannot be generalized.

Q. How long does it take for PZP to begin reducing a wild horse population?

A. On ASIS, the first sign of population reduction took about eight years, but herd reduction has been moving more quickly since then. The following eight years, herd numbers went down from 175 to 116, without any removal of horses, treating anywhere from 48 % to 79% annually. The lag time between initiation of treatment and decline in numbers is largely a function of increased longevity in treated horses, but, as pointed out above, there are other variable factors involved (fertility rates, mortality rates, sex ratios, and so forth). Fertility rates are average on ASIS (45-60%), and mortality is low (<5%).

***Q*. How can you tell if a wild mare is pregnant, so you don't treat her with PZP?**

A. In some cases, a fecal or urine sample is collected off the ground, or from yellow snow following urination. Reproductive steroid hormone metabolites are measured that tell us, with almost 100% accuracy, which mares are pregnant and which are not. A pregnancy can be diagnosed from 40 days post-conception until the day of parturition, and the animal does not have to be touched. That said, there is no danger to either the mother or the *in utero* foal, if the mare is treated with PZP during pregnancy (Kirkpatrick and Turner 2003, 2007).

***Q*. Is the drug residual in urine or feces or in the dead carcasses of treated mares, where PZP could get into the food chain or cause adverse effects to wildlife, or even contaminate water?**

A. Because PZP is primarily protein, it is readily destroyed in digestion, reduced to amino acids, and therefore cannot pass through the food chain intact and with biological activity (Oser 1965).

***Q*. What about compensatory reproduction in PZP-treated herds?**

Thus far, after 22 years of PZP treatment, there is no evidence for compensatory reproduction in a PZP-treated wild horse herd. This might be an issue if a herd is treated for long periods of time and then all treatment withdrawn, but that flies in the face of an effective management plan (Kirkpatrick and Turner 1991b).

BEHAVIORAL EFFECTS OF PZP

***Q*. Is wild horse behavior affected by PZP use? Are there any effects on motivation or drive, general contentedness, and the emotional stability of mares treated with PZP? Is band social stability affected negatively? Has any aberrational behavior been seen in PZP-treated mares, band stallions, or bands where mares have been treated with a contraceptive? What behavioral studies have been conducted on wild horses, both in eastern and western wild horse herds? Do you plan additional behavioral studies?**

A. After 22 years of treating the ASIS mares, there is still no evidence of altering behaviors. The baseline behaviors of eastern wild horses were the same as western horses. In order to understand this, a great deal of information must be read, which examines wild horse behavior from a variety of sites around the world. A huge body of literature exists on this subject, and a few of the more salient publications include: Berger 1977; Feist and McCullough 1976; Keiper 1976, 1986; Klingel 1975; McCort 1984; Rubnestein 1981; Rutberg 1990; Rutberg and Greenberg 1990; Salter and Hudson 1982. An independent investigator from the National Zoological Park has confirmed earlier results that show no behavioral changes (Powell 2000). Thirty-years of observing wild horses in North America and Australia and New Zealand have revealed no difference in fundamental behavioral structures. On the other hand, the affects of gathers on social behaviors are obvious (Ashley and Holcombe 2001; Hansen and Mosley 2000).

A good start on this subject can be obtained by reading Powell (1999), which reports on a study done by researchers from the National Zoological Park/Smithsonian. They found no behavioral effects, at that time, after almost eight (8) years of PZP treatment. The same results were reported in several of the Assateague Island papers, including (1) Kirkpatrick 1995, and (2) Kirkpatrick et al. 1995. Also, other studies (Fayrer-Hosken et al. 2000; Delsink et al. 2002) showed a lack of behavioral effects of this same vaccine on free-roaming African elephants, which have an even more complex social order than wild horses.

One critic of PZP claims, “The horses [on Assateague Island] seem more listless than western wild horses...” However, this could only be determined by time budget studies, and, in fact, no evidence for this has been found (referenced above). Casual observation of wild horses proves nothing. For example, casual observation has reported that Pryor horses travel less than ASIS horses, but that has no scientific significance. If one understands the biology of PZP, one would never suggest there is a "psychological" impact of the vaccine.

The research has already shown that band structures do not change and neither do hierarchies. The only major change in hierarchies that occurs is when mares get pregnant, and then they drop down the ladder even more. Most wild horse behavioral researchers still don't know how to measure hierarchy rank.

A more recent study (Nunez et al. 2009) on Cape Lookout National Seashore indicated that treated mares change bands more often outside of the breeding season. However, the control group for this study is a group of mares that become pregnant and have their foals removed from them. One could just as easily conclude that removing foals from untreated mares causes the mares to stay with the band for longer durations.

Q. What about behavioral changes, recently observed in mares, attributed to native PZP?

A. After 23 years of experience in the field, using native PZP, researchers observing wild horse mares feel that fundamental wild horse social behavior is not changed by the vaccine. However, other researchers are looking at issues such as "time budgets" to find any potential changes. It is the opinion of long-term PZP researchers, however, that these changes are neither of significance, nor are these studies controlled properly. For example, do time budgets differ for horses on good range as opposed to poor range? No one has looked at this, but if there are differences (and logic tells you there should be differences in time budgets between horses living in knee-deep alfalfa and those scratching out a living in a place like the Pryor Mountain Wild Horse Range), then we might expect the time budget of a chronically treated horse to change from untreated horses because of the better body condition scores of the former. These studies have not been controlled for mares with foals (usually untreated) and those without (usually treated), but the important point is that if the fundamental social structure and behavior do not change, it is of no consequence if time budgets change.

Q. Won't mares just keep coming back into estrus (heat) if they don't get pregnant? Won't prolonged estrus cycling make stallions "edgy" and aggressive, creating continuous "unrest?" In the chaos, won't foals be harmed or even killed?

A. At the heart of this issue is the subjective nature of casual observation. Science is based on data, not informal surveillance. Systematically collected data, reviewed by other scientists, accepted as legitimate, treated appropriately statistically, and published in a recognized journal is the only acceptable means for arriving at generalizable, accurate behavioral information. A good start for understanding the rudiments of behavioral research in social animals can be found in Craig (1986).

In 1983, it was shown (Kirkpatrick and Turner 1983; 1986 a,b) that wild horses do not have the same ovulatory patterns as domestic horses, and that wild horses have well-defined breeding seasons (usually from about late March until July, but this will vary somewhat from herd to herd). Wild mares do not extend their breeding season if they do not become pregnant. Keiper and Houpt (1984) also showed this for Assateague horses. This DOES happen, however, in deer (McShea et al. 1997) but not with wild horses. In 27 years of data collection on Assateague Island, only a single documented incident of a stallion killing another stallion, because of fighting, has been observed. This occurred in the middle of breeding season (late May).

The PZP vaccine does not prevent ovulation in horses and there is some limited data that it might interfere with ovulation in deer, at least after the initial treatments. Wild horses do not come into estrus every month, whether or not they have been treated with a contraceptive. They have a breeding season that barely makes it from April through July. Many wild mares have but a single estrous cycle and some have none in a given year, but they are highly seasonal and do not ovulate year-round, or even half the year.

The implication of the question is that by treating wild horse mares with PZP, they will continue to cycle throughout the year, and that this will cause stallion "unrest," aggression, and potential injury. By contrast, documented evidence shows that mares will NOT continue to cycle if they do not conceive, at least beyond the normal 3-4 month breeding season.

If critics were correct, and PZP did cause “unrest” and continuous cycling, which, in turn, led to worked-up stallions and foals dying as a result of this behavioral turmoil, then any area using PZP would have greater foal mortality. However, after 15 years of management-level treatment on ASIS, foal mortality has decreased. That is a data-driven fact.

Granted… wild horse behaviors are subtle, and individual horses will show a wide range of variability in behavioral patterns. It takes a great deal of observational experience to pick them up. We do know that hierarchies and band fidelity, are not affected by PZP application. We also know that aggressiveness and aberrational behaviors are not caused by PZP use. Perhaps, however, there may be a subtle change in daily routine. However, the larger question is, even if subtle alterations in behavior may occur, this

is still far better than the alternative of wild horses being rounded up, bands broken apart, and all of the other negatives that go with traditional management. These issues need to be put into the perspective of risk-benefit by PZP opponents.

There may be some minor time budget changes, but this was addressed several quesitons above. In any case they are not significant in the world of wild horse behavior.

***Q.* I "live" with wild horses and feel that some of your behavioral studies (measuring PZP effects) are wrong or incomplete.**

A. Living with wild horses and seeing them every day is one thing, but while of interest, this doesn't necessarily hold noteworthy meaning, unless a parameter for study is identified, a hypothesis established, and a means of testing that hypothesis is conducted. Additionally, this still does not indicate a significant behavioral or other casually observed pattern for an individual animal or for a band or herd unless the data is analyzed properly.

***Q.* I wish the BLM had used a bit of its research money or allocated new money to do a study regarding the effects of PZP on the social structure and health of wild horses in the west.**

A. The effects of PZP on social structure and herd health have been studied on herds within the Pryor Mountain Wild Horse Range and Little Book Cliffs Wild Horse Range, and no behavioral changes have been noted, nor have any behavioral changes been noted on wild horses at Return To Freedom (American Wild Horse Sanctuary) in California, where animals are observed daily.

***Q.* Isn't the use of PZP "against nature?" Why can't you just leave these animals alone?**

A. Except in a small number of wild horse herds (such as in the Montgomery Pass herd (Turner et al. 1992), Bordo Atravasado in New Mexico, and a few others), mountain lions cannot predictably predate a sufficient number of wild horses to keep herd levels at population numbers in balance with the carrying capacity of their ecosystem. The potential for both wolf and grizzly bear predation of wild horses is in question, as well,

especially if grizzlies and wolves are delisted from the Endangered Species Act, making grizzlies, wolves, and mountain lions all open to hunting pressures.

OPPOSITION TO PZP

Q. Why are some wild horse advocacy groups so vehemently opposed to PZP? It seems like the perfect solution.

A. Opposition to the contraception arises for several reasons. Wild horse advocates do not trust the BLM with the PZP vaccine, despite assurances that the agency cannot use it without approval from The Humane Society of the United States (HSUS). BLM has inflamed the issue by asking FDA for their own INAD, so they could bypass The HSUS. FDA told the BLM that no more "use" INADs would be issued; so, currently, the agency has no choice but to work with HSUS, unless they are willing to change horses in the middle of the race. The HSUS will permit the use of PZP to manage, even reduce, but not to eliminate wild horses.

This has now led the BLM to seek as many other forms of wild horse contraception as possible, from other groups, but it will take significant time to match the safety data studies that have been generated on PZP over many years.

All wild horse advocates want horses to have a better life, but if this entails a choice between having 130 healthy horses versus 200 living on the nutritional edge (in the event of a drought or a severe winter), some would choose the 130 healthy-horse option, out of (what they see as) concern for the well being of the horses. The irony is that those who seek to control wild horse populations through immunocontraceptive measures often spar with other horse advocates who (in the opinion of PZP supporters) object to what pro-PZP factions perceive as the humane treatment of wild horses. The anti-PZP community, who often question factual information and historic success, distrust the morals of those who strongly profess they care (about the well being of the herds). Pro-PZP individuals and groups believe, with conviction, that the primary motivation behind wild horse contraception is keeping healthy wild horses in the wild, on the land forever, in as natural a state as possible, with minimal interference from humans.

Many of these opponents dislike PZP because they fear it will reduce the herd to lower numbers than they want. That has been the major contention with most gathers. After 22 years of contraception on ASIS, and 15 at the management level, contraception has only been able to reduce that herd from 173 to 116. Zero population growth was achieved, and, to date, there has been no need for gathers, but reduction has been slow. So, there is little danger of massive reductions happening anywhere. Even the event of a catastrophic winter has less danger inherent than most advocates might think. The Pryor Mountain herd in Montana/Wyoming went from about 140 horses to 70 in a tragic winter die-off of 1977-1978, but the population had recovered within three years. The only thing that would have changed, had there been 200 animals instead of 140 is that more animals would have had less to eat, and therefore more would have died. The severity of the winter determined that 70 horses would survive, and not the starting population number.

Q. Aren't you trying to bring wild horses to extinction (using PZP)?

A. The concerns of some anti-PZP wild horse groups over BLM use of the vaccine are justifiable, and the BLM's proposal to use PZP to cause an Oregon herd to approach extinction, and other proposals that have surfaced to use PZP to manipulate herd composition, prove this. These apprehensions are legitimate and acknowledged by PZP researchers. However, Assateague Island data have proven the safety and efficacy of the vaccine, and it is obvious that the BLM is not going to be able to treat 30,000 wild horses to extinction with contraception, especially with continued involvement from The HSUS. Vigilance is important in the continued utilization of the PZP vaccine and in monitoring questionable research studies by state and federal agencies not sanctioned by The HSUS or the BLM, some involving the use of contraceptives that may potentially cause complete sterilization or deleterious effects in mares. Despite the utter rejection of scientific data as a legitimate form of persuasion by some anti-PZP individuals and groups, their hearts are in the right place. They are not the natural enemies of those promoting PZP as a humane management tool. Affable cooperation is needed to resolve issues of wild horse over-population, when and where it legitimately exists, once other means of population reduction have failed or are found to be undesirable.

****

REFERENCES

References below are a sampling of the only known published reports, to date, on the subject of PZP use in wild or domestic horses, or in zebras, wild burros or Przewalski's (Mongolian) horses. However, additional peer-reviewed papers, not listed below, have been published on these topics. Those selected were chosen to support material included in answers to the questions above.

Reproduction Supplement **60**, 197–202

Reversibility of action and safety during pregnancy of immunization against porcine zona pellucida in wild mares (*Equus caballus*)

J. F. Kirkpatrick[1] and A. Turner[2]

[1]Science and Conservation Center, ZooMontana, 2100 South Shiloh Road, Billings, MT 59106, USA; and [2]Assateague Island National Seashore, 7206 National Seashore Drive, Berlin, MD 21811, USA

Contraceptive management of publicly valued wildlife species requires safeguards to ensure that these populations are preserved in a healthy state. In addition, reversibility of contraceptive effects and safety in pregnant animals are major concerns. A population of wild horses has been immunized against porcine zona pellucida (PZP) over a 12 year period on Assateague Island National Seashore, MD (ASIS). Mares initially received one or two 65 μg inoculations and once a year 65 μg booster inoculations, all delivered by dart. All young mares aged > 2 years were treated with PZP for 3 consecutive years regardless of whether they have bred successfully and they were then removed from treatment until they had foaled. All mares vaccinated for 1 or 2 consecutive years became fertile again and 69% of mares treated for 3 consecutive years returned to fertility. All five mares treated for 4 or 5 consecutive years have also returned to fertility, but over longer periods of time. Mares treated for 7 consecutive years have not returned to fertility, but several, while still infertile, have started ovulating again. There was no difference in survival rates between foals born to treated and untreated mares, and PZP treatment of pregnant mares did not affect subsequent fertility of their female offspring.

Introduction

Contraception is used increasingly to manage valued wildlife species; however, concern by the public for these animals requires safeguards to ensure that these populations will be preserved in a healthy state and with the potential to propagate successfully in the future. This is particularly true for species such as the North American wild horse, genetically valuable and rare captive exotic species in zoos, and animals with highly developed social behaviours, such as elephants.

In the USA, all wild and feral equids inhabiting public lands are protected under federal law, and public scrutiny of management by government agencies is intense. Where fertility control is used as a management technique, reversibility of contraceptive effects is crucial to the intelligent management of wild horses and is perhaps the single largest public issue. The only contraceptive agent used to treat wild horses routinely in the USA to date has been

porcine zona pellucida (PZP). Most PZP studies to date have focused on contraceptive efficacy (Kirkpatrick *et al.*, 1990a, 1995a,b, 1996a,b; McShea *et al.*, 1997; Turner *et al.*, 1992, 1997) and short-term safety (Kirkpatrick *et al.*, 1991a, 1992, 1995a; Turner *et al.*, 1996), but certain management applications require a more complete understanding of long-term effects and safety in pregnant mares. In certain species, such as white-tailed deer, or captive exotic species in poor health, or older animals that have already made genetic contributions, reversibility of contraceptive effects is not an issue and often the goal is to prevent animals becoming pregnant in their declining years. However, in other cases, the management goal may be simply to delay reproduction until a later time to keep populations under control, or to allow for later breeding of genetically valuable animals to maintain genetic diversity in the population. In these latter cases, reversibility of contraceptive effects becomes a major issue.

The question of vaccine use in pregnant animals, the possible health effects on pregnancies in progress and the health and subsequent fertility of animals whose mothers were treated while they were *in utero* must also be considered. Again, in some species, for example white-tailed deer, in which seasonal breeding occurs and gestation is approximately 6 months, this is not a significant issue and these animals may be treated at any time during the other 6 months without danger of treatment during pregnancy. However, it is unlikely that large numbers of wild horses (gestation = 340 days) or elephants (gestation = 22 months) can be treated without including pregnant animals.

The published literature regarding PZP provides a diverse and often conflicting view of the reversibility of this vaccine. Reversibility has been documented after a single year of treatment in domestic horses (Liu *et al.*, 1989), wild horses (Kirkpatrick *et al.*, 1991a), white-tailed deer (Turner *et al.*, 1996) and African elephants (Fayrer-Hosken *et al.*, 2000). However, in other species, including dogs (Mahi-Brown *et al.*, 1985; Brandon *et al.*, 1998), rabbits (Wood *et al.*, 1981; Skinner *et al.*, 1984) and baboons (Dunbar *et al.*, 1989), PZP treatment indicates long-term impairment or complete cessation of ovarian function. Although no data have been presented to indicate deleterious effects on fetuses when the mother has been vaccinated during the pregnancy, this issue is nevertheless of concern with regard to the safety of the vaccine.

A herd of wild horses has inhabited Assateague Island National Seashore, MD (ASIS), for more than 300 years. The national seashore is charged with maintaining a herd of these horses as part of the island's historic and cultural resource, but the delicate ecology of the barrier island requires some form of population management. At the same time, there is concern about loss of genetic diversity through population control programmes, which remove horses and, therefore, genes, from the island forever. ASIS implemented immunocontraceptive research in 1988 and a fertility control management programme in 1994, based on the application of PZP to this population. In the present paper, the following are reported: (i) reversibility of contraception in treated mares over a 12 year period; (ii) survival of foals born to treated mares over the period 1988–1999; (iii) maintenance of pregnancy and live births among 26 mares treated while pregnant; and (iv) fertility of mares that were *in utero* at the time of PZP treatment of their mothers. On the basis of the accepted mechanism of the PZP contraceptive vaccine, the first hypothesis was that contraceptive effects would disappear in most animals, and the second hypothesis was that the vaccine would not interfere with pregnancy or the survival or fertility of the foals.

Materials and Methods

Study animals

The entire ASIS wild horse herd is observed for band composition and counted monthly. All individual animals are known by unique markings and band affiliations. Reproductive and

genealogy data for each individual animal have been maintained since 1974. The population has ranged in size from 43 horses in 1974 to 172 in 2000.

Vaccination

PZP glycoprotein was isolated and extracted by a modification of the method described by Dunbar *et al.* (1980) and stored at –44°C until used. The initial inoculation consisted of 65 µg PZP emulsified in Freund's complete adjuvant (FCA) and all subsequent inoculations were given with Freund's incomplete adjuvant (FIA) as described by Kirkpatrick *et al.* (1990a). All inoculations were administered i.m. remotely, using a 1.0 cc Pneu-Dart® dart (Pneu-Dart, Inc., Williamsport, PA). A single 65 µg PZP booster inoculation was given annually to those mares in which contraception was desired for > 1 year (Kirkpatrick *et al.*, 1991a). Initial inoculations were always administered in March, whereas booster inoculations were administered in either March or August–September. Contraception was considered successful if no foal was born during the 12 months after treatment. Depending on their role in the original study or their place in the management plan, mares were treated with the PZP vaccine for 1, 2, 3, 4, 5 or 7 consecutive years.

Remote pregnancy testing

Remote pregnancy testing was performed on 97 mares between 1988 and 2000, by measuring urinary or faecal oestrone conjugates (E1C) concentrations, or both, as described by Lasley and Kirkpatrick (1991) and Kirkpatrick *et al.* (1990b, 1991b), and immunoreactive pregnanediol-3-glucuronide-like progesterone metabolite (iPdG) concentrations, as described by Kirkpatrick *et al.* (1990c). Urine or faeces were collected directly from the ground following an observed excretion from an individual mare, placed on ice packs for approximately 12 h and frozen until assayed. Collection of these faecal samples was conducted from late August to December, or during the first third of pregnancy in horses.

Foal survival

Foals were defined as surviving if they lived for 12 months after birth.

Results

Of 53 mares treated with PZP for 1, 2 or 3 consecutive years, the reversibility of contraceptive action and a return to fertility (pregnancy) was 100, 100 and 68.8%, respectively, over a 4 year

period after the last PZP treatment (Table 1). Only a limited number of mares ($n = 10$) were treated for > 3 consecutive years, but 100% of the mares treated for 4 or 5 consecutive years returned to fertility, whereas none of the mares treated for 7 consecutive years has yet returned to fertility over a 7 year interval since the last PZP treatment.

