HORMONES AND BEHAVIOR 14, 46–54 (1980)

Sexual Behavior in Ovariectomized and Seasonally Anovulatory Pony Mares (*Equus caballus*)

CHERYL S. ASA, DAVID A. GOLDFOOT,* M. C. GARCIA, AND O. J. GINTHER

*Department of Veterinary Science, University of Wisconsin, Madison, and *Wisconsin Regional Primate Research Center, Madison, Wisconsin 53706*

Ten ovariectomized (OVEX) and ten intact, but seasonally anovulatory (ANOV), pony mares were observed for sexual activity with five stallions, using a "harem group" social testing paradigm (two OVEX and two ANOV mares plus one stallion per group) for 15 consecutive daily tests lasting 20 min each. All mares in both conditions showed proceptive behavior in at least one test, all mares but one were mounted, and 14 of 20 mares received ejaculations. No statistical differences were found between the two conditions for any measure of proceptivity, copulatory activity, or days in estrus. The quality of estrus was judged to be equivalent to that displayed by periovulatory mares during their initial and terminal days of estrus, but less intense than that seen near ovulation. Mares in both groups were in estrus during approximately 60–70% of the tests and only 3 of the 20 mares were sexually refractory for more than five consecutive tests. Thus, the typical 2-week phase of sexual refractoriness seen in intact diestrous mares was absent in OVEX and ANOV mares, suggesting that the ovary plays a major role in actively suppressing estrous responses during the luteal phase of the cycle.

Steroids of gonadal origin have long been assumed necessary for the induction of estrous behavior in female mammals. Although Old World primates, such as the majority of rhesus and stumptail macaques, continue to show some copulatory behavior following ovariectomy (Goldfoot, Wiegand, and Scheffler, 1978; Baum, Everitt, Herbert, and Keverne, 1977), as is apparently also the case with a small percentage of rabbits (Yaschine, Mena, and Beyer, 1967), gonadectomized females of most mammalian species do not solicit coitus nor tolerate mount attempts unless administered exogenous steroids (Young, 1961; Goy and Goldfoot, 1975).

In this laboratory, estrous behavior has been noted in long-term ovariectomized mares (Garcia, published in Ginther, 1979). Estrous response has also been reported in mares whose ovaries were involuted during the nonbreeding season (Van Niekerk, 1967; Ginther, 1974; Webel, Franklin, Harland, and Dzuik, 1977). The present study was undertaken

to investigate in more detail the sexual response of mares in which ovarian hormones are absent (ovariectomized mares) or minimal (seasonally anovulatory mares).

METHODS

Subjects

Five stallions, 10 ovariectomized (OVEX) mares, and 10 seasonally anovulatory (ANOV) mares were used. The ponies were of apparent mixed breeding and weighed between 160 and 250 kg. The stallions ranged in age from approximately 3 to 20 years and the mares from 5 to 15 years. Four of the stallions were intact and one was vasectomized. The sexual experience of the mares before ovariectomy was not known. Gonadectomy was performed 6 months to 2 years before the present project. Rectal palpation revealed no evidence of ovarian fragments in any of the OVEX mares. After the completion of behavioral testing, an OVEX mare which had shown consistently high levels of estrous behavior was sacrificed and the entire reproductive tract removed after gross inspection of the body cavity. The tract was examined and the ovarian pedicles excised for histology.

In a previous study of intact, ovulating mares (Asa, Goldfoot, and Ginther, 1979), estrous behavior was never observed in mares with follicles of less than 15 mm diameter. Day (1940) reported that diestrus was accompanied by 10- to 15-mm follicles in pony mares. Therefore, the 10 ANOV mares were assigned to the project only after rectal palpation revealed small ovaries with follicles of no more than 10 mm diameter.

Mares were pastured together outdoors and provisioned with hay. Stallions were stabled separately and fed hay and grain.

Behavioral Testing

The study was conducted for 15 consecutive days from January 9 to 23, 1978. Behavior tests were given for 2 days before the study began to familiarize the animals with the testing situation. Five harem groups, each consisting of two OVEX mares, two ANOV mares, and one stallion, were assembled daily. Assignment of animals to harems was random each day with the exception that stallions were sometimes chosen to insure that each mare was tested with each stallion at least one time. Each harem group was observed daily for 20-min periods in the early afternoon. The outdoor paddock used for testing was approximately 6 by 9.6 m, with a straw-covered concrete base.

Behavioral data were taken on an SSR event-recording keyboard (Stephenson and Roberts, 1977) which allowed rapid notation of the incidence, latency, duration, and sequence of behaviors onto magnetic tape for subsequent computer analysis. Behaviors reported included approach, follow, urination, tail raise near stallion (TRNS), walk away,

mount, intromission, and ejaculation, which are defined elsewhere (Asa, Goldfoot, and Ginther, 1979). Kick, which was not defined previously, was scored only when both hind feet were used to strike out forcefully.

A behavioral index of estrus was developed in an earlier study in which all observations were made for 1-hr periods (Asa *et al.*, 1979). That index has been modified here for 20-min tests and expanded to allow quantitative analysis of the behavior of mares in conditions less vigorous than full estrus. For this study mares were considered in full estrus when they had more than two occurrences of urination and ≥20 sec of tail raise near the stallion (TRNS) during the 20-min test. The category of weak estrus included mares with one of the following: one occurrence of urination plus ≥20 sec TRNS, two or more urinations but no TRNS, or no urination but ≥60 sec TRNS per 20-min test.

Statistical Analysis

Comparison of the OVEX and ANOV groups for the display of various proceptive and receptive measures of the mares as well as for copulatory activity of the stallions was made by *t* tests for independent samples. A paired *t* test was used to evaluate the effect of weak or full estrous conditions on the frequency of kicks or walk-aways per mount.

To investigate the possibility of changes in the expression of estrus as the study progressed, the 15 days were divided into three 5-day segments. Analysis of variance for repeated measures (Winer, 1962) was used, with means for each mare for each 5-day period used as the three repetitions. The relationship between frequencies of urination (an indicator of proceptivity) and kicks and walk-aways per mount (indicators of nonreceptivity) was calculated using the Pearson product-moment correlation and the *t* test for significance of a correlation.

RESULTS

All mares in both groups showed proceptive estrous signs on at least one of the test days, although the intensity of estrus was sometimes low. Estrus determinations for the OVEX group ranged from one mare that was only in weak estrus in one test to another that was in full estrus for all 15 tests. The OVEX group means, as shown in Table 1, were 7.7 (± 1.75 SEM) tests with full estrus and 2.9 (± 0.74 SEM) tests with weak estrus for the 15 tests. The ANOV group means were 4.8 (± 1.45 SEM) tests with full estrus and 3.9 (± 0.98 SEM) tests with weak estrus. The ANOV group had one mare that was only in weak estrus for one test, but another that was in full estrus for 14 tests.

That mares in both groups were attractive and receptive to the stallions was demonstrated by male approaches and by precopulatory investigation and stimulation similar to that displayed to periovulatory estrous mares (Asa *et al.*, 1979), as well as by the complete male ejaculatory pattern. All

TABLE 1
Comparison of Ovariectomized and Seasonally Anovulatory Mares for Mean Number of Tests with Estrus and Copulatory Activity

	Meal number of tests[a] per mare with					
	Weak estrus	Full estrus	Total	Mounts received	Intromissions received	Ejaculations received
Ovariectomized mares (n = 10)	2.9 ±0.74[b]	7.7 ±1.7	10.6 ±1.5	7.2 ±1.1	2.3 ± 0.52	1.8 ±0.47
Seasonally anovulatory mares (n = 10)	3.9 ±0.98	4.8 ±1.4	8.7 ±1.3	5.8 ±1.1	2.7 ±1.0	2.0 ±0.84

mares, except one in the ANOV group, were mounted at least once and all but four ANOV and two OVEX mares received ejaculations. Most of the ejaculations (94.8%) occurred with full estrous mares, 5.1% with mares in weak estrus, and none with mares judged not to be in estrus.

No differences were found between the two groups of mares on any of the 15 behavioral endpoints (Tables 1, 2). The means for the two groups for incidence of estrus and selected measures of proceptivity, attractiveness, and copulatory activity are shown in Tables 1 and 2. The mean frequencies for two forms of negative behavior, walking away during a mount (OVEX 1.2 ± 0.1, ANOV 1.2 ± 0.2) or kicking at any time during a test in which a mount occurred (OVEX 3.6 ± 1.8, ANOV 3.1 ± 0.5) were not different for the two groups of mares. The proportion of kicks and

TABLE 2
Comparison of Ovariectomized and Seasonally Anovulatory Mares for Mean Frequency or Duration of Selected Measures of Proceptivity and Copulation

	Mean frequency or duration per mare per test						
	Tail raise near stallion (sec)	Female urination	Female approach plus follow	Male approach	Mount	Intromission	Ejaculation
Ovariectomized mares (n = 10)	278 ±51[a]	2.3 ±0.49	5.5 ±0.24	2.5 ±0.22	1.2 ±0.28	.26 ±0.07	.11 ±0.03
Seasonally anovulatory mares (n = 10)	209 ±57	1.7 ±0.62	3.7 ±0.52	2.4 ±0.21	1.3 ±0.34	.21 ±0.08	.13 ±0.13

[a] $\bar{x}$ ± SEM.

walk-aways was no higher for weak estrus than for full estrus in either group. The mean number of kicks, but not walk-aways, per mount was negatively correlated with the mean frequency of urination, a measure of estrous intensity, for both groups (OVEX: $r = -0.359$, $P < 0.005$; ANOV: $r = -0.423$, $P < 0.005$).

Only one mare was consistently in estrus throughout the 15 days of the study. The others displayed an irregular pattern of full, weak, or no estrus from day to day (Fig. 1). Comparison of means for estrus and copulatory activity among the first, second, and third 5-day segments of the study yielded no differences. There was a mean of 1.58 (± 0.07) mares in full estrus and 1.18 (± 0.03) in weak estrus per harem group per test (out of four mares/harem group), with medians of two in full and one in weak estrus per test. The identity of those females in estrus in each test varied from day to day.

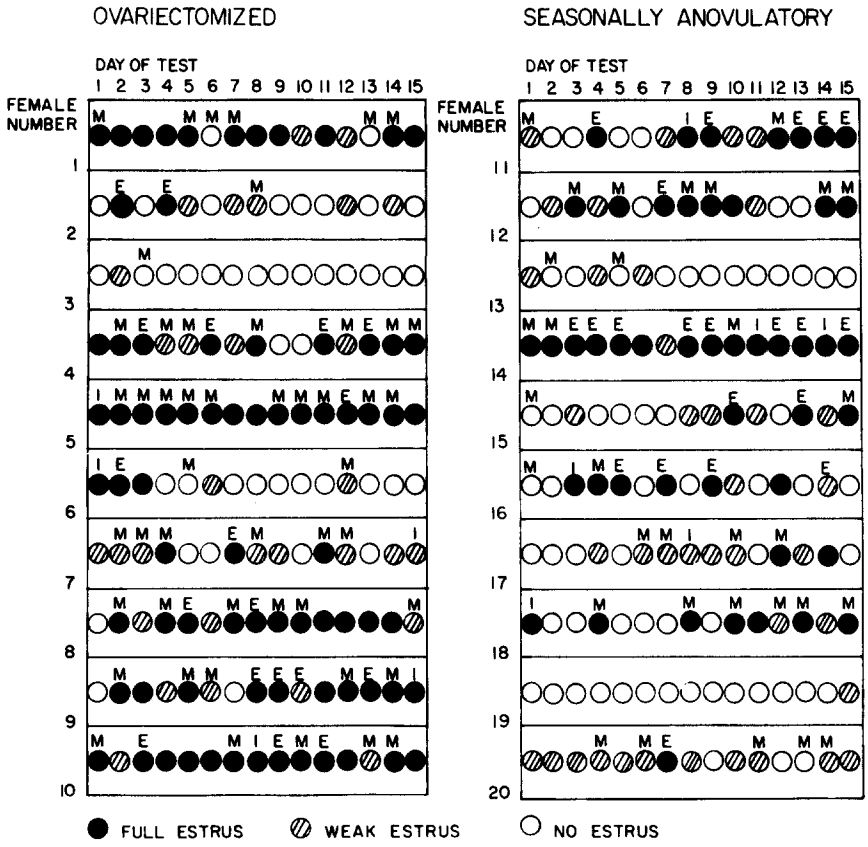

FIG. 1. Pattern of incidence of full, weak, or no estrus for 10 OVEX and 10 ANOV mares during 15 consecutive days of testing in harem groups. E, ejaculation; I, intromission; M, mount.

The five stallions displayed wide variability in copulatory performance, although mean number of mares in estrus per test was not different among stallions. In 15 days of testing, stallion 400 achieved only four ejaculations while stallion 100 had 12. The ratio of mounts per ejaculation was 3.25 for stallion 100, but 31.5 for the younger, less experienced stallion 200. The amount of time spent in precopulatory activity was reflected by latencies to first mount. These times ranged from a mean of 0.3 min for stallion 200 to 9.7 min for stallion 400. Stallion 100, the oldest, had the highest total number of ejaculations and the shortest latency to ejaculation while stallion 200, the youngest, had the most mounts and the longest ejaculation latency. For ejaculatory mounts, however, the mean interval from mount to ejaculation was not different among stallions.

Gross inspection of the body cavity and the reproductive tract of the sacrificed OVEX mare revealed no signs of ovarian-like tissue. Likewise, microscopic examination of the sectioned and stained ovarian pedicles disclosed no ovarian remnants or regrowth.

DISCUSSION

In this study both seasonally anovulatory mares and ovariectomized mares solicited copulation from stallions, were sexually attractive to them, and tolerated mounts, intromissions, and ejaculations. Such behavior in the pony under reduced hormone conditions is striking in light of the widely held belief that hormones of ovarian origin are exclusively responsible for displays of estrus in infraprimate mammals (Goy and Goldfoot, 1975; Leshner, 1978; Young, 1961). Nonetheless, it would be misleading to conclude that the pony is "gonadally emancipated," since the ovary is clearly involved in the regulation of estrous behavior during normal ovulatory cycles. Intact mares display very clear patterns of estrus for approximately 1 week out of every 3 throughout the spring and summer (Ginther, 1979). The week of behavioral estrus, with ovulation on about the fifth day, is followed by a period of marked sexual refractoriness during the 2-week diestrous phase, when mares respond to a stallion's approach and investigations with avoidance or threats (Asa *et al.*, 1979).

Comparisons of mares from this study to intact estrous and diestrous mares of a previous study suggest that the removal of the ovaries or the natural suppression of ovarian function during the winter months results in a chronic condition of moderate behavioral estrus, in which behavioral measures of attractivity, proceptivity, and receptivity are found with probabilities of at least 50% on any given test day. In contrast, estrus is seen on only about 33% of the days for intact mares during the ovulatory season (Asa *et al.*, 1979).

Proceptive components of estrus, such as the frequency of urinations, of following, or of standing near the stallion with the tail elevated were displayed with rates similar to those of intact mares during the initial and

terminal days of ovulatory estrus. Receptive elements of the response pattern were slightly reduced, however, in that proceptive OVEX and ANOV mares seemed to show more hard kicking and avoidance responses than intact estrous mares.

The intensity of estrus in ANOV and OVEX mares fluctuated in irregular patterns throughout the course of this study, perhaps due to the specific social composition of the groups formed on a given day, including individual preferences by mares for certain stallions, and dominance/subordination relationships among mares. Alternatively, these daily changes might have been related to changes of nonovarian-source steroids which could have been contributing to the phenomenon.

Only 3 of the 20 mares in this study displayed periods of sexual refractoriness for longer than 5 consecutive days, whereas half of the ponies never had more than a 2-day period in which estrous responses were not displayed. Thus, the absence of *cyclic* periods of nonreceptivity and nonproceptivity most accurately characterizes the behavioral changes following ovariectomy or seasonal ovarian quiescence in the mare. In contrast, a continual absence of estrous responses is typical of other ovariectomized or anovulatory infraprimate species.

These several observations and comparisons suggest the following three hypotheses. First, the luteal ovary appears to play a controlling role in the inhibition of estrous behavior, raising the possibility that progestational secretions of the corpus luteum provide the mechanism for periodic sexual inhibition during diestrus.

Second, although a nonhormonal mechanism might be responsible for estrous activity after ovariectomy, we hypothesize that the estrous behavior seen in this study was most likely supported by sex steroids, probably from the adrenals. Adrenal cortical mediation of sexual activity has been extensively considered in primate species (Everitt and Herbert, 1971; Everitt, Herbert, and Hamer, 1972; Goldfoot *et al.*, 1978; Baum, Slob, de Jong, and Westbroek, 1978). Hay and forage, which may contain phytoestrogens, present another potential source of steroids.

Third, since periovulatory estrus is more vigorous than that observed in OVEX and ANOV females, it is hypothesized that additional steroidal stimulation for these behavioral tendencies is supplied by the ovarian follicles in the days just prior to ovulation. Thus, it is likely that the follicular ovary of the mare, as in other species, increases the probability that copulation will occur during fertile phases of the cycle. However, the luteal ovary of the mare appears necessary to suppress estrus during the infertile phase of the cycle and therefore might be exhibiting a more potent inhibition of estrus than that thought to exist in most other infraprimate species (Feder, 1977).

The steroid condition resulting from ovariectomy represents an experimental manipulation which mares would normally never experience.

However, winter anestrus does occur naturally (Ginther, 1979), and 40–50% of mares in a typical free-ranging herd fail to deliver live young in a given season (Nelson, in press; Feist & McCullough, 1975). Thus, estrus might be displayed by some percentage of the nonpregnant, free-ranging mares during winter months.

The display of estrous behavior by mares at times during which conception is impossible might have functional significance to this species. The most commonly reported social unit of ponies and horses is of the harem type, with a stallion, several mares and their offspring (Feist and McCullough, 1976). Sexual activity outside of the breeding season, made possible by the absence of complete control of steroids from the ovaries over estrous behavior, could contribute to the maintenance of social bonds between the harem stallion and his mares. Further work directed to this possibility as well as toward the question of whether sex steroids from adrenal sources mediate these events is currently being investigated.

Effect of stress induced by gathers and removals on reproductive success of feral horses

Michael C. Ashley and Dale W. Holcombe

Abstract Successful management of many species often relies on actions that involve intensive handling of individuals. Knowledge of how such handling may affect reproduction of a particular species is important and may be applicable to managing other species. We used pregnancy testing, field observation, Bureau of Land Management (BLM) records, and adopter surveys to determine effects of stress induced by gather and removal management practices on the reproductive success of feral horses in the Garfield Flat (GF) Herd Management Area (HMA) in Nevada. We analyzed pre-release confinement effect data from gathers conducted in August 1993 and January 1997 and data on the additional effect of removal in 1997. We used data for an ungathered population in the Granite Range HMA (GR) in Nevada as controls both years. Data from ungathered GR horses also were used as controls for habitat effects on reproduction. Granite Range and ungathered GF mares in 1997 had similar reproductive success rates (P=0.42). Pregnant removed mares in 1997 had less reproductive success than ungathered mares at GR (P=0.003) and GF (P=0.005). Gathered and released GF mares had less reproductive success than ungathered GF mares (P=0.05). The results suggest that minimizing time that mares are held prior to release will reduce fetal loss.

Key words abortion, horses, management, reproductive success, stress

In several studies, fetal loss in feral and domestic horses has been attributed to stress, often associated with frequent and extensive handling of pregnant mares (Mitchell 1971, Osborne 1975, Roberts 1986). Berger's (1983) study of feral horses in the wild found that forced copulation and social environment change after band takeovers in the Granite Range of Nevada caused abortions.