Of 246 births between 1976 and 2000 among mares not treated with the PZP vaccine, 206 foals (83.7%) survived to 1 year of age. In a study of a subset of these 246 births, 76 of 86 (88.4%) foals born to mares never exposed to the PZP vaccine survived to 1 year (Keiper and Houpt, 1984). Of 80 foals born to mares that were treated with PZP during the course of their pregnancy between 1988 and 2000, 67 (83.8%) survived to 1 year. Of these 80 pregnancies among the PZP-treated mares, 26 were first diagnosed pregnant between month 8 and month 11 before parturition and all 26 mares produced live foals.

Fourteen filly foals that were born to mares exposed to the PZP vaccine during the course of their pregnancies have now lived to ⩾ 6 years of age. Of these 14 foals, eight were permitted to breed without PZP contraception upon reaching sexual maturity at 3 years old, and all eight have produced live foals (11 in total) that have survived to at least 1 year of age.

Discussion

Safety must be a major component of any wildlife contraceptive programme because of its potential application to genetically valuable and often publicly valued species. Reversibility of contraceptive action is one of the primary concerns, at least for certain species such as wild horses, free-ranging elephants and captive exotic species. The mechanisms of action of the PZP vaccine are not entirely understood, but there are several reliable models to explain the basic principles underlying its ability to inhibit fertility (Shivers and Liu, 1982; Florman and Wassarman, 1985). Administration of the vaccine to mammals results in a classic humoral immune response and B-cell-mediated production of antibodies against the glycoprotein components of the native PZP, namely ZP3, ZP1 and ZP2 (Skinner *et al.*, 1989). These IgG class antibodies will bind to the zona pellucida of mammalian ova and presumably block fertilization by causing steric hindrance of the zona sperm receptor (Florman and Wassarman, 1985). This model is consistent with the contraceptive effects of the PZP vaccine in wild mares, at least after 1–3 consecutive years of treatment. Although it was not possible to collect blood from the ASIS mares for measurement of antibody titres, similar studies with domestic mares (Liu *et al.*, 1989), deer (Turner *et al.*, 1996; McShea *et al.*, 1997; Miller *et al.*, 2000) and elk (Garrott *et al.*, 1998) support the model. As anti-PZP antibody titres increase, contraceptive effectiveness increases and as titres decrease, fertility recurs. This would explain the rather high degree of fertility recovery and the relatively short period of time necessary for return to fertility of the mares treated for 1–3 consecutive years.

The increased time for return to fertility in animals treated for 4 or 5 consecutive years, and the complete lack of reversibility in the five mares treated for 7 consecutive years, may be the result of sustained high antibody titres from longer periods of treatment. Alternatively, there may be additional mechanisms at work.

Immune responses can generally be partitioned into two general types, one of which is the B-cell-mediated humoral response, which, in the case of PZP, results in a fertilization block without accompanying oophoritis (Afzalpurkar and Gupta, 1997). The second response is a T-cell-mediated response, in which a variety of defensive phagocytic cells descend upon the target tissue and, in the case of PZP, cause moderate to severe oophoritis (Tung *et al.*, 1996). In most mammals, a particular immune response is dominated by one of these major forms of immunity, but not usually to the complete exclusion of the other. Oophoritis may become a serious long-term impediment to ovarian function and, therefore, fertility, usually as a result of

autoimmune responses and autoantibodies directed against the zona pellucida, or it may be a temporary condition with full recovery at some point (Lou *et al.*, 1996). Thus, the important question with respect to the mares treated for 7 consecutive years is whether the prolonged contraceptive effects are merely a function of sustained high antibody titres or are perhaps a result of a cellular response that has caused physical damage to the ovary.

Previous studies of the long-term effects of the PZP vaccine (Kirkpatrick *et al.*, 1992, 1995a) have indicated decreased oestrogen secretion, but fertility has always recovered except in animals treated for 7 consecutive years. This finding indicates both a humoral response, which interferes with fertilization and perhaps also a cellular response, which causes the mild reduction in oestrogen production. It is noteworthy that immediately after 7 consecutive years of PZP treatment none of the five mares was ovulating. However, a more recent investigation (D. Powell, personal communication) measuring urinary progesterone metabolites has shown evidence of high luteal phase progesterone concentration. Complete elucidation of the mechanisms at work in the mares treated for 7 years remains to be discovered.

Finally, the equal survival among foals whose mothers had and had not been treated during pregnancy strengthens the model for a simple fertilization block as the predominant immunological mechanism in horses. Furthermore, the normal fertility displayed by mares that were *in utero* at the time of their mothers' vaccinations provides further evidence of the safety of this vaccine in pregnant animals and indicates that the antibodies either do not cross the placenta or, alternatively, that their passage represents passive immunization, which would not be expected to last for the 3 years taken for the mares *in utero* at the time of vaccination to reach sexual maturity.

In conclusion, it is clear that, in horses, the contraceptive effects of PZP treatment administered annually for up to 5 consecutive years are reversible, although the time for reversal is highly variable and may extend to 6 or 7 years. The treatment of pregnant animals does not cause harm to the pregnancy, the survival of the foals or the subsequent fertility of the foals. This finding, coupled with the lack of behavioural side effects (Powell, 1999) indicates that the PZP vaccine represents an extremely safe approach to fertility control in wild horses.

These studies were supported by the National Park Service, Assateague Island National Seashore, The National Institutes of Health and the Science and Conservation Center of ZooMontana.

Summary. Ten feral mares free-roaming in Maryland, USA, were inoculated with porcine zonae pellucidae (PZP) protein before the breeding season for three consecutive years (1988–90). Ovarian function was monitored for 51 days during the peak of the breeding season after the third annual PZP inoculation, in seven of these mares and in four untreated control mares, by means of urinary oestrone conjugates and non-specific progesterone metabolites. None of the ten inoculated mares became pregnant in 1990, compared with 55% of 20 control mares, which included two of the four monitored for ovarian function. Three of the untreated mares demonstrated apparent normal ovarian activity, characterized by preovulatory oestrogen peaks, concurrent progesterone nadirs at ovulation, breeding activity, and luteal-phase progesterone increases after ovulation. Two of the seven monitored PZP-treated mares demonstrated ovulatory cycles that did not result in conception. One was pregnant as a result of conception in 1989 and demonstrated a normal, late-gestation, endocrine profile. The remaining four PZP-treated mares revealed no evidence of ovulation, and urinary oestrogen concentrations were significantly depressed. The experiments indicated that (i) a third consecutive annual PZP booster inoculation is >90% effective in preventing pregnancies in mares and (ii) three consecutive years of PZP treatment may interfere with normal ovarian function as shown by markedly depressed oestrogen secretion.

Keywords: zona pellucida; contraception; ovary; immunocontraception; oestrogen; progestin; horse

Introduction

Immunization with porcine zonae pellucidae (PZP) is a promising approach to immunocontraception. This glycoprotein layer is composed of several protein fractions of which a fraction of M_r 55 000, referred to as ZP3, has been identified in the species studied to be the specific zona receptor for sperm recognition and attachment (Sacco *et al.*, 1984).

Immunization with PZP has resulted in significant zonae antibody titres and fertility inhibition in a range of laboratory species (Tsunoda & Chang, 1976; Gwatkin *et al.*, 1977) and non-human primates (Gulyas *et al.*, 1983; Sacco *et al.*, 1983a, 1987; Aitken *et al.*, 1984; Bamezai *et al.*, 1986; Dunbar *et al.*, 1989). Sacco (1977), Hasegawa *et al.* (1985) and Trounson *et al.* (1980) have demonstrated that human and porcine zonae share common antigens. In several of these studies, the administration of PZP or purified ZP3 was accompanied by disruption of ovarian function and

cyclic endocrine patterns, but, in most cases, normal ovarian function returned over an interval ranging from several cycles to 300 days.

A concern regarding the potential use of PZP, ZP3 or any antigenic epitope of ZP3 in humans or exotic species is the possible permanent loss of fertility or the disruption of normal reproductive endocrine events. Studies in three species have indicated adverse side-effects on ovarian function. Mahi-Brown *et al.* (1985) found that immunization of bitches led to long-term alterations in oestrous cycles and to abnormal steroid profiles. Immunization of rabbits with PZP also led to disruption of hormone profiles (Wood *et al.*, 1981; Skinner *et al.*, 1983). Ten baboons immunized with ZP3 showed reduced oestrogen concentrations in plasma and numbers of antral follicles; two of these animals failed to ovulate, and five became amenorrheic by 8 months after immunization (Dunbar *et al.*, 1989).

Liu *et al.* (1989) demonstrated that PZP immunization could render mares infertile, but that fertility returned during the following breeding season. Kirkpatrick *et al.* (1990a) also used PZP to inhibit fertility in free-roaming feral horses and demonstrated that fertility returned during the next breeding season. In a continuation of that study, Kirkpatrick *et al.* (1991) demonstrated that a single annual booster inoculation of PZP was sufficient to extend the contraceptive efficacy of PZP through a second breeding season.

Despite the data accumulated from studies of non-human primates and horses, little is known about the effects of continuous PZP treatment on the mammalian ovary over several years. The present study evaluated the effectiveness of monitoring ovarian function in uncaptured feral mares by means of urinary steroid metabolites and determined the effects of PZP immunization for three consecutive years upon fertility, ovarian endocrine function, and sexual behaviour in feral mares.

Materials and Methods

Animals

Ten free-roaming feral mares inhabiting Assateague Island National Seashore, MD, USA, were evaluated for the contraceptive efficacy of a third consecutive annual PZP inoculation; ovarian function was assessed in seven of these mares. Twenty untreated mares served as controls and ovarian function was studied in four of them. Ages and fertility records were known for six of the seven PZP-immunized mares and for three of the four control mares. Ages ranged from 3 to 16 years. Each mare possessed unique markings and was photographed for later identification.

PZP immunization

The PZP antigen was prepared from porcine ovaries as described by Liu *et al.* (1989) and stored frozen until used in the field. In 1988 (year 1 of this study), the ten experimental mares were immunized with two or three inoculations of PZP. The schedule of inoculations and the resulting contraceptive effects have been described (Kirkpatrick *et al.*, 1990a).

In February, 1989 (year 2 of this study) the ten PZP-treated mares were given a single PZP booster inoculation and the contraceptive efficacy was assessed (Kirkpatrick *et al.*, 1991). The ten mares were given a further single booster inoculation in March 1990 (year 3 of this study) identical to the booster treatment in year 2. Between 4 May and 24 June 1990, urine samples in soil or sand were collected daily or every other day, without capture, from seven of these ten treated mares and four untreated control mares. The selection of the seven mares from among the ten was made on the basis of accessibility for urine collections, and the timing of the collections was based on peak breeding activity among the Assateague population (Keiper & Houpt, 1984). The age distributions of the 20 mares selected as controls for the assessment of contraceptive efficacy was similar to that of the ten treated mares. Pregnancy was determined during October 1990, on the basis of concentrations of urinary oestrone conjugates as described by Kirkpatrick *et al.* (1988). Differences in rates of pregnancy between treated and control mares were tested for significance by means of binomial probability distribution (Freedman *et al.*, 1978).

Behavioural assessments

Sexual behaviour of treated and control mares was assessed in terms of behavioural oestrous patterns including (i) raised tail when stallions attempted mounting, (ii) eversion of the clitoris, (iii) absence of kicking or biting by the mare during attempted or successful mountings and (iv) copulation, as described by Waring (1983). The period for which

each mare was observed each day ranged from 1 to 3 h depending upon the duration of the interval between sighting and urination.

Assessment of ovarian function

Unextracted urine samples, collected from the soil, were assayed for oestrone conjugates and non-specific progesterone metabolites by microtitre enzymeimmunoassays. The oestrone conjugate assay has been described (Daels *et al.*, 1991) and validated for the Equidae (Evans *et al.*, 1984; Czekala *et al.*, 1990; Monfort *et al.*, 1991) and reflects plasma oestrogen concentrations (Daels *et al.*, 1991); the inter- and intra-assay coefficients of variation were 11·10 ($n = 7$) and 3·82% ($n = 7$), respectively. The lower limit of sensitivity for the assay was 6·25 pg and concentrations of oestrone conjugates in serially diluted urine samples extracted from soil have exhibited parallelism to the standard curve (Kirkpatrick *et al.*, 1988). Recovery of ^{3}H-labelled steroid metabolites from the soil has been demonstrated to be >95% (Kirkpatrick *et al.*, 1988).

The enzymeimmunoassay for non-specific progesterone metabolites has been described and validated in the Equidae by Kirkpatrick *et al.* (1990b) and employs monoclonal antibody 1284-1 raised against 20δ-hydroxyprogesterone (provided by R. Chatterton, Northwestern University). The inter- and intra-assay coefficients of variation were 12·38 ($n = 8$) and 10·42% ($n = 8$), respectively. The lower limit of sensitivity was 0·075 ng. To account for differences in urine concentrations, all urine samples were assayed for creatinine by the microcolorimetric method of Taussky (1954), and steroid metabolite concentrations were converted to ng/mg creatinine. Differences in mean hormone concentrations were tested for significance by means of Student's t test.

Results

None of the ten mares treated with PZP for the third consecutive year became pregnant by October 1990, but 11 of 20 control mares (55%) were pregnant in October 1990. The difference in pregnancy rates was significant ($P < 0·001$). Two of the four control mares for which breeding-season serial urine samples were collected were pregnant in October 1990.

The four control mares monitored for ovarian function demonstrated evidence of pregnancy and parturition (M13, 15 years), oestrous cycles without conception (Speckles, age unknown but < 10 years, and M4, 18 years) and a conceptive cycle (M17GL, 3 years). Pregnancy and parturition (Fig. 1a) was characterized by concentrations of urinary oestrone conjugates which fell rapidly ~7 days before parturition and urinary non-specific progesterone metabolite concentrations which fell abruptly on the day before parturition. There were no endocrine indications of *post-partum* ovulation during the 39 days of urine collection following parturition. A marked increase in oestrone conjugates occurred 6 days after parturition, but, on the basis of non-specific progesterone metabolite concentrations, did not culminate in ovulation; this increase in oestrone conjugates was accompanied by repeated behavioural oestrus in the presence of the band stallion. A second control mare demonstrated an ovulatory oestrous cycle (Fig. 1b) based on urinary oestrone conjugates and non-specific progesterone metabolites, with a clear peak in preovulatory oestrone conjugates (375 ng/mg creatinine) coinciding with a non-specific progesterone metabolite nadir (20 ng/mg creatinine) and a subsequent luteal-phase increase in non-specific progesterone metabolites (330 ng/mg creatinine). Urinary non-specific progesterone metabolites reached basal concentrations (15 ng/mg creatinine) by Day 36 of collection, without behavioural or endocrine evidence for a second oestrous cycle. At the same time as the preovulatory increase in oestrone conjugates, this mare demonstrated behavioural oestrus in the presence of the band stallion. A third control mare demonstrated a conceptive ovulatory oestrus (Fig. 1c) characterized by an exceptionally high peak in preovulatory oestrone conjugates (1·1 μg/mg creatinine) coinciding with a nadir in non-specific progesterone metabolite (27 ng/mg creatinine) and a subsequent and sustained rise in this urinary metabolite (1·7 μg/mg creatinine). Concentrations of non-specific progesterone metabolites remained above 1·0 μg/mg creatinine throughout the remainder of the collection period. Urinary oestrone conjugates fell to basal concentrations (15–55 ng/mg creatinine) for 35 days after the ovulatory nadir in non-specific progesterone metabolites and then rose abruptly to 1·45 μg/mg creatinine, which is a characteristic signal of pregnancy in mares (Evans *et al.*, 1984). During the first 5 days of urine collection, which coincided with the preovulatory oestrone conjugate increases,

M17GL displayed behaviour associated with oestrus and was witnessed being successfully mounted on Days 3–5 of collection. By October, M17GL had a urinary oestrone conjugate concentration of 31·3 ng/mg creatinine, indicating that the pregnancy had terminated, a common event in feral 3-year-old mares (Lucas *et al.*, 1990). The fourth control mare produced a foal on 6 April, 1 month before the initiation of urine collection. Urinary oestrone conjugates and non-specific progesterone metabolite concentrations revealed a portion of an ovulatory cycle during the first 20 days of the collection period and a second ovulatory cycle during the 31 remaining days of the collection period.

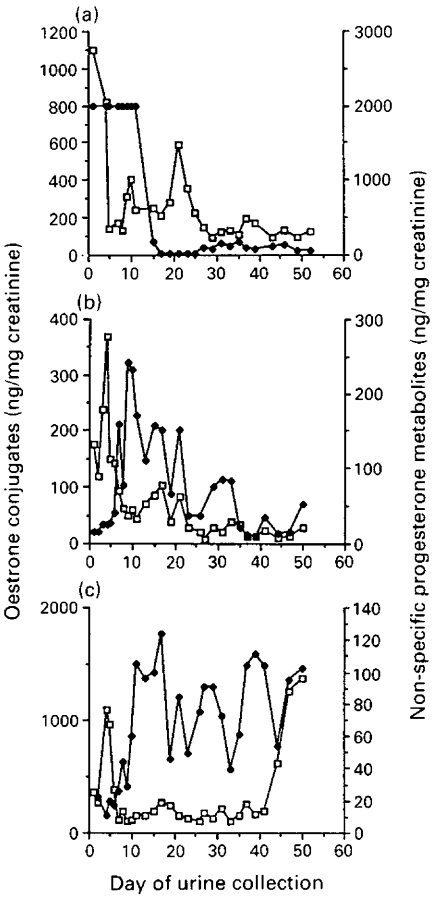

Fig. 1. Profiles of urinary oestrone conjugates (□) and progesterone metabolites (◆) in three control mares: (a) M13 (a foal was born on Day 12), (b) an oestrous cycle without conception in Speckles and (c) an oestrous cycle with conception in M17GL. Day 0 was 4 May.

Four of the seven PZP-treated mares (T5AE, 10 years; M17GJ, 5 years; M2E, 10 years; M13F's Bay, age unknown) displayed no endocrine evidence of ovulation during the 51-day collection period. Concentrations of urinary non-specific progesterone metabolites revealed no luteal-phase increases. Similarly, urinary oestrone conjugate concentrations and patterns revealed no signs of an oestrous cycle and concentrations during the 51-day collection period were extremely variable and significantly lower ($P < 0{\cdot}05$) than those of the control mares Speckles and M4, which demonstrated ovulatory cycles. Neither T5AE nor M17GJ displayed any signs of behavioural oestrus during the study. M2E displayed three incidences of behavioural oestrus on Days 16, 20 and 35 of

collection, in the absence of any significant increases in oestrone conjugates, but the band stallion showed no interest in this mare during these displays. The mare M13F's Bay had a significant increase in oestrone conjugates between Days 25 and 35 of collection, which was accompanied by eversion of the clitoris and four successful mounts by the band stallion during this time. Urinary endocrine profiles are shown for two of these non-cyclic mares in Fig. 2a, b.

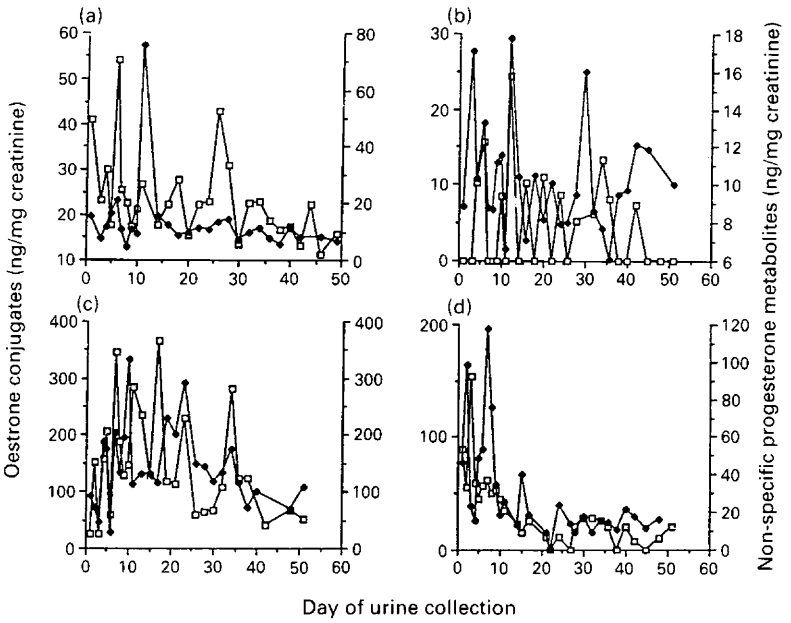

Fig. 2. Profiles of urinary oestrone conjugates (□) and progesterone metabolites (◆) in four mares treated with porcine zonae pellucidae: non-ovulatory patterns of urinary steroids in (a) T5AE and (b) M2E; ovulatory cycles without conception in (c) M6I and (d) T2BE.

The PZP-treated mares M6I (6 years old) and T2BE (10 years old) displayed urinary non-specific progesterone concentrations and patterns characteristic of ovulatory oestrous cycles (Fig. 2c, d, respectively), but mare M6I did not have the characteristic preovulatory peak in oestrone conjugates.