Most feral horse herds in the United States are managed intensively by the Bureau of Land Management (BLM, Boyles 1986). The Public Rangelands Improvement Act of 1978 authorized excess feral horse removal to preserve the quality of range habitat. Gathers and removals are the principal means to reduce populations to acceptable management levels (AML) for individual herd management areas (HMA; Boyles 1986). Each HMA is assessed by BLM range-condition specialists to determine stocking levels for livestock, feral horses, and game species. A 3- to 5-year interval between gathers and removals is necessary as many horse herds increase ≥20%/year (Wolfe 1980, Eberhardt et al. 1982, Berger 1986, Garrott and Taylor 1990). The removal magnitude depends on number of excess horses and the desired ending population size relative to the AML.

Gathers and removals may induce stress in several ways and for varying periods of time. Large-scale BLM gathers involve helicopter use to chase horses into a funnel trap leading to a corral. Trapped horses are individually restrained, aged, examined for physical

Address for Michael C. Ashley: Ecology, Evolution, and Conservation Biology Program, Biology Department/314, University of Nevada-Reno, Reno, NV 89557, USA; e-mail: ashley@scsr.nevada.edu. Address for Dale W. Holcombe: School of Veterinary Medicine, University of Nevada-Reno, Reno, NV, 89557, USA.

condition, and segregated for removal or release as adult and juvenile males, lactating mares and foals, and nonlactating mares. *Ad libitum* food and water is provided in corrals to minimize nutritional stress.

Horses released after a gather typically have been held for 2 to 4 days at the capture site. Horses removed for adoption face longer periods of stress. From the capture site horses are trucked to a processing facility, often hundreds of km away. Here they are again individually restrained for blood sampling, aging, and freeze-branding. Some adoption occurs locally; however, many more horses are transported to satellite adoption centers across the country. Horses can spend months in confinement before adoption. We investigated the role that stress plays in reproductive failure following gathers and removals. We feel that the results of this study are valuable to BLM management and are applicable to managing large-bodied ungulates in general, when translocations involve extensive handling or long periods of confinement.

Study sites

For >20 years, BLM has actively managed feral horses at the Garfield Flat (GF) and Granite Range (GR) HMAs in the Great Basin by conducting periodic gathers and removals to control population size. Both areas are subject to cattle grazing. The vegetation at both study areas is predominantly mixed grass and shrubs at lower elevations. At higher elevations, pinyon pine (*Pinus monophylla*) and western juniper (*Juniperus occidentalis*) predominate at GF. Western juniper also occurs at higher elevations at GR with stands of quaking aspen (*Populus tremuloides*) at some springs. The 607-km^2 GF HMA, located in Mineral County in west-central Nevada, is bordered on the east, north, and west by the Garfield Hills and on the south by the Excelsior Mountains. The playa at GF is 1,700 m above sea level (asl), with the Garfield Hills and Excelsior Mountains each rising above 2,400 m asl (United States Department of Interior 1985). Water is available year-round from 4 springs and ephemerally from 4 small catchments, ≤100 m^2 each (Figure 1). The 411-km^2 GR HMA is located in Washoe and Lander counties in northwest Nevada in the Granite

A mare being herded toward a squeeze chute for tissue collection and freeze-branding at the 1993 gather.

Range Mountains. Elevations range from 1,200 m asl in the surrounding lowlands to 2,735 m asl at Granite Peak (United States Department of Interior 1981). At this site, water is available year-round from numerous permanent springs and ephemeral ponds ranging from 50 to >400 m^2 in size.

Materials and methods

Gathers and removals

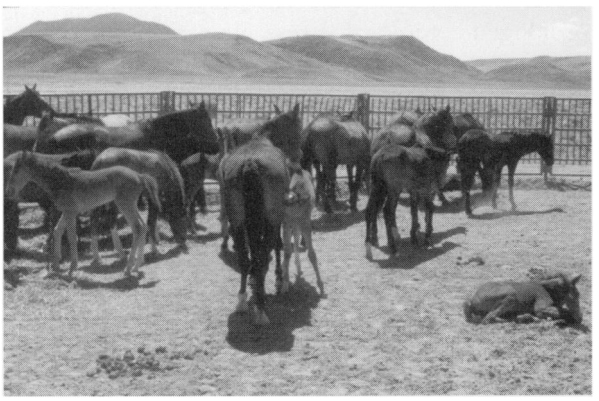
The first gather at GF was conducted in August 1993. The second occurred in January 1997. For both, a helicopter, drift fence, and funnel trap were used to capture horses. In the 1993 gather, resident horses in the eastern portion of the HMA were captured the first day and processed and released the second day. This procedure was repeated for horses in the western portion of the HMA on the following 2 days (Figure 1). Eighty-eight horses from the eastern area and 81 horses from the western area were captured, accounting for about 95% of the total HMA population. All horses gathered in 1993 were released except for 4 foals that were removed and one foal that was destroyed because of injuries. In 1997, horses were captured from the entire HMA over a 2-day period. Processing started immediately and continued for 2 days post-capture, culminating with the release of horses not shipped for adoption. The released horses were held 3 or 4 days, depending on capture order. Horses removed for adoption were trucked on days 3 and 4 to the Palomino Valley Center (PVC), a BLM adoption and processing center 246 km from the study site. Horses from the 1997 gather were examined and freeze-branded at PVC 2 weeks after the conclusion of the gather.

Horses appeared to be stressed at gathers, exhibiting agitated behavior. Confinement kept horses from different bands, groups of ≥1 adult female and any offspring attended by ≥1 adult male, at much closer quarters than we observed on the range. Mares too close to an unrelated foal were often threatened or kicked by the foal's mother. In contrast, we found that intra-band female–female aggression in the field was infrequent and limited to mild threats. Band spacing in the field generally precludes aggressive behavior. Inter-band aggression was usually observed between band stallions that often traveled >100 m to interact. Some bands were permanently disrupted after the release.

Tissue collection

In January 1997, we collected jugular blood samples at the gather site and at PVC in evacuated tubes from horses that would be ≥2 years old the following spring. We separated the serum component on site with a portable centrifuge (5,000 × g for 5 minutes) and stored the samples on ice for transport. We found that centrifugation at greater gravity than applied by Wolfe et al. (1989) efficiently separated the serum in less time. At the lab, we pipetted ≥1 ml serum/sample into individually labeled 1.5-ml microcentrifuge tubes and stored them at −80°C until samples could be assayed. Serum progesterone was determined using a solid phase radioimmunoassay kit (Coat-a-Count, kit #TKP6, Diagnostic Products Corporation, Los Angeles, Calif.; Wolfe et al. 1989). The coefficients of variation for progesterone were 8.1% for intra-assay and 9.7% for inter-assay results. Because nonpregnant mares generally do not cycle during the winter, we classified mares that had titers of ≥2 ng/ml serum progesterone as pregnant (Plotka et al. 1988).

Field methods



All released horses from both gathers at Garfield Flat were photographed and left-hip freeze-branded with unique numbers. Age (American Association of Equine Practitioners 1981), sex, and distinguishing marks were noted to aid in field identification. In February 1993 and November 1995 the BLM conducted gathers and removals at the GR HMA, releasing 359 and 123 freeze-branded horses, respectively. Identifying marks also were recorded for many of these horses.

We conducted intensive ground surveys of the GF and GR horses from March through August of

1994 and 1997 to assess reproductive success. Using 80-mm, 20X60-power spotting scopes, we identified horses by number and, when necessary, unique markings. To have reasonable confidence of accurately assessing reproductive success or failure, we only used data on mares that were sighted prior to, during, and after the prime foaling season, April to July. These sightings allowed us to assess whether an animal was visibly pregnant and whether a viable foal was produced. Mares classified as pregnant that were not accompanied by a foal by the end of August were scored as reproductive failures. We verified the foaling success or failure of all GF mares released after the 1997 gather. All successful pregnancies at both study sites were detected pre-partum in that surveyed mares seen with foals had been classified correctly as pregnant prior to foaling. Some of these mares at both sites were classified pregnant but were unaccompanied by foals at the end of the season. These reproductive failures of visibly pregnant mares may have included losses to mountain lions (*Puma concolor*) or coyotes (*Canis latrans*), even though we found no direct evidence of predation.

We assessed reproductive success for GR horses in 1994 and 1997 to serve as unmanipulated controls for the GF horses. The GR horses were gathered February 1993 and November 1995, early enough that there should have been no negative impacts on foaling in 1994 and 1997.

We collected GF removed mare reproductive success data in 1997 from BLM adoption records, adopter questionnaire, and telephone interviews with adopters. Unable to separate early foal death from fetal abortion in the field population, we included one stillborn, one death during birth, and the death after 1 day of a premature foal as evidence of reproductive failure for removed horses. In this tally, we also included 3 cases of pregnant removed mares that died prior to adoption. The BLM determined that the cause of these deaths was "poor condition" that could have been influenced by prolonged stress.

Segregated bands of lactating mares and foals at the 1993 gather.

Data analysis

Foaling success is a dichotomous event suitable for 2-by-2 contingency table analysis for pairwise comparisons. We used the 1-tailed Conditional Binomial Exact Test (CBET, Rice 1988) for these analyses, expecting that increased periods of stress would result in lesser foaling rates. This test is robust with moderate to small sample sizes and occasional small cell values.

The tests of differences in 1997 foaling success between gathered Garfield Flat mares and ungathered GR and GF mares are not equal comparisons, as the last 2 classes of mares were not tested for pregnancy. It is unlikely that all of the ungathered GR and GF mares assessed for foaling success were pregnant. Accordingly, this makes the comparisons of foaling success conservative tests.

Results

At GF, 45 (67.2%) of 67 marked mares foaled in 1994. These data represented all but 2 of the mares released in 1993 that would be ≥2 years old the following year. At GR, 20 (71.4%) of the 28 marked mares we surveyed foaled during the 1994 field season. Gathered and released GF mares had a foaling rate little different from GR mares (CBET: $P=0.43$). The minimum age of marked GR mares in 1994 was 4. Garfield Flat mares ≥4 years old ($n=34$) foaled at a greater rate (77.4%) than GR but did not differ significantly (CBET: $P=0.30$).

At the 1997 gather, released horses were held somewhat longer than in 1993, 3 to 4 days depending upon capture order. Removed horses were held ≥21 days before adoption. During the 14-day period prior to blood sampling at PVC, there were 15 to 18 spontaneous miscarriages as evidenced by shed fetuses (Sharon Kipping, PVC Manager, personal communication). One mare died that had a well-developed fetus *in utero*. Two pregnant mares died at interim locations before being adopted.

We pregnancy-tested 21 mares that were released at GF in 1997 and found 18 (85.7%) pregnant. Ten of these mares (55.6%) foaled. Of the mares removed in 1997 (66 tested, 1 autopsied), 43 (64.2%)

were pregnant. We verified the reproduction of 37 pregnant mares with only 17 (45.9%) producing viable foals. We also collected resighting data to determine reproductive success of 17 ungathered mares at GF in 1997. Fourteen (82.4%) produced foals. That same season we identified 54 mares at GR and found that 40 (74.1%) produced foals.

Two bands in the field, summer 1996.

At GF in 1997, stress duration for the 3 classes of mares was 0 days for ungathered ($n = 17$), 3.5 days for gathered and released ($n = 18$), and 21 days for removed mares ($n = 37$). Pairwise comparisons of the 3 classes of mares showed that pregnant mares exposed to longer periods of stress had lesser reproductive success. The greatest difference in reproductive success was between ungathered and removed mares (CBET: $P = 0.005$). There also was a significant difference between ungathered and released mares (CBET: $P = 0.05$). There was, however, no significant difference between released and removed mares (CBET: $P = 0.26$).

The reproductive rates of GR and the ungathered GF horses did not differ (CBET: $P = 0.42$). Granite Range horses had a greater reproductive rate than the pregnant released mares at GF, but the difference was not significant (CBET: $P = 0.08$). As expected, GR horses had greater reproductive success than pregnant mares removed from GF (CBET: $P = 0.003$).

Discussion

The effect of gather-and-removal-induced stress on pregnant feral horses is reduction in foaling success, sensitive to the duration of the stressor. The GF horses that were removed for adoption were transported long distances and subjected to repeated handling. Long-distance transportation has been linked to abortions in 2-year-old domestic mares (Roberts 1986). Mitchell (1971) and Osborne (1975) associated abortions in yearling and 2-year-old domestic mares with extensive handling. Generally, high pregnancy rates for yearlings and 2-year-olds followed by fetal losses have been reported for domestic (Mitchell and Allen 1975) and feral horses (Lucas et al. 1991). The reproductive losses for GF mares, however, were spread across age classes.

Stress, whether acute or chronic, stimulates the release of cortisol and other adrenocorticoids in mammals (Yates and Urquhart 1962). For example, in studies of gray squirrels (*Sciurus carolinensis*, Guthrie et al. 1967) and snowshoe hares (*Lepus americanus*, Boonstra et al.1998), trapping stress elevated serum corticosteroids. Snowshoe hares produced smaller litters during the decline phase of their 10-year cycles because of chronic stress imposed by elevated predation (Boonstra et al. 1998). Decline in serum progesterone has been linked to acute stress (van Niekerk and Morgenthal 1982). Serum progesterone is critical to pregnancy maintenance (Ball 1993). It likely is that severe and chronic reduction of serum progesterone due to prolonged removal stress was responsible for spontaneous abortions at PVC and overall decrease in reproductive success. An examination of serum cortisol and progesterone levels in response to gathers and removals would provide a definitive causal relationship between stress and reduced reproductive success.

Band takeover is another possible source of stress for feral mares. Berger (1983) reported instances of harassment and forced copulation in the Granite Range by stallions that had taken over bands. The stress of forced copulation coupled with changes in social structure caused induced abortions in mares

less than 6 months pregnant (Berger 1983). During our 6 seasons of field work, we observed many cases of harassment but only one forced copulation. The sole forced copulation was performed by a resident band stallion upon an unreceptive yearling mare. Most harassment incidents, however, were performed by bachelor males directed at harem mares. We saw no cases of harassment or forced copulation by stallions that acquired new bands. Further study is necessary to better evaluate the potential effects of forced copulation, harassment, and change in social structure on reproduction.

Removals from managed herds reduce the number of young horses ≤ 5 years old. Interestingly, this has the effect of temporarily increasing the proportion of the more reproductively successful horses in the population (Garrott et al. 1991). Seemingly, this works at cross purposes to desired population sizes at or below AML. To counter this effect, horses of all ages or a greater proportion of prime-age horses should be removed. Additionally, timing of removals can be exploited to extend the period of reduced population size. Gathers conducted in September or October, after the foaling season (Garrott et al. 1991), would reduce the next year's reproduction by interrupting early-stage pregnancies at a time when successful re-impregnation is unlikely. Feral horses are protected federally, and the BLM is charged with maintaining the general health and well-being of those horses under its jurisdiction (Boyles 1986). Such pregnancy disruptions would achieve a temporary reduction in population growth without large impacts on mare condition due to the small resource investment in early-stage fetuses.

Induction and Immunohistology of Autoimmune Ovarian Disease in Cynomolgus Macaques (*Macaca fascicularis*)

Harini Bagavant,* Colin Sharp,* Barbara Kurth,† and Kenneth S. K. Tung*

From the Departments of Pathology and Cell Biology and Anatomy,† University of Virginia, Charlottesville, Virginia*

Autoimmune ovarian disease (AOD) is a probable cause of human premature ovarian failure, and a potential complication of contraceptive vaccines based on ovarian antigens. The diagnosis depends on detection of noninfectious ovarian inflammation (oophoritis) and serum antibody to ovarian and placental antigens. Mechanisms underlying AOD have been investigated in mice but not in primates. Herein, we report induction of AOD in primates, and compare the immunopathology between monkey and murine AOD. Four cynomolgus macaques immunized with monkey or human zona pellucida 3 peptide (pZP3) in adjuvant, developed T-cell responses to the immunizing peptide and produced antibody that bound to native zona pellucida *in vivo*. Immunostaining of ovaries from pZP3-immunized macaques showed numerous clusters of T cells co-localized with major histocompatibility complex II-positive macrophages in the ovarian interstitium. Such foci were not detected in untreated or adjuvant-treated control monkeys. This finding is comparable to murine pZP3-induced AOD. However, unlike murine AOD in which numerous granulomatous lesions are detected, severe granulomatous inflammation was detected in only one of three monkeys with abnormal immunohistology. Similar to mice with pZP3-induced AOD, the immunized monkeys retained normal ovarian function. The results are discussed in the context of complications of ZP-based human immunocontraceptive vaccines and case reports of human autoimmune oophoritis. *(Am J Pathol 2002, 160:141–149)*

Autoimmune ovarian disease (AOD) is considered to be a cause of human premature ovarian failure (POF).[1–3] However, the immunological basis of POF remains poorly understood. This is in part because early POF is clinically silent and advanced stages of the disease lack ovarian inflammation (oophoritis), a diagnostic feature of autoimmune etiology.[4] The strongest evidence for human AOD is the finding of oophoritis in a subset of patients with POF,[4,5] as well as the co-existence of ovarian inflammation with autoimmune adrenal disease or autoimmune polyglandular syndrome.[6] The diagnosis of immune POF is based on detection of circulating autoantibodies to ovarian or placental antigens. However, there is currently no consensus on the antigen specificity of these antibodies or the clinical assay system for their detection. Although serum autoantibodies to ovarian 17α-hydroxylase and side-chain cleavage enzyme of steroid-producing cells have been characterized, they are detected only in POF patients associated with autoimmune polyglandular syndrome type I or type II.[7,8]

Studies on rodent models of AOD have added some insights into the pathology and mechanisms of immune-mediated ovarian injury. Neonatal thymectomy in susceptible mouse strains causes ovarian inflammation and autoantibodies resulting in ovarian atrophy and ovarian dysfunction.[9] This model has been used to understand regulation of autoimmune disease in general and AOD in particular.[10,11] The second rodent model of AOD is elicited by immunization with a self-peptide of murine zona pellucida (ZP)3 (330 to 342).[12] Murine pZP3 immunization causes activation of autoreactive T cells and generation of anti-ZP autoantibody. The autoreactive T cells mediate autoimmune oophoritis characterized by focal or diffuse inflammation in the ovarian interstitium and organized monocytic granulomata. Although oophoritis alone does not affect ovarian function, a high level of ZP autoantibody reduces fertility in female mice.[13] On the other hand, combined ZP antibody and T-cell-mediated inflammation are required for the induction of ovarian atrophy and infertility.[14] Chimeric peptides that contain foreign T-cell epitope and native ZP3 B-cell epitope induce ZP antibody without inducing ovarian inflammation, and they are potential candidate antigens for contraceptive vaccine development.[15]

In primates, long-term immunization with zona pellucida proteins for >1 year resulted in antibodies to zona pellucida with contraceptive effect. However, the infertility was irreversible and the monkeys developed POF.[16,17]

The ovaries from immunized animals show few oocytes or developing follicles but increased numbers of aberrant granulosa cell nests. Ovarian inflammation was not reported in the atrophic ovaries of animals after long-term immunization. To investigate AOD as a basis for POF and a complication of ZP vaccination, we have developed a primate model of AOD. In this study, we demonstrate that cynomolgus macaques are indeed susceptible to AOD using human and macaque homologues of murine pZP3 (330 to 342). The resulting ovarian histopathology is compared to murine AOD, and with the reported findings in human AOD.