During two of the increases in oestrone conjugates, on the 10th and 34th days of collection, M6I displayed tail raising and evoked attention from the band stallion, but no mounting was observed. Urine collection with T2BE began in the latter stages of the luteal phase, concentrations of non-specific progesterone metabolites falling from 199 ng/mg creatinine to non-detectable concentrations 15 days later. T5AE displayed intermittent behavioural oestrus throughout most of the collection period despite very low oestrone concentrations of conjugates and on one occasion, on Day 27 of collection, was mounted successfully by the band stallion; this mounting coincided with a rapid rise in concentrations of oestrone conjugates from non-detectable to 45 ng/mg creatinine.

The seventh PZP-treated mare (M17G, 8 years old) was pregnant at the time of urine collection and produced a foal on 1 August 1990. This was the only foal produced among the mares treated with a booster inoculation in the second year of this study. The date of parturition indicates an unusually late conception (~25 August) for Assateague mares and suggests that her antibody titres had fallen to a concentration which allowed conception. Urinary endocrine data for oestrone conjugates and non-specific progesterone metabolites were consistent with data on plasma hormones for mares in late pregnancy (Ginther, 1979).

Discussion

This study demonstrates that a single annual PZP booster inoculation given after 2 years of treatment will extend the observed infertility in such treated mares for a third year. Only two of the seven monitored PZP-treated mares demonstrated ovulatory cycles and it is probable that treatment with PZP for 3 years altered ovarian function. The absence of a luteal phase in four of these mares, coupled with significantly lower and intermittent increases in oestrone conjugates may indicate incomplete folliculogenesis, with reduced secretion of oestrogen and failure to ovulate. These alterations in ovarian function are consistent with data from PZP-treated rabbits (Skinner *et al.*, 1983, 1984), dogs (Mahi-Brown *et al.*, 1985) and baboons (Dunbar *et al.*, 1989).

The urinary endocrine data and the correlated behavioural observations and events, such as parturition and breeding behaviour for the four control mares, reflect functional ovaries. These data provide an initial view of ovarian function in feral mares which is consistent with data derived from domestic horses based on plasma steroid concentrations (Ginther, 1979) and urinary steroid metabolites (Daels *et al.*, 1991).

Three previous studies with horses point to long-term treatment, as opposed to a single treatment, as the factor which resulted in the alteration of ovarian function in PZP-treated mares. Liu *et al.* (1989) treated mares with PZP for only one breeding season and demonstrated the occurrence of ovulation after 7 months of infertility. This was indicated by normal patterns of luteal-phase plasma progesterone and normal fertility rates for up to 3 years after the single inoculation. These results are consistent with the proposed mechanisms of contraceptive action of antibodies to PZP in mares, which include a fertilization block brought about by steric hindrance of the sperm receptor (Liu *et al.*, 1989) and an acrosome reaction in horse spermatozoa induced by zona pellucida (Arns *et al.*, 1990). Kirkpatrick *et al.* (1990a, 1991) demonstrated the return of normal fertility rates among feral mares 1–2 years after a single immunization with PZP and, although ovarian endocrine function was not monitored in these two studies, the normal fertility rates indicate that ovulation occurred and that preovulatory oestrogen concentrations were sufficient to elicit breeding behaviour. Similarly, short-term active immunization of non-human primates led to infertility, but with undetectable or only temporary disruption of ovarian function (Gulyas *et al.*, 1983; Sacco *et al.*, 1983a, b, 1987; Bamezai *et al.*, 1986).

Zonae antibodies have been shown to bind to the developing follicular zona pellucida as well as to the zona of ovulated ova (Henderson *et al.*, 1988). This may indicate that zonae antibodies disrupt some developmentally critical cellular communication between differentiating follicular cells and the growing oocyte (Skinner *et al.*, 1990), which ultimately leads to the destruction of a portion or all of the oocyte pool (Skinner *et al.*, 1984).

At least three factors may play a significant role in long-term alterations of ovarian function. The duration of contraceptive efficacy is directly related to the amount of PZP antigen administered (Henderson *et al.*, 1988) and to the resulting antibody titres (Millar *et al.*, 1989), and ovarian dysfunction may likewise be related to PZP dose.

The purity of the PZP antigen may be a second factor in the possible alteration of ovarian function. Most of the early studies with rabbits, dogs and some non-human primates which demonstrated ovarian dysfunction used crude preparations of PZP, which included the entire complement of zonae protein. These various preparations also include associated carbohydrate moieties which are thought to be important antigenic components (Paterson & Aitken, 1990). More recent studies have used preparations of higher purity and even genetically engineered epitopes of the ZP3 protein. Dunbar *et al.* (1989) used both ZP1 and ZP3, which share a common antigenic epitope, but serious ovarian dysfunction still occurred in baboons after 49 weeks and nine cycles. The horses in this study received crude PZP antigen which may have exacerbated long-term effects despite the small dose of 65 μg.

The duration of treatment may contribute to long-term effects. Small doses of high purity may produce long-term effects through cumulative effects upon follicular pools. No other mammals,

apart from the horses in this study, have been treated with PZP for 3 years. Thus, our current understanding of long-term effects is poor. Based on the work of Liu *et al.* (1989) with captive mares, and the initial field tests with feral mares (Kirkpatrick *et al.*, 1990a, 1991), all of which used the same antigen and doses and demonstrated a return to normal fertility, the data from three consecutive years of treatment suggest that the duration of treatment may be the primary factor for this observed ovarian dysfunction in mares.

The authors gratefully thank G. Olson, Assateague Island National Seashore, for logistical support, B. L. Lasley, UC-Davis, for the oestrone conjugate antibodies, and A. G. Sacco, Wayne State University, for the careful review of the manuscript, and K. Asis for assistance in collecting urine samples. This study was funded by the World Society for the Protection of Animals and National Park Service Grant CA-1600-30005.

COMPENSATORY REPRODUCTION IN FERAL HORSES

JAY F. KIRKPATRICK, Department of Biological Sciences, Eastern Montana College, Billings, MT 59101
JOHN W. TURNER, JR., Department of Physiology, Medical College of Ohio, Toledo, OH 43699

Abstract: We estimated fetal loss rate in 2 separate herds of feral horses (*Equus caballus*) with significantly different foaling rates that inhabited the same barrier island. We estimated pregnancy rates for 40 feral mares from Assateague Island National Seashore (NS), where the foaling rate was 32.5% and for 48 mares from Chincoteague National Wildlife Refuge (NWR) where the foaling rate was 62.5%. Fetal loss rates were estimated by comparing fall pregnancy rates with foaling rates during the following spring and summer. The estimated fetal loss for mares from Assateague Island NS and Chincoteague NWR was 7.1 and 6.2%, respectively. Ten of the 40 mares from Assateague Island NS (25%) were lactating and only 2 produced foals, whereas 2 of the 48 mares from Chincoteague NWR (4.1%) were lactating and neither produced foals. These data indicate that (1) the differential foaling rates are not the result of fetal loss after 90-days postconception, (2) lactational anestrus is a contributing factor to differential foaling rates, and (3) the annual removal of foals from the Chincoteague NWR herd results in compensatory reproductive mechanisms and higher foaling rates.

J. WILDL. MANAGE. 55(4):649–652

Compensatory reproduction might be an important adaptive response to various natural, population-limiting pressures such as predation, food availability, and disease. Human intervention into wildlife populations by means of hunting or removal of animals can also affect population growth. Two populations of feral horses inhabiting Assateague Island, a barrier island off the Maryland/Virginia coast, provide an excellent model for the study of compensatory reproduction. The island's feral horses are maintained in 2 separate herds, one on the Maryland portion of the island and the other on the Virginia portion. Peak breeding activity for both herds is May and June, with peak foaling activity during April and May (Keiper and Houpt 1984). Weaning occurs at age 1 year for mares foaling 2 consecutive years but often occurs at ages 2 or even 3 years for mares that do not foal on consecutive years.

The Maryland herd consists of approximately 150 horses living on Assateague Island National Seashore, and, in keeping with National Park Service policies of nonintervention, management is minimal. The Virginia herd consists of approximately 200 horses inhabiting Chincoteague NWR; these horses are intensively managed through the annual removal of approximately 80% of the foals, a practice dating back >30 years. In an 8-year study of reproduction among the Assateague Island horses conducted between 1975 and 1983, Keiper and Houpt (1984) reported an annual foaling rate of 74.4% among sexually mature mares on the Chincoteague NWR. In contrast, the foaling rate for the unmanaged Assateague Island NS horses was only 57.1%, with an age-specific range of 40–70%. Since 1986, the Assateague Island NS foaling rate has dropped below 50% (J. F. Kirkpatrick, unpubl. data).

The purpose of our study was to examine fall pregnancy rates in the 2 herds and to compare these with respective foaling rates during the following spring and summer, thereby determining the extent of fetal loss between the 2 herds. We hypothesized that the physiological stresses of concurrent pregnancy and lactation among the Assateague Island NS horses cause a greater incidence of fetal loss than among the horses of Chincoteague NWR, where the physiological stress of lactation is removed annually.

The authors gratefully acknowledge the logistical support provided by G. Olson. We also thank B. L. Lasley and S. E. Shideler for assistance in establishing the urinary steroid assays. Our study was supported in part by National Park Service grant CA-1600-30005.

METHODS

Forty mares whose home ranges were exclusively confined to Assateague Island NS and 48 mares whose home ranges were exclusively confined to Chincoteague NWR were included in our study. All mares were sexually mature and ≥3 years old. The ages of 29 of the Assateague Island NS mares were known, but the ages of the Chincoteague NWR mares were not known exactly. Ten of the 40 Assateague mares (25%) and 2 of the Chincoteague mares (4.1%) had foals at their sides and were lactating.

Table 1. Pregnancy and foaling rates (%) for lactating and nonlactating feral mares in 2 separate herds.

	Assateague Island National Seashore		Chincoteague National Wildlife Refuge	
	n	%	*n*	%
Total mares tested	40		48	
Diagnosed pregnant	14	35.0	32	66.6
Live foals	13	32.5	32	66.6
Lactating mares	10	25.0	2	4.1
Diagnosed pregnant	2	5.0	0	
Live foals	2	5.0	0	

During October 1989 urine and/or fecal samples were collected from each mare as described by Kirkpatrick et al. (1988, 1990*b*). Urine was aspirated directly from the ground immediately following elimination by a mare, or it was hand-centrifuged from sand, placed on ice at the time of collection, and stored frozen at the end of each day. Fecal samples were placed in plastic bags, kept on ice during the day and frozen each evening. For the 40 Assateague mares, we collected urine samples from 18 mares, fecal samples from 17 mares, and both urine and fecal samples from 5 mares. For the Chincoteague mares, urine samples were collected from 23 animals and fecal samples from 25. All horses had distinctive markings which we recorded on drawings or with photographs for later identification.

Unextracted urine samples were assayed for (1) creatinine (Cr), (2) estrone conjugates (E_1C) by enzyme immunoassay as previously described by Shideler et al. (1990) and modified for use in the horse (Kirkpatrick et al. 1990*b,c*), and (3) nonspecific immunoreactive progesterone metabolites (iPdG) as described by Kirkpatrick et al. (1990*a*). The reliability for the E_1C assays and the 100% accuracy for predicting pregnancy, which has been tested in domestic horses and confirmed by rectal palpation (Evans et al. 1984, Kasman et al. 1988) and has been demonstrated in feral horses (Kirkpatrick et al. 1990*a,b,c,* 1991), have been reported elsewhere. Urinary steroid metabolite concentrations were indexed to urinary Cr to account for differences in urine concentrations, and they were reported as ng/mg or μg/mg Cr. We considered concentrations of E_1C in excess of 1.0 μg/mg Cr (Evans et al. 1984, Kasman et al. 1988, Kirkpatrick et al. 1988) and iPdG in excess of 100 ng/mg Cr (Kirkpatrick et al. 1991) as indicative of pregnancy.

We used methods described by Kirkpatrick et al. (1991) to measure fecal E_1C and iPdG concentrations. Fecal total estrogens were assayed by radioimmunoassay as described by Bamberg et al. (1984) and Kirkpatrick et al. (1990*c*). Fecal steroid metabolites and free estrogens were reported as ng/g feces. Pregnancy was predicted on the basis of >1.0 ng/g E_1C, >150 ng/g iPdG, and 5.0 ng/g total estrogens (Kirkpatrick et al. 1990*c,* 1991). During the summer and fall of 1990 we located all pregnancy-tested mares and recorded the presence or absence of foals. Ownership of foals was based on witnessed lactation. We used a binomial probability distribution (Freedman et al. 1978) to test for differences in pregnancy, lactation, and foaling between the 2 herds.

RESULTS

A significantly ($P < 0.001$) greater proportion of Chincoteague mares tested positive for pregnancy, and a significantly ($P < 0.001$) greater number of foals were produced by Chincoteague mares than by Assateague mares (Table 1). There was a 7.1% and a 6.2% fetal loss rate among the 40 Assateague and 48 Chincoteague mares, respectively, with no significant difference between the 2 herds. Annual foal removal resulted in a significant ($P < 0.01$) difference in lactating mares between the 2 herds, with only 2 lactating Chincoteague mares and 10 lactating Assateague mares. Collectively, the 12 lactating mares produced only 2 foals.

DISCUSSION

Early neonatal death is almost impossible to detect on Assateague Island habitat because of dense vegetation and the pregnant mares' behavior of isolating themselves at parturition. Thus, we could not distinguish between fetal loss and neonatal loss. Nevertheless, the nearly doubly great pregnancy rate for Chincoteague horses indicates that the differential foaling rates between the 2 herds is determined by October pregnancy rates, and not by fetal loss after approximately 90–150 days postconception.

Among domestic mares, Ginther (1979) reported an 80% seasonal pregnancy rate and a 70% live foal crop. Van Niekerk (1965) reported a 12.5% pregnancy loss among domestic mares, with greater pregnancy loss during the first half of pregnancy. The suggested critical period for pregnancy loss was Days 25–31. Estimates of abortion rates in the domestic mare, after Day 45 of pregnancy, range from 7 to 12% (Platt

All use subject to http://about.jstor.org/terms

1973, Irwin 1975, Sullivan et al. 1975, Chevalier and Palmer 1982), and major causes of this loss are thought to include foal heat conceptions in lactating mares (Platt 1973) and periglandular fibrosis of the uterine mucosa (Kenney 1978). In our study fetal loss after Day 90 postconception in both herds of feral mares was not different from that reported for domestic mares after Day 45 postconception.

Among island feral horses, age has also been shown to be a major factor in fetal loss rates. Lucas et al. (1990) demonstrated that fetal loss among mares of Sable Island, Canada, between Days 120 and term was 9.7, 40.3, 25.0, and 26.3% annually over 4 years. The fetal loss rates were age-dependent, with a 16.7% loss for 3 year olds and a 5.6% loss for 4 year olds. In our study, only mares ≥3 years old were included, thus it is unlikely that age had a significant effect upon the 2-fold difference in pregnancy and foaling rates. Furthermore, an environmental basis for the differences seems unlikely, because the 2 herds inhabit the same island. Photoperiod, climate, and food supplies are equivalent, and both herds originate from the same genetic forebearers.

The most probable cause for the differences in pregnancy and foaling rates is lactational anestrus, a condition in mares during which ovulation does not occur (Day 1939, Burkhardt 1948, Roberts 1971, Lieux 1973). In domestic mares, this condition persists in a large percentage of lactating mares until the foal is weaned, usually at 4–6 months. This period of an ovulatory lactational anestrus has been characterized by very small or absent ovarian follicles (Day 1939). In controlled experiments with domestic mares, removing the foal at parturition hastened the return of estrus in 3 of 4 mares, whereas all 4 mares that nursed their foals normally were anestrus (Ginther et al. 1972). On Assateague Island, weaning seldom occurs sooner than 1 year, is fairly common at 2 years, and in some instances has been observed at 3 or 4 years. In contrast, about 80% of the foals of Chincoteague NWR mares are removed annually in July.

Our results differ significantly from those of Wolfe et al. (1989), who examined pregnancy rates among 553 feral mares >2 years old, in Nevada, Oregon, and Wyoming. The pregnancy rates for horses in these states were 57.0, 61.0, and 81.4%, respectively, with no differences between lactating and nonlactating mares. Some of the differences between the results of our study and those of Wolfe et al. (1989) could be the result of different pregnancy testing procedures and the accuracies of these tests. Wolfe et al. (1989) reported accuracy rates of 81.8% for plasma progesterone concentrations, 63.0% for plasma estrogen, and 53.7% for plasma pregnant mares' serum gonadotropin (PMSG). The use of only plasma progesterone measurements for pregnancy detection in horses is potentially inaccurate (Hyland 1990), and the same is true for urinary iPdG measurements alone, largely because of the high incidence of persistent corpora lutea in mares. Urinary E_1C concentrations, however, reflect the presence of a viable embryo and drop precipitously within hours of the death of the fetus (Kasman et al. 1988). Consequently, accuracy of pregnancy detection in mares approaches 100% with urinary E_1C concentrations alone (Evans et al. 1984, Kasman et al. 1988), 100% for urinary E_1C and iPdG concentrations together (Kirkpatrick et al. 1990*a*), and 95% for total fecal estrogens (Bamberg et al. 1984, Kirkpatrick et al. 1990*c*).

MANAGEMENT IMPLICATIONS

Control policies for feral horses have historically centered around the removal of horses, particularly young horses. Because our results suggest that feral horses increase conception rates in response to the removal of foals before weaning, a policy of removing young, unweaned horses can lead to greater fecundity among their mothers. Conversely, the removal of weaned horses will be unlikely to have any significant effect upon fecundity of the mothers. Future management policies for the control of feral horse populations should consider compensatory reproductive responses of the mares. Regardless of whether actual removal or contraception is employed as the control method, efforts should focus on mares >3 years old, and those without foals. Conversely, the removal of foals or yearlings should be avoided because of the probability of increasing fecundity among their mares.

Absence of Effects From Immunocontraception on Seasonal Birth Patterns and Foal Survival Among Barrier Island Wild Horses

Jay F. Kirkpatrick

Science and Conservation Center
Zoo Montana
Billings, Montana

Allison Turner

Assateague Island National Seashore
Assateague, Maryland

Despite a large body of safety data, concern exists that porcine zonae pellucidae (PZP) immunocontraception—used to manage wild horse populations—may cause out-of-season births with resulting foal mortality. Our study at Assateague, Maryland indicated the effects of immunocontraception on season of birth and foal survival between 1990 and 2002 on wild horses from Assateague Island. Among 91 mares never treated, 69 (75.8%) of foals were born in April, May, and June (in season). Among 77 treated mares, 50 (64.9%) were born in season. Of 29 mares foaling within 1 year after treatment (contraceptive failures), 20 (68.9%) were born in season. Of 48 mares treated for greater than 2 years then withdrawn from treatment, 30 (62.5%) of 48 foals were born in season. There were no significant differences ($p < .05$) between either treatment group or untreated mares. Survival did not differ significantly among foals born in or out of season or among foals born to treated or untreated mares. Data indicate a lack of effect of PZP contraception on season of birth or foal survival on barrier island habitats.

The use of porcine zonae pellucidae (PZP) contraceptive vaccine has been widely applied to wild horses in numerous research studies (Kirkpatrick, Turner, Liu, & Fayrer-Hosken, 1996) and also has been applied to several wild horse herds as a management tool (Turner & Kirkpatrick, 2002). Issues of efficacy, reversibility, long-term health (Kirkpatrick & Turner, 2002; Turner & Kirkpatrick, 2002), and behavior (Powell, 1999) have been addressed through past research efforts. Two remaining issues that have not been addressed are the effect of PZP on out-of-season births among treated mares and the effects of PZP on the survival of foals born to treated mares.

The concern with the possibilities of out-of-season births arises from the possibility that anti-PZP antibody titers may, over time, fall below contraceptive levels at times of the year when a pregnancy and the resulting birth would be injurious to the foal. Although no body of data suggests that foals born to treated mares are less healthy or survive at lower rates than foals born to untreated mares, this is a safety issue not addressed since the original study of PZP contraception of wild horses in 1988 (Kirkpatrick, Liu, & Turner, 1990). This retrospective study was conducted to determine if (a) PZP treatment led to significant out-of-season births, (b) PZP treatment led to a significant decrease in foal survival, and (c) foal births out of season led to decreased survival.

METHOD

The identities of all 172 wild horses inhabiting Maryland's Assateague Island National Seashore (ASIS) are known by individual markings and band affiliations. Birth dates, by month, exist for 168 foals born on ASIS from 1986 through 2002. Birth dates are acquired by visual sighting of foals during monthly surveys by National Park Service personnel. Foal survival is defined as surviving to age 1 or older.

To insure that very early neonatal losses do not go undetected, mares were tested for pregnancy each year by means of urinary and/or fecal steroid metabolite analysis (Kirkpatrick, Kasman, Lasley, & Turner, 1988; Kirkpatrick, Lasley, et al., 1990; Kirkpatrick, Shideler, Lasley, & Turner, 1991). Specifically, the excreta is analyzed for both estrone conjugates (E1C) or immunoreactive pregnanediol-glucuronide-like progesterone metabolites (iPdG). Both metabolites are significantly higher in pregnant animals. However, although progesterone levels (and therefore iPdG) will remain high for months after a fetal death, E1C concentrations fall within 12 hr of fetal loss (Hyland & Langsford, 1990). Thus, the pregnancy detection methods are virtually 100% accurate. In this way, very early neonatal losses do not go undetected.

The normal season of foaling is defined as April, May, and June (called *in season* hereafter), based on previous studies with wild horses (Hall, 1972; Keiper &

Houpt, 1984; Palmer, 1978; Satoh & Hoshi, 1932). Comparisons were made in the number and percentage of foals born in season and those born outside this seasonal window between mares (a) never treated with PZP, (b) treated with PZP for 1 year before the birth (i.e., contraceptive failures), and (c) those treated with PZP for at least 2 years before the birth of a foal. The group treated with PZP for 1 year before the birth (contraceptive failures) included 9 mares who became pregnant after only a single initial inoculation was given to 41 mares in 1994 as opposed to the standard two-inoculation protocol (Kirkpatrick, Liu, & Turner, 1990). Foal survival also was calculated as a function of whether the foal was born in season or outside this window and whether or when the mother had been treated with PZP prior to the birth. Differences in season of birth, foal survival as a function of birth date, and foal survival as a function of PZP treatment were tested for significance by Fisher's exact test for contingency tables.

RESULTS

Among foals born to mares who never had been treated, 69 of 91 (75.8%) were born in season; among 77 treated mares, 50 of 77 (64.9%) were born in season. The difference was not significant ($p = .122$; standard error [*SE*] of difference = .085). Among foals born to mares treated with PZP for 1 year before the birth of a foal, 20 of 29 (68.9%) were born in season. The difference was not significant from foals born to untreated mares ($p = .463$; *SE* of difference = .090). Among foals born to mares who had been withdrawn from treatment or who had experienced a contraceptive failure after at least 2 years of treatment, 30 of 48 (62.5%) were born in season. The difference was not significant from foals born to untreated mares ($p = .111$; *SE* of the difference = .090). Table 1 shows foal birth by month.

TABLE 1
Births by Months for PZP-Treated and Untreated Wild Mares

Mare Status	*Month of Birth*											
	J	*F*	*M*	*A*	*May*	*Je*	*Jy*	*Au*	*S*	*O*	*N*	*D*
UT[a]	2	0	3	23	23	23	10	4	2	0	0	1
T1[b]	1	1	1	12	1	7	1	3	2	0	0	0
T > 2[c]	1	4	1	12	14	4	4	3	1	1	1	2
Total	4	5	5	47	38	34	15	10	5	1	1	3

Note. J = January; F = February; M = March; A = April; JE = June; Jy = July; Au = August; S = September; O = October; N = November; D = December; UT = untreated; T1 = mares treated the year before the birth of a foal; T > 2 = mares withdrawn from treatment more than 2 years before the birth of a foal.

[a]69 of 91 (75.8%) of foals born in season to UT mares. [b]20 of 29 (68.9%) of foals born in season to T1 mares ($p = .463$). [c]30 of 48 (62.5%) of foals born in season to T > 2 mares ($p = .111$).

Foal survival did not differ significantly ($p = .471$; *SE* of the difference = .100) between foals born in season and foals born outside this seasonal window. Among foals born in season, 104 of 119 (92.9%) survived to age 1 or older; of those born outside this window, 42 of 49 (85.7%) survived. Among foals born to mares never treated with PZP, 77 of 91 (84.6%) survived and did not differ significantly ($p = .825$; *SE* of difference = .109) from foals born to mares treated at some time before their birth, of whom 67 of 77 (87.0%) survived.

DISCUSSION

These data indicate there was no significant effect of PZP treatment on out-of-season births, with only 13.3% separating the two treatment groups and untreated mares. This is in contrast to white-tailed deer in which significant extensions of the breeding season and, by implication, ovulation occurred after treatment of does with PZP (McShea et al., 1997), and almost all treated animals extended their breeding season by as much as 2 months. The failure of a larger effect in horses probably is a function of the reproductive biology of this species.

Photoperiod Influence on Ovulation

Ovulation in the modern horse is seasonal and influenced largely by photoperiod, with peak reproductive activity and foaling correlating with increased photoperiod (Kenney, Ganjam, & Bergmen, 1975). In the domestic mare, ovulation reflects this seasonal pattern, but significant percentages of mares will ovulate well into the fall and winter (Kenney et al., 1975). Photoperiods of 16 to 24 hr induced the onset of breeding in domestic mares, and photoperiods of less than 9 hr caused a cessation in ovulation and breeding (Kooistra & Ginther, 1975).

Patterns of Foaling

Among other horses, the patterns of foaling differ. On Assateague Island, Keiper and Houpt (1984) reported that 88% of foals were born in season. Feist and McCullough (1975) reported that no foals were born in the Pryor Mountains, MT outside season, and Tyler (1972) reported that 96% of births among New Forest ponies occurred in this same period. On Sable Island, Nova Scotia, Canada, foals were born year round, but 77% were born in season (Welsh, 1975). Similar patterns have been reported for wild horses of Wyoming's Red Desert (Boyd, 1979) and the Great Basin (Berger, 1986).

Foaling and Ovulatory Activity

Foaling patterns however, do not necessarily reflect ovulatory activity. Among domestic mares, the stallion does not always have access to the mare, and the timing of reproduction most often will reflect management of the stallion rather than environmental, nutritional, or genetic influences.

Palmer (1978) found that Welsh ponies had no ovarian activity during the winter months, whereas 66% of saddle breeds did. Satoh and Hoshi (1932) found that semiwild Korean ponies ceased ovulating by October. Kirkpatrick and Turner (1982) demonstrated that ovulation, determined endocrinologically, among Pryor Mountain wild mares was confined to April to July—even when the plane of nutrition was increased—whereas estrous behavior was observed occasionally well into October. Ginther (1979) speculated that wild horses, as they adapt to a free-ranging life and most often a harsh environment, develop a breeding pattern that begins and ends more abruptly and during a period when survival of the foal would be most favorable. This, in turn, implies a genetic basis for the control of ovulation.

Liu, Bernoco, and Feldman (1989) demonstrated that antibody titers to PZP treatment fall over time and that fertility will be restored when they reach minimal levels (below 64% of positive reference standards). If ovulatory activity is confined more or less to a highly seasonal pattern, successful reproduction out of season would not be significant. In any case, the more restricted breeding/ovulatory season in wild horses is the most plausible explanation for the lack of effect seen in PZP-treated wild horses.

Two Phenomena

This study draws attention to two additional phenomena that must be taken into consideration when examining the effects of PZP contraception in wild horses. First, there is a considerable spread in the percentage of foals born in season among the eight different populations referenced previously. This in turn requires, to assess any possible effects, that careful examination of foaling patterns be conducted prior to PZP treatment. If 23% of foals normally are born out of season among Sable Island horses, and only 4% are born out of season among New Forest ponies, these figures must be incorporated into any assessment of PZP treatment effects on a site-specific basis. Put another way, individual herds may be predisposed more or less to out-of-season births among PZP-treated animals, depending on their normal foaling patterns.

The second interesting aspect of this study is that out-of-season births in untreated mares have been increasing on ASIS since 1984, from 12% to 26% in 2001. The causes for this phenomenon are unknown but merely may reflect increased

variation coincident with increased population size. There were 80 horses on ASIS in 1984. Currently, there are 173.

A Surprising Discovery

The discovery that month of birth has no effect on survival on Assateague Island is surprising considering the harsh winter ocean-side weather patterns and storms. This suggests that horses living in milder climates such as the Shackleford Banks of Cape Lookout, NC, where horses also are being managed with PZP, will not suffer from out-of-season births whether they are associated with PZP treatment. In harsher climates, however, such as mountainous country where significant snow accumulates, the survival data derived here may not be valid or predictive.

The lack of any effect on survival as a function of PZP treatment in this retrospective study was expected. In the original study of PZP contraception in wild horses (Kirkpatrick, Liu, et al., 1990), 60% of treated animals were pregnant at the time of PZP treatment; survival of the foals was no different from that of foals born to untreated mares. This is consistent with the mechanism of the PZP vaccine: fertilization block. There is no known physiological link between an immunological block to fertilization and postfertilization gestational physiology.

SUMMARY

The use of PZP immunocontraception among selected wild horse populations can be carried out without fear of causing out-of-season births. Any population control measures applied to wild horses on public lands will come under severe scrutiny. The possibility of causing the death of foals, even indirectly, will be unacceptable to the public. The data in this retrospective study indicate that PZP immunocontraception is not implicated in out-of-season births and that this characteristic is driven by the unique reproductive physiology of equids. The difference in the percentage of out-of-season births between different wild horse ranges, and even the changing figures for the same herds over time point to the need to understand the reproductive biology of each individual herd before population models are constructed or contraceptive management plans are developed.

The Effects of Porcine Zona Pellucida Immunocontraception on Health and Behavior of Feral Horses (*Equus caballus*)

Colleen M. Knight

Department of Ecology and Evolutionary Biology
Princeton University
Adviser Daniel I. Rubenstein
May 2, 2014

Acknowledgments

There are many people to whom I would like extend my thanks:

First and foremost, to my adviser, Professor Dan Rubenstein, not only for his support and guidance throughout this entire process, but also for providing me with opportunity to study on Shackleford Banks, an opportunity I never imagined possible.

To the Office of the Dean of the College, the Department of Ecology and Evolutionary Biology, and the Princeton Environmental Institute, for providing the funding for my equipment, transportation, and living expenses for the duration of my field study.

To Blair Streater, for roughing it and putting up with me for the nine weeks we spent together on Shackleford and in Havelock; for trudging through (and getting stuck in) marsh mud, getting cut on oysters, getting swarmed by biting flies and nesting terns, and walking on a sprained ankle, all for the sake of data collection; for helping with my lab work; and for being a constant source of companionship, emotional support, and – most importantly – laughter during an unforgettable summer.

To Cassandra Nuñez, for sharing her expertise and tricks of the trade, not only about data collection but also about living on Shackleford, and for always being there to answer questions and give advice.

To the National Park Service, for permitting us to perform this research on Shackleford and for providing resources, data, and support.

To Sue Stuska, for being an endless source of knowledge, advice, and both emotional and physical support on Shackleford; for bringing me fecal samples and cold water on her days on the island; for always being accessible by email to send me more data and answer more questions.

To the Duke University Marine Lab for allowing us to use their facilities, especially to Doug Nowacek for letting me use his lab space and materials and to John Wilson for ferrying us to and from Shackleford so many times in his boat.

To Morgen Harvey, for spending three weeks of her summer helping with data collection and general sanity as our time on Shackleford drew to an end.

And finally, to all of my friends and family for the support, encouragement, and motivation that I needed to finish this thesis and my final semester at Princeton.

Abstract

The horse population on Shackleford Banks, a barrier island off the coast of North Carolina, has been controlled using a program of porcine zona pellucida immunocontraception since 2000. Prior studies found no negative physiological effects of the immunization, but suggested some adverse effects on behavior such as increased harem switching and extended reproductive season. Although no mares were immunized in the year of study (2013), we examined the effects of past contraception and foaling on health and behavior of the mares in an attempt to better understand its impacts on both the individual and the population. Current lactation was found to be the best predictor of health and behavior: lactating mares were in worse physical condition, spent more time grazing, and switched harems fewer times. Mares that had never foaled also were in better physical condition than mares that had foaled in the past, but did not differ in behavioral measures. There were indications that the PZP treatment has had effects other than preventing pregnancy: an increased number of years since immunization was correlated with better body condition and fewer harem switches, independent of lactation. Contraception treatment intensity or timing did not have any significant adverse effects on health and behavior on its own. However, three or more consecutive years of treatment or administration of the first dose before sexual maturity may have triggered infertility in some mares. Inducing sterility, while relieving the mares from the energetic costs of lactation and reducing the stress from harem switching, may have unintended consequences on population dynamics by increasing longevity and eliminating the mares' ability to contribute genetically.

Chapter 1
Introduction

Shackleford Banks, a small barrier island located off the coast of North Carolina, is home to a herd of approximately 100 feral horses (*Equus caballus*). The horses are of unknown origin, but have lived on the island for multiple centuries. In 1986, the cattle, sheep, and goats inhabiting the island were removed in an attempt to restore the vegetation to its native state. Released from the competition of the other herbivores, the horse population grew exponentially, reaching 185 in 1996. The Shackleford Banks Wild Horses Protection Act was passed in 1997 to ensure proper management of the herd to maintain its size between 100 and 110 horses (United States Congress, 1997). To that end, the National Park Service instituted a program of porcine zona pellucida (PZP) immunocontraception in 2000. Each spring, some of the females of reproductive age are immunized with the contraceptive agent, preventing them from conceiving in the upcoming summer breeding season. Other than the contraception, the management of the Shackleford Banks herd is "hands-off," with no human intervention such as feeding or veterinary care.

Despite its many advantages as a method of population control, prior studies both on Shackleford Banks and elsewhere have brought up potential concerns about its effects. This study examined the effects of the past 13 years of contraception treatment on the mares of Shackleford Banks in an effort to more fully understand its implications for the health and behavior of both the individual mares and the population as a whole.

1.1 Horse Behavior

1.1.1 Sociality

The horses of Shackleford Banks live in harems, the social system typical of horses and other equids. A harem usually consists of one or two stallions (sexually mature males), one or more mares (sexually mature females), and their immature offspring. Bachelor stallions are also found on the island, either alone or in groups. In the 1980s, the Shackleford herd consisted of temporary assemblages of horses of both genders, territorial harems that defended a permanent territory and water source, as well as non-territorial harems (Rubenstein, 1981). Since then, all Shackleford harems have transitioned to being non-territorial, inhabiting overlapping home ranges (Nuñez, Adelman, & Rubenstein, 2010; personal observation). Living in such groups has advantages such as increased vigilance and subsequent safety during grazing, as well as decreased harassment from unfamiliar stallions and aggression from other mares (Linklater et al., 1999; Rubenstein, 1986; Rubenstein, 1994). However, increased contact with other individuals can cause increased parasite infection and decreased health in the subsequent year (Rubenstein, 1986; Rubenstein & Hohmann, 1989).

1.1.2 Reproduction

The breeding season of feral horses runs between late winter and early fall. During the mare's period of estrus, the frequency of her interactions with the stallion increases; she often approaches him and assumes a receptive "sawhorse" posture. The precopulatory sequence includes vocalizations, sniffing, nuzzling, flehmen response (baring of upper teeth), and mounting without erection (McDonnell, 2000).

After successful conception, there is an 11-12 month gestation period. This timing ensures that foals are born in late spring or summer, when food is most abundant and the climate hospitable for survival (Rubenstein, 1994). During pregnancy, a female is forced to invest her energy in the production of fetal, uterine, placental, and mammary tissue; subsequent lactation is the most energetically costly part of foal-bearing (Gittleman & Thompson, 1988). Because of this investment in production and lactation, nursing mares

often are found to be in worse physical condition than non-nursing mares (Ransom, Cade, & Hobbs, 2010; Rubenstein, 1986; Turner & Kirkpatrick, 2002).

1.2 Horse Health Measures

There are multiple ways to measure health that are relevant to the study of feral horses. The first of this is the overall physical condition, as quantified by a body condition score indicating the amount of fat in the rump. For horses in the wild that are not able to be handled, this score is determined by examining the horse's rump, from behind, looking at the curve between the spine and the curve of the hip. On a commonly-used five-point scale, a body condition score of 5 indicates the best physical condition and 1 the poorest, as the amount of fat decreases and the rump takes on a more concave shape (Nuñez et al., 2010; Rubenstein, 1986).

Another, less direct, way of measuring overall health of a horse is to examine the amount of time it spends grazing. Horses spend a substantial portion of their time feeding on large quantities of low-quality grasses, so foraging success is limited by the time spent grazing (Rubenstein, 1994). Horses in lower body condition are likely to spend more time grazing, because they are in need of more energy to compensate for their poorer health (Ransom et al., 2010).

Endoparasite infection can also be used as a more specific indicator of health, measuring the health of the immune system. An increased number of endoparasites in the intestinal tract, as measured by the number of parasite eggs excreted in feces, signify a weaker immune system that is unable to fight off the infection, and thus a less healthy horse. The primary parasites found in horses are nematodes of the family Strongylidae, commonly known as "strongyles," which are divided into large and small strongyles (cyathostomes), based on their size (Lichtenfels, 1975). These parasites can cause anemia, diarrhea, and intestinal damage, and inflammatory enteropathy, respectively (Love, Murphy, & Mellor, 1999; Stoltenow & Purdy, 2003). Other nematodes that are commonly found in horses include large roundworms (*Parascaris equorum*) that damage the intestines, threadworms (*Strongyloides westeri*) that cause diarrhea, and pinworms (*Oxyuris equi*) that cause irritation of the anus (Stoltenow & Purdy, 2003). One study on Shackleford Banks by Rubenstein and Hohmann (1989) found the eggs of those

parasites, among others, in the feces of the horses and found that egg load was negatively correlated with body condition in the following year.

1.3 Porcine Zona Pellucida Immunocontraception

1.3.1 Vaccine Development

The porcine zona pellucida (PZP) vaccine is a form of *immunocontraception*: contraception that uses the animal's own immune system to render her infertile. The zona pellucida of a pig embryo (the outer glycoprotein membrane) is used to make a vaccine. When this vaccine is injected into the female animal, it acts as an antigen to which the immune system produces antibodies; these antibodies then cross-react with her own eggs, binding to the zona pellucida and preventing sperm attachment and subsequent fertilization (Sacco, 1977).

An early study on feral horses found that of ten PZP-immunized mares released back into their natural habitat, only one became pregnant within eight months. Anti-PZP antibodies were found to remain high in the immunized mares, demonstrating the importance of the antibody titer in the contraception's efficacy (Liu, Bernoco, & Feldman, 1989). Further studies on the feral horse herd inhabiting Assateague Island confirmed the vaccine's potential to control populations of feral horses, with a 90-100% success rate at preventing pregnancy in the year of immunization (Kirkpatrick et al., 1997; Kirkpatrick, Liu, & Turner, 1990).

The PZP vaccine has also been used for population control of deer and exotic zoo animals (Kirkpatrick et al., 1996; Kirkpatrick et al., 1997).

1.3.2 Implementation on Shackleford Banks

The PZP contraception program on Shackleford Banks was initiated by the National Park Service in 2000. Each year, the decision of which mares to treat is made based on various factors, such as the representation of her genetic line in the population and her foaling history (S. Stuska, personal communication). Between 2000 and 2009, an average of 63% of mares were inoculated each spring to prevent conception in the upcoming breeding season (Nuñez et al., 2010). However, the mares were not treated in

2010, 2011, or 2012; in those years, the population was deemed to be small enough and the trend in foaling and mortality indicated that the treatment was not needed. The exception to this was the mare Anastasia, who was treated in 2012 to prevent her from foaling because her low body condition and prior failed pregnancies indicated she was not healthy enough to reproduce. The contraception was resumed in the spring of 2014, the year after this study (S. Stuska, personal communication).

1.3.3 Practicality

PZP immunocontraception is an advantageous form of population control for several reasons. First, preventing pregnancy controls the population's size without having to physically remove foals from the herd, which is not always accepted by the public (Nuñez, 2009). Because PZP causes infertility through activation of the immune system, it does not alter hormones, which could have adverse effects; the mares continue to cycle normally throughout the year, and just fail to become pregnant after insemination. The ease of administration is also an advantage because the vaccine can be administered using a long-distance dart gun that eliminates the need for potentially stressful human interaction.

The PZP vaccine has been found to have no effect on somatic tissues because the antibodies only bind to egg tissue (Barber & Fayrer-Hosken, 2000). It also has no effect on intact pregnancies (foals born to an immunized mare are healthy a year after birth) and is reversible once the antibody titers naturally decrease over time (Kirkpatrick et al., 1990). Studies on herds other than Shackleford Banks have found no differences in behavior – activity budget, aggression, harem stability, spatial relationships with the stallion – between treated and non-treated females in a given year (Kirkpatrick et al., 1990; Powell, 1999).

1.3.4 Concerns

Recent research has discovered potentially significant effects of the contraception on behavior and health, especially in the Shackleford herd. Multiple studies have found that treated mares switch harems more times than non-treated mares, both in the reproductive and non-reproductive seasons (Madosky et al., 2010; Nuñez et al., 2009). Increased harem switching, in turn, is correlated with higher levels of fecal cortisol, an

indicator of physiological stress (Nuñez et al., 2014). Additionally, females that have been given PZP contraception were found to have an extended reproductive period past the normal breeding season, which could result in foals being born at times not optimal for their survival (Nuñez et al., 2010). In other herds in the western United States, treated females received more reproductive interest from stallions than the mares that had not been treated, though all other behaviors were not affected (Ransom et al., 2010).

There also may be detrimental effects of continued treatment on the mares' ovarian function. Assateague Island mares that had three consecutive years of treatment had depressed estrogen secretion, suggesting impaired ovarian function, but they all returned to fertility within three years of treatment. Mares that had more than three consecutive years of treatment took even longer to return to fertility after they were released from treatment, up to six or seven years (Kirkpatrick et al., 1992). It is possible, then, that even further treatment with PZP may permanently damage mares' ovaries.

1.4 The Current Study

The PZP contraception program was implemented in the Shackleford Banks horse herd to reduce its size in a way that would eliminate the need for foal removal. However, potential negative effects of the contraception on mare health and behavior must be explored in order to fully evaluate this program. Changes in the immunized mares' behavior, such as those found in prior studies, may have more far reaching effects that should not be ignored.