Materials and Methods

Peptides

The ZP3 peptides from different species used in this study are as follows: human 328 to 341 [GTPSHSRRQPH-VMS pZP3(hu)]; macaque 328 to 341 [GTPSHSRRQPH-VVS pZP3(mac)], and mouse 330 to 342 [NSSSSQFQIH-GPR pZP3 (mou)].[18] The peptides were synthesized in an automated peptide synthesizer (Beckman Instruments, Fullerton, CA) using F-moc chemistry. Deprotection was achieved by 20% piperidine in dimethyl formamide, and the peptides were chemically cleaved from the resin with 85% trifluoroacetic acid. The peptides were purified by HPLC eluting as a single peak on PRLP-S columns (Waters, Milford, MA) and were of >90% purity.

Monkeys: Immunization, Cyclicity, Surgery, Sacrifice

All animal housing and procedures were performed in accordance with the National Institutes of Health guidelines. Adult female cynomolgus macaques (*Macaca fascicularis*) were anesthetized with ketamine hydrochloride (10 to 20 mg/kg) for immunization and bleeding. Experimental groups included immunization with peptides [pZP3(mac) or pZP3(hu): two animals per group] or controls (untreated or adjuvant-treated: two animals per group). Immunizations were done on days 0, 14, and 28 intramuscularly with 50 nmol/L of peptide and 0.1 mg of nor-muramylated dipeptide (a gift from Dr. Vernon Stevens, Ohio State University, Columbus, OH) in phosphate-buffered saline (PBS) emulsified in equal volume of squalene:arlacel A (4:1, v:v; Sigma Chemical Co., St. Louis, MO). Animals were given booster immunizations at times indicated. Blood collected from the femoral vein was used for serum antibody analyses, T-cell responses, and circulating steroid levels. All of the animals were monitored daily for menstrual bleeding. Ovaries were surgically removed under general anesthesia through a midline abdominal incision. To study ovarian immunopathology at multiple time points, the first ovary was removed between 1.5 to 6 months and the second between 11 to 16.5 months. Each ovary was cut into 4 to 5 pieces collected in buffered formalin for histopathology. One piece was snap-frozen in liquid nitrogen for detection of ZP-bound IgG. The animals were euthanized at the end of the study and organs collected for histopathological analysis.

Mice: Immunization and Sacrifice

(C57BL/6 X A/J)F1 females were obtained from the National Cancer Institute, Bethesda, MD and housed as per National Institutes of Health guidelines. As previously described, for induction of AOD, mice were anesthetized by intraperitoneal injection of tribromoethanol (0.5 mg/mouse) and immunized subcutaneously with 50 nmol/L of pZP3(mou) emulsified in CFA (*Mycobacterium* tuberculosis H37RA strain, 0.16 mg/mouse) (Difco Laboratories, Detroit, MI) and sacrificed 14 days later.[12] Control mice were injected with CFA alone. One ovary was collected in Bouin's fixative for histopathological grading of AOD and the other ovary was collected in 4% paraformaldehyde in PBS (w/v), pH 7.4, for immunohistochemical staining.

Detection of Antibody to Peptides by Enzyme-Linked Immunosorbent Assay

Serum IgG to pZP3(hu) or pZP3(mac) were detected by enzyme-linked immunosorbent assay.[18] Ninety-six well plates (Corning Glass Works, Corning, NY) were coated overnight at 4°C with 25 nmol/L of peptide in 0.1 mol/L bicarbonate buffer, pH 9.0. All subsequent incubations were performed for 2 hours at room temperature. The plates were washed with 0.05% Tween 20 in PBS, pH 7.4, and blocked with 3% bovine serum albumin (BSA) in PBS. The plates were incubated with serial dilutions of monkey sera. The plates were then washed and incubated with horseradish peroxidase-labeled goat anti-monkey IgG (Nordic Immunological Laboratories, Capistrano Beach, CA) (1:3000 dilution). After washing, the reaction was developed by *o*-phenylene diamine (0.5 mg/ml; Sigma Chemical Co.) with freshly added 0.06% H_2O_2 in 0.1 mol/L citrate buffer, pH 5.0. The color intensity was read at 490 nmol/L by an enzyme-linked immunosorbent assay reader (Molecular Devices, Menlo Park, CA). The end-point titer was calculated as dilution of serum giving an absorbance of 2 SD above the background reading using preimmune monkey serum.

Detection of Anti-ZP Antibody by Direct and Indirect Immunofluorescence

In vivo binding of ZP antibody was detected by direct immunofluorescence. Frozen monkey ovary sections from peptide-immunized macaques or adjuvant-treated controls were fixed in 95% ethanol for 10 minutes and rinsed with PBS. The sections were then blocked with normal goat serum (1:10 v/v) diluted in PBS with 3% BSA for 20 minutes in a humid chamber at room temperature. After rinsing with PBS, the bound antibody was detected by fluorescein isothiocyanate conjugated to anti-monkey IgG (1:100; Nordic Immunological Laboratories) for 30 minutes. The slides were rinsed and mounted in Vectashield medium (Vector Laboratories, Burlingame, CA).

Antibody to zona pellucida in serum was detected by indirect immunofluorescence. The procedure followed was same as above with some differences. Five μm sections of snap-frozen normal monkey ovary were fixed in 95% ethanol, blocked with normal goat serum in PBS with 3% BSA (1:10 v:v). The sections were then incubated with immune serum or adjuvant control serum diluted in 3% BSA in PBS for 1 hour. IgG antibody bound to ZP was detected by fluorescein isothiocyanate conjugated to anti-monkey IgG (Nordic Immunological Laboratories).

Lymphocyte Proliferative Responses in Monkeys

Estimation of T-cell proliferative responses was done as previously described.[18] Monkey peripheral blood was collected in heparinized tubes and centrifuged to separate supernatant plasma. The cell pellet was resuspended in sterile PBS, layered over Histopaque 1083 (Sigma), and centrifuged at 400 $\times$ *g* for 20 minutes. Mononuclear cells at the interphase were collected, washed, and resuspended at 2 $\times$ 10^6/ml in Dulbecco's minimum essential medium supplemented with 1% sodium pyruvate, 1% of 200 mmol/L glutamine, 1% nonessential amino acids, 5 $\times$ 10^{-5} mol/L β-mercaptoethanol, 100 U/ml penicillin, 100 mg/ml streptomycin, and 10% heat-inactivated fetal calf serum. The assay was set up in triplicates in which cells (0.1 ml/well) were cultured with an equal volume of peptide (0 to 30 μmol/L) in 96-well flat-bottom plates for 4 days at 37°C in 5% CO_2. [^{3}H]-thymidine (0.5 μCi/well; Dupont NEN Products, Boston, MA) was added to each well 16 hours before harvesting the cells (Skatron Instruments, Sterling, VA), and the cell-associated thymidine measured by scintillation counting (Beckman Instruments). Results are presented as stimulation index (experimental counts per minute with peptide/background counts per minute without peptide). The monkeys Babs and Harriette gave high background counts when cultured in media with 10% fetal calf serum. For these animals, fetal calf serum was substituted with 10% autologus heat-inactivated plasma.

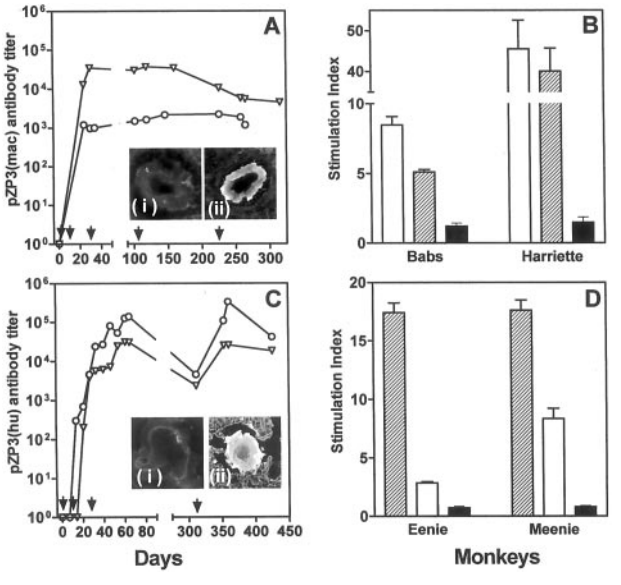

Figure 1. Immune response in female macaques immunized with pZP3(mac) (**A** and **B**) or pZP3(hu) (**C** and **D**). Serum antibody titers to the immunizing peptide were detected by enzyme-linked immunosorbent assay (**A** and **C**). **Arrows** indicate time of primary and booster immunizations. **A:** Antibody titers to pZP3(mac) [Babs (**circles**) and Harriette (**triangles**)]. Serum antibody from peptide-immunized Harriette recognized macaque zona pellucida (**inset Aii**) whereas sera from adjuvant-treated controls did not (**inset Ai**). In lymphocyte proliferation assays (**B** and **D**) animals immunized with pZP3(mac) (**B**) respond to the immunizing macaque peptide (**open bars**) and its human homologue (**hatched bars**) but not to the mouse peptide (**solid bars**). **C:** Antibody titers to pZP3(hu) [Meenie (**circles**) and Eenie (**triangles**)]. Direct immunofluorescence showed antibody bound to ZP (**inset Cii**) in Meenie but not in an adjuvant-treated macaque (**inset Ci**). In lymphocyte proliferative assays animals immunized with pZP3(hu) (**D**) respond to the immunizing peptide (**hatched bars**) and its homologous macaque peptide (**open bars**) but not to the dissimilar mouse peptide (**solid bars**). Data show stimulation index (±SEM) at 30 μmol/L concentration for each peptide. **C** is reprinted with permission from the Society of Reproduction, Inc. (Biol Reprod 1997, 56:767).

Immunohistology: Monkey and Mouse Ovaries

Serial sections (5 μm) were cut through the entire formalin-fixed, paraffin-embedded, monkey ovaries. Every 10th section was stained with hematoxylin and eosin. Adjacent sections were stained with the following antibodies at indicated dilutions. Polyclonal rabbit antibody to human CD3 and mouse monoclonal antibodies to HLA (CR3/43), CD20 (L26), CD 68 (KP1), and myeloid/histiocyte antigen (Mac 387) obtained from DAKO Corporation, Carpinteria, CA. A rabbit polyclonal antibody to HLA DR (a gift from Dr. S. M. Fu, University of Virginia, Charlottesville, VA)

was also used in some of the studies. Optimal dilutions of primary antibody (1:20 for rabbit anti-HLA polyclonal; 1:50 for L26, Mac387, CR3/43; and 1:100 for anti-CD3 and KP1) were determined using control monkey spleen sections.

The tissues were deparaffinized in xylene, transferred to absolute alcohol, rehydrated with decreasing grades of alcohol, and rinsed in PBS. Endogenous peroxidase was inactivated with 0.6% hydrogen peroxide in methanol PBS (4:1, v:v). Because some antibodies (CD3, CD68, and Mac 387) did not recognize their cognate antigens, unmasking of epitopes was performed by digestion with pepsin (4 mg/ml) in 0.1% HCl at 37°C for 7 minutes. For HLA monoclonal and polyclonal antibodies, antigen retrieval was done by heating slides in 10 mmol/L of citrate buffer, pH 6.0, for 20 minutes in a microwave. Evaporated fluid was replaced with water every 4 minutes. The slides were allowed to cool to room temperature before use. Sections were rinsed in PBS after antigen retrieval and blocked with normal goat or rabbit serum followed by primary antibody diluted in 3% BSA PBS. After washing, the slides were incubated with biotinylated goat anti-mouse or anti-rabbit Ig (Vector Laboratories) (1:100 dilution). Detection of bound antibody was done by avidin-biotinylated enzyme complex (Vectastain ABC kit; Vector Laboratories) and visualized by incubation with diaminobenzidine substrate (Biogenex Corp., San Ramon, CA). The sections were counterstained with methylene blue, rinsed with water, and dehydrated with ascending grades of alcohol. The slides were then rinsed with xylene and mounted with Cytoseal60 (Stephens Scientific, Kalamazoo, MI). Monkey spleen sections concomitantly processed were positive controls and ovaries without primary antibody served as negative controls.

Immunochemical staining of mouse ovaries was done as previously described.[13] Briefly, 5-μm sections from mouse ovaries fixed in 4% paraformaldehyde were incubated with primary antibody to CD5 (Lyt1 53-7.313), major histocompatibility complex (MHC) class II (M5/114.15.2), B220 (RA3-3A1/61), or macrophage (F4/80). After washing in PBS, the sections were incubated with biotinylated rabbit anti-rat antibody. Bound antibody was visualized by the ABC detection system followed by diaminobenzidine and counterstained with methylene blue as described above.

Steroid Assays

For analysis of ovarian function, monkeys were bled every 3 days for 1 to 3 consecutive months at two phases of the study, with the first early phase starting 1 to 2 months before immunization until 2 months after immunization and the second late phase between 3 to 11 months when the antibody titers were high. Endocrine function was monitored by estimation of circulating steroid hormone levels. One hundred μl of serum was used in competitive radioimmunoassays for progesterone and estradiol estimations, as per the manufacturer's instructions (ICN Pharmaceuticals, Costa Mesa, CA, for progesterone and Diagnostic Products Corporation, Los Angeles, CA, for estradiol). The detection limit for progesterone was 0.27 ng/ml with an interassay coefficient of variation (CV) of 11.7% and intra-assay CV of 8.9%. For estradiol, the sensitivity limit was 27 pg/ml with an interassay and intra-assay CV being 7.4% and 4.5%, respectively.

Results

ZP3 Peptide from Macaque or Human Elicits an Autoimmune Response in Female Cynomolgus Macaques

Two normal, cycling, adult female cynomolgus macaques were immunized with 50 nmol/L of pZP3(mac) in a squalene arlacel A emulsion. Both animals (Babs and Harriette) had detectable serum anti-peptide antibody on day 24 after immunization (Figure 1A). The titers were maintained at 10^3 to 10^5 by subsequent booster immunizations until sacrifice. Their serum IgG reacted with macaque ZP by indirect immunofluorescence (Figure 1A, inset). Antibody bound to ovarian ZP was also detected by direct immunofluorescence at time of sacrifice (data not shown). Thus pZP3(mac) includes a native B-cell epitope. The antibody detected was of the IgG isotype suggesting a helper T-cell response and the presence of a T-cell epitope in pZP3(mac). T-cell proliferative response was detected *in vitro* by days 28 to 32 in both animals (data not shown). The T-cell proliferative response could also be recalled 10 days after the final booster immunization (Figure 1B).

Two macaques immunized with a homologous human ZP3 peptide [pZP3(hu)] were also studied for AOD. Therefore, we evaluated the immunological cross-reactivity between the two peptides. The human ZP3 protein has 94% homology with the monkey ZP3, and the peptides used in this study differ at only a single amino acid residue (340V to M).[19] As previously reported, macaques (Eenie and Meenie) were immunized with pZP3(hu) in adjuvant.[18] Antibody to pZP3(hu) of the IgG isotype was detected in the serum and titers sustained at 10^4 to 10^5 for >400 days by repeated boosting (Figure 1C). Antibody bound to ovarian ZP was detected by direct immunofluorescence at the time of sacrifice (Figure 1C, inset). Circulating antibody to ZP was also detectable by indirect immunofluorescence (data not shown). T cells from pZP3(hu)-immunized animals proliferated strongly in response to the immunogen and cross-reacted to a lesser extent with the homologous pZP3(mac) but not at all with pZP3(mou) (Figure 1D). These experiments demonstrate

Figure 3. Ovarian inflammation in pZP3(mac)- and pZP3(hu)-immunized macaques. **A–D:** Adjacent sections of a typical primate AOD lesion consisted of clusters of CD3+ T cells (**A**, **arrows**) and MHC II + cells (**B**, **arrowheads**). **C** and **D:** Adjacent sections of another typical primate AOD lesion stained for CD3 (**C**) and MHC II (**D**). Adjacent sections of a large granuloma in the ovary of Eenie that was immunized with pZP3(hu) in adjuvant. **E:** Typical granulomatous inflammation with eosinophilic center (**arrowheads**) surrounded by cuff of lymphocytes (**arrows**) (H&E). The granuloma contains many macrophage (Mac 387+) (**F**), a central core of MHC II-positive cells (**G**), and a rim of CD3+ T cells (**H**). Original magnifications, ×400.

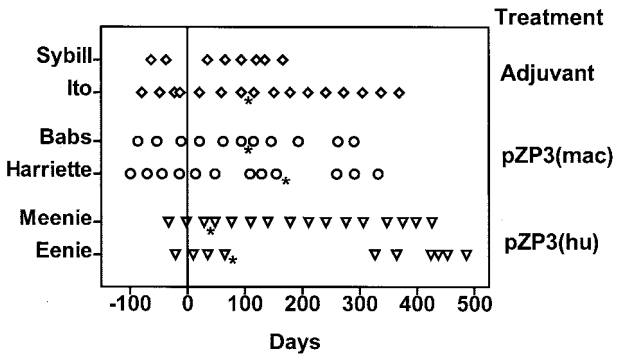

Figure 4. Ovarian cyclicity in adjuvant-immunized (Sybill, Ito), pZP3(mac)-immunized (Harriette, Babs), and pZP3(hu)-immunized (Meenie, Eenie) macaques monitored until sacrifice. Each point indicates time of menstrual bleeding. Time of first immunization is indicated as day 0. **Asterisk** denotes surgical removal of one ovary.

that the macaque and human peptides cross-react at the B-cell and T-cell levels even in outbred macaques. Our subsequent investigations showed that immunization with these immunologically cross-reactive peptides have similar effects on the ovary and on ovarian function.

pZP3(mac) and pZP3(hu) Immunization Is Associated with Ovarian Infiltration of T Cells and Activated Macrophages without Detectable Oophoritis

The ovary has many leukocytes that play a critical role in normal ovarian function including follicular atresia, ovulation, and involution of the corpus luteum.[20–22] Thus we first examined the distribution of T cells and macrophages in the ovaries from two untreated and two adjuvant-treated cycling adult macaques. As described in Materials and Methods, serial sections were cut through the entire ovary for each animal, and every 10th section was studied histologically. Adjacent sections were immunostained with antibodies to CD3, MHC II, macrophages (CD68, Mac 387) and B cells. As reported in humans,[23] T cells and macrophages expressing MHC II were detected in normal or adjuvant-treated monkey ovaries. In addition, atretic follicles and corpora lutea were infiltrated by small numbers of T cells and MHC II-positive macrophages (Figure 2, A and B). Occasional clusters of T cells were also located in the ovarian cortex and medulla (Figure 2C). However, these T-cell clusters did not contain any detectable MHC II-positive macrophages (Figure 2D).

In contrast, a unique pattern of cellular infiltration was detected in three of four pZP3-immunized monkeys. In these lesions, the T cells were found to co-localize with MHC II-expressing cells (Figure 3; A to D). These clusters of inflammatory cells were found in the interstitial or perifollicular locations. Because these typical leukocyte infiltrates were detected in pZP3-immunized monkeys but not in monkeys injected with adjuvant alone, they were considered to be pathologically relevant. Although macrophages (Mac 387 or CD68 positives) were detected in these T-cell- and MHC II-positive cellular infiltrates, they did not account for all of the MHC II staining in the inflammatory foci (data not shown). The additional MHC II-expressing cells may represent ovarian dendritic cells or granulosa cells of adjacent follicles, as described in human AOD.[24]

Interestingly, despite the impressive cellular infiltrates detected immunohistologically, inflammatory leukocytes were not visualized histologically on adjacent sections of the same ovaries. This was true for formalin-fixed or the Bouin's-fixed tissues. An exception was the ovary of Eenie, which was studied at 3 months after immunization with pZP3(hu) and adjuvant. This ovary contained several foci of granulomatous inflammation characterized by a central eosinophilic area surrounded by a cuff of lymphocytes (Figure 3E). Immunostaining of adjacent sections showed invasion of macrophages in the region (Figure 3F). The granuloma showed characteristic features of central MHC II-expressing cells surrounded by a ring of CD3-positive T lymphocytes (Figure 3, G and H). Histopathological evaluation of other organs collected at sacrifice failed to show any detectable inflammation.