During the year of this study (2013), no mares on Shackleford Banks were given PZP contraception, so there were no true "treated" and "untreated" categories, and the direct effects of contraception could not be distinguished as in previous studies. Instead, we measured various indicators of health and behavior and first analyzed the relationships between them in an attempt to understand the interactions between the social and physical domains. We then examined each mare's contraception history since the program's induction in 2000, including factors such as intensity and timing of treatment and foaling history. Relating this history to the mares' health and behavior in the year of study will help us further understand the long-term effects of the treatment on the mares, as well as the implications for the entire population.

Chapter 2
General Methods

2.1 Study Site

This study was conducted on Shackleford Banks, a barrier island about 15 km long (east-west) and varying between 0.5 and 3 km in width (north-south). It is located approximately 3 km off of the coast of North Carolina and is a part of the Cape Lookout National Seashore, managed by the National Park Service. The island is comprised of a variety of habitats, including marsh, forest, swale, dunes, and beach. A maritime forest lines the majority of the north coast, separating the bayside beach from the dunes and swales covering the rest of the island; marshes are spread out along the north side. The island can be divided into three regions, distinguishable by landscape and each containing at least one permanent water source. The western end of the island contains more tall dunes, which flatten out into sparser dunes (and more flat swales) in the mid-east. The far-east is home to large areas of marshland, including a "submerge" marsh area that floods during high tide.

2.2 Study Subjects

During the majority of the study, the number of horses on the island held steady at 106; for a brief period there were 105, after the death of one young male (Scorpio) on July 4 and before the birth of a female foal (Djambi) on July 20. Most horses formed harems of one stallion, multiple females, and their young offspring. Two of the harems

also had an established beta stallion, and one had a suspected beta (Shakespeare, a four year old stallion still in his mother's harem). Additionally, several bachelor stallions roamed with no females. The harems inhabited overlapping ranges and were not territorial, as was found in the past (Rubenstein, 1981). There were five harems in the west, five in the mid-east, and seven in the far-east, ranging in size from three to 11 horses; throughout the study, about half of the females changed harems at least once. Of the 61 mares in the population, data was collected on only 45 of them because of ease of location and data collection.

2.3 PZP Contraception

In 2000, the National Park Service instituted a porcine zona pellucida (PZP) contraception program to control the growing horse population on the island. Eight mares were designated as controls based on age, prior breeding success, and genetic representation in the population. Each year, between late February and April, an average of 63% of the eligible mares were inoculated (range 37-88%); mares were given their first dose when they were approximately two years old. Each vaccine contained 100 μg of PZP mixed with an adjuvant (Nuñez et al., 2010). The National Park Service made the decision about which mares to inoculate each year; the researchers of this study had no involvement in the decisions. Whether or not a mare was inoculated was based on the representation of her genetic line; if a mare's line was not well-represented in the herd, then she was not administered the contraception so that her genes would have a chance to be passed on in the population (S. Stuska, personal communication). In 2009, the controls were administered the vaccine primarily because of their increased productivity. In the years after 2009, the Park Service did not inoculate mares because the herd was at a manageable size. Only one mare (Anastasia) was given contraception in 2012 and 2013 to prevent her from conceiving because she was in poor physical condition and pregnancy could have posed a danger to her survival. Contraception history of the mares used in this study can be found in Appendix I, along with foaling history.

2.4 Data Collection

Data was collected between June 13, 2013 and August 7, 2013.

2.4.1 Behavioral Sampling

When we located a harem, we identified its members using several factors: sex, coat color, mane direction (falling to the left or right of the head), facial markings, and brand (number, location on rump, brightness). Scan sampling methods were used to record the behavior of each member every three minutes for a one hour period (Altmann, 1974). The different behaviors that were differentiated can be found in Table 2.1. Additionally, during the hour period, we recorded the following qualitative observations:

- Incidences of reproductive interest (including genital sniffing, nose-to-nose behavior, rump rubbing, mounting, and copulation)
- A stallion herding some or all of his mares

We also noted interactions between mares that demonstrated dominance, including displacements from food or water sources and direct physical conflict/fights, both during the scan sampling periods and at other points during general observation.

2.4.2 Fecal Sampling and Testing

Samples of the mares' feces were collected immediately following defecation, before the stallions could mark them with urine. Portions from multiple fecal balls were collected to ensure a representative sampling of the pile. Samples were placed in plastic bags, labeled with the mare's name and the date and time of collection, and stored in

Table 2.1. Behaviors observed and recorded during scan sampling.

Behavior	Description
Grazing	Horse ingesting food with the head down, including grazing while walking
Standing	Horse standing still, but not alert
Walking	Horse walking while not grazing
Vigilant	Horse's head up and alert, i.e. looking at a nearby horse
Resting	Horse sitting or laying down
Grooming	Horse biting or scratching itself or another horse
Urinating/defecating	(when occurring exactly at time of data point collection)
Herding	Stallion herding mares, or mare being herded by stallion
Nursing	Mare nursing her foal
Fighting	Horse engaged in antagonistic interaction with other horses, i.e. kicking or chasing
Drinking	Horse drinking or digging for water
Reproduction	Horse engaging in mating behavior, i.e. genital sniffing, nose-to-nose, mounting
Out of sight	Horse not in sight of observer, i.e. behind a dune or in the forest

coolers with frozen ice packs until they could be taken back to the laboratory on the mainland.

Collecting the feces took preference to behavioral sampling, if being done simultaneously, and occasionally caused missed time points during scan sampling (which were then treated as "out of sight" points during analysis). If, after the hour-long behavioral sampling period, some of the mares had not yet defecated, we remained with the harem in an attempt to collect as many fecal samples as possible.

The eggs in each fecal sample were counted using a variation of the McMaster technique. Three grams of feces were measured using a hanging scale and a plastic bag and mixed with 12 ml of tap water in a 50 ml beaker using a tongue depressor. The mixture was poured through a tea strainer into another beaker to filter out the plant material, using the tongue depressor to press out as much of the liquid as possible. The resulting liquid was poured into a 15 ml disposable centrifuge tube, which was spun on a manual centrifuge for two minutes, and the supernatant was discarded. Ten ml of saturated salt solution (made by dissolving 400 g of table salt in 1 L of tap water) was poured into the centrifuge tube on top of the spun-down pellet. The tube was then covered and shaken manually to loosen the sediment from the bottom. The suspension was poured from the centrifuge tube into a clean 50 ml beaker and an additional 35 ml of salt solution was added. The solution was allowed to settle and the eggs to float to the surface. Using a disposable pipette, a sample of the eggs was drawn from the top of the solution and transferred into one chamber of a McMaster slide. The other chamber was filled with a new sample from a different section of the fecal float. The slide was transferred to a microscope and all of the eggs in the slide's grids were counted. The number of eggs in both chambers cumulatively was multiplied by 50 to calculate the number of eggs per gram of feces.

Eggs of strongyles could not be identified by species, but instead were grouped into "large strongyles" and "small strongyles." Eggs of the species *Parascaris equorum*, *Strongyloides westeri*, *Oxyuris equi* (pinworm), and *Anoplocephala spp.* (tapeworm) were identified separately; other eggs were counted in an "other" category, and adult worms were noted but not included in the egg counts. The counts of the various egg types were added together to give a total number of eggs per gram in the fecal sample.

Photographs of some of the eggs observed in the mares, including the common large strongyles, can be seen in Appendix II.

2.4.3 Body Condition Scoring

We gave each mare a body condition score based on the amount of fat in her rump, determined by examining the curvature of the rump between the spine and the point of the hip, as seen from directly behind her. Scores were allocated on a scale from 1 to 5, with 1 being the poorest condition and 5 being the best. A mare with a body condition of 3 displayed a flat line between the spine and the hip. A score of 4 manifested in a smoothly rounded rump across the spine, and a 5 had an "apple" shape, with the rump bulging above either side of the spine. In a horse with a body condition lower than 3, the rump muscle took on a gradually more concave shape. Physical condition of the mares was assessed at multiple times throughout the data collection period, and an average body condition score was calculated. Photographs of horses with common body condition scores can be found in Appendix III.

Chapter 3
Mare Health and Behavior

3.1 Introduction

Data collection, as described in Chapter 2, included measuring various indicators of the mares' health and behavior. Health was measured in two main ways: body condition and parasite load. Physical condition, as quantified by a body condition score between 1 and 5, revealed the mare's average overall health; a healthier horse would have more fat deposits in her rump, giving her a higher body condition score. Parasite load – the number of parasite eggs per gram in her feces – measured a more specific factor of health: immune function. A healthier mare with a stronger immune system should be better able to resist parasite infection and have a lower egg count at the time of sampling.

Behavior, in the form of the amount of time spent grazing, was also used to assess the mares' health. A mare in worse health would theoretically need more energy and subsequently spend more time grazing as a percentage of her total time budget. Additional behavioral factors such as harem switches, harem size, harassment rate, stallion temperament, and mare dominance were also measured to form a quantitative and qualitative description of the mares' social environment.

In this chapter, we describe the creation and calculation of these various health and behavior indices. We then examine the relationships between the variables in an attempt to describe what shapes the health and behavior of the mares. We also look at the effects of lactation on the mares before turning to the effects of contraception in the next chapter.

3.2 Data Analysis

From the various data collected (see Chapter 2), the following indices and variables were calculated to describe the social environment and health of the mares.

3.2.1 Time Budgets

During each one-hour time budget collection, 21 events were possible (one every three minutes for 60 minutes). The total number of events observed was then:

Events = 21 – # "Out of sight" instances

For each type of behavior (see Section 2.4.1), the proportion of time spent doing that behavior was calculated as:

Proportion(behavior) = # Instances of that behavior / # Events

This resulted in a calculation of how much of the time during that hour-long observation the horse spent on each type of behavior. Time budgets were collected throughout the study period, and an average proportion of time spent on each behavior was calculated by averaging the proportions from each individual time budget. For example, each mare had a data point of *Average time spent grazing*, given as a proportion (0.0-1.0).

3.2.2 Parasite Egg Counts

Over the period of data collection, we attempted to collect at least three fecal samples for each mare. This goal was met for all but a few mares because of difficulty finding them or a lack of defecation during observation. The samples were collected at times spread throughout the nine week study period. We first needed to determine if there was a temporal pattern of parasite infection. If there was none, then the egg count data could be pooled into an average for the entire study period; otherwise, we would have to look at the parasite data from the time periods separately.

To do this, we first had to find a date in the study period that would divide it approximately in half in terms of number of fecal samples in each half for each mare. For five dates that appeared to split the data approximately in half, the number of fecal samples before and after that date was recorded for each mare. For some mares, the different dates would not change their sample distribution (i.e. would have two samples in one half and one sample in the other half). The mares for which the choice of date

would change the distribution (i.e. turn a 2:2 to a 1:3) were then examined, and the date was chosen that had the least number of "bad" splits (1:3 instead of 2:2, 0:2 instead of 1:1, etc.). The "middle" date was determined in this way to be July 13.

We then needed to statistically determine if the parasite egg counts were significantly different between the two halves of the study period to see if they could be considered together in further analyses. Some mares only had samples collected in one half or the other, so they were excluded from this test. For each of the 29 mares with samples both before and after July 13, we calculated the mean number of total eggs found in the fecal samples during each time period – a *first half mean* and a *second half mean*. Then the difference between the second half and first half means was calculated for each mare. The resulting distribution was analyzed using a t-test against 0. The mean difference in the number of eggs between the second half and the first half was 308.929 eggs per gram (more eggs in the second half) and the t-test gave a p-value of 0.0107. This showed that the egg counts from the two halves of the summer were significantly different so the samples could not just be lumped into an overall mean for the whole study period. Therefore, each mare had two separate data points: *first half mean eggs* and *second half mean eggs*. The value for *total mean eggs* was also recorded, with the acknowledgement that it was not as significant of a measurement as the separate half means. The counts were all log-transformed to improve normality.

3.2.3 Age

The age of each mare was calculated as:

$$Age = 2013 - Birth\ year$$

This did not account for exact birth day/month but rather grouped the mares into approximate ages based on the year in which they were born. Because the foaling season is limited to a few months during the summer, this gave an accurate approximation of age to within a few months.

3.2.4 Lactation in 2013

Each mare was assigned a value for the categorical variable *Lactating in 2013.* If she was nursing during the study period – either a foal born in 2013 or a yearling – she was

said to be lactating (referred to in data analysis and graphing as "L"). If she was not nursing a foal, she was non-lactating ("NL"). In the mares studied, 10 were lactating and 35 were non-lactating. Two of the non-lactating mares (Hermione and Wallace) gave birth later in the 2013 foaling season after the study period was complete, and one gave birth in 2012 and in 2014 (Sydney). Because this was not during the period of study, these three mares remained in the non-lactating category for analyses.

3.2.5 Stallion Associations

In order to evaluate the mares' associations with different stallions throughout the data collection period, a large table was made with the mares' names down the left side and stallions' names across the top. A list of all sightings of all harems throughout the data collection period had been made previously. For each mare, we went down the sightings list and noted (in order) which stallion she was seen with. At each sighting, a tally was made in the column of that stallion. If she was seen with stallion A at one sighting, and then stallion A was seen without her at a subsequent sighting, a tally was made in an "unknown" column; she was no longer with that stallion but we could not identify her location on that day. From this, the *Primary stallion* could be identified: the stallion with which the mare was seen with the greatest number of times. From this, *Percentage of time with primary stallion* was also calculated: the number of times seen with the primary stallion divided by the number of total times seen.

3.2.6 Harem Switches

When going through the list of horse sightings for stallion associations (as in Section 3.2.4), switches between harems were also noted. If a mare was seen with stallion A at one sighting, then with stallion B at the next sighting, that was tallied as one harem switch. If she returned to stallion A at a later time point, that was another switch. Additionally, if she was seen with stallion A at one sighting, and then stallion A was seen without her at a subsequent sighting, this was considered a switch despite the fact that her exact location was unknown at the time of that sighting. If she was then seen again with stallion A, this was considered two switches (leaving stallion A to an unknown other location, then coming back). From these tallies, we determined the total *Number of harem switches* for each mare. Because a significant number of mares (25 mares, 56%)

did not ever switch harems, the mares were divided into two categories, "switchers" and "non-switchers."

3.2.7 Harem Size and Variation

The list of harem sightings was again traversed, and for each sighting of the mare, the number of horses in her harem (the one she was with at that specific time point) was noted. From those values, *Average harem size* was calculated for each mare.

The *Variance in harem size* was also calculated for each mare as a measure of group stability. This was done using the individual harem size values pulled from the sightings list, as above. Then the *Standard deviation of harem size* was calculated (square root of the variance). The *Coefficient of variance of harem size* was also calculated as a way to normalize the variance.

Coefficient of variance = Standard deviation / Average harem size

3.2.8 Stallion Harassment

The data necessary to determine the rate of mares' "harassment" by the stallions was extracted from the qualitative observations made during each hour-long behavioral observation (see Section 2.4.1). The behaviors of note were herding (when the stallion physically caused a mare to change location) and sexual approaches/behaviors (genital sniffing, nose-to-nose behavior, rump rubbing, mounting, and copulation); these behaviors will hereafter be referred to together as "harassment." The record of qualitative observations was traversed, and each time a herding or sexual behavior was observed, a tally was made for all mares involved. Adding up all instances for a mare gave a total number of harassment instances during all observation times. In order to standardize these numbers into a rate of harassment, we added up the total time that each mare was observed (i.e. the number of time budgets multiplied by their length). The only time budgets considered were those done by the primary researcher, because the other researchers only collected time budgets, not qualitative data, during their behavioral observations. From this the *Harassment rate,* a measure of total stress behaviors per hour, was calculated:

Harassment rate = Total herds and sexual approaches /
Number of hours of observation

3.2.9 Stallion Temperament

The temperament of the stallion with which each mare was primarily associated was used to measure a social variable similar to her harassment rate. However, rather than just measuring the harassment behaviors directed at the mare in question, it determined the overall harassment in her social environment by determining if her primary stallion was "mean" or "docile." When the record of qualitative observations was traversed (as in Section 3.2.7), in addition to tallying herding and sexual behaviors for each mare, it was noted which stallion was initiating such behavior. For harems that had both an alpha and a beta stallion, their harassment behaviors were added together. This resulted in a total number of "harassments" for each stallion/harem, which also needed to be standardized into a rate; this was done in the same way as the *Harassment rate* for the mares (Section 3.2.7). In order to classify the stallions based on aggression, the median value of *Harassments per hour* for the stallions was found to be 0.5. Stallions with *Harassments per hour* below this median were considered "docile," and above the median, "mean." Then, using this *Stallion quality* index, each mare was assigned a variable *Quality of Primary Stallion*, either *mean* or *docile.*

3.2.10 Mare Dominance

Dominance interactions between mares were recorded whenever they were seen (both during the hour-long behavioral observations and at other times) in an attempt to get the most accurate picture of harem hierarchy (Section 2.4.1). If mare A displaced mare B from her grazing spot, mare A was considered the "winner" of that interaction and mare B the "loser." Similarly, mare A chasing, biting, or otherwise fighting mare B was the "winner" of the interaction. From these observations, the total number of "wins" and "losses" were added up for each mare. The number of wins divided by the total interactions (wins + losses) determined *Percent wins*. From this, an index of *Dominance rank* was created; this assigned a rank to only the mares involved in dominance interactions, as some were not observed in any such interactions during the entire study period. "Low" dominance mares were those with a *Percent wins* of less than 50%. Those with a value of exactly 50% were considered "Neutral," and above 50% were "High" dominance.

3.3 Statistical Analysis

All statistical analyses were performed in JMP Pro (version 10.0.0). Quantitative data was checked for normality by histograms. Most data was not normally distributed, so nonparametric statistics were applied. However, the parasite egg count data was able to be made more normal through log-transformation, so parametric statistics were applied. T-tests performed were all two-tailed tests, because the null hypotheses were that the two groups were different (no directionality). When variances in two groups were determined to be unequal, a Welch's test was used. Significance was determined when $p < 0.05$.

3.4 Results

3.4.1 Relationships between Health Variables

Among all 45 mares in the study population, a nearly significant trend of negative correlation was found between body condition score and percentage of time spent grazing ($F_{1,43} = 4.03$, $r = 0.06$, $p = 0.0511$, Figure 3.1). No correlations were found between body condition score and parasite egg counts (first or second half mean, or total mean), or between the parasite egg counts and the time spent grazing.

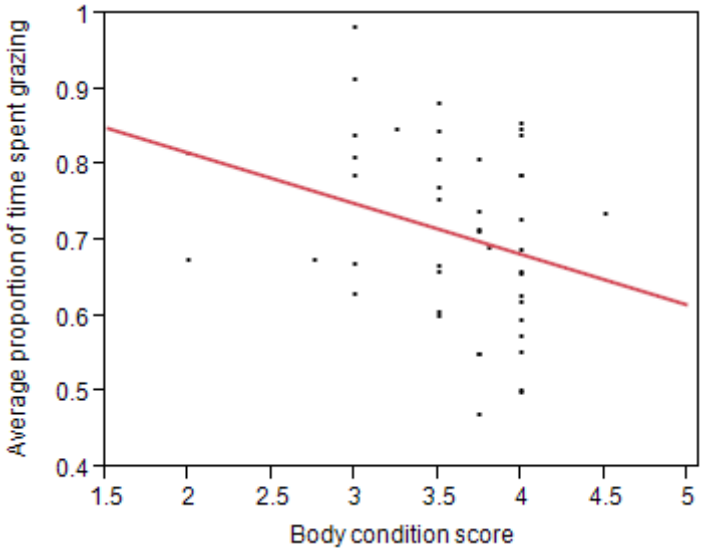

Figure 3.1. Average time spent grazing, as a proportion of the total time budget, by body condition score ($F_{1,43} = 4.03$, $r = 0.06$, $p = 0.0511$).

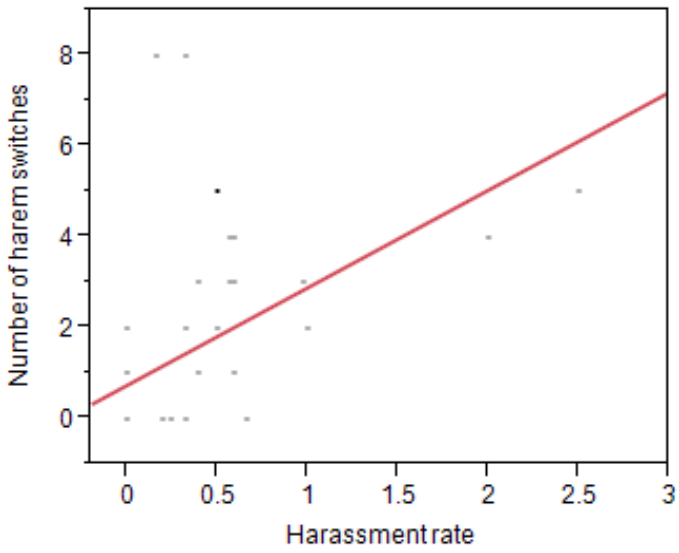

Figure 3.2. Number of harem switches during the study period by rate of harassment (number of reproductive behaviors and herding per hour of observation) ($F_{1,43} = 15.73$, $r = 0.25$, $p = 0.0003$).