Ovarian Function Is Retained in the Presence of Oophoritis

Menstrual bleeding in the pZP3-immunized and adjuvant-treated animals was monitored. The cycles in all of the animals except Eenie (the animal with granulomatous oophoritis) were found to be regular and comparable to adjuvant-treated controls (Figure 4). Eenie stopped menstruating for 7 months after ovariectomy after which menstrual bleeding resumed spontaneously. Sera were collected at two phases of the study to monitor endocrine function as described in Materials and Methods. The mean peak estradiol and progesterone levels studied early (when antibody titers were low) and late (when ZP antibody titers remained high) were comparable in all of

Table 1. Peak Serum Estradiol and Progesterone in Macaques Immunized with ZP3 Peptides

	Early phase		Late phase	
Animal	Peak estradiol (pg/ml)	Peak progesterone (ng/ml)	Peak estradiol (pg/ml)	Peak progesterone (ng/ml)
Babs	127.3 ± 79.5* (3)†	37.1 ± 13.5 (3)	56.9 ± 14.9 (2)	40.0 ± 31.82 (2)
Harriette	61.8 ± 37.5 (3)	24.6 ± 6.2 (3)	64.9 ± 44.2 (3)	21.9 ± 3.18 (2)
Meenie	145.7 ± 26.5 (3)	21.1 ± 5.5 (3)	84.3 ± 50.5 (2)	27.7 ± 7.4 (2)
Eenie‡	31.4 ± 11.7 (2)	26.9 (1)	119.6 (1)	15.7 (1)

*Data are mean ± SD of peak values in sera.
†No of peaks studied.

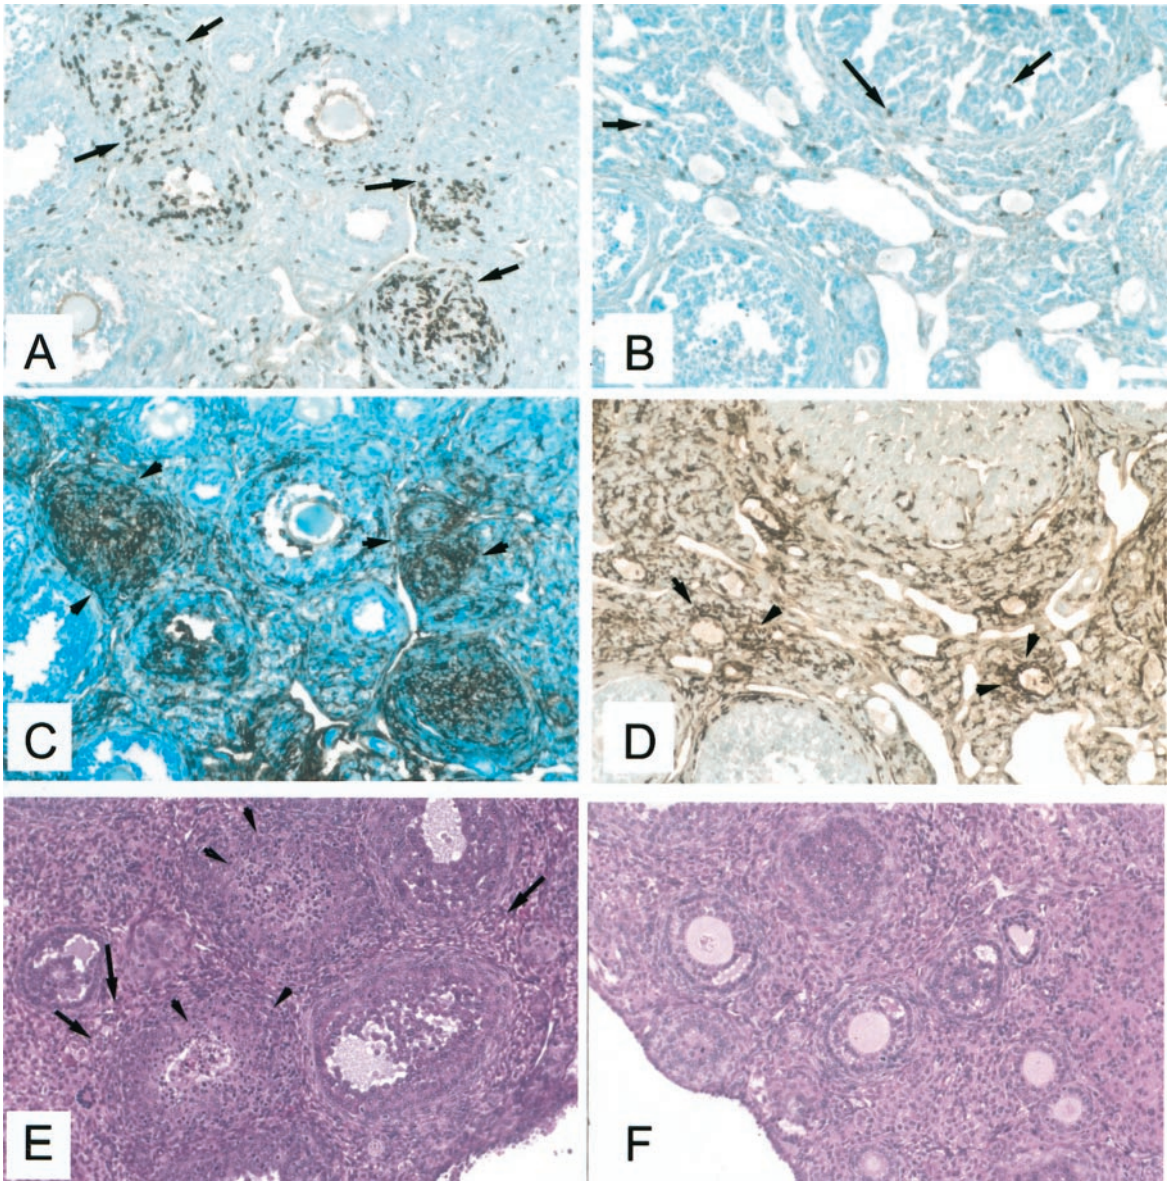

Figure 5. Immunohistopathology of murine AOD. **A**, **C**, and **E:** Ovary of a mouse immunized with pZP3(mou) in CFA. Adjacent sections showing clusters of cells T cells (CD5+) (**A**, **arrows**) that co-localize with intensely MHC II+ cells (**C**, **arrowheads**). The opposite ovary stained with H&E (**E**) shows lymphocytic infiltration in the interstitial regions (**arrows**) and the ovarian follicles (**arrowheads**). **B**, **D**, and **F:** Ovary of an adjuvant-treated mouse showing a few T (CD5+) cells (**B**) and an adjacent section (**D**) with many MHC II+ macrophages in the interstitium and the corpus luteum. The opposite ovary (**F**) stained with H&E appears completely normal.

the animals except Eenie (Table 1). Although the data collected is during a limited period of study, the pattern showed functioning ovaries with an estradiol peak preceding the progesterone peak (data not shown). Steroid analysis after ovariectomy in Eenie showed loss of cyclicity with estradiol <20 pg/ml and peak progesterone reaching only 2.3 ng/ml.

Comparative Histology and Immunopathology of Murine ZP3 Peptide-Induced AOD

AOD is induced by injection of pZP3(mou) in adult B6AF1 female mice,[12] but a detailed analysis of the immunopathology of the oophoritic lesion has not been described. To compare murine and macaque AOD, we evaluated mouse ovaries for the distribution of T cells (CD5), macrophages (F4/80), MHC II, and B cells (B220).

Immunostaining of the ovarian inflammatory infiltrates in murine AOD and the primate AOD are similar. In murine AOD, the infiltrating lymphocytes were predominantly T cells (Figure 5A), with only occasional B cells (data not shown). Like the lesion in macaque AOD, T cells were found to form clusters with F4/80-positive macrophages that expressed MHC II (Figures 5, A and C). Macrophages were normally present in large numbers in the normal mouse ovary. Adjuvant treatment resulted in the increase in ovarian macrophages that expressed MHC class II (Figure 5D), but there was no increase in T-cell infiltration (Figure 5B).

In contrast to macaque ovaries, histological evidence of oophoritis was readily detected in murine AOD. The lesions consisted of inflammation in the interstitium and some involvement of developing follicles (Figure 5E). The inflammation was focal or diffuse, frequently appearing as monocytic granulomata and in some cases, multinucleated giant cells. No inflammatory lesions were seen in animals immunized with adjuvant alone (Figure 5F).

Discussion

Human AOD is characterized by a wide spectrum of histopathological changes.[3–6] Lonsdale and colleagues[25] have summarized a comprehensive list of histologically confirmed reports of human autoimmune oophoritis. The inflammation may involve ovarian follicular structures or interstitial regions. The interstitial inflammation may be restricted to the hilar region, perifollicular regions, or may extend diffusely throughout the ovary. The wide range of inflammatory lesions is associated with varying clinical presentation from asymptomatic oophoritis, menstrual disturbances, to POF and infertility. Lymphocytes and plasma cells are the most common infiltrating cells. The distributions of inflammatory cells in normal human ovary defined by immunohistology serve as a baseline for identification of pathological infiltrates.[23] However, immunohistological studies on the ovarian disease are limited to three published reports on four patients.[25–27] They have identified T cells as the dominant infiltrating cells. Some macrophages were also detected in the infiltrates. Local production of proinflammatory cytokines such as interferon-γ by infiltrating T cells has been implicated in the aberrant expression of MHC II on granulosa cells at the site of inflammation.[24] These features are similar to our findings in the macaque and mouse ZP-induced AOD. Although typical granulomatous oophoritis resembling the inflammation seen in Eenie, has been reported in patients their immunohistological findings were not studied.[5] B cells and plasma cells are identified in the human AOD as well as murine AOD induced by neonatal thymectomy (preliminary data) but are rarely found in monkey or murine AOD induced by pZP3. Another type of human oophoritis contains mainly eosinophils,[28] and similar pathology has been elicited in mice by adoptive transfer of Th2 (interleukin-4 and interleukin-5 producing), pZP3-specific T cells (P Alard and KSK Tung, unpublished), and in pinworm-infected neonatal mice injected with pZP3(mou) without adjuvant.[29]

Immunization with zona pellucida proteins and peptides has also been investigated as immunocontraceptive vaccine. Vaccines based on the whole porcine zona pellucida proteins have been applied effectively to control feral horse and elephant populations.[30,31] As a potential vaccine for human population control, primates (marmoset, baboons, squirrel monkeys, and macaques) have been immunized with heterologous zona pellucida proteins. Although this approach resulted in infertility,[16,17,32] varying extents of irreversible ovarian dysfunction were also observed. Antibody to ZP was postulated to interfere with junctional complexes between granulosa cells and oocytes leading to the loss of developing follicles, and accelerated recruitment of the primordial follicles. However, other studies on squirrel monkeys and bonnet monkeys immunized with porcine ZP proteins with alum and muramyl di-peptide (MDP) adjuvants were found to develop high levels of circulating ZP antibodies. These studies showed a reversible contraceptive effect without any loss of ovarian function.[33,34] These contradictory data suggest that the high titers of ZP antibody alone are not sufficient to explain irreversible loss of ovarian function after ZP protein immunization in primates. Because no obvious inflammation was detected, autoimmune oophoritis was not considered a basis for ovarian failure in ZP-immunized primates.

The ZP3 peptide with well-defined T- and B-cell epitopes capable of eliciting a restricted immune response has been used to dissect the mechanism of AOD[12] in the mouse model. Transfer of ZP3 peptide-specific T cells into naïve recipient mice resulted in granulomatous oophoritis and enhanced ovarian expression of interleukin-1, tumor necrosis factor-α, and interferon-γ. However, the ovarian function of cell recipients was normal and the mice remained fertile.[13] Antibody to ZP3 also does not cause any ovarian pathology. These results indicate that T-cell-mediated ovarian inflammation alone or ZP antibody alone does not affect ovarian function. However, co-transfer of pathogenic T cells and ZP antibody targets the inflammation into developing follicles leading to their destruction and the development of ovarian atrophy.[14] Thus combined action of both antibody and proinflammatory T cells is required for severe ovarian injury leading to POF. In this study we show that ZP3 peptide immunization in primates can elicit a T-cell response and cause ovarian immunopathology that is similar to murine AOD. These data suggest a role for T cells in macaque AOD. It will be important to determine in the future whether the combined effects of antibody and proinflammatory T cells are responsible for the long-term ovarian changes in monkeys injected with ZP3.

became pregnant. The records prior to treatment showed that in 24 doe-years, 34 fawns were born (1.4 fawns/doe-year). In contrast, during 54 doe-years posttreatment with SpayVac®, only one fawn was born (0.019 fawns/doe-year). SpayVac has also been proven to provide multi-year efficacy with a single dose in Fallow Deer (*Dama dama*), White-tailed Deer (*Odocoileus virginianus*), horses (*Equus caballus*), and Gray Seals (*Halichoerus grypus*).

Field Evaluation of the Immunocontraceptive, GonaCon-B, in Free-ranging Horses (*Equus caballus*) at Theodore Roosevelt National Park

D. L. Baker, J. G. Powers, M. Oehler, J. Ransom, J. P. Gionfriddo, and T. M. Nett

From Colorado State University, Animal Reproduction and Biotechnology Laboratory, Fort Collins, Colorado, USA (Baker, Nett); National Park Service, Biological Resource Management Division, Fort Collins, Colorado, USA (Powers, Ransom); Theodore Roosevelt National Park, Medora, North Dakota, USA (Oehler); and USDA/National Wildlife Research Center, Fort Collins, Colorado, USA (Gionfriddo)

Unchecked free-ranging horse populations can have adverse effects on native plant communities and ecosystem processes, and may lead to conflict regarding appropriate resource allocation between sympatric grazing ungulate species. In response, many land management agencies have reduced free-ranging horse populations through periodic roundups and adoption or sale of excess animals. These methods are time and resource intensive, and can result in injuries to animals and humans. Consequently, more efficient, effective, and humane approaches are desired. One alternative is controlling the fertility of female horses through immunocontraception. We are currently in the final year of a 3-year study at Theodore Roosevelt National Park (ND) to evaluate the effects of the gonadotropin-releasing hormone vaccine, GonaCon-B, on fertility, behavior, and injection site reactions in female horses. In October 2009, park horses were captured via helicopter round-up. All mature mares and band sires were retained to avoid disrupting existing herd dynamics, whereas foals, yearlings, and most satellite males were removed. Mares were blocked according to age and pregnancy status and randomly assigned to a treatment ($n = 29$; 2.0 ml GonaCon-B) or control ($n = 28$, 2.0 ml 0.9% NaCl) group. During March and July 2010 there was no difference between treatment groups in the number of foals observed with mares ($P = 0.65$). During the same time period in 2011 treated mares were three times less likely to have a foal by side than control mares (odds ratio 0.11–1.01, 95% CI). Estimated foaling rate in 2011 was higher ($P = 0.04$) in control mares (0.74, 0.56–0.88) than treatment mares (0.48, 0.31–0.66). Between 25 and 280 days posttreatment nearly 80% of treated mares had visible swelling at the site of injection and a purulent draining abscess was observed in one animal. By 380 days posttreatment approximately half of these swellings were no longer visually detectable. No treatment effects were observed on mare activity budgets, and sociosexual behavior data are currently being analyzed. Our preliminary examination of the data indicate that vaccination with GonaCon-B during gestation does not affect foaling success, decreases fertility for one year posttreatment, is associated with injection site swelling, and does not affect general activity budgets in free-ranging female horses.

Effects of Gonadotropin-releasing Hormone Vaccination (GonaCon-B) on Fertility in Free-ranging Female Rocky Mountain Elk (*Cervus elaphus nelsoni*)

J. G. Powers, D. L. Baker, R. J. Monello, T. S. Spraker, T. M. Nett, J. P. Gionfriddo, and M. A. Wild

From the National Park Service, Biological Resource Management Division, Fort Collins, Colorado, USA (Powers, Monello, Wild); Colorado State University, Animal Reproduction and Biotechnology Laboratory, Fort Collins, Colorado, USA (Baker); Colorado State University, Veterinary Diagnostic Laboratory, Fort Collins, Colorado, USA (Spraker); and the USDA/National Wildlife Research Center, Fort Collins, Colorado, USA (Gionfriddo)

Fertility control is one method, among a suite of management tools, which may assist in mitigating conflicts associated with locally overabundant wildlife. Rocky Mountain elk (*Cervus elaphus nelsoni*) are resilient, adaptable cervids that can have ecological as well as socio-political impacts on the coupled human-natural environment. We evaluated the safety and efficacy of the gonadotropin-releasing hormone vaccine, GonaCon-B, in free-ranging elk. In January 2008, 120 mature (>2 yr) female elk were captured in Rocky Mountain National Park (CO) and randomly assigned to treatment ($n = 60$; 1.5 ml GonaCon-B) or control ($n = 60$; 1.5 ml 0.9% NaCl) groups. All injections were given with hand-held syringes in the biceps muscle. Location of the injection was recorded in reference to anatomic landmarks. Transrectal palpation and pregnancy specific protein B analyses were used to diagnose pregnancy at the time of application. During the following three winters females were recaptured and euthanized in conjunction with park management culling operations (2009, $n = 20$; 2010, $n = 25$; 2011, $n = 34$). At necropsy pregnancy status was determined. Tissues were collected and preserved from organs associated with the hypothalamic-pituitary-gonadal (HPG) axis. Injection sites were relocated, muscle tissue collected, and microbial culture performed when gross evidence of inflammation was present. There were no differences in pregnancy rates between groups at the time of treatment ($P = 0.558$). In the following three years saline administered control females ($n = 36$) had a mean pregnancy rate of 0.83 (0.71 - 0.95, 95% CI). Pregnancy rate in the treatment group was 0.0 (0.0 - 0.22, $P = 0.0001$) year one, 0.33 (0.12 - 0.61, $P = 0.05$) year two, and 0.65 (0.43 - 0.83, $P = 0.17$) year three. Study animals showed no evidence of lameness or external swelling at the injection site prior to euthanasia; however, at the time of necropsy all females in the treatment group had pyogranulomatous inflammation at the site of injection.

Gonadotropin-releasing hormone vaccine (GonaCon-Equine) suppresses fertility in free-ranging horses (Equus caballus): Limitations and side effects of treatment

In many areas of the western United States, overabundant and rapidly expanding feral horse (Equus caballus) populations pose a significant challenge for natural resource managers. There is wide-spread concern that unregulated feral horse populations are severely altering or degrading native plant communities. Controlling the fertility of female horses offers a potential strategy for limiting the growth of overabundant populations.

We evaluated the long-term effectiveness of GonaCon-Equine vaccine both as primary immunization and subsequent reimmunization four years later to suppress fertility in free-ranging female horses at Theodore Roosevelt National Park, North Dakota. In the fall of 2009, horses were gathered via helicopter and 57 adult mares were randomly assigned to either a treatment (n = 29; 2.0 mg GnRH conjugate + 2.0 mL adjuvant) or control (n =28; 2.0 ml 0.9% saline) group. Females in both groups received an intramuscular injection in the gluteal musculature by hand-injection. Four years later, in 2013, horses were similarly gathered and revaccinated with the same doses. We determined the effectiveness, duration, and reversibility of vaccination with GonaCon on reproduction by comparing foaling rates of treated and control mares during 1 March to 31 December, 2009-2016. In conjunction with foaling observations, we also evaluated potential side effects of GonaCon on pregnancy, neonatal health and survival, injection site reactions, daily activity patterns and socio-sexual behaviors.