3.4.2 Harem Switches

No correlation was found between the number of harem switches and body condition ($F_{1,43} = 0.24$, $p = 0.628$). There was no significant difference in body condition between those mares that switched harems at least once and those that did not switch at all ($t_{39} = 0.67$, $p = 0.5091$), nor a correlation between number of switches and body condition within the switchers. Number of harem switches was also not found to be correlated to parasite egg counts (first or second half mean, or total mean) or time spent grazing. However, a positive correlation was found between the number of harem switches and the rate of harassment ($F_{1,43} = 15.73$, $r = 0.25$, $p = 0.0003$, Figure 3.2).

3.4.3 Harassment Rate

Other than the relationship with harem switches (above), harassment rate was not found to be correlated with any of the other health and behavior indicators (body condition, parasite egg load, time spent grazing, dominance rank).

3.4.4 Average Harem Size and Variance

The average size of the harem with which the mare cohabitated was not correlated with body condition, parasite egg counts (either half mean or total mean), time spent

grazing, harassment rate, or harem switches. Variance in average harem size (*Coefficient of variance of harem size*) was also not correlated with those variables.

3.4.5 Dominance

Dominance rank (from the variable *Dominance rank*, which only included mares that were observed participating in interactions with other mares) was not correlated to parasite egg loads (either half mean, or total mean), time spent grazing, number of harem switches, or harassment rate. However, mean body condition was significantly higher for mares of high rank ($Z = -2.15$, $p = 0.032$, Wilcoxon test); mares of high dominance had an average body condition score of 3.85, and low dominance, 3.45).

3.4.6 Stallion Temperament

Stallion temperament, either "docile" or "mean" based on the number of aggressive actions towards his mares, was not correlated to any of the relevant variables (body condition score, parasite egg loads, time spent grazing, number of harem switches).

3.4.7 Age

Age was not significantly correlated to body condition, parasite egg loads, number of harem switches, or harassment rate. There was a trend for increased age to be correlated with decreased average time spent grazing ($F_{1,43} = 3.96$, $r = 0.062$, $p = 0.0531$).

3.4.8 Lactation Status

Lactating mares had a significantly lower average body condition than non-lactating mares ($t_{43} = 5.21$, $p < 0.0001$); average body condition was 2.98 for lactating mares and 3.75 for non-lactating mares (see Figure 3.3a). There were no significant differences in mean parasite egg load over the entire summer; notably, the ranges of average fecal egg counts were approximately equal for the two groups ($t_{37} = 1.17$, $p = 0.2485$, Figure 3.3b). Lactating mares spent more time grazing as a percentage of their average overall time budget, 79.64% in relation to the non-lactating mares' 68.59% ($t_{43} = -2.75$, $p = 0.0087$, Figure 3.3c). An analysis of variance model found that the main effect of lactation status on body condition was significant ($F = 16.21$, $p = 0.0002$), but the main

effect of time spent grazing was not significant ($F = 0.19$, $p = 0.6692$), nor was the interaction ($F = 0.005$, $p = 0.9442$); non-lactating mares had a higher average body condition, and the proportion of time spent grazing had no correlation to body condition when the variance due to lactation was removed (Figure 3.4).

Lactating mares switched harems fewer times than non-lactating mares: 0.40 and 1.74 times during the study period, respectively ($F_{1,39.8} = 8.21$, $p = 0.0066$, Welch's test, Figure 3.3d). Similarly, lactating mares also spent more time with their primary stallion ($F_{1,42,4} = 12.99$, $p = 0.0008$, Welch's test). There was a trend for lactating mares to have a lower harassment rate, but not significantly (Welch's test $F_{1,25.6} = 2.63$, p = 0.1174).

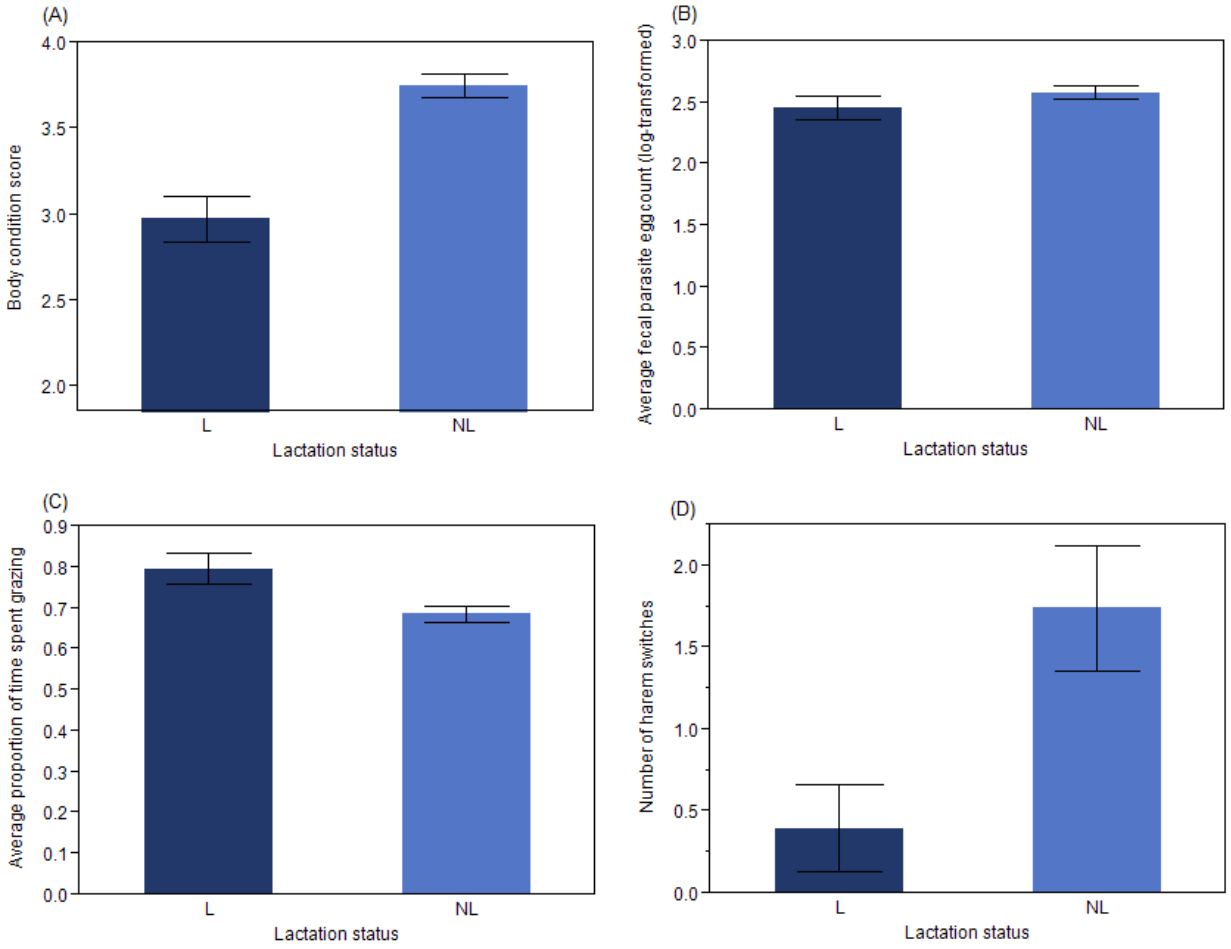

Figure 3.3. (A) Body condition score by lactation status (means ± S.E., $t_{43} = 5.21$, $p < 0.001$). (B) Fecal parasite egg count, averaged over the entire study period and log-transformed, by lactation status (means ± S.E, $t_{37} = 1.17$, $p = 0.2485$). (C) Average time spent grazing, as a proportion of the total time budget, by lactation status (means ± S.E, $t_{43} = -2.75$, $p = 0.0087$). (D) Number of harem switches during the study period by lactation status (means ± S.E, $F_{1,39.8} = 8.21$, $p = 0.0066$, Welch's test).

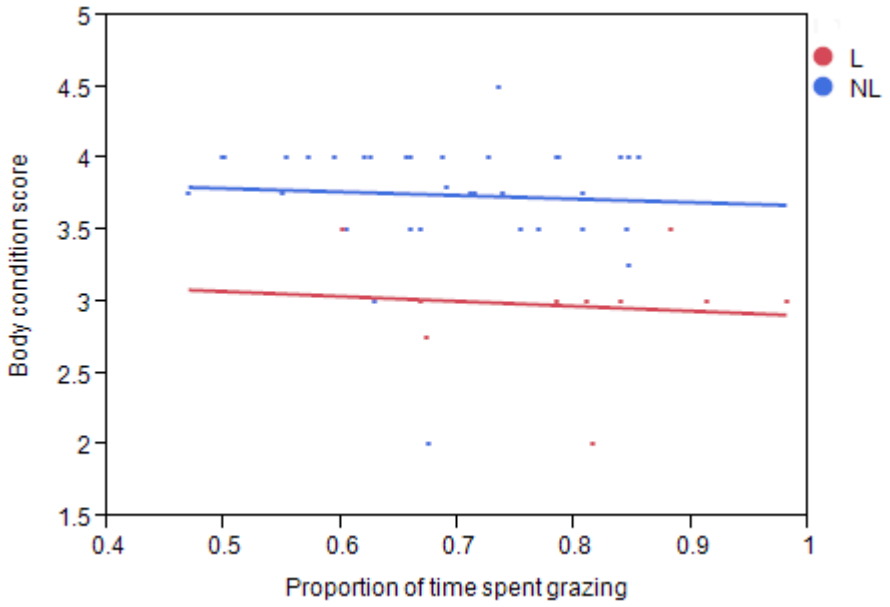

Figure 3.4. The separated main effects of current lactation ($p = 0.0002$) and proportion of time spent grazing (non-significant, $p = 0.6692$) on body condition score, with no significant interaction ($p = 0.9442$). L (red) = lactating; NL (blue) = non-lactating.

There was no significant difference in the distribution of dominance ranks between lactating and non-lactating mares ($\chi^2 = 0.321$, $p = 0.8516$). Lactating mares were on average 10.3 years old, significantly lower than the non-lactating mares average age of 15.37 years ($t_{43} = 2.46$, $p = 0.018$).

3.5 Conclusions

We proposed in this study to use parasite load, as quantified by the number of parasite eggs per gram of feces, to assess the mares' immune function and, indirectly, their health. However, the results from this primary analysis suggested that parasite egg load may not be a reliable or straightforward indicator. Egg counts were not significantly correlated with any other measure of health or behavior, including body condition score, which is a known measure of overall health. This, along with the fact that egg load did not differ between mares that are lactating or switching harems more (known physiological stressors), suggests that the parasite infection intensity is determined by a different mechanism. For this reason, we could not be sure what the egg levels were communicating, and could not use them to make any substantial conclusions about the immune health of the mares. Rubenstein and Hohmann (1989) found that parasite egg

counts were negatively correlated with body condition in the subsequent year; perhaps the same would be true if we measured body condition of these mares in the subsequent year. The body condition score will therefore be used in further analysis as the long-term average measure of health, disregarding the originally proposed finer scale measure of immune function through parasite eggs.

At first, we found a negative correlation between body condition score and time spent grazing, suggesting that less healthy mares were eating more, possibly to compensate for lower physical condition. However, this result was nullified when controlling for lactation. Lactating mares had a lower average body condition score. Analysis of variance modeling showed that there was no relationship between time spent grazing and body condition, as was initially believed, once this variance due to lactation was removed. The lactating mares, by spending more time grazing and also having lower body condition scores, drove the original correlation (Figure 3.1). This indicated that lactation, as a physical stressor that requires a large output of energy, required the mares to graze more to increase their energy input and simultaneously decreased their body condition.

Of the rest of the behavioral measures, only mare dominance rank was correlated with health as measured by body condition. Dominance was, however, not correlated with time spent grazing, suggesting that dominance and time spent grazing act on body condition in different ways.

The fact that the number of harem switches was not indicative of lower body condition was a surprising result. Prior studies on Shackleford Banks found that fecal cortisol levels were elevated during harem switching (Nuñez et al., 2014), but it seems that such physiological stress was not manifested immediately in body condition. The number of harem switches was not also correlated with time spent grazing; mares switching more were not taking time away from grazing, but rather from other activities such as sleeping.

Two behavioral measures, number of harem switches and rate of harassment, were positively correlated, but the direction of this correlation is ambiguous; a mare exposed to more instances of harassment (i.e. sexual advances and herding) from the stallion could switch groups more, or a mare switching more and not establishing stable social relationships could cause her to be harassed more by the stallion. Neither harassment nor harem switching were correlated with overall health, but they could still cause increased

physiological stress that was just not manifested immediately in body condition. Prior research on other herds has found that increased harassment is predictive of lower body condition (Linklater et al., 1999), but it is possible that just not enough instances of harassment were observed in this herd to make an accurate correlation. Additionally, the fact that harems switches did not differ based on stallion temperament suggest that it was the individual harassment, not the harassment occurring in the rest of the harem, that was related to harem switching. It is also possible that we were unable to sufficiently differentiate stallion temperament from the limited harassment data.

The fact that average harem size, harem size variation, or stallion temperament did not predict any changes in health or behavior indicated that they were not agents of stress significant enough to cause changes in health. This allowed us to assume that these factors did not need to be controlled for in further analyses, because they were not influencing our conclusions about health.

Age was similarly not correlated with body condition, suggesting that age is not influencing overall health. Increased age did predict decreased time spent grazing; this could be a function of lactation, because we found that non-lactating females were more likely to be older, and non-lactating females spend less time grazing. This could in turn be a function of increased contraception application in older females rendering them sterile, preventing them from lactating and therefore requiring less food intake, a topic which will be discussed further in the next chapter.

In addition to being correlated with lower body condition and more time spent grazing, current lactation was also a significant predictor of fewer harem switches. Remaining with a primary stallion would be favorable for a mare with a foal to ensure protection and reliable food and water sources. No difference was found in harassment rate between lactating and non-lactating mares. The fact that harem switches and harassment were previously found to be correlated, and switches but not harassment differed with lactation, could have two explanations: harem switches and lactation interact with harassment differently, or there were just not enough harassment instances observed to reach an accurate conclusion; we support the latter alternative.

From this preliminary investigation, we have concluded that body condition was a more reliable measure of health than parasite egg counts, which will hereafter be discarded as a health indicator. Lactation had significant effects on health and behavior:

non-lactating females had higher average body condition, spent less time grazing, and switched harems more. These differences will be taken into account in further analysis in the subsequent chapter.

Chapter 4
Contraception and Foaling History

4.1 Introduction

Each mare on Shackleford Banks has had a unique pattern of contraception and foaling. Mares born in the early 1990s were able to foal before the PZP program was begun in 2000. Some of those born after 2000 were able to foal before their first immunization, but some were not. The total number of times contraception was given varied, as well as if the doses were given in consecutive years or with breaks to foal in between. Such variation in contraception administration resulted in large variations in foaling frequency and timing. Each mare's contraception and foaling history since 2000 can be seen in further detail in Appendix I.

In this chapter, we use the contraception and foaling histories of each mare to explore the effects of PZP contraception on the mares' health and behavior, as measured by the variables described and deemed significant in Chapter 3 (body condition, time spent grazing, harassment rate, and harem switches). The different factors considered include: *recovery* from contraception, *timing* of contraception (first dose given before or after puberty, year of last dose), and *intensity* of contraception (number of doses, number of consecutive doses, and percentage of reproductive life treated).

4.2 Data Analysis

Multiple variables were created to describe the mares' history of contraception and

foaling. The abbreviation "BC," i.e. birth control, is used in place of "PZP contraception" in the names of variables for the sake of brevity.

4.2.1 Timing of Contraception

The year of last contraception was drawn from data provided by the National Park Service. This was used to calculate the number of years since the last dose of contraception:

$$\textit{Years since BC} = 2013 - \textit{Year of last BC}$$

This was an approximation, like age, ignoring slight differences in the timing of the last dose, instead providing a relative length of time since that dose.

Of significant interest was whether the mares were given their first dose of PZP before or after puberty and first foaling. The categorical variable *BC before puberty* was assigned to each mare: mares were given the value "no" if they foaled before their first dose, and "yes" if they were given the first dose before they were able to foal for the first time, either in the second or third year after birth.

Many of the mares were given their first dose of contraception before reaching sexual maturity (i.e. conceiving their first foal, at age two or three). A table was made distinguishing which mares had and had not foaled since the inception of contraception treatment, based on this timing (Table 4.1). A Chi-squared test was performed on this table to determine if differences in foaling based on timing differences were significant, or due to random chance.

4.2.2 Intensity of Contraception

The intensity of the contraception treatment for each mare was operationalized in three different ways. The first was the *Total number of years on BC*, a count of the number of separate years in which the mare was given PZP. The *Maximum number of consecutive years of BC* was also recorded as the maximum number of years in a row

Table 4.1. Foaling based on timing of first dose of PZP contraception.

	Foaled since PZP started?	
	Yes	No
PZP before puberty	7	14
PZP after puberty	13	7

that the mare was given PZP. The number of years that the mare had been of reproductive age between the start of the contraception program (2000) and the last possible year of reproduction (2012) was then determined; reproductive age was considered to start during the year in which they turned two years old. From this, the *Percentage of reproductive years on BC* was calculated:

% Reproductive years on BC = # Years on BC / # Reproductive years

4.2.3 Recovery from Contraception

A few different categorical variables (with "yes" or "no" values) were created to describe the mares' recovery from the contraception, i.e. whether or not the PZP had worn off, as evidenced by foaling. These variables included:

Ever foaled: If she had ever had a foal, whether before, during, or after contraception

Foal since end of BC: If she had foaled since the contraception was ceased, whether in 2009 or before, or after the study period (late 2013 or early 2014)

Foal since BC started: If she has foaled at any time since her first dose of PZP

4.2.4 Recovery Based on Intensity

A table was created to depict the mares' abilities to recover (i.e. foal again) after consecutive years of PZP immunization (see Appendix IV). For each mare, each stretch of years of consecutive doses was identified. Then the mare was written into the appropriate cell in the table based on the number of consecutive years and whether or not she foaled afterwards. A mare could be put into this table more than once if she had more than one period of multiple consecutive years of immunization; we were not looking at the maximum number of consecutive years of treatment for each mare, but rather each treatment period and the potential recovery. For the mares Tiger and Bridget, who each had two separate periods of consecutive years of treatment but did not foal in between, only the first period was considered and entered into the table; it was impossible to differentiate them as two separate data points without a foal in between to indicate recovery from the first period.

From this data, another table was created that indicated if the mares had been rendered sterile by their consecutive years of treatment (Table 4.2). A mare was considered "fertile" if she had foaled since the stretch of contraception. She was

Table 4.2. Foaling patterns based on consecutive years of PZP contraception treatment (for mares whose last dose was in 2006 or before)

Consecutive years of PZP	Foaled since that period	Not foaled since that period
1-2	4	1
3	5	3
4-5	2	9

considered "sterile" if she had not foaled, and her last dose was in or before 2006; it has been reported that mares with many consecutive years of PZP treatment can take up to six years to return to fertility (Kirkpatrick et al., 2002), so mares whose last dose was prior to 2006 could be assumed to be sterile. For each cell, rather than the names of all the mares with that fertility indication and number of consecutive years of PZP, the total number of mares with that outcome was entered. The mares with only one and five consecutive years were binned with those with two and four years, respectively, because of low group membership. A Chi-squared test was performed on this table to determine if differences in foaling ability after various numbers of years of contraception were significant, or due to random chance.

4.3 Statistical Analysis

All statistical analysis was performed in JMP Pro (version 10.0.0). All quantitative data sets were checked for normality by histograms. Most were not normally distributed, so nonparametric statistics were applied. When variances in two groups were determined to be unequal, a Welch's test was used. T-tests performed were all two-tailed tests, because the null hypotheses were that the two groups were different (no directionality). Significance was determined when $p < 0.05$. In tests relating to the contraception history (i.e. time since last dose, treated before puberty, etc.), the young mares that had never been given contraception were excluded from the analysis (Chacha, Hiphop, Desdemona, and Selena).

4.4 Results

4.4.1 Effects of foaling over the lifespan

Mares that had at least one foal during their lives (*Ever foaled* = Yes) had an average body condition score of 3.4, which was significantly lower than the average of 3.93 of

mares that had not foaled ($F_{1,33.6} = 25.0$, $p < 0.0001$, Welch's test). This effect remained when the mares that were currently lactating during the study were excluded from the analysis to eliminate lactation as a confounding factor ($F_{1,21.6} = 7.54$, $p = 0.0119$, Welch's test); the body condition scores were 3.61 and 3.93 for non-lactating mares that had and had not ever foaled, respectively (Figure 4.1). There were no differences in time spent grazing, number of harem switches, harassment rate, or dominance rank between mares that had and had not foaled.

There was no significant relationship between the total number of foals a mare had birthed and her body condition score ($F_{1,43} = 0.8861$, $p = 0.3518$). An analysis of covariance model was created to separate the effects of the number of foals and current lactation status on body condition. The main effect of lactation status during the study period on body condition was significant ($F = 29.2$, $p < 0.0001$), but the main effect of the number of foals was not significant ($F = 0.17$, $p = 0.6853$); the interaction was also not significant ($F = 3.78$, $p = 0.0588$). There was also no relation between the total number of foals and time spent grazing, dominance, number of harem switches, or harassment rate.

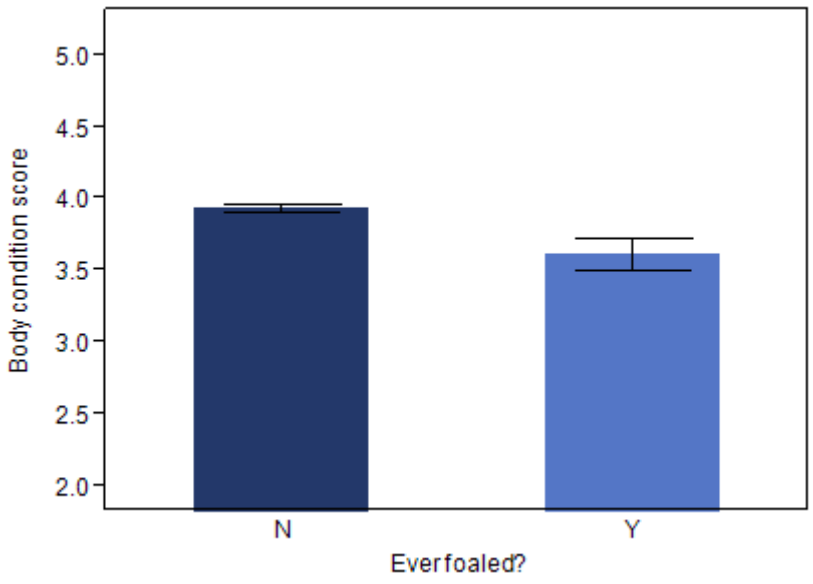

Figure 4.1. Mean body condition scores of mares that had never foaled (N) and mares that had foaled at least once (Y), while excluding those that are currently lactating (means ± S.E., $F_{1,33.6} = 25.0$, $p < 0.0001$, Welch's test).

4.4.2 Recovery from Contraception

The category of mares that had foaled since their last dose of PZP contraception (*Foal since end of BC* = Yes) aligned with those who were lactating during the study period (*Lactating in 2013* = Yes) with the exception of three individuals. Sydney, Hermione, and Wallace had recovered (*Foal since end of BC* = Yes) but were not lactating during the study period (*Lactating in 2013* = NL). Sydney foaled in 2012 and again in 2014; Hermione and Wallace foaled in 2013, but only after the study period.

Mares that had foaled since the end of contraception treatment had a significantly lower average body condition than mares that had not (t_{39} = -2.82, p = 0.0075); average body condition score was 3.25 for recovered mares and 3.74 for non-recovered mares. Mares that had foaled switched harems fewer times than those that had not ($F_{1,38.1}$ = 8.25, p = 0.0066, Welch's test). On average, mares that had foaled switched harems 0.40 times, and those that had not switched 1.81 times during the study period. There was no significant difference in time spent grazing (t_{39} = 1.77, p = 0.0844) or harassment rate ($t_{1,39}$ = -1.16, p = 0.2532) between the two categories of mares.

4.4.3 Timing of Initial Contraception Dose

A Chi-squared test on Table 4.1 (foaling based on if the mare's first dose was given before or after puberty) found that the difference in foaling pattern was significant (χ^2 = 4.11, df = 1, p = 0.04); mares that were given PZP before puberty were less likely to have foaled since the inception of the PZP regimen.

A two-way ANOVA test found that the main effect of having a foal since the inception of PZP contraception significantly impacted body condition score (F = 8.42, p = 0.0062), but the main effect of having PZP administered before puberty did not (F = 0.25, p = 0.6203); the interaction was also not significant (F = 0.65, p = 0.4249). Similarly, no effects of having the first dose before puberty were found on the amount of time spent grazing, number of harem switches, or harassment rate when the effects of current lactation were removed.

4.4.4 Time Since Last PZP Dose and Last Foal

The mares that foaled and did not foal since their last dose of contraception did not

differ in the number of years since that last dose (t_{39} = -1.16, p = 0.2551). There was a significant positive relationship between the number of years since the last immunization and the number of years since the last foal ($F_{1,25}$ = 10.36, p = 0.0035).

When looking at all of the mares studied, the number of years since the last PZP dose and the body condition score were significantly positively correlated; as years since treatment increased, so did body condition ($F_{1,39}$ = 13.80, p = 0.0006). An analysis of covariance model was created to remove the variance in body condition that we had already determined arose from foaling since the PZP was ceased (Section 4.4.2). The main effect of foaling since the end of treatment on body condition was significant (F = 6.17, p = 0.0177), as was the main effect of years since PZP treatment (F = 8.96, p = 0.0049), but the interaction of these two factors was not significant (F = 0.07, p = 0.7930). Mares that had not foaled since their last dose of contraception had a significantly higher body condition than those that had. And for both mares that had and had not foaled, as the years since last treatment increased, the average body condition increased. This model can be seen in Figure 4.2.

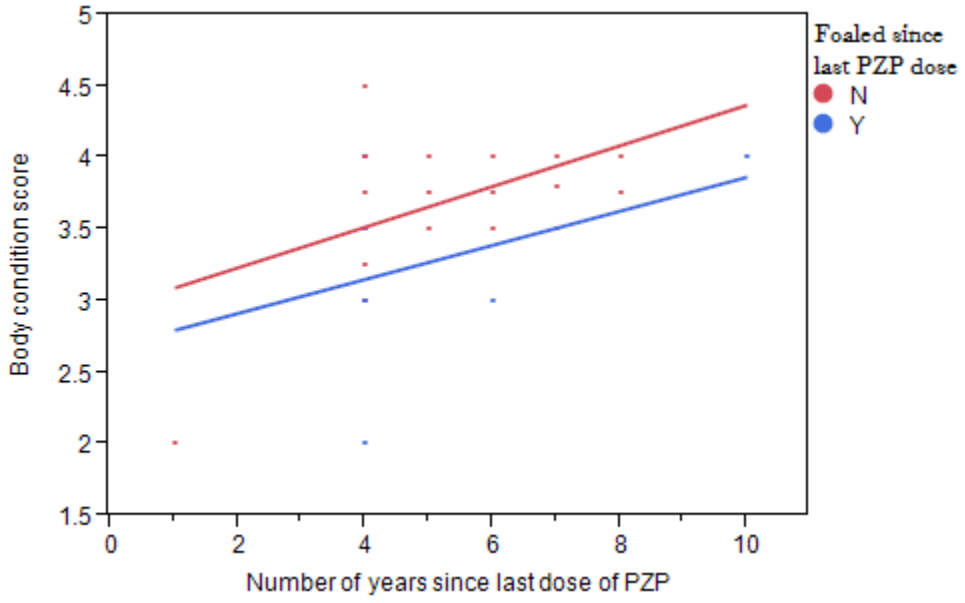

Figure 4.2. The separated main effects of the number of years since the last PZP dose (p = 0.0049) and foaling since that last dose (p = 0.0177) on body condition score, with no significant interaction (p = 0.7930). N (red) = not foaled since last dose, Y (blue) = foaled since last dose.

An analysis of covariance model (as above, to remove the effects of foaling since the last PZP dose) found no significant effects of number of years since the last foal on body condition ($F = 0.71$, $p = 0.4097$), or foaling since the last dose ($F = 1.52$, $p = 0.2305$), or any interaction between the main effects ($F = 2.02$, $p = 0.1691$).

When looking at all of the mares studied, the number of harem switches decreased as the time since the last PZP dose increased ($F_{1,39} = 4.08$, $p = 0.05$). There was no correlation between the number of switches and the time since the last foal ($F_{1,28} = 1.32$, $p = 0.2602$). This result was supported by an analysis of covariance model: the main effect of years since PZP on the number of harem switches was significant ($F = 4.92$, $p = 0.0368$), the main effect of years since a foal was not significant ($F = 3.22$, $p = 0.086$), nor was the interaction ($F = 0.18$, $p = 0.6782$).

This trend was more statistically significant when only considering the mares that had not foaled since their last treatment. The number of harem switches decreased as the time since the last PZP dose increased ($F_{1,29} = 8.36$, $p = 0.0072$, Figure 4.3). There was no correlation between the number of harem switches and the time since the last foal ($F_{1,18} = 0.0019$, $p = 0.9657$). In an analysis of covariance model, the main effect of years since PZP was significant ($F = 4.92$, $p = 0.0368$), but the main effect of years since a foal was not ($F = 3.22$, $p = 0.086$), nor the interaction effect ($F = 0.18$, $p = 0.6782$). An increased number of years since PZP, in non-recovered mares, predicted fewer switches even when the variance due to the number of years since the last foal was removed.

The same trend could not be examined in the mares that had foaled since their last dose of PZP because low sample size led to loss of degrees of freedom in models.

Analysis of variance models with the same main effects but harassment rate and grazing time as the response variables revealed no significant correlations or interactions.

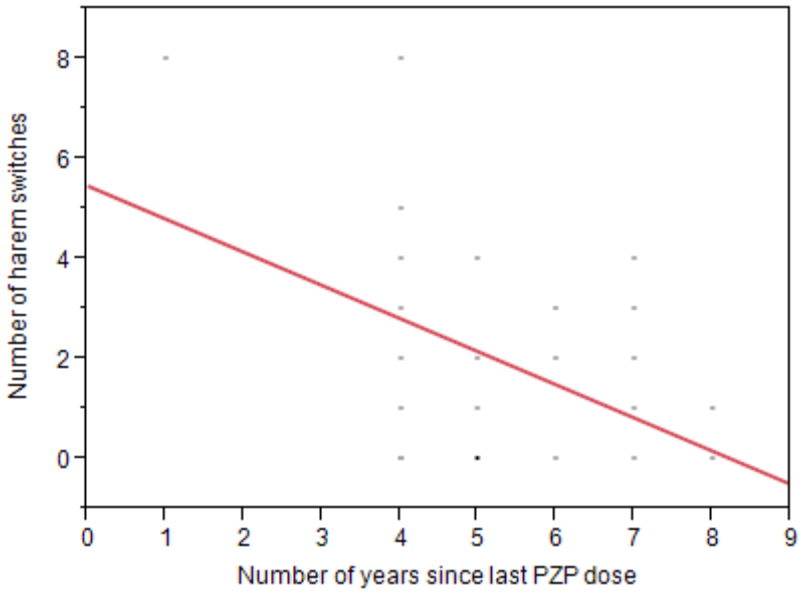

Figure 4.3. In only the mares that had not foaled since the last dose of PZP, the relationship between the number of years since that last dose and the number of harem switches ($F_{1,29} = 8.36$, $p = 0.0072$).

4.4.5 Intensity of Contraception

The Chi-squared test on Table 4.2 (foaling patterns based on consecutive years of PZP contraception treatment) indicated that the deviations from the expected values of mares who foaled and did not foal were not random ($\chi^2 = 6.634$, $df = 2$, $p = 0.04$). The mares with more consecutive years of PZP treatment (three or four years) had a significantly reduced chance of having foaled since that last treatment.

When looking only at the mares that were not lactating in this year (to eliminate the significant effects of lactation) there were no significant relationships between the measures of contraception intensity (number of consecutive years of treatment, total years of treatment, and percentage of reproductive life treated) and any of the measures of health and behavior (body condition score, proportion of time budget spent grazing, number of harem switches, or harassment rate); all *p*-values were greater than 0.05.

4.5 Conclusions

Based on the results from initial analysis in Chapter 3, parasite egg loads were not included as a measure of health, only body condition score. Time spent grazing, number of harem switches, and harassment rate were deemed to be the important indicators of

behavior and were used along with body condition score to determine the effects of past contraception and foaling.

It was previously determined that mares lactating at the time of the study were, on average, in worse physical condition than mares that were not lactating. Here, we found that mares had a lower average body condition score if they had ever had a foal, an effect that held true even when currently lactating mares were excluded from analysis. Additionally, there was no relationship between the total number of foals and body condition; mares that had one foal did not have a higher body condition than mares that had many foals, which would be expected if foaling had a cumulative effect. It appears from these analyses that the detrimental effect of foaling on physical condition is an "all or none" response: having at least one foal at any time over a mare's lifespan predicted that she was in worse physical condition at the time of study.

Having foaled at any point was not predictive of any of the other measures: time spent grazing, number of harem switches, or harassment rate. The fact that ever foaling predicted lower body condition but not increased grazing agrees with the former conclusion (Chapter 3) that current lactation, but not body condition itself, is what determines the amount of time spent grazing. Mares that had foaled in the past were in poorer body condition from that energetically-costly process of foal-bearing and lactation, but did not require extra intake of food if not currently nursing a foal in the year of study. The amount of time spent grazing therefore seems to be a measure of current, but not past, energetic needs; the increased cost of lactation leads nursing mares to graze more. These results suggest that harem switches and harassment rate are also indicators of current lactation status, but not past foaling.

Mares that had foaled since their last dose of PZP contraception were able to do so because the PZP antibody titers had dropped low enough to permit the sperm's binding to the egg. Mares that had recovered and foaled were found to have a lower average body condition than those who had not. This result is consistent with the above finding that foaling even once lowers body condition. However, the difference in average body conditions could be merely mirroring the difference caused by current lactation; the group of mares who had foaled since their last dose was the same as the group of mares who was currently lactating, plus three additional mares who foaled after the study period (Hermione, Sydney, and Wallace).

This possibility is supported by the fact that the difference in body condition between lactating and non-lactating mares was more significant ($p < 0.0001$) than the difference between recovered and non-recovered mares ($p = 0.0075$). Adding Hermione, Wallace, and Sydney to the lactating group (forming the "foaled since last dose" group) reduced the difference in body condition between the two groups, suggesting that the lowered body condition was primarily an effect of the current lactation, not recovery.

Mares that had foaled since their last dose of PZP switched harems significantly fewer times during the study period, but that was also probably because most of them currently had a foal and remained faithful to one stallion for protection of the foal. The mares that were pregnant during the study (Hermione, Sydney, and Wallace) also had good reason to remain with a single stallion because they were not in estrus and needed the protection and steady food source the stallion provided as they prepared to foal. Without a larger group of mares that had foaled since their last dose but were not currently lactating (larger than the three used in this analysis), no confident conclusions can be drawn about the differences between mares who had recovered from the contraception and mares who had not.

Two results from these analyses indicated that several of the mares were likely sterile as a result of repeated PZP contraception administration, a possibility that had been suggested previously (Kirkpatrick et al., 1992; Nuñez et al., 2010). Firstly, the mares that had and had not foaled since their last dose of PZP, i.e. recovered from the dose and become fertile again, did not differ significantly in the number of years since their last dose. We would expect that the longer it had been since a mare's last contraception dose, the more likely she would be to have recovered and subsequently foaled; if this were the case, the mares that had recovered would have had a higher average number of years since the last dose. Instead, there were mares that had not had PZP in many years, but also had not since recovered, suggesting that they had become sterile and could no longer foal. Another result implying sterility was that the length of time since the last foal and the length of time since the last dose of PZP were positively correlated. Again, the expected result would be a negative correlation: the longer since PZP, the less time since the last foal, because the mare would have more time to recover and foal. These two results showed statistically that there were mares in the population not foaling after their contraception treatment, and may have been made sterile by such treatment.

Kirkpatrick & Turner (2002) found that mares on Assateague Island with a higher number of consecutive years of treatment took longer to return to fertility. From this finding, we hypothesized that high intensity of treatment may be a cause of sterility in some Shackleford Banks mares. A Chi-squared test on the distribution of mares that had and had not foaled since their last dose, differentiated by the number of consecutive years of treatment, was significant enough to conclude that the differences in distribution were not by chance (Section 4.4.5, Table 4.2, $p = 0.04$). Only mares that had their final PZP dose in 2006 or earlier were considered in this analysis, because Kirkpatrick & Turner (2002) observed that mares could take up to six years to return to fertility; mares with the last dose in 2006 and not foaled since had surpassed this six year mark and were surmised to be sterile. From this test, we can conclude that the higher the number of years of consecutive treatment, the more likely it was that the mares had not returned to fertility. Of mares that had only one or two years of treatment, four out of five (90%) had since returned to fertility at the time of this study; of mares that had three years of treatment, only five out of eight (63%) foaled again. Most significantly, out of the 11 mares that had four or more years of PZP in a row, only two (18%) had recovered and foaled since the end of their treatment. Three or four years of PZP in a row appears to have significantly reduced chances of recovery and subsequent foaling, most likely because the higher number of consecutive doses compromised ovarian functioning to an irreparable extent.

It was noted upon preliminary inspection of the contraception histories that many mares were given their first PZP dose before they were able to foal for the first time. This was also considered a potential source of sterility, because those mares may have not yet reached sexual maturity before having their fertility compromised. Of those that had their first dose before puberty, seven of 21 had since foaled (33%), as compared to 13 of 20 of those who were allowed to foal before being administered their first dose (65%). This difference was found to be statistically significant by a Chi-squared test (Section 4.4.3, Table 4.1, $p = 0.04$): mares that were immunized before reaching sexual maturity were less likely to have recovered and foaled since the treatment ended. The effects of these two sources of sterility (intensity and timing) were not able to be separated because of relatively low sample size.

The contraception history itself (i.e. intensity or timing) was not found to be correlated to any of the measures of health and behavior when the variance from lactation was removed. However, the amount of time since the last dose of contraception was negatively correlated to the number of harem switches. In all of the mares, the number of harem switches was found to decrease as the number of years since the last dose of PZP increased. This effect was even stronger and resulted in a more statistically significant trend when only the mares that had not foaled since their last dose were considered, which removed the variance due to lactation. This could have two explanations. The contraception treatment could have caused an increase in harem switches during the year of its administration, an effect that wore off as the contraception wore off; Madosky et al. (2010) found that mares that had been administered contraception switched harems more times than mares that had not. Alternatively, an increased number of years since PZP in those mares that had not foaled could have been an indicator of sterility; sterile mares may switch harems fewer times because they are not reproductively active and do not solicit reproductive interest. These hypotheses will be more fully discussed in Chapter 5.

Also significantly, as the number of years since the last dose of PZP increased, the body condition score increased (Figure 4.2). This effect held true for both mares that had foaled since that last dose and those that had not, when they were assessed separately in an analysis of variance model. That is, regardless of if a mare had or had not foaled since her last dose of contraception, her body condition was higher the longer it had been since that last dose, with foaling mares at a significantly lower body condition at all time points. This suggests that the immunocontraception may have had some negative impact on the health of the mares, one that they are able to recover from over time, which cannot be explained by lactation status. Other than these two phenomena, lactation – both in the current year and over the lifespan – was found to be the most significant predictor of health and behavior, with contraception patterns only affecting whether or not the mares were able to foal.

Chapter 5
Discussion and Conclusions

5.1 Study Limitations

In this study, we were able to examine the relationships between various health and behavior indicators and the history of PZP immunocontraception and foaling of the mares of Shackleford Banks. However, various limitations prevented us from drawing certain conclusions. With no mares administered PZP in the spring of 2013, there were no immunized mares during our study period, the summer of 2013, to compare to non-immunized mares. Consequently, no conclusions about the direct effects of the contraception dose could be reached. This differed from previous studies on the Shackleford Banks mares, which were conducted during years of contraception administration, and from which the authors could make more specific conclusions about its effects (Madosky et al., 2010; Nuñez et al., 2009; Nuñez et al., 2010, Nuñez et al., 2014). Instead, rather than examining the direct effects of contraception in the current year, we took a more historical perspective and determined the effects of past years of treatment and the resulting foaling. We acknowledge that these are correlations and cannot determine causality with certainty.

Each mare had a unique history of contraception and foaling each year, making it impossible to statistically remove all variance to examine a single variable (i.e. mares who did not foal in the year of study differed not only in the number of years since PZP treatment, but the total number of years treated, the age, the total number of foals, etc.). When doing statistical analysis, we controlled for the most relevant variables to reach a

confident conclusion, but variation could still confound the results. This variation in histories also resulted in small group sizes for many combinations of variables, making certain tests impossible due to loss of degrees of freedom (i.e. looking at the differences in body condition due to varying intensity of treatment, in only mares that were immunized before puberty).

Additionally, we used foaling as the indicator of a mare's recovery from the contraception, which may not have been 100% accurate; a mare could have successfully conceived but not carried the foal to term, resulting in an incorrect judgment about fertility in that year. Pregnancy testing would have been a more accurate test of fertility, but this data was not available to us for the entire 2000-2013 period.

Limited data became a problem when determining mares' harassment rate and dominance rankings. Harassment events were rarely observed during the study period, so the calculated harassment rates may have been results of unequal sampling and thus not accurately reflect the actual daily harassment rates. Dominance rankings were determined based on mare-mare interactions, which were also relatively rare. Many of the mares were seen to participate in only one antagonistic interaction with another mare, if any, so conclusions drawn from such a small data set may be incorrect. For these reasons, the correlations between harassment rate or dominance ranking and other variables were not always as expected, and conclusions could not be made with much confidence.

5.2 Parasite Load as a Health Indicator

One of the original goals of this study was to examine the effects of PZP contraception on the health of the mares' immune systems, as quantified through the number of parasite eggs found in their feces; a mare with a healthier, stronger immune system is better able to fight off infection and should have a lower parasite load. Because PZP contraception works through activation of the immune system, we expected some effect of treatment on immune function. However, because there were no currently immunized females, there was no direct comparison and no conclusion about the effect of the contraception treatment on immune functioning to be made.