Foaling proportions in GonaCon-vaccinated mares, following the primary vaccination were lower than for control mares for the second (2011) (44.8% (13/29) vs 70.3% (19/27) (P= 0.047) and third (2012) (53.6% (15/28) vs 77.8% (21/27) (P = 0.053) post-treatment foaling seasons but were absent the fourth (2013) (73.1% (19/26) vs 69.2% (18/26) (P = 0.50) post-treatment season, demonstrating reversibility of the vaccine. However, the effectiveness of a single immunization, measured as the percent decrease in foaling when compared with control mares, was low to modest; estimated at 36.3% and 31.1%, in years 2 and 3, respectively. In contrast, revaccination with GonaCon, four years post-primary treatment was 100% (0/25) effective in suppressing fertility, whereas mean foaling rate of control mares was 84% (21/25) (95% CI = 65.3-93.6%) in 2015 and 2016. The effectiveness of revaccination persisted, although slightly diminished, during the second year (2016) at 80.9% (16% (4/25) foaling rate; 95% CI = 6.4-34.6).

With the exception of non-debilitating inflammation at the vaccine injection site, no other adverse effects were observed. These data indicate that GonaCon-Equine can be effective in suppressing fertility in free-ranging horses when both a primary immunization and booster are administered. Ongoing research will inform the optimum revaccination schedule for effective contraception.

Abstract

Wildlife and humans are increasingly competing for resources worldwide, and a diverse, innovative, and effective set of management tools is needed. Controlling abundance of wildlife species that are simultaneously protected, abundant, competitive for resources, and in conflict with some stakeholders but beloved by others, is a daunting challenge. Free-ranging horses (*Equus caballus*) present such a conundrum and managers struggle for effective tools for regulating their abundance. Controlling reproduction of female horses presents a potential alternative. During 2009–2017, we determined the long-term effectiveness of GnRH vaccine (GonaCon-Equine) both as a single immunization and subsequent reimmunization on reproduction and side effects in free-ranging horses. At a scheduled management roundup in 2009, we randomly assigned 57 adult mares to either a GonaCon-Equine treatment group ($n = 29$) or a saline control group ($n = 28$). In a second roundup in 2013, we administered a booster vaccination to these same mares. We used annual ground observations to estimate foaling proportions, social behaviors, body condition, and injection site reactions. We found this vaccine to be safe for pregnant females and neonates, with no overt deleterious behavioral side effects during the breeding season. The proportion of treated mares that foaled following a single vaccination was lower than that for control mares for the second ($P = 0.03$) and third ($P = 0.08$) post-treatment foaling seasons but was similar ($P = 0.67$) to untreated mares for the fourth season, demonstrating reversibility of the primary vaccine treatment. After two vaccinations, however, the proportion of females giving birth was lower ($P < 0.001$) than that for control mares for three consecutive years and ranged from 0.0–0.16. The only detectable adverse side effect of vaccination was intramuscular

Competing interests: The authors have declared that no competing interests exist.

swelling at the vaccination site. Regardless of vaccine treatment (primary/secondary), approximately 62% (34/55) of immunized mares revealed a visible reaction at the vaccine injection site. However, none of these mares displayed any evidence of lameness, altered gait or abnormal range of movement throughout the 8 years they were observed in this study. Our research suggests that practical application of this vaccine in feral horses will require an initial inoculation that may provide only modest suppression of fertility followed by reimmunization that together could result in greater reduction in population growth rates over time.

Introduction

Anthropogenic disturbance of landscapes and natural resources is pervasive across much of the earth, resulting in increased conflict between humans and wildlife and a need for effective resource management [1]. Humans indeed have tried to control animal abundance in some capacity for over 13,000 years [2]. Regulating abundance of wild animals using fertility control or contraception is a relatively new development, emerging only 50 years ago [3]. Such tools are appealing to wildlife managers and stakeholders because they present a non-lethal solution for regulating abundance when species pose a risk to human interests and safety, and when wildlife densities are high enough to disrupt ecosystem function [4,5].

Feral horses (*Equus caballus*) present perhaps one of the most unique wildlife management problems worldwide. Humans have spent centuries propagating and dispersing domestic horses to every continent except Antarctica over the last several centuries, only to have inadvertently created expansive feral populations that now compete with humans, wildlife, and domestic animals for resources [6]. The unique relationship between humans and horses has resulted in a precarious dichotomy, with the struggle for relief from conflict and resource competition challenged by a mutualistic societal view where feral horses are perceived as part of our social environment. This struggle is elevated in the United States, where federal law (*P*. L. 92–195, as amended) provides protection for feral horses and burros (*Equus asinus*) on large expanses of public land, and establishes guidance for their management as a wildland species [7].

Current methods of population control for free-ranging horses in the U.S. involve periodic removals and adoption or sale of surplus animals, or maintaining excess animals in long-term holding facilities which are expensive, resource intensive, and unsustainable [8]. Clearly, more efficient, cost effective, and humane approaches to reducing feral horse densities on public lands are needed. Controlling the fertility of female horses offers a potential complementary or alternative strategy for limiting the growth of some populations [9].

A promising immunological approach to contraception in feral horses and other wild ungulate species involves immunization against gonadotropin- releasing hormone (GnRH), a small neuropeptide that performs an obligatory role in mammalian reproduction [10]. When conjugated to a highly immunogenic carrier protein and combined with a potent adjuvant, GnRH vaccination actively stimulates a persistent immune response resulting in prolonged antibody production against endogenous GnRH. These antibodies induce transient infertility by binding to GnRH, thus preventing attachment to receptors on pituitary gonadotropes, suppression of gonadotropin release, and ultimately ovulation in females [11, 12]. As anti-GnRH antibodies decline over time, the availability of endogenous GnRH increases and treated animals generally regain normal fertility [13–17].

The GnRH-based contraceptive agent known as GonaCon-Equine (National Wildlife Research Center, Fort Collins, CO, USA; [18] is registered by the United States Environmental Protection Agency as a restricted-use pesticide for contraception of adult female feral horses and burros. A single immunization with this or earlier versions of this vaccine (more generally referred to as GonaCon) have been shown to induce extended infertility ($\geq$ 2 yr) in numerous wild ungulate species including captive and free-ranging elk (*Cervus elaphus*) [15–17] white-tailed deer (*Odocoileus virginianus*) [18–20], bison (*Bison bison* [21]), and feral horses [22– 24]. However, multiple years of infertility are only experienced in a fraction of vaccinated animals. In free-ranging elk, for example, there was approximately a 90% treatment effect the first year after vaccination but this declined to 50% by the second year; with no measurable effect by year three [16]. Similar declines in effectiveness have been reported for captive feral horses treated with the same vaccine [22].

Booster vaccinations generally result in a more profound and longer-lasting antibody production due to the anamnestic (cell memory) response [25]. Traditional veterinary vaccinology suggests that non-replicating vaccines most often require two initial doses 2–6 weeks apart followed by booster vaccinations every 1–3 years [26]. Repeat immunizations using a variety of GnRH vaccines in domestic horses improves contraceptive efficacy and suppress behavioral and physiological estrus [27–29]) However, these GnRH vaccines differ from GonaCon-Equine in that they incorporate different protein carrier molecules and adjuvants, and are formulated for short duration ($<$ 1 yr.) effectiveness. They are also administered on a more traditional vaccination schedule with a primary set of immunizations followed by periodic boosters.

Other forms of wildlife fertility control vaccines have adopted comparable initial and booster recommendations [30–32]. However, this intensive vaccination schedule places significant logistical barriers on application in free-ranging animals. GonaCon vaccine is formulated with highly immunostimulating mycobacteria as a component of the adjuvant. This may prolong the initial and subsequent booster vaccination windows for optimum efficacy as initial antibody concentrations are maximal 2–12 months post-primary vaccination [15]. GonaCon vaccine is one of the rare exceptions among animal vaccines in that the formulation initiates high antibody titers that remain elevated in some individuals after a single-injection ; however, little research has been conducted to evaluate booster doses of this vaccine in any free-ranging wild ungulate [17, 24] or domestic species [33]. While a single immunization against GnRH may be preferred from a practical perspective, there may be a more optimal vaccination schedule that balances the need for minimizing animal handling or contact while maximizing vaccine effectiveness. Thus, it's imperative to investigate the safety and long-term effectiveness of repeat vaccination and to evaluate its potential to limit fertility in this long-lived and perennially pregnant species.

In female wild ungulates, adverse side effects following a single immunization against GnRH appear to be minimal. Evaluation of biological side effects has been reported for numerous wild ungulate species including white-tailed deer [13, 34], elk [15, 16, 35], feral pigs [36], bison [21], and free-ranging horses [17, 24]. A summary of results from these investigations indicate that GonaCon is reversible, safe for use in pregnant females, does not significantly change social behaviors [37] or negatively affect neonatal development, survival, or maturation [15, 35]. No adverse effects of vaccination have been shown to be related to general health, body condition, blood chemistry parameters, or hematology of treated animals. The most apparent pathological side effect has been the development and persistence of non-debilitating granulomatous and often purulent inflammation at the site of injection. In all studies, where post-mortem examinations have been conducted, injection-site lesions were pervasive, but in some species, such as white-tailed deer and elk, they were not apparent antemortem. Likewise,

in cases where injection-site reactions have been documented, no clinical evidence of lameness, impaired mobility, or depression, have been reported [13, 15–17, 21, 24, 34, 35].

While documentation of contraceptive efficacy and side effects of GonaCon have been described for a variety of wild ungulates, similar evidence for feral horses is limited. To our knowledge, only two long-term ($\geq$ 3 years) empirical investigations have been conducted using GonaCon-Equine. These include a clinical trial with captive feral mares [22] and the other with free-ranging mares in a natural environment [23]. In the study with free-ranging horses, vaccination significantly reduced foaling rates of treated females, however, effectiveness was inconsistent over time and was substantially lower than that reported for captive feral mares treated with the same vaccine [22]. Furthermore, neither of these studies integrated revaccination as a strategy to increase vaccine efficacy. Lastly, these inquiries provide little quantitative evidence of the reversibility of the effects of this vaccine, the presence or absence of adverse side effects related to inoculation of pregnant mares, and neither examined the potential for increased side effects with reimmunization.

Knowledge of the effects of GonaCon-Equine on equid fetal health, neonatal survival, and body condition is largely anecdotal, whereas injections site reactions to booster immunization and the efficacy of revaccination are limited to two investigations [24, 33]. Clearly, additional research is needed to further define the long-term therapeutic effectiveness and contraindications of this potential technology before resource managers can make informed decisions regarding its practical application for stabilizing the growth rate of free-ranging feral horse populations.

Consequently, the fundamental objectives of this investigation were: 1) to determine the duration, effectiveness, and reversibility of both a single immunization and subsequent reimmunization against GnRH in suppressing reproductive rates of free-ranging mares in a natural environment, 2) to determine the safety and adverse side effects (if any) in free-ranging mares including assessment of general health, body condition, effects on current pregnancy, injection site reactions, and neonatal health and survival and, 3) to compare the effects of a single vaccination against GnRH on time budgets and social behaviors [37] to similar behaviors following reimmunization. Based on evidence from prior studies with feral horses and other wildlife species, we predicted ($H_{1:}$) that a single vaccination against GnRH would suppress fertility for multiple years with decreasing effectiveness over time but would not result in permanent infertility. Furthermore, we surmised ($H_{2:}$) that the anamnestic immune response to revaccination would be more effective and longer lasting in suppressing fertility than the initial immunization alone. Moreover, we reasoned ($H_{3:}$) that except for localized inflammatory reactions at the injection site, we would not observe other adverse side effects (i.e. lameness, detrimental effects on existing pregnancy, neonatal health and survival, body condition, behavioral changes). Apart from determination of return to normal fertility of treated mares, these objectives and hypotheses were addressed and accomplished in this investigation.

Materials and methods

Study area

We conducted this research in the South Unit of Theodore Roosevelt National Park (THRO), USA) (45˚ 55'N/103˚ 31'W). This unit is located near the town of Medora in southwestern North Dakota and encompasses approximately 19,000 ha of native vegetation. The landscape is topographically diverse and consists of eroded badlands with gullies and ravines separated by relatively large upland plateaus and small erosion-resistant buttes capped by scoria. Elevation ranges from 683 m to 870 m. Its continental climate is characterized by short, arid summers (mean temperature 21^0 C) and long, cold winters (mean temperature -12^0 C) [38].

Precipitation is irregular in amount and distribution with a long-term annual mean of 38 cm with most of this falling as rain showers from April to June [39].

Vegetation is primarily mixed-grass prairie dominated by needle-and -thread grass (*Hesperostipa comata)*, western wheatgrass (*Pascopyrum smithii)*, threadleaf sedge (*Carex filifolia)*, blue gramma (*Boutelous gracilis)*, and little blue-stem (*Schizachyrium scoparium)*. Cottonwood (*Populus deltoides)* gallery forests occur along perennial water courses while hardwood stands of green ash (*Fraxinus pennsylvanica)* and chokecherry (*Prunus virginiana)* dominate the upland drainages. Dense stands of Rocky Mountain juniper (*Juniper scopulorum*) are common on steep north-facing slopes [40].

Besides feral horses, sympatric wild ungulate species include bison, elk, mule deer (*Odocoileus hemionus)*, white-tailed deer, and pronghorn (*Antilocapra americana)*. Horses and bison are confined to the South Unit of the Park by a 1.8–2.4 m woven-wire boundary fence. Currently, horse numbers are controlled through periodic live capture and removal of select individuals. Free-ranging horses at THRO are classified by the National Park Service (NPS) as "feral livestock" and managed as a "historical demonstration herd". The most recent estimate of population size (2017) is 150–175 horses and the Park has set a management goal for this herd at approximately 50–90 animals.

The social structure of this population consists of 14–16 social groups (bands) that include a single dominant stallion, subdominant stallions, and 1–5 adult mares, yearlings, and foals of both sexes. Males greater than 1 year of age that have not acquired a band are usually found in ephemeral bachelor groups of 3–6 individuals. These bands are non-territorial and are spatially distributed across the South Unit primarily east of the Little Missouri River. All horses are known by unique coloration and markings and have been previously identified and assigned individual identifiers by managers. Photographs of each animal from birth to adulthood assist in the identification of individuals. Age, reproductive history, and genealogy data for each animal has been maintained since 1993.

In spring/summer 2009, we collected pre-treatment data on all mares and bands within THRO. The purpose of this effort was: 1) to determine the sample size and sampling intensity required to achieve acceptable statistical power ($\geq$ 80%) to detect fixed differences ($\geq$ 50%) in foaling proportions of experimental groups, 2) to assess unknown logistical limitations of locating and identifying specific study mares within bands of horses, and 3) to train field technicians to observation protocols, and collect pre-treatment time budget and social behavioral data.

Experimental animals and treatments

Primary vaccination (2009–2013). During a scheduled management roundup at THRO (18–23 October 2009), 160 horses were guided by helicopter into permanent corrals and handling facilities. An attempt was made to capture the entire population to maximize sample sizes for this research project and to remove excess horses to meet desired herd management objectives. A total of 57 adult mares (2–17 years of age) and associated foals, and band stallions, were captured, identified, treated, and retained in the Park for this experiment. Using a randomized complete block design, we established two experimental groups consisting of a GonaCon-Equine treatment group (n = 29) and a saline control group (n = 28). Mares were paired (blocked) based on age and pregnancy status such that animals within a block were as similar as possible. Within each block, individual mares were then randomly assigned to either a control or treatment group.

Equine veterinarians and a reproductive specialist, blinded to treatment status, assessed the general health, body condition, pregnancy status, and approximate gestational stage of each

mare. We determined pregnancy status and gestational age by transrectal palpation and ultrasonography of the reproductive tract [41]. We collected whole blood (up to 50 mL) via jugular venipuncture (BD Vacutainer SST; Becton Dickinson and Co., Franklin Lakes, NJ) then centrifuged these samples at the capture site, and temporarily stored serum in cryovials at -20^0 C. We later transferred frozen serum on dry ice to Fort Collins, Colorado, where it was stored at -80^0 C. We also assessed serum for exposure to common pathogens known to cause abortions in horses (e.g. equine herpesvirus-1, equine infectious anemia, equine viral arteritis and contagious equine metritis) that could confound the interpretation of treatment-induced infertility [42].

We applied treatments while mares were restrained in a squeeze chute. Females in the treatment group received an intramuscular injection in the lower left gluteal musculature, by hand-held syringe (18-gauge, 3.8 cm needle) containing GonaCon-Equine (2.0 mg GnRH conjugate + adjuvant; 2.0 mL). The vaccine contained multiple synthetic copies of GnRH coupled to a large immunogenic carrier protein (Blue Carrier; Biosonda, Santiago, Chile) that was combined with a water-in-oil adjuvant containing killed *Mycobacterium avium* ssp. *avium* (AdjuVac, National Wildlife Research Center) [18]. Mares in the control group were injected in a similar manner, with an equal volume of physiologic saline solution (0.9% NaCl; 2.0 mL). We chose to inject the vaccine into the gluteus muscle (~ 15 cm distal to the point of the hip) rather than the neck because of greater safety for hand-injection, enhanced detection of potential injection site reactions under field conditions, and the preferred location for potential remote dart delivery of the vaccine.

Secondary vaccination (2013–2017). Four years later, during 23–25 September 2013, we similarly rounded up the entire THRO horse population and moved and handled them through existing corrals and chute systems to remove excess animals from the Park. Given this unique opportunity and endorsement from the Park, we retained all available mares previously immunized and control mares, retreated them, assessed pregnancy status, and determined body condition using techniques identical to those applied at the 2009 roundup. Two mares in the control group and 4 mares in the treatment group died between 2009–2013 and therefore, were not available for this experiment. We attributed these mortalities to malnutrition, dystocia, broken appendage, and unknown causes not related to treatments. The one exception in our 2013 protocol was that we injected the booster vaccination into the opposite (right) hip from where the primary (left hip) vaccination was previously administered. This provided the opportunity to simultaneously evaluate injection site reactions related to both immunizations. Treatment mares again received 2.0 mL GonaCon-Equine and control mares 2.0 mL saline.

Field measurements

Using 2–3 trained technicians and occasional equally trained volunteers, we conducted field measurements and observations consistently from year to year. Prior to field observations, technicians were provided with photographic images of individual horses and required to recognize them by band association, natural markings, and pelage coloration. They were also trained or had previous experience in identifying prepartum characteristics of pregnancy (e.g., enlarged abdomen, mammary gland development, waxing teats, behavior, etc.), as well as, body condition scoring, and the appearance and classification of injection site reactions to the vaccine. We collected all data from ground surveys (foot, vehicle, horseback) using binoculars and spotting scopes. Although technicians were unaware of treatment assignments of individual mares, the presence of injection site reactions in several GonaCon-treated mares could have revealed their treatment designation.

Reproduction. We predicted that pregnant females inoculated with GnRH at the fall gathers of 2009 and 2013 would give birth to a healthy foal the following spring (2010 or 2014) and presumably be infertile during subsequent breeding seasons. Thus, the effects of the primary or booster vaccinations on reproduction (foaling proportions) would not be observed until the 2011 and 2015 foaling seasons, respectively. These are the first breeding seasons that a treatment or retreatment effect on mare fertility could be detected when using foaling observations to assess successful contraception by the vaccine.