Even when looking at the relationships between the parasite egg loads and other health and behavior measures, surprisingly, no significant relationships were found.

Linklater et al. (1999) found that more parasite eggs predicted lower body condition and higher harassment rate; these results were not corroborated by our results. It was also surprising to find no difference in egg loads between lactating and non-lactating females since lactating females were under physiological stress which could have weakened their immune systems, along with lowering overall health. Rubenstein and Hohmann (1989) found that increased harem size predicted increased endoparasite load, another result that our results did not agree with.

This lack of correlation between parasite egg loads and any of the other measures could stem from one of two sources. It is possible that the parasite egg load is indicative of something other than overall health, resulting in it not being correlated with body condition score, which does measure overall health. The fact that the lactating and non-lactating mares had similar ranges and similar mean values of egg counts suggested that parasite load is more than just a simple measure of physiological stress or energy use. In fact, Rubenstein and Hohmann (1989) also found no differences in parasite loads between lactating and non-lactating mares on Shackleford Banks. It is also possible that the number of eggs produced in this year will be indicative of future body condition score, because the negative impacts of the parasites may not affect overall health immediately; this was also a finding by Rubenstein and Hohmann (1989).

Another alternative is that the sampling performed did not sufficiently capture the actual intensity of parasite infection in the mares. We collected three fecal samples from most of the mares throughout the study period, and only two for a few. This may not have been enough samples to obtain an accurate measure, because the average would have been easily skewed by outliers or unequal egg distribution within the fecal piles. The storage of the fecal samples until transfer to the laboratory for fecal flotation and egg counting may also have posed a problem. The samples were kept cool using frozen ice packs, but successive days of storage could have caused them to become too warm as the ice packs melted. Samples were stored for any amount of time between a few hours and two days before being taken to the lab for processing; this lack of consistency also could have affected the relative number of eggs found in the samples (i.e. by some eggs dying or hatching into worms because of the increased temperatures).

For whichever reason, the lack of patterns in the parasite egg count data led us to discard it as a measure of immune function or overall health. In future studies, sampling

the feces more frequently and having a more invariable form of fecal storage and preservation could result in more accurate and reliable parasite egg data from which conclusions about health and immune function could be drawn.

5.3 Effects of Lactation

Ransom et al. (2010) found that body condition was the strongest predictor of feeding and social behaviors in harems in the Midwest that were treated with PZP contraception. In this study, we instead found that lactation was the strongest predictor not only of feeding and social behaviors, but also of body condition itself. Lactating mares were not only in poorer physical condition – a finding found previously (Ransom et al., 2010; Rubenstein, 1986; Turner & Kirkpatrick, 2002) – but also grazed more in order to offset the high energetic cost of lactation. Lactating mares were found to spend an average of 11% more of their time grazing which, over a day of 20 hours of grazing, would equal 132 additional minutes of food intake, which they could then invest in milk production. Mares not currently nursing a foal, released from the demands of lactation, were found to have higher average body condition and spent less time grazing. No relationship between body condition and time spent grazing was found independent of the effects of lactation.

Significantly, this negative impact of lactation had no dose-response relationship: having more foals over the life span was not correlated with lower body condition, as might be expected. Rather, there was an "all or none" response that predicted mares that had ever had a foal, even just one, would have a lower average body condition score. This was corroborated by the fact that increased time since the last foal did not predict higher body condition, which would be expected if the lactation was causing a lower physical condition from which the mares could recover with time. This suggests that the negative impact of foaling is relatively long-lasting or permanent, which could be confirmed with longitudinal studies tracing the mares' body conditions over time.

Lactating mares also switched harems fewer times throughout the study period. In fact, only two of the ten currently nursing mares switched harems at all, and even they remained faithful to the primary stallion for all but a few days spent with a secondary stallion before returning to the primary stallion. Those two mares, Keller and Hezekiah, were not nursing new foals, but rather a yearling and a two-year-old, respectively. The

remaining four mares with yearlings (Carrot, Hedvig, Sadie, and Tahiti) did not switch harems, and neither did the four mares with new foals (Chacha, Daisy, Desdemona, and Hiphop). The mares who were later found out to have been pregnant during the time of this study (Hermione, Sydney, and Wallace) also did not ever switch harems. Remaining faithful to a single stallion is practical for both nursing and currently pregnant mares because it ensures protection and more stable food resources for both themselves and their foal. Nunez et al. (2009) found that reductions in mare fidelity, caused by increased switching harems, disturbs all of the mares in the harem and can promote aggression, which would not be favorable for a mare with a foal.

In Chapter 3, we found a positive correlation between harassment rate and number of harem switches. The direction of this correlation was unclear; a mare could have been switching harems to escape increased harassment from the stallion, or a mare switching into a group may have been experiencing increased harassment because she was unfamiliar or in estrus. Because of this correlation, we expected to find that lactating mares, who switched harems fewer times, experienced fewer instances of harassment during the study period.

This trend was observed but was not statistically significant ($p = 0.1174$). This could be a result of the small sampling, and therefore low reliability, of the observed harassment events (Section 5.1). If that were the case, more extensive observation that better captures the actual relative rates of harassment of the mares may reveal this trend to be significant. An alternative conclusion is that harassment and lactation interact with harem switching in different ways. A lactating mare may remain faithful to a stallion for protection, but may not necessarily have a lower harassment rate. She would receive more reproductive interest if she were in estrus again; the mares foaling during the study period would have gone into estrus a few weeks after foaling (S. Stuska, personal communication), and the mares with yearlings could also have been in estrus during the study period. The lactating mares then may be remaining with a primary stallion for the benefits of protection, despite harassment rate; the non-lactating mares may be the only ones subject to the positive correlation between harem switching and harassment. This would result in no definite relationship between lactation and harassment rates. These two hypotheses are not mutually exclusive.

Thus it can be concluded from our data that lactation is a significant predictor of both health and behavior. A lactating mare will be in lower body condition than a non-lactating mare; this negative impact of foaling is not cumulative, but a one-time hit that lowers average body condition for mares that have ever had a foal. To compensate for the increased energy output of lactating, nursing mares increase the amount of time they spend grazing. They also switch harems less frequently, if at all. These last two measures, grazing time and harem switches, were not found to be significantly different between mares that had ever foaled and those that had not; they measured current energy needs and social state, not historical. Body condition, on the other hand, is reflective of both current and past foaling, a long-term measure of overall physical health.

5.4 Effects of Contraception

5.4.1 General Effects

As can be gleaned from the contraception and foaling histories of each mare, the contraceptive's main effect was prevention of pregnancy. However, this was not always 100% effective, as some mares were able to foal in the year following immunization. Of the 59 foals born since 2000, 14 were born in a year following the mare's immunization with PZP. Some of these instances could be explained by either the contraception given or the foal born late in the respective seasons (the antibody would have been low enough to allow conception) but some were inexplicable. See Appendix I for full histories.

As explained previously, we were unable to make any direct conclusions about the effects of current contraception because of a lack of treated and non-treated groups during the year of study. But by releasing a mare from lactation, contraception leads to better physical condition, less time spent grazing, and more harem switches.

However, when removing the effects of lactation, the patterns of past years of contraception treatment did not seem to have any significant measurable effects on health and behavior. Mares that were given their first dose before reaching sexual maturity had no difference in physical condition or behavioral measures, nor were there any differences based on the intensity of treatment (number of total years of treatment, number of consecutive years, or percentage of reproductive life treated).

5.4.2 Effects on Body Condition

One significant finding independent of foaling or lactation was that a longer time since PZP treatment was correlated with higher body condition score. This was a trend that held true both for mares that had foaled since that last dose and mares that had not. Additionally, longer time since foaling was not predictive of higher body condition, suggesting that this finding was not mediated by merely lactation differences. However, there is a possibility that causality is reversed in this correlation. Mares that were in lower body condition may have been more likely to be given contraception in a given year to prevent them from carrying a foal, which could be hazardous to their already diminished health, which would result in fewer years since treatment being predictive of lower body condition score. A longitudinal study would be able to investigate this relationship further. But if this were found to be a true trend, higher body condition the longer it has been since PZP administration, it would suggest that the contraception was negatively impacting physical health in a way that could be recovered from in subsequent contraception-free years. This would shed light on a potentially detrimental physical effect of the contraception treatment that has not yet been explored.

5.4.3 Effects on Harem Switching

Lactating mares switched harems statistically fewer times; only two of them switched harems at all, and those were only short-lived switches. But there also appeared to be an effect of PZP on harem switching independent of lactation status. When looking at all mares, there was a significant negative correlation between the number of years since the last dose of PZP and the number of harem switches, when the variance due to the number of years since the last foal was removed. This relationship was even more evident in the mares that had not foaled since their last immunization. As more time since treatment passed without a foal, the mares switched harems fewer times.

This may be a result of the contraception treatment increasing the number of switches in the year in which it is administered, an effect that is able to wear off with time. Madosky et al. (2010) found in two separate years that mares administered PZP in that year switched harems more than the control mares that had never been given PZP. Because there were no control mares in the year of this study (except for the few who had just become of reproductive age) such a comparison could not be made to determine

if the contraception itself was increasing the number of switches above and beyond the lack of a foal. But it does appear that the number of years since the last treatment is predictive of the number of switches, pointing out a direct effect of PZP.

Prior to the contraception program's inception, only about 10.8% of mares changed harems in a given summer, which increased to 66% of mares in 2007, 73% in 2008, and 44% in 2013, the year of this study: the number of mares to switch harems has increased since they started being immunized with PZP (Madosky et al, 2010). The fact that the number was lower in 2013 than 2007 or 2008 could be indicative of the fact that there were no mares actually treated in this year, so the only ones manifesting the effects (more switches) were those whose antibody titers were still high enough to be physiologically effective.

If contraception treatment is in fact increasing harem switching, whether in the short- or long-term, such a disturbance to natural behavior could have significant impacts on the mares' health. Although we were unable to find a correlation between the number of harem switches and body condition or parasite load, that is not to say that switching does not create physiological stress that will result in poorer health in the future. Harem switches decrease harem stability, which disturbs mares in the harem, promotes aggression and stallion harassment, and prohibits the formation of dominance hierarchies or group cohesion (Nuñez et al., 2009). Our findings supported this positive correlation between harem switches and harassment. It was recently found that the mares on Shackleford in the middle of changing groups had higher fecal cortisol levels, a measure of physiological stress (Nuñez et al., 2014). Harem stability has also been correlated with yearly reproductive success (Rubenstein, 1986).

Increased harem switching and its resulting physiological stress caused by recent treatment thus could be one negative impact of the PZP contraception program. Further study during years in which mares are immunized could determine if contraception does increase the number of harem switches above and beyond the lack of a foal. This would lead to better understanding of this detrimental effect of PZP treatment.

5.4.4 Sterility: Causes

Negative effects of PZP treatment on ovarian function have been suggested in the past. Mares on Assateague Island had depressed estrogen secretion when treated for

three consecutive years (Kirkpatrick et al., 1992), and Shackleford mares that had ever been treated were found to have an extended reproductive period and to foal over a greater range of months, suggesting altered cycling (Nuñez et al., 2010). But despite these potential reproductive effects, sterility was not induced in the Assateague population; all mares returned to fertility after as much five consecutive doses of PZP (Kirkpatrick et al., 2002; Powell, 1999), and ovarian failures were not linked to contraception treatment (Powell & Monfort, 2001).

However, in this study of the Shackleford Banks mares, we did find evidence that sterility was likely being induced by the contraception treatment. If all mares were still fertile, mares not foaled since their last dose should have had that last dose more recently than mares that have foaled, since they would not have yet returned to fertility merely because of lack of time to recover; this trend was not found. Additionally, there was a positive correlation between the years since treatment and the year since a foal, which should have been an inverse relationship if all mares were fertile. These statistical indications can be corroborated by a visual assessment of the foaling and contraception history. Fourteen different mares whose last dose of PZP was in 2006 or earlier have not since returned to fertility. It is highly likely that these mares have been rendered infertile by the contraception treatment, because they have surpassed the expected time frame in which mares return to fertility after PZP immunization.

Two factors were found to be potential causes of this sterility. The first of those was the timing of the initial dose of PZP. Mares that were immunized for the first time before they reached puberty were statistically less likely to have foaled since the inception of treatment than mares that were able to reach puberty and foal before initial treatment. This is likely because they were not able to fully develop sexually before having their reproductive cycling altered by the immunocontraception, and this made them unable to reproduce in the future.

Increased intensity of contraception (more consecutive years of treatment) also appeared to decrease a mare's probability of foaling after PZP treatment, suggesting induced sterility. This was a statistically significant result. Of the five mares that had been given only one or two consecutive doses, with the last dose in 2006 or earlier (outside of the range of expected return to fertility), four had returned to fertility by the time of study. The chances of returning to fertility after three consecutive years of

treatment were decreased, with only five out of eight mares foaling again afterwards. A significant difference was seen after four years of consecutive immunization: of the 11 mares who had received four or more consecutive years of PZP ending in 2006 or before, only two had returned to fertility since the last dose. The other nine mares, having not foaled in six or more years, were assumed to be sterile because they were outside of the expected time frame of fertility returning. There were mares that may still return to fertility in the years after this study, those whose last dose was in 2007 or later. Examining these mares in the next few years may provide further insight and statistical evidence that an increased number of consecutive years of treatment increases the chances of inducing sterility.

While both consecutive years of treatment and early initial administration may independently increase the chance of resulting sterility, when combined they may be exceptionally hazardous to fertility. Of the 14 mares that had never foaled in their lifespan, 12 of them were both treated before puberty and given 3-4 years of consecutive treatment; the other two had only been given two doses, ending in 2009, and were still expected to foal at the time of this analysis. Although the effects of these factors were not able to be statistically separated because of low sample size, it remains a notable trend that the majority of mares that have never foaled were exposed to this combination of conditions, a likely cause of their sterility.

5.4.5 Sterility: Effects

Rendering a mare sterile through PZP immunocontraception treatment will subsequently prevent her from foaling. Since the detrimental effect of foaling on body condition is "all or none," as described above, the mare will have a higher body condition if she is sterilized before ever foaling. If the mare had foaled before treatment began and was subsequently rendered infertile by the PZP, she would not be expected to have a higher body condition. We did find that mares that had not foaled after treatment were in higher body condition, but this was most likely because many of them had never foaled at all; these two effects could not be statistically separated due to loss of degrees of freedom in modeling.

It is possible that the previously discussed negative correlation between harem switches and time since PZP treatment was also the result of induced sterility. The

mares that were last treated more recently were likely still fertile, but had not foaled yet because they were still under the contraceptive effects of the PZP. These mares would have increased reproductive cycling without successful conception; they may therefore switch groups more often in an attempt to conceive or to escape intense sexual interest and harassment by the stallions (Madosky et al., 2010). On the other hand, mares that had that last dose longer ago (without foaling since) were likely sterile and unable to foal at all, otherwise they would have foaled in the high number of years since treatment. If the intensity of contraception had effectively destroyed their ability to cycle normally (and therefore become pregnant) by depressing estrogen secretion, they would not solicit the same reproductive interest from the stallions or undergo normal estrus cycling, which could explain why they did not switch harems as often. Whether by male or female choice, the effect would be the same: effective contraception increases cycling and therefore switches, whereas sterility destroys cycling and motivation for switches.

This hypothesis and the previous proposal (Section 5.4.3, that contraception is increasing the number of harem switches in a way that can be overcome in time) are not necessarily mutually exclusive. The contraception could increase the number of switches, an effect that is maintained as long as the mares are not sterile. Sterility then could reduce the number of harems switches for the reasons explained above. Both would result in the observed trend of a longer time since PZP immunization predicting fewer harem switches. This differentiation cannot be confidently made without studies that include true control mares that were not administered PZP but also did not foal.

5.5 Population-Level Implications

We concluded that certain aspects of PZP contraception (specifically, a high number of consecutive years of treatment and administration of the first dose before sexual maturity) are likely causes of sterility in several of the Shackleford mares. Making a mare sterile appears to have positive impacts on her health. By preventing her from foaling, she will have a higher body condition on average, and will spend less of her time grazing because she does not require as much energy without the high cost of lactation. A sterile mare may also switch harems less, resulting in less physiological stress and less harassment.

However, this increase in average body condition and overall health may have unintended impacts on the dynamics of the population. Mares in better health will live longer on average, so PZP contraception may be artificially extending their lifespan. This was found in the Assateague Island herd, where mares treated for three or more years had the highest longevity, followed by mares treated for less than three years, and untreated mares had the lowest longevity (Kirkpatrick & Turner, 2007). In the population as a whole, even though the mares were not made sterile, mortality decreased, overall body condition increased, and a new higher age class emerged after inception of the PZP contraception program (Kirkpatrick and Turner, 2002).

We did not have historical information on the Shackleford mares to be able to make age class and longevity comparisons, but it is suspected that the PZP may be having the same effect on this herd. The contraception treatment and its probable induced sterility release mares from the energetic costs of lactation, resulting in better physical health that will cause them to live longer, resulting in a higher age class in the population. By reducing mortality, fewer mares will die each year. In order to maintain the goal population size of 100-110 individuals, more mares will have to be administered contraception each year to prevent too many foals from being born. In the year of this study, this did not appear to be a problem; only eight foals were born despite no PZP administration in the previous year, probably because many of the non-foaling mares were in fact sterile because of their contraception history. This may become an important consideration in the future. As new mares come to reproductive age, they may have to be immunized with PZP more frequently so that the number of foals born does not exceed the number of deaths in that year, and the population can remain at the intended size. This will raise the dilemma of how to increase their immunization frequency without inducing sterility.

Sterility induced by the immunocontraception program also has impacts on the genetic makeup of the population. Mares that are prevented from reproducing are not able to pass along their genes to future generations, thus reducing the different combinations of genes that are possible for the offspring of any given generation. This could result in an overall loss of genetic diversity in future generations as a few genetic lines are perpetuated while others are lost due to the sterile mares' inability to pass along their genes. Genetic diversity is what allows a population to adapt to changing

environments and reduces the chances of detrimental effects caused by inbreeding. By artificially limiting which mares are able to reproduce throughout their lifespan, it is possible that the PZP contraception program could be negatively impacting the health and long-term prospects of the population.

Representation of the mares' genetic lines within the population is currently factored into decisions about which mares on Shackleford Banks receive PZP in a given year: if a mare's genetic line is under-represented, she is less likely to be given contraception, so that the line can be perpetuated (S. Stuska, personal communication). However, if some mares are rendered sterile through intense PZP contraception, this eliminates the possibility of them ever foaling in the future. If their genetic lines do become under-represented, i.e. by death of many of their close relatives, there is no longer the choice to allow those mares to foal and contribute to the perpetuation of the lineage.

Our analysis has demonstrated the importance of considering not only a mare's foaling history and genetic line representation when making contraception decisions, but also her own contraception history and how to best prevent her from becoming sterile. Through examining current patterns of fertility on Shackleford Banks, we concluded that a mare is more likely to maintain her fertility if she is allowed to foal before her first dose of PZP and if she is only ever given three or fewer consecutive doses, with a break to foal in between. Each mare will vary in her physiological response to the PZP – she may become sterile after only one dose or have other health problems making her infertile – but these guidelines may help reduce the incidence of sterility in the future. If fewer mares are made sterile from PZP contraception, this will ensure more flexibility in which mares can be permitted to foal in a given year, leaving more mares able to contribute to the genetic diversity of the population.

5.6 Study Conclusions

Ideally, a feral horse population would not require any human intervention to endure. However, the rapid expansion of the herd on Shackleford Banks prompted the National Park Service to institute a program of porcine zona pellucida immunocontraception of the mares in 2000. By preventing pregnancy, the contraception is working to reduce the population so that horses will not need to be physically removed from the island, but it is important to consider the effects that PZP may have on the mares' health and behavior.

In this study, although we were unable to directly determine the effects of the contraception because it was not administered to any mares during the year of study, we were able to indirectly look at its effects through the histories of contraception treatment and foaling for each mare. Lactation was the most significant predictor of health (lower body condition) and behavior (more time grazing, fewer harem switches). By releasing mares from lactation, PZP contraception results in better physical condition, but also more harem switching, a physiological stressor. Independent of lactation, two main effects of the contraception treatment on the health and behavior of the mares were found. It appeared that the PZP treatment was lowering body condition and increasing the number of harem switches, both effects that diminished as time since the last dose passed. Increased group switching could subject mares to higher rates of harassment and resulting physiological stress that could later manifest in further poor body condition. Future studies that either directly compare treated and non-treated mares or more closely track changes in mare body condition and behavior over time could enhance understanding of these detrimental effects of the PZP immunization.

Administration of PZP before puberty and high intensity of treatment were found to be likely causes of sterility in many of the mares on Shackleford Banks. Though this may have the initial positive effect of freeing them from lactation and therefore increasing their physical health, this benefit should be weighed against the impacts on population dynamics when making decisions about the contraception regimen. Through careful execution of the PZP contraception program, the impacts of the human intervention on the natural behavior of the mares of Shackleford Banks can be minimized, and the population will continue to thrive.

Appendix I: Contraception and Foaling Histories

PZP = treated with PZP contraception, F = foaled in that year (+ = yes; - = no).
"n/a" indicates the mare was not yet born.