We determined the effectiveness, duration of effects, and reversibility of the primary and booster vaccinations on reproduction by comparing foaling proportions of treated and control mares during 1 March to 31 December 2009–2017. We chose to use the term vaccine "effectiveness" rather than "efficacy" because it more realistically represents how GonaCon-Equine affects fertility under more natural field conditions compared to a controlled clinical trial [43, 44]. We defined vaccine effectiveness (VE) as the proportional reduction in annual foaling (F = number of mares with a foal/ total number of mares in a treatment group) between control and treated mares. Vaccine effectiveness is equivalent to relative risk reduction (RRR) in medical statistics and was calculated from the risk ratio $\left(\mathrm{RR} = \frac{\mathrm{F}_{Trt}}{\mathrm{F}_{Con}}\right)$ where F_{Con} = foaling proportion of the control mares, and F_{Trt} = the foaling proportion of the treated mares. Risk ratio was calculated using the *fmsb* package in program R [45–47] and we then solved for VE as follows:

$$\mathrm{VE} = \frac{\mathrm{F}_{Con} - \mathrm{F}_{Trt}}{\mathrm{F}_{Con}} = 1 - \frac{\mathrm{F}_{Trt}}{\mathrm{F}_{Con}} = 1 - \mathrm{RR}$$

Each year of the study, we estimated annual foaling proportions by locating all bands to identify individual mares and determine the presence or absence of foals. During the intensive sampling period (1 March–1 August), we attempted to observe 95% or greater of all experimental mares and foals (when present) at least weekly and 100% of them every two weeks, then opportunistically until 31 December. We did not attempt to assess contraceptive effect based on visual characteristics of pregnancy but did use these criteria to prioritize weekly observations of individual mares. Instead, we defined foaling as a parturition event or neonatal foal by side, as detected by direct observation. We matched foals with dams through observations of nursing and repeated close association during feeding, bedding, and traveling [48, 49]. We collected neonatal data at first sighting of a foal and estimated date of birth by observing the foal's level of activity, presence of an umbilicus, and elapsed time since the dam was last observed pregnant [50]. We photographed and estimated the age of each new foal when first observed, recorded its sex, general health (vigorous, average, poor), markings, and band association, and gave it a unique identifier; then entered these observations into a herd database. Finally, we assessed the utility of using foaling proportions as a proxy for pregnancy proportions by comparing pregnancy proportions determined at the time of each gather in 2009 and 2013 to foaling proportions observed in 2010 and 2014.

Side effects

Behavioral. We repeated thee behavioral measurements with the same treatment groups of mares that were previously conducted during an earlier phase of this project [37]. We proposed that, if greater contraceptive effectiveness after reimmunization against GnRH was achieved, it would potentially provide a larger and more statistically powerful sample size of contracepted animals in which to detect behavioral changes related to this vaccine (if they occurred).

We completed an intensive behavioral study during an earlier phase of this larger GnRH study during 2009–2010 [37]. To make these analyses directly comparable to that prior study, we followed the same behavioral sampling design as that described previously [50]. Briefly, this included blocking observations into three daylight time periods (08:00–12:00 h, 12:01–16:00 h, and 16:01–20:00 h) with observations conducted during the primary breeding season, 1 March– 1 August 2014. Each observation session included collection of a 20-min instantaneous scan sample of time budgets at 1 min intervals for each adult band member (≥1 year old), and all-occurrence data collection for social interactions [37].

Primary behavior categories included feeding, resting, locomotion, maintenance, and social behaviors [51]. Social behavior data included herding, reproduction, agonism, harem-tending, and harem-social behavior, and were collected at all occurrences throughout the observation sessions. Harem-social behavior was not collected through all-occurrence sampling in our previous study; however, it was collected during the scan sample in the previous study and was worthy of further consideration here. We defined this category as interactions between two individuals that did not meet the definition of the other all-occurrence behaviors (e.g. allogrooming and non-reproductive olfactory investigation).

We observed all horses from the nearest distance that did not elicit attention to the presence of the observer, typically 50–200 m. All observations were conducted using a 15–45 × 600 mm spotting scope or 10 × 42 mm binoculars when the distance between horses and observers was too far to allow unassisted detailed observation. We observed each band of horses weekly or bi-weekly in conjunction with other field assessments.

Physiological. Concurrently with foaling and behavior observations, we evaluated and compared potential adverse side-effects of treatment on injection-site reactions, body condition, success of existing pregnancy, and neonatal survival in treated and control mares. We made assessments of these potential side-effects monthly during the primary foaling season and opportunistically for the remainder of the year. We observed each mare for the presence or absence of visible lesions, swellings, or discharge at the injection site. In addition, we documented evidence of lameness (e.g. limping, gait alteration, reluctance to stand or bear weight on a limb), as well as behavioral depression, muscle tremors, or other systemic reactions that could be related to the vaccine treatment. We classified injection-site reactions according to the following criteria: 1) **abscess**–an open sore usually with fluid drainage or discharge, 2) **swelling**–a raised area of tissue of variable size and shape with no visible fluid drainage, 3) **lameness**–any abnormal range of movement or stiffness in the leg where the vaccine injection was delivered, 4) **none**–no observable reaction [52]. These categories were not mutually exclusive with respect to a single observation and both sides of the animal were observed, when possible. For these observations, we approached as near as possible to individual horses (≤ 50 m) and assessed and photographed each injection-site reaction for later evaluation. At the same time, we visually evaluated body condition of each mare and scored condition as previously described [53]. We evaluated the success of the existing pregnancy by comparing foaling proportions between treated and control groups in 2010 and 2014. We measured neonatal survival as the proportion of foals surviving to 14 days of age and post-natal survival to 200 days.

Statistical analysis

Reproduction. Yearly foaling data are reported as the proportion of mares observed with a foal in each group. We used asymptotic approximation to the binomial distribution to compute 95% confidence intervals for these proportions using package *binom* in program R [45, 47]. We used a risk ratio analysis ($\alpha = 0.05$) to compare all observed annual proportions between treatment groups. We used the same method to evaluate the success of the existing

pregnancy between groups during the first foaling season post-vaccination (2010 and 2014). All comparisons between treatment groups were made within a single year and without multiple testing corrections.

Behavior. We used the same statistical approach for the analyses in 2014 as that used in 2010 [37]. We modeled the frequency of each behavior using mixed-effects linear regression, where individual female identity and sampling time (time of day) were included as random effects on the intercept term of each model. This accounted for variation that may have been present among individuals who were sampled repeatedly, though not always equally over time, and for temporal variation in behavior when samples were not equally collected across all times of the day. Time budget behaviors sampled at 1-min intervals were aggregated into proportion of time spent per behavior to calculate an independent measure of behavior per observation session. We used the *lme4* package of R version 3.1.2 (The R Foundation for Statistical Computing 2014) and SYSTAT 12.02.00 (SYSTAT Software, Inc. 2007) to calculate descriptive statistics and obtain mixed-effects model estimates using restricted maximum likelihood [54]. Separate models were fitted for each time budget behavior with the fixed effects of treatment group (treated or control), foal presence (dependent foal $<$ 1 year of age present with the female, or no foal present with the female), female age, and band size. In the previous study, we considered band fidelity (number of times a female moved bands within a year), but data were too homogeneous to consider that factor in 2014: only 8 horses moved bands at all (4 treated/4 saline) and five of those moved collectively to a different stallion.

Physiological. We used descriptive statistics (arithmetic means with ± 95% CI) to compare, occurrence of lesions at the injection site and 1-tailed Fisher's exact test ($\alpha = 0.05$, 1df) to compare foal survival proportions of treated females to that of controls. We used normal binomial distributions to compute confidence limits for the differences between proportions using Jeffrey's interval for small sample sizes [55]. Effects on body condition scores were examined using generalized linear models in the *lmer* package in program R [56]. We employed random effects for year and individuals and then compared this nested model to full models which added the effect of either treatment or foaling using an ANOVA.

This research was approved by the Institutional Animal Care and Use Committees of the National Park Service (NPS) (Permit Numbers: MWR_THRO_Baker_Horse_2013.A3, MWR_THRO_Baker_Horse_2015.A3) and Colorado State University (IACUC Protocol No. 17-7651A). This study was conducted in accordance with good laboratory practices (GLP) and oversight from United States Department of Agriculture/National Wildlife Research Center (No.QA1647). All data collections were conducted after obtaining a scientific collection permit issued by Theodore Roosevelt National Park (THRO-2010-SCI-0010). All work, other than animal handling and vaccination at the two feral horse roundups, was observational. Every effort was made to prevent and minimize disruption of natural band dynamics and individual horse behavior and well-being during handling and treatment application.

Results

The statistical process used to select experimental mares for this investigation resulted in two treatment groups that were relatively homogeneous in age, body condition, body mass, and pregnancy status [S1 Table]. Results of pregnancy assessment indicated that most mares were pregnant at the 2009 (0.86 (49/57), 95% CI = 0.74–0.93) and 2013 (0.90 (46/51), 95% CI = 0.79–0.96) roundups, thus providing sufficient opportunity to evaluate and compare the safety and potential side effects of vaccine treatment on pregnancy and neonatal survival.

Transrectal ultrasonography revealed that the fetuses of most pregnant females were approximately 120+ days old at the roundup and that most had descended over the pelvic rim

preventing a more accurate assessment of gestational age at treatment application [57]. To provide a more precise estimate, we used an estimated gestation period for horses of 342 days [58] and the approximate foaling date (± 5 days) of each mare in 2010 and 2014 and then back-calculated to the date of treatment application at the 2009 (18–23 October) and 2013 (23–25 September) roundups. Using these calculations, we estimated mean gestational age at vaccine inoculation in 2009 to be 162 days (95% CI = 150–175) for treated mares and 154 days (95% CI = 138–170 days) for control mares. For 2013, we used the same calculation and projected that, on average, females were reimmunized against GnRH at approximately 129 days (95% CI = 105–151 days) of gestation and saline-treated control mares at 132 days (95% CI = 119–144 days).

Following the 2009 and 2013 roundups and release, experimental mares distributed themselves among 16–19 individual bands. At least one treated or control mare was present in all bands during 2010–2017. Likewise, the composition of adult mares in each band, as well as the band stallions, remained relatively stable during this period. By the end of the 2017 foaling season, 14% (4/29) of treated mares and 11% (3/28) of control mares had died of various causes (e.g., malnutrition, broken appendage, dystocia, unknown causes). Except for these mares and one vaccinated mare that was not re-captured at the 2013 gather, all others were observed for foaling and other field measurements for all eight years of this investigation.

We met our sampling objective by observing more than 95% of all mares weekly (and sometimes more often) from 1 March to 1 August each year of the study. It is possible that some foals were born and died without being detected but given the intensity of the sampling observations, we feel that this was highly unlikely. Observations during the remainder of the year and following winter were less intense and more opportunistic depending upon available personnel, weather, and road conditions. During this time, mortality of foals was more likely to have gone undetected.

Vaccine effectiveness

Primary vaccination (2009–2013). Mean foaling proportions of treated (0.62 (18/29) 95% CI = 0.44–0.79) and control (0.68 (19/28) 95% CI = 0.50–0.85) mares during the 2009 pre-treatment foaling season were not different ($P = 0.65$) indicating that prior to contraception, treatment groups exhibited equal fertility [S1 Table]. Further evidence was provided by individual mares at the 2009 gather and primary vaccine inoculation. The proportion of treated (0.86 (25/29), 95% CI = 0.71–0.95 and control (0.85 (24/28), 95% CI = 0.70–0.95) mares determined to be pregnant, via transrectal ultrasonography, were not different ($P = 0.63$) [S1 Table, Fig 1]. This provided an opportunity to compare the effects of GonaCon-Equine vaccination on the existing pregnancy of treated mares and neonatal health and survival to that of untreated control mares. Foaling proportions of treated (0.68 (19/28) 95% CI = 0.50–0.85) and control (0.64 (18/28), 95% CI = 0.46–0.82) mares during 2010 were not different ($P = 0.78$) (Fig 1). Births occurred from early March to early September with 97% (35/36) observed during the first four months of the foaling season (1 March to 1 June). Average foaling dates in 2010 for treated and control mares were 5 May (95% CI = 22 April–18 May) and 10 May (95% CI = 25 April–25 May), respectively. No foal was detected for 12 mares (6 treated: 6 control) that were determined to be pregnant at the 2009 gather. None of these mares showed evidence of pregnancy during the intensive foaling period or for the remainder of the year. We surmised that most of these foals were either aborted or died as neonates between the periods from 20 October 2009 (gather) to 1 March 2010 (beginning of foaling observations). Regardless of timing or cause of death, the proportion of mares that foaled in

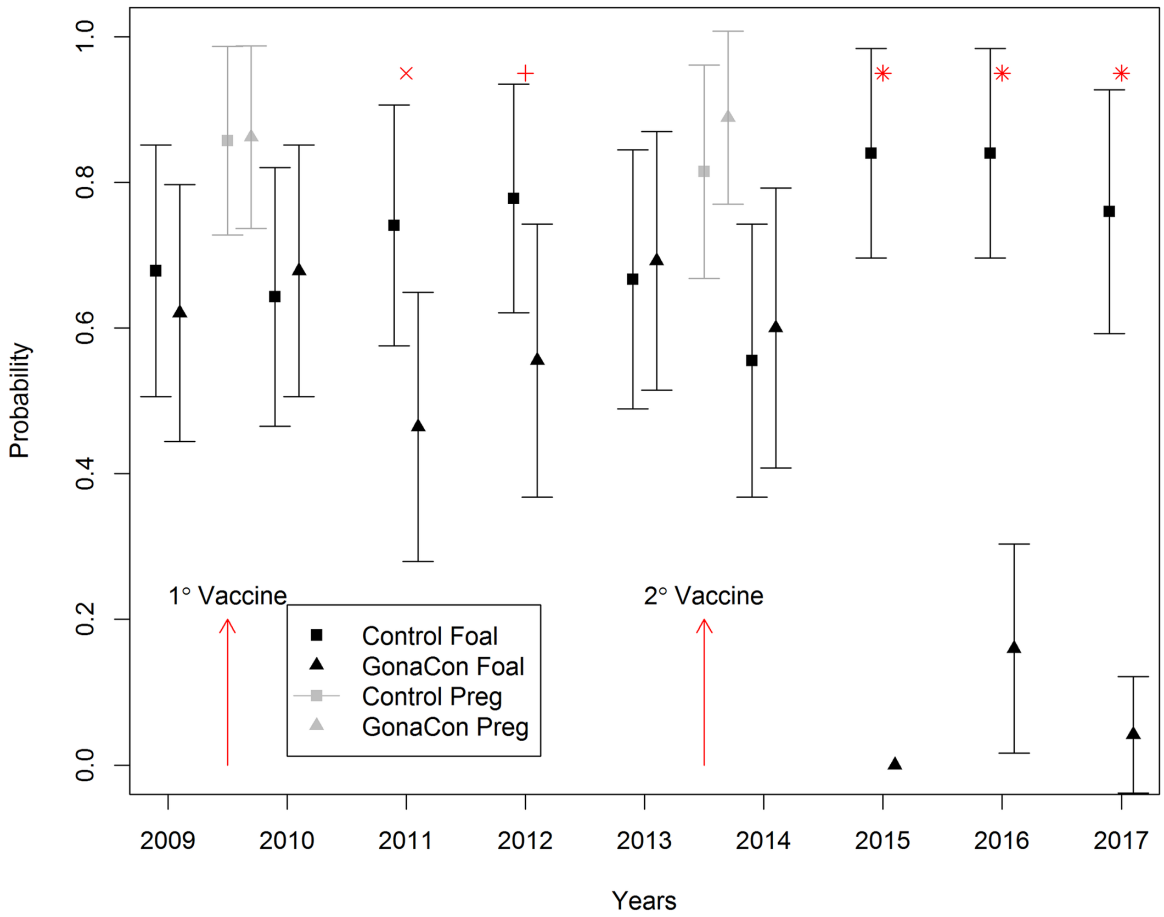

Fig 1. Comparative probability of foaling and pregnancy for treatment and control groups of free-ranging feral horses (*Equus caballus)* mares selected for this experiment. Mares were treated with a primary vaccination of GonaCon-Equine in October 2009 and then reimmunized with the same vaccine in September 2013 at scheduled gathers at Theodore Roosevelt National Park, North Dakota, USA. GonaCon vaccinations occurred at the time points represented by the red arrows. Symbols correspond to observed p-values for relative risk comparisons between treatment groups within years (p-value between 0.05 and 0.1 = +, for < 0.05 = x, and for $< 1x10^{-05}$ = *).

https://doi.org/10.1371/journal.pone.0201570.g001

2010 underestimated the proportion of mares that were determined to be pregnant at the 2009 gather by 24% for treated mares and 21% for control mares.

Estimated age of all foals at first observation was 2.4 days (95% CI = 1.7–3.1days). Most neonates (97%), from both experimental groups, were classified as vigorous and in good to excellent condition when first observed. Neonatal survival rate from parturition to 14 days of age was estimated to be 0.95 (18/19, 95% CI = 0.75–0.99) for foals born to GonaCon-treated females and 0.88 (16/18, 95% CI = 0.64–0.98) for foals born to control mares ($P = 0.54$). After 14 days of age, post-neonatal survival rates (14–200 da) averaged 0.97 (30/31, 95% CI = 0.84–0.99) and were similar for both experimental groups ($P = 0.57$). These results support our prediction (H_3) that inoculation with GonaCon-Equine vaccine, during approximately the second trimester of pregnancy, does not affect the existing pregnancy of treated females or neonatal health and survival.

The proportion of treated mares that foaled (13/28) following a single vaccination was lower than that for control mares (19/26) for the second (2011) ($P = 0.04$) and third (15/27 vs 21/27) (2012) ($P = 0.08$) post-treatment foaling seasons but was similar (18/26 vs (18/27)

($P = 0.67$) to control mares for the fourth (2013) season, demonstrating reversibility of the primary vaccine treatment (Fig 1). Even though we observed a significant reduction in foaling proportions between treated and control mares during 2011 and a declining effect in 2012, therapeutic effectiveness and relative risk reduction estimates were low to modest and estimated to be 0.37 (95% CI = 0.01–0.60) and 0.28 (95% CI = -0.06–0.51), respectively (Table 1). These findings lend support to our hypotheses *(H_1)* that a single vaccination with GonaCon-Equine is reversible and suppresses fertility for multiple years post-treatment in a portion of treated animals but with diminished effectiveness over time.

Secondary vaccination (2013–2017). At the scheduled gather in October 2013, we extended our evaluation of GonaCon-Equine by assessing the effects of revaccination on fertility and safety in these same experimental mares treated four years after the primary vaccination. Evidence of similar fertility for individual mares was demonstrated at the 2013 gather, where pregnancy proportions of treated (0.92 (23/25), 95% CI = 0.75–0.98) and control (0.88 (23/26), 95% CI = 0.71–0.96) mares were similar ($P = 0.86$) [S1 Table]. Except for one treated and one control mare, all others had conceived and given birth to at least one foal during 2009–2013. For the 2013 foaling season, foaling proportions of treated (0.69 (18/26), 95% CI = 0.51–0.87) and control (0.66 (18/27) 95% CI = 0.49–0.84) mares were not different ($P = 0.84$) providing additional evidence that treatments groups were of equal fertility prior to reimmunization (Fig 1).

Like 2010, mean foaling proportions during the first post-treatment foaling season (2014) were not different ($P = 0.74$) between treated (0.60 (15/25), 95% CI = 0.41–0.79) and control (0.56 (15/27), 95% CI = 0.37–0.74) mares (Fig 1) supporting similar observations in 2010 that revaccination could be applied to pregnant mares, during mid-gestation, without risk to the existing pregnancy. Foaling date distribution was comparable to that observed in 2010 following the primary vaccination. Average foaling date for treated mares was estimated to be 27 April (95% CI = 5 April– 20 May) and 19 April (95% CI = 6 April– 2 May) for controls. No foal was observed for 15 mares (8 treated: 7 control) that were determined to be pregnant at the 2013 gather. Like 2010 estimates, foaling proportions underestimated pregnancy proportions determined at the 2013 gather for both treated and control mares by approximately 30% and 34%, respectively (Fig 1). These data, together with similar observations in 2010, support the inference that foaling proportions are not an accurate proxy for pregnancy proportions but provide a limited but practicable field measurement for determining contraceptive

Table 1. Comparative relative risk reduction (RRR), 95% confidence intervals, and p-values associated with differences in foaling proportions between GonaCon-treated and control mares during 2009–2017.

Year	Relative Risk Reduction	95% Confidence Interval		p-value
	(RRR)	Lower	Upper	
2009	0.0852	0.3757	-0.3402	0.6500
2010	-0.0555	0.2750	-0.5301	0.7797
2011	**0.3732**	**0.6028**	**0.0109**	**0.0381***
2012	0.2857	0.5178	-0.0581	0.0861
2013	-0.0384	0.2826	-0.5032	0.8430
2014	-0.08	0.3216	-0.7194	0.7482

effectiveness. Average foal age at first observation across both treatment and control groups was 2.6 (95% CI = 1.5–3.3) days. Nearly all foals born to revaccinated and control mares were classified as vigorous and found to be in good to excellent condition when first observed.

Neonatal survival rate to 14 days of age for foals born to revaccinated mares was 0.87 (13/15), 95% CI = 0.62–0.96 and 0.93 (14/15), 95% CI = 0.70–0.98) for foals born to control mares ($P = 0.49$). After 14 days of age, post-neonatal survival rates were 0.80 (12/15), 95% CI = 0.55–0.92) for revaccinated mares and 0.73 (11/15), 95% CI = 0.48–0.89) for control mares ($P = 0.55$). These results reflect similar findings following a primary vaccination with GonaCon-Equine and reinforces the deduction (H_3) that reimmunization is safe for treatment of pregnant females and does not affect neonatal or post-neonatal health or survival when applied at approximately mid-gestation.

Unlike results from the single vaccination trial, we observed, not only highly significant reduction in foaling proportions between treated and control mares following reimmunization but also a remarkably effective contraceptive response. Except for the first foaling season following treatment application, (2014) in which the vaccine was not expected to have an effect ($P = 0.75$), foaling proportions in reimmunized mares were lower ($P < 0.001$) than that for control mares for all subsequent years (2015–2017) (Fig 1). This was particularly evident for the second post-treatment foaling season (2015) when none 0.00 (0/25), 95% CI = 0.0) of the reimmunized mares produced a foal while the proportion of control mares foaling was estimated to be 0.84 (21/25, 95% CI = 0.69–0.98). During the third post-treatment foaling season (2016), four treated mares produced a foal resulting in a foaling proportion of 0.16 (4/25), 95% CI = 0.01–0.30) while the proportion of control mares foaling was identical to that observed in 2015 (Fig 1). These foals were determined to be vigorous and in good to excellent condition at birth, however, two of these foals, born in September, were not observed the following spring and were categorized as post-natal mortalities and presumed to have died during winter (2016/2017).

In 2017, no additional treated mares produced a foal or showed evidence of pregnancy. However, one of the treated mares that had foaled in 2016 died of apparent natural causes (age-related malnutrition) during 2017 and two other revaccinated mares that had foaled in 2016 failed to produce a foal that year resulting in a foaling proportion of 0.041 (1/24), 95% CI = 0.03–0.12) (Fig 1). The foaling proportion for mares in the control group (2017) was 0.84 (21/25, 95% CI = 0.69–0.98) and higher ($P < 0.001$) than that for GonaCon-treated mares (Fig 1). It should be noted that the apparent decrease in foaling proportions in GonaCon-treated mares from 2016–2017 and resulting increase in vaccine effectiveness (Table 1) is likely due to the inherent error associated with the small sample size ($n = 4$) of mares in this treatment group that regained fertility. Overall, there was both a substantial decrease in foaling proportions (Fig 1) and an exceedingly high level of effectiveness (Table 1) for treated mares compared to controls for 3 years post-revaccination (2015–2017) ($P < 0.001$). Thus, fertility measurements during 2015–2017 support our prediction (H_2) that revaccination with GonaCon-Equine would be more effective in suppressing foaling proportions in treated females compared to controls than a single immunization (Fig 1, Table 1).

Side effects

Behavioral. We collected behavioral data on 73 feral horses (22 males, 25 treated females, 26 saline females) for 218.3 h in 2014. The median age of observed stallions was 12 years (range = 9–19 years), median age of observed control females was 8 years (range = 7–20), median age of observed treated females was 9 years (range = 7–22), and median band size was 8 horses (range = 2–14). There were no differences detected between treatment groups in any

time budget behavior category (Table 2). As band size increased, feeding decreased 1.24% (95% CI = 0.48–2.00) per additional horse in the band. Likewise, locomotion increased 0.20% (95% CI = 0.07–0.33) and maintenance decreased 0.10% (95% CI = 0.01–0.19) per additional horse in the band.

Foal presence influenced locomotion, with barren females moving 1.24% (95% C I = 0.40–2.08) more than females with dependents. Foal presence also influenced the social behavior component of time budgets, with barren females interacting with others 2.74% (95% CI = 0.59–4.90) more than females with dependents.

Variance among individuals had little influence on any of the behaviors modeled (Table 2). Variance was also minimal between time periods of observation; however, there were some significant differences in amount of activity by time of day. An estimated 6.88% (95% C I = -0.73–14.5) more feeding occurred in the 1601–2000 h time-period than did earlier in the day, and this was reciprocated by an estimated 3.33% (95% CI = 1.09–7.79) less resting, 0.34% (95% CI = 0.15–0.82) less maintenance, and 1.30% (95% CI = 0.51–3.11) less social behavior during the same period.

There were no differences detected between treatment groups in herding, reproduction, or agonism, but treatment group did influence harem-social behavior. Observed instances of harem-tending behavior provided too few data to model. Because these social behaviors were not as dependent on other broad categories as is the case with compositional time budgets [51], we re-estimated the social behavior models with only treatment and supported effects to allow for clearer interpretation of the results.

Stallions initiated harem-social behavior 13.9% (95% CI = 3.25–24.68) less toward control females than toward treated females. Though all harem-social records were analyzed as a group, it should be noted that 55.8% of the 308 harem-social events were sub-categorized as allogrooming. While the significant difference between treatment groups was detected, the variance among individuals for this behavior was near zero (Table 2).

Physiological. No study mares exhibited antibody titers to any of the infectious diseases that were surveyed for (i.e., equine herpesvirus-1, equine infectious anemia, equine viral arteritis and contagious equine metritis) thus eliminating this factor as a potential cause of infertility in GonaCon-treated females.

No control mares, treated with saline, showed any evidence of injection site reactions. Swelling and discharge were never observed in this group. Likewise, these mares showed no evidence of lameness or gait abnormalities in either hind limb. Consistent with our hypothesis (H_3), approximately 72% of treated mares (21/29) displayed a visible reaction at the site of injection after a single vaccination with GonaCon-Equine (S1 Photo). A single mare developed a draining abscess after the initial vaccination. These lesions were persistent over multiple years. At the time of the 2013 roundup and revaccination, 81% (21/26) of vaccinated mares continued to have palpable swelling at the original site of vaccine injection.

Like initial vaccination reactions, during the first-year post-revaccination, approximately 50% (13/26) of mares continued to show swelling on the left hip at the site of the 2009 injection and 50% developed a reaction on the right hip at the site of revaccination in 2013. Two of these new reactions were draining abscesses. Yet again, injection site reactions were persistent with approximately half of the mares with swellings at one or both injection sites, 3 years after revaccination. None of the GonaCon-treated mares displayed any evidence of lameness, altered gait or abnormal range of movement throughout the 8 years they were observed.

While body condition varied between individuals and study years, it did not vary between treatment groups ($P = 0.14$) over the course of the study. Likewise, there was no effect of presence of a foal on body condition ($P = 0.16$). Average body condition ranged from 3.7–4.9

Table 2. Treatment and supported effects in a mixed-effects linear regression of feral horse (*Equus caballus*) time budget behaviors (e.g. feeding, resting, locomotion, maintenance, social) and all-occurrence social behaviors (e.g. herding, reproduction, agonism, harem- social) at Theodore Roosevelt National Park, USA. Variance for the random effects of time of day (j) and individual horse identity (k) are shown as σ_j^2 and σ_k^2.

(moderately thin to moderate body condition) for all study animals over the 8 years that mares were observed. Individual body condition scores ranged from 1–7.

Discussion

Reproduction

This study demonstrated that a single vaccination against GnRH, using GonaCon-Equine, administered during mid-gestation, was safe, initiated short duration (2 yrs.) infertility in some mares, and was reversible, but was minimally effective in reducing fertility of treated females compared to controls. For two foaling seasons following vaccine treatment, we observed statistically significant reductions (28–38%) in foaling proportions of treated versus control mares but no effect by the third-year post-treatment, thus confirming the reversibility of the vaccine.

These results parallel similar findings from other experimental evaluations of GonaCon-Equine reported for captive and free-ranging mares. In a comparable study in Nevada with feral horses in a natural environment, GonaCon-Equine reduced foaling proportions by an average of 33% over a 3-year period but, like our study, contraception was only modestly effective over this period [23]. In contrast, contraceptive effectiveness of captive mares treated with GonaCon was greater and longer lasting ($\geq$ 4yrs) than either of these studies [22]. The disparity between captive and free-ranging animals in contraceptive response to GonaCon vaccine is not limited to feral horses but has also been observed between captive and free-ranging white-tailed deer [14, 18, 20] and elk [15, 16, 19]. Although these investigations did not suggest a definitive causation for these differences, they all pointed to suppressed and less persistent GnRH antibody concentrations in free-ranging ungulates compared to their captive counterparts suggesting a relatively compromised or weakened immune response to the vaccine that resulted in reduced contraceptive effectiveness.

It is widely acknowledged that differences in vaccine effectiveness can be attributed to increased environmental stressors (i.e., nutritional status, injuries, parasite load, pathogen exposure, and social dynamics) that can inhibit a more vigorous immune response in free-

ranging animals in a natural environment [59, 60]. It follows that while efficacy trials with captive animals can provide an important first approximation of vaccine safety and performance under controlled conditions; they may offer only limited inference to free-ranging animals that are not buffered against natural stressors that may decrease immune response and vaccine effectiveness. Regardless of the factor(s) contributing to the limited effectiveness of GonaCon in free-ranging animals, it appears that the immune response from a single vaccination does not consistently provide multiple years of infertility in all or even a high proportion of these animals.

In comparison to a single inoculation with GonaCon-Equine, the effect of reimmunization on foaling proportions was highly significant which allowed clear differentiation between treated and control mares for multiple breeding seasons. Compared to a single vaccination, reimmunization of mares in this study resulted in a much higher (58%) average vaccine effectiveness (range = 0.80–0.94) than the single vaccination for a 3-year period (2015–2017). Likewise, this level of effectiveness following reimmunization was on average higher than that previously reported for free-ranging mares treated with a single application with GonaCon-Equine [23] and 32% above what was reported for captive mares treated with the same vaccine formulation [22]. These results support the conclusion that a booster immunization with GonaCon-Equine can provide a highly effective, multi-year suppression of fertility in free-ranging horses and these results may be consistent in other animal species, as well.

It is fundamental knowledge that a secondary response to a vaccine generally results in a more rapid production of antibodies that are produced in greater amounts and over a longer time compared to the primary vaccination [25]. Repeat immunizations using a variety of GnRH vaccines in domestic horses have been shown to improve contraceptive efficacy. However, unlike commercially available short duration vaccines ($<$ 1 yr.) developed for domestic horses [29, 61], GonaCon-Equine is formulated by combining a non-biodegradable oil in water-based emulsion and an optimum concentration of immunostimulatory killed mycobacteria to form a depot usually deep in muscle tissue. This depot injection is thought to allow for a slow release and prolonged stimulation so that the formulation can act for much longer periods of time (years) than is possible with standard injections (months). This effect is thought to be responsible for the extended antibody response of 3–4 years in vaccinated deer [14, 18, 20, 62], elk [15, 16], and horses [22].

While this response was not unexpected, the magnitude and duration of effectiveness of GonaCon-Equine following revaccination, even 4 years after the initial vaccination, is salient and relevant to the management of fertility in free-ranging horses. First, it demonstrates that a booster vaccination can stimulate a highly effective immune response that can result in multiple years ($\geq$ 3 yrs.) of contraception. Second, it provides an initial reference point for defining the optimum revaccination schedule required for long-term reproductive management of female horses in a natural environment. And finally, it supports the consideration that while a single application may be preferred from a practical management perspective, GonaCon-Equine is more effective, in free-ranging horses, if repeat vaccinations are delivered on a periodic basis. While initial results are encouraging, additional research is needed to complete the objectives of this study including: 1) to define the duration of effective contraception post-revaccination, 2) to determine if long-term or permanent infertility is a possible outcome, and 3) to assess if return to fertility (if it occurs) results in altered birth phenology of treated mares. We will investigate these questions over the next three years of this study. Additionally, there may be a more optimal revaccination schedule which allows for altered duration of effectiveness or is more conducive to management schedules.

Side effects

After revaccinated in October 2013, time budget and social behaviors of mares in spring/summer of 2014 were comparable to those observed during the same period in 2010, following the initial treatment in October 2009. We found no evidence of differences in frequency or intensity of social behaviors including estrous behavior associated with treatment. Both treatment and control groups displayed few estrus behaviors in either 2010 [37] or during 2014. Behaviors associated with estrus were observed only 17 times in treated and 57 times in control mares out of 1148 observed social behavior events. This supports our earlier findings that pregnant mares rarely show overt estrous-related behaviors and similarly GonaCon-Equine treated mares only occasionally display these behaviors, although each for different reasons. Once a mare is pregnant, progesterone likely subverts much of the estrous type behavior that would generally be displayed with high estrogen levels, and only occasionally do domestic horses display and stand for mounting when pregnant [63]. Relatively small amounts of estrogen are secreted as follicles develop and then regress. In the absence of progesterone, relatively small amounts of estrogen are likely sufficient to induce erratic estrous behavior as was observed in these mares. However, the small amounts of estrogen were likely insufficient to induce an LH surge and subsequent ovulation.

Regardless of the underlying endocrinology associated with these behaviors, vaccinated and control mares both displayed social interactions that maintained herd structure; herding, tending, and defending behaviors from the stallion; and social hierarchies. The only meaningful factor that influenced the amount of time spent in social behaviors (e.g. allo-grooming, herding and tending) was the presence or absence of a foal. Mares with foals spent more time alone with the foal than those without off-spring, which is to be expected given their social and nutrient requirements during the neonatal and post-natal periods [50]. It is possible that long-term absence of foals could influence social behavior on a longitudinal scale, but additional studies are needed to investigate such phenomena on an appropriate time scale.

Other techniques for reducing the fertility of free-ranging species, such as vaccination with the native porcine zona pellucida vaccine (PZP) and tubal ligation, maintain the competency of the endocrine aspects of fertility. This can lead to unintended consequences with repeated estrous cycling in polyestrous species. In fact, in a population of white-tailed deer, where most reproductive females had received tubal ligations, fawning was negligible; however, there was more than a 700% increase in the number mature males attracted to the area occupied by a high number of estrous cycling females [64]. Similarly, PZP vaccination has extended the length and intensity of breeding seasons in horses [49, 65–68], deer [69, 70], and elk [71]. GonaCon-Equine may avoid these inadvertent consequences by functionally inducing mimicry of pregnancy in females which continues to be an important part of the social structure of the group but does not invite intense adverse breeding behaviors.

Researchers have generally hypothesized that by alleviating the energetic demands of gestation and lactation, contracepted females will attain improved body condition over pregnant females that require additional food resources to produce and rear an offspring. However, for free-ranging large ungulates, empirical evidence supporting [72] or refuting [73–75] this prediction is limited and equivocal. In this investigation, contracepted mares that experienced no gestation and lactation did not exhibit improved body condition over mares that successfully reproduced. Individual mares in each experimental group, attained an average BCS of 5.0 (moderate) or better, which has been reported to be the minimally optimal level of stored fat necessary to achieve maximum reproductive efficiency during pregnancy and lactation [53, 76]. These levels of body condition were reflected in the high proportion of pregnant mares (0.85–0.92) observed in each treatment group at the management roundups in 2009 and 2013.

We acknowledge that our sampling intensity and/or sensitivity of our ocular index to body condition may not have enabled us to detect fine-scale differences between experimental groups. However, we conducted these evaluations during time periods when differences in body condition between pregnant and non-pregnant (GonaCon-treated) females should have been the greatest. Namely, during early spring (March) when fats deposits are depleted over winter and during April–August when the energetic demands of late gestation and lactation are increasing.

The body condition of an animal is dependent on a balance between energy intake and expenditure. When intake is not sufficient to meet energy requirements for various activities (i.e. maintenance, growth, activity, gestation, lactation, etc.), fat reserves and eventually lean body tissue will be lost. The fact that pregnant and lactating mares in this study were in similar body condition to that of contracepted ones suggest that food is unlikely a limiting factor for free-ranging horses at THRO. This is primarily due to the conservative management of multiple species of ungulates and their food resources [77–79]. The consequence of this approach is that only under the most extreme climatic conditions, such as prolonged drought, will forage be limiting to herbivores at THRO, regardless of reproductive status.

The only detectable adverse side effect of vaccination was intramuscular swelling at the vaccination site. Mares treated with GonaCon-Equine consistently showed evidence of inflammatory reactions at the injection site. While we never observed lameness associated with this reaction, several mares revealed draining abscesses within one-year post-vaccination. This is consistent with results for other wild ungulates treated with the same or similar GonaCon vaccines [13, 15, 34]. Given the designed highly inflammatory nature of both the adjuvant, which contains killed mycobacteria and non-biodegradable oil, as well as, the foreign protein carrier molecule, these types of reactions are predictable. In fact, they are likely necessary for optimum vaccine efficacy [80]. It is impossible to assess the total impact of these lesions on animal welfare; however, in this investigation, these did not have a measurable effect on body condition, locomotion, or social behaviors. Therefore, until additional research suggests otherwise, we conclude that the presence of injection site lesions following GonCon vaccination do not pose a serious contraindication associated with the application of this vaccine, and there appear to be minimal long-term effects on individual animal welfare.

Conclusions

Controlling abundance of wildlife species that are simultaneously protected, abundant, competitive for resources, and in conflict with some stakeholders is a formidable challenge for resource managers. We demonstrated that the GnRH vaccine, GonaCon-Equine, could be an effective immunocontraceptive for free-ranging feral horses, particularly when the primary vaccination is followed by reimmunization four years later. This vaccine was shown to be safe for pregnant females and neonates and did not result in deleterious behavioral side effects during the foaling/breeding season. The only adverse reactions to vaccination were non-debilitating inflammatory responses at injection sites. One noteworthy implication has emerged regarding long-term management of free-ranging horse populations using GonaCon-Equine vaccine: effective management and development of population models will need to incorporate repeat immunizations of this vaccine to optimize management strategies aimed at stabilizing the growth rate of feral horse populations. Our research suggests that practical application of this vaccine in feral horses will require an initial inoculation that may provide only modest suppression of fertility followed by reimmunization over time that together could result in greater reduction in population growth rates. Future research will begin to define the most effective revaccination schedule with GonaCon-Equine for suppressing reproductive rates in

free-ranging horses, the duration of effectiveness, and the return to fertility following treatment. Moreover, applying GonaCon-Equine to control the growth of feral horse populations will require that resource managers choose specific tactics for treating animals. Choices must be made on the number and age to treat and the frequency of treatment needed to maintain the desired population age structure and genetic diversity. Decisions on the most beneficial tactics will depend on overarching management goals and long-term objectives for the population.

Acknowledgments

This research could not have been conducted and completed without the tireless dedication and commitment from numerous field research technicians: Julien Appignani, Neali Austin, Maggie Bauer, Deb Carson, Lindsey Eby, Lincoln Eddy, Heidi Garbe, Johanna Hodge, Wade Jones, Alana Kirby, Jan Peterson, Tiana Pirtle, Al Schaefer, Jennifer Schaefer, Rachel Serkasevich, Hedrick Strickland, Melissa Thompson, Marylu Weber, Henry Weber and many volunteers that kept vigilant eyes on these study horses throughout the year. A special thanks to Marylu and Henry Weber for being a part of this project since its conception in 2009 and for sharing historical records, photographic files, their extensive knowledge of all the horses in this Park and above all else, their steadfast support and good friendship. Many thanks to the superintendents at Theodore Roosevelt National Park, Valerie Naylor and Wendy Ross, for their unwavering support of our endeavors to conduct meaningful and practical research at THRO. Glen Sargeant provided significant statistical support in the design of this experiment. Paul Griffin provided a much-appreciated critical review of an earlier version of this manuscript. Thanks to Brenda Martin for her experience and patience in handling administrative issues. We also thank U.S.D.A., Animal Plant Health Inspection Service, National Wildlife Research Center for administrative and technical support throughout this project.

ABSTRACT

Suppression of cyclic activity in cattle is often desired in alpine farming and for feedlot cattle not intended for breeding. A cattle-specific anti-GnRH vaccination (Bopriva, Zoetis Australia Ltd., West Ryde, Australia) is approved for use in heifers and bulls in New Zealand, Australia, Mexico, Brazil, Argentina, Turkey, and Peru. Eleven healthy, cyclic Swiss Fleckvieh cows were included in the study and vaccinated twice with Bopriva 4 wk apart. Injection site, rectal body temperature, and heart and respiratory rates were recorded before and 3 d following each vaccination. Blood samples were taken weekly for progesterone and estrogen analysis and to determine GnRH antibody titer. Ovaries were examined weekly, using ultrasound to count the number of follicles and identify the presence of a corpus luteum. Thirty weeks after the first vaccination, the cows were subjected to a controlled internal drug-releasing device-based Select-Synch treatment. The GnRH antibody titers increased after the second vaccination and peaked 2 wk later. Estrogen levels were not influenced by vaccination, and progesterone level decreased in 7 of 11 cows up to 3 wk after the second vaccination and remained low for 10 to 15 wk following the second vaccination. The number of class I follicles (diameter $\leq$5 mm) was not influenced by vaccination, whereas the number of class II follicles (diameter 6–9 mm) decreased between 7 and 16 wk after the first vaccination. Class III follicles (diameter >9 mm) were totally absent during this period in most cows. The median period until recurrence of class III follicles was 78 d from the day of the second vaccination (95% confidence interval: 60–92 d). After vaccination, all cows showed swelling and pain at the injection site, and these reactions subsided within 2 wk. Body temperature and heart and respiratory rates increased after the first and second vaccinations and returned to normal values within 2 d of each vaccination. The cows in our study were not observed to display estrus behavior until 30 wk after the first vaccination. Therefore, a Select-Synch protocol was initiated at that time. Ten cows became pregnant after the first insemination (the remaining cow was reinseminated once until confirmed pregnancy). Bopriva induced a reliable and reversible suppression of reproductive cyclicity for more than 2 mo. The best practical predictor for the length of the anestrus period was the absence of class III follicles.

Key words: anti-gonadotropin releasing hormone (anti-GnRH), gonadotropin releasing hormone (GnRH), immunization, antibody titer, anestrus

INTRODUCTION

Estrus inhibition is frequently requested by livestock owners. Preventing recurrent estrus is desired for alpine farming and for feedlot cattle not intended for breeding. These cows, when untreated, cause disturbance in the herd during estrus and, additionally, are often pregnant at slaughter. In contrast to surgical methods (ovariectomy; Hobson and Hansel, 1972; Bleul et al., 2005), mechanical contraception methods (foreign objects in the uterus; Turin et al., 1997), or permanent administration of progesterone derivatives (Burns et al., 1993; Jacobsen et al., 1995; Denicola et al., 1997; Petta et al., 1998), immunological techniques represent an animal-friendly method for controlling populations (Miller et al., 2000; Curtis et al., 2002). Immunization against GnRH has been used to suppress sexual behavior and to prevent the development of secondary sexual characteristics in males (Finnerty et al., 1998; Cook et al., 2000; Thompson, 2000; D'Occhio et al., 2001; Aïssat et al., 2002; Janett et al., 2003, 2009b, 2012a; Turkstra et al., 2005; Theubet et al., 2010) as

well as in females (Dalin et al., 2002; Imboden et al., 2006; Elhay et al., 2007; Janett et al., 2009a). In heifers, administration of a human chorionic gonadotropin or LH vaccine (Johnson et al., 1988), as well as a GnRH vaccine (Johnson et al., 1988; Adams and Adams, 1990; Prendiville et al., 1995; Bell et al., 1997; Stevens et al., 2005), has been tested. It could be demonstrated that antibody titers, ovarian function, progesterone concentration, and uterus weight differed significantly after immunization with a recombinant GnRH antigen from nonimmunized heifers (Geary et al., 2006). Note that these studies all used different presentations of the GnRH antigen as well as different adjuvants. Immunization with GnRH prevented the growth of follicles >5 mm in diameter and induced anestrus. However, as in mature mares (Dalin et al., 2002; Imboden et al., 2006), the effect of the vaccine varied individually in terms of duration and behavior (Prendiville et al., 1995; Crowe et al., 2001). No information is available in the literature regarding reversibility to estrus in cows after vaccination against GnRH.

The aim of the present study was to evaluate the effect of an active immunization against GnRH (Bopriva, Zoetis Australia Limited, West Ryde, Australia) on GnRH antibody titer, plasma progesterone and estrogen concentrations, and ovarian activity. Of particular interest were the duration and reversibility of the vaccination-induced anestrus. We hypothesized that the vaccine would increase GnRH antibody titer, decrease the plasma concentrations of progesterone and estrogen, and reduce the number of follicles >5 mm in diameter and therefore induce a phase of anestrus of unknown length. Once pregnancy was confirmed, cows were terminated from the study.

MATERIALS AND METHODS

Animals and Inclusion and Exclusion Criteria

Eleven lactating Swiss Fleckvieh cows (cows A through M), from second to sixth lactation (median = third lactation) and 88 to 201 d postpartum (median = 137 d) were included in the study. Inclusion criteria were regular cyclicity before first treatment and uterine health. A uterine swab was taken in diestrus for microbiological and cytological analysis. Results of microbiological samples had to be negative on bacterial culture, and less than 5% neutrophils (as a proportion of total cells) had to be counted to demonstrate uterine health, according to Gilbert et al. (2005). Exclusion criteria were a history of preceding dystocia or caesarian section, acute or chronic endometritis, cystic ovarian disease, or general diseases (e.g., chronic mastitis, claw diseases).

Animal Care and Housing

The cows were housed in tie-stalls on straw bedding. From May to October, the cows had daily access to pasture. During winter months, they had access to a courtyard 3 times a week. They were fed an individually calculated ratio of hay and concentrate determined on the basis of individual milk yield, had free access to water, and were milked twice daily.

Treatment with GnRH Vaccine

The treatment consisted of 2 vaccinations (initial and booster) with the anti-GnRH vaccine Bopriva (Zoetis Australia Ltd.) 4 wk apart (d 0 and 30). Bopriva contains an analog of GnRH linked to a carrier protein combined with a synthetic aqueous adjuvant (400 μg of GnRH-protein-conjugate per mL) and is registered with claims to suppress testosterone blood levels in postpubertal bulls and estrus behavior in postpubertal heifers. The dosage used for both the initial and the booster vaccination was 400 μg of GnRH-protein-conjugate (1 mL of Bopriva). All injections were administered subcutaneously on the right side of the neck.

All animal experimentation was performed with permission and in accordance with Swiss law (Nr. BE 29/11).

Clinical Evaluation and Side Effects

Clinical evaluation included the parameters of body temperature, heart and respiratory rates, and daily milk production. The injection site was meticulously inspected for signs of tissue reaction. Cows were examined directly before each vaccination (d 0) and daily on the following 3 d or until all parameters examined had returned to normal. Estrus behavior observation was conducted daily after feeding on pasture or in the courtyard.

Blood Sampling, GnRH Antibody Titer, and Hormones

In all animals, blood was sampled weekly starting 3 wk before vaccination until pregnancy was confirmed. The blood samples were collected by venipuncture from the coccygeal vein into heparinized tubes and centrifuged (4,000 × *g*, 10 min), and plasma was then stored at −18°C for later analysis.

GnRH Antibody Titers. Antibody titers of GnRH were determined by dissociation-enhanced lanthanide fluorescence immunoassay (**DELFIA**; PerkinElmer Pty Ltd., Glen Waverly, Australia) and results were expressed as relative light units (**RLU**). Briefly, 384-well,

streptavidin-coated plates (PerkinElmer Pty Ltd.) were coated for 1 h at room temperature with 1 μg/mL of biotinylated modified GnRH peptide in DELFIA buffer (50 m*M* Tris-HCl, 0.9% NaCl, 0.05% Tween 20, 20 μ*M* EDTA, 0.2% ovalbumin). Plates were washed and then incubated for 1 h at room temperature with 50-μL aliquots of cattle samples serially diluted to 1:800 in DELFIA buffer. Unbound plasma and antibodies were removed by washing, and bound antibody was detected by incubating plates for a further 1 h with 50 μL of europium-labeled protein G (PerkinElmer Pty Ltd.). After washing off excess europium-labeled protein G, DELFIA Enhancement Solution (PerkinElmer Pty Ltd.) was added to all wells to dissociate bound lanthanide from the antigen, forming a highly fluorescent chelate. After 10 min, the intensity of fluorescence was measured by excitation at 340 nm and emission readings at 615 nm using a time-resolved fluorometer (Envision 2102 Multireader, PerkinElmer Pty Ltd.). Pooled nonvaccinated cattle samples served as a negative control. Unknown samples were compared with serial dilutions of a standard positive reference immune cattle sample. Calculation of a standard curve and reading of unknown samples were performed using the WorkOut 2.5 software (Dazdaq Solutions Ltd., East Sussex, UK). Intra- and interassay coefficients of variation (**CV**) were 6.7 and 8.5%, respectively. Serology titers showed a 120-fold range from 3,850 RLU for negative samples to 495,000 titers units for immune samples, with 11,500 RLU being taken as the lower cut-off differentiating positive from negative samples. The lowest detection level of GnRH antibody titer was 3,850 RLU.

Hormone Analysis. Progesterone concentration was measured using RIA (Immunotech, Beckman Coulter, Sinsheim, Germany). The intraassay CV was 5.3% and the interassay CV was 7.7%, determined by using a bovine serum pool measured 30 times within a test routine and within 25 assay runs. The analytical sensitivity was 0.05 ng/mL and the measurement range was 0.05 to 50 ng/mL. The assay was performed according to the manufacturer's instructions. Total estrogen concentration was measured after cleavage of glucoronidated and sulfated estrogen by using 0.2% β-glucoronidase-acrylsulfatase (Merck, Darmstadt, Germany) for 2 h at 37°C in sodium actetate buffer (Sigma Aldrich, pH 4.8). Then, steroid hormones were extracted from plasma (300 μL) by adding 3 mL of ether (30% butylmethylether, 70% benzene). Then, a direct enzyme-immunoassay on microtiter plates using a secondary antibody-coating technique and horseradish peroxidase as the enzyme label were used to measure total estrogen concentration. The enzyme-immunoassay was previously described by Meyer et al. (1990) and Prakash et al. (1987). The used antiserum was raised against 17-estradiol hemisuccinate, and 17-estradiol hemisuccinate horseradish peroxidase was used as steroid-enzyme conjugate (purchased from Technical University of Munich, Freising-Weihenstephan, Germany). The intra- and interassay CV were calculated by repeated measurements of bovine plasma samples. The minimal detectable concentration was 8 pg/mL. The recovery was 84.6 to 96.2%, the intraassay CV was 8.5% and the interassay CV was 17.4%.

Gynecological Examination, Insemination, and Pregnancy

The cows were examined weekly by rectal palpation until they were inseminated. Using ultrasonography (Aquila Pro Vet, Esaote Piemedical, Köln, Germany), the number of follicles was recorded and assigned to 1 of 3 categories, according to the classification of Moreira et al. (2000): class I follicles (≤5 mm in diameter), class II follicles (6–9 mm in diameter), and class III follicles (>9 mm and <2 cm in diameter) (Vanholder et al., 2006). The presence of a corpus luteum (**CL**) was also noted. Thirty weeks after the first vaccination, all cows were treated with a Select-Synch protocol and inseminated. The Select-Synch protocol started with an injection of 20 μg of buserelin i.m. (Receptal, MSD Animal Health GmbH, Lucerne, Switzerland) and an intravaginal progesterone-releasing device containing 1.9 g of progesterone (Eazi-Breed CIDR B, Zoetis, Zurich, Switzerland). Six days later, the cows were injected with 500 μg of cloprostenol i.m. (Estrumate, MSD Animal Health GmbH), and the CIDR was removed the next day. Cows were inseminated 48 and 72 h after CIDR removal and received 20 μg of buserelin i.m. with the first insemination. Pregnancy diagnosis was performed 35 d after the first insemination. Cows not pregnant were further treated individually. Cows with confirmed pregnancies were slaughtered.

Statistical Analysis

Metric variables were described with means, medians, standard deviations, and ranges. Categorical data were analyzed by using contingency tables. We applied nonparametric methods, as the rank correlation coefficient for the relationship of variables that were at least ordinal, and nonparametric confidence intervals. The cow was the statistical independent unit; we observed dependent data within each cow. Because the number of cows was small, we could not apply simple statistical methods, and more sophisticated methods were not appropriate. Hence, *P*-values (e.g., of the rank correlation or χ^2 test of the contingency tables) should be interpreted only as an explorative indication. Only

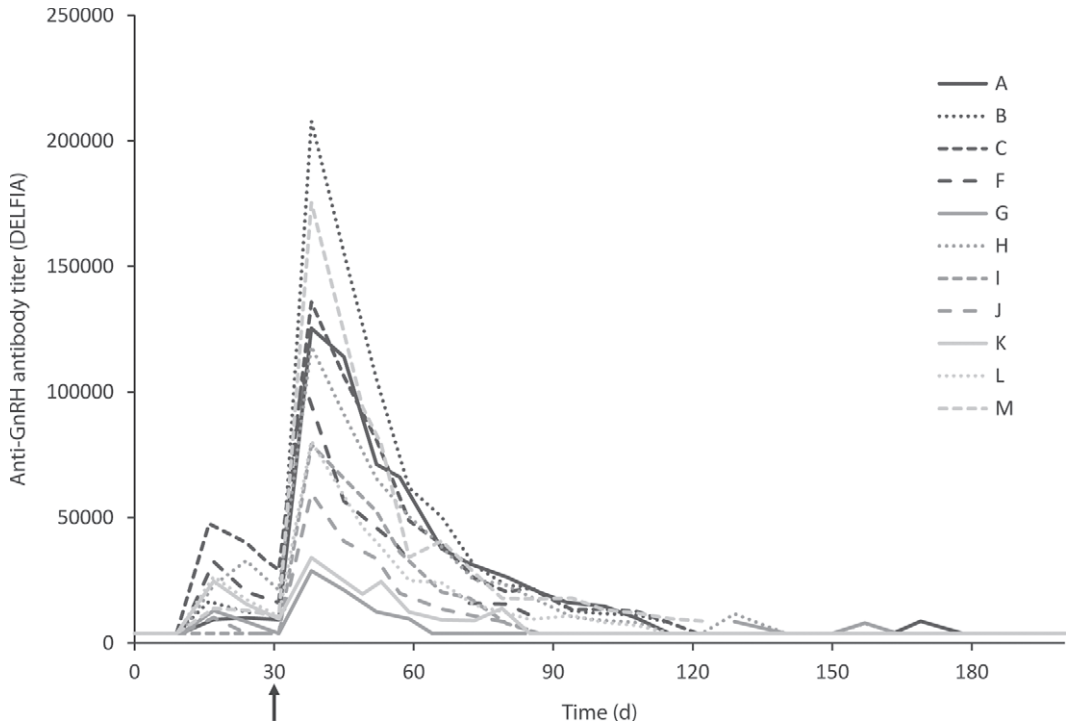

Figure 1. Gonadotropin-releasing hormone antibody titers of 11 cows (A through M) after 2 vaccinations (d 0 and d 30, arrow) with anti-GnRH vaccine (Bopriva, Zoetis Australia Ltd., West Ryde, Australia). Peak values are shown 6 wk after the first vaccination. DELFIA = dissociation-enhanced lanthanide fluorescence immunoassay.

when the cow was used as statistical unit were the *P*-values of test and nonparametric confidence intervals appropriate and exact. We used SAS software (SAS Institute Inc., Cary, NC) and Statxact software (Cytel Inc., Cambridge, MA) for the statistical analyses.

RESULTS

GnRH Antibody Titers

Antibody titers began to increase 2 to 3 wk after the first vaccination but increased significantly after the second vaccination and reached peak values at approximately 6 wk after the first vaccination (Figure 1). Titers decreased to basal values approximately 12 to 17 wk after the first vaccination in all cows. In 7 of 11 cows, the titers remained at basal levels for the rest of the study. In 4 cows, titers increased slightly from basal values at wk 18 and 22 (cows G and H, respectively) and at wk 24 and 25 (cows A and F, respectively). The GnRH antibody levels were below the detection limit at the time of insemination in all cows. A large variation in the maximum titer was seen in individual vaccinated cows, ranging between 21,174 units (cow G) and 207,830 units (cow B). A titer exceeding 3,850 units (detection limit) was found from 17 d (95% CI: 16.5–17) to 97.5 d (95% CI: 83–111.5) after the first vaccination.

Plasma Progesterone and Estrogen Concentration

The maximal plasma progesterone concentration measured during the entire study was 49 ng/mL and the minimal value was 0.1 ng/mL (Figure 2). The maximal plasma total estrogen concentration measured during the study was 102.0 pg/mL and the minimal value was the detection limit of 8 pg/mL.

At the time of the first vaccination, 6 cows (A, B, F, G, L, M) showed plasma progesterone concentrations >3 ng/mL, 4 cows (H, I, J, K) had values <1 ng/mL, and cow C had a concentration of 1.8 ng/mL. The individual plasma progesterone level fluctuated greatly in the first weeks after vaccination. In 7 cows (A, B, C, G, H, K, M), plasma progesterone decreased to a basal level 3 to 7 wk after the first vaccination (i.e., up to 3 wk after the booster) until wk 14 to 19. After this time, an increase in plasma progesterone concentration was apparent in 6 cows (A, C, G, H, K, M). One cow (F) showed an increase in plasma progesterone concentration from wk 5 that remained high until wk 16. Cows I and J showed a plasma progesterone concentration >5 ng/mL in wk

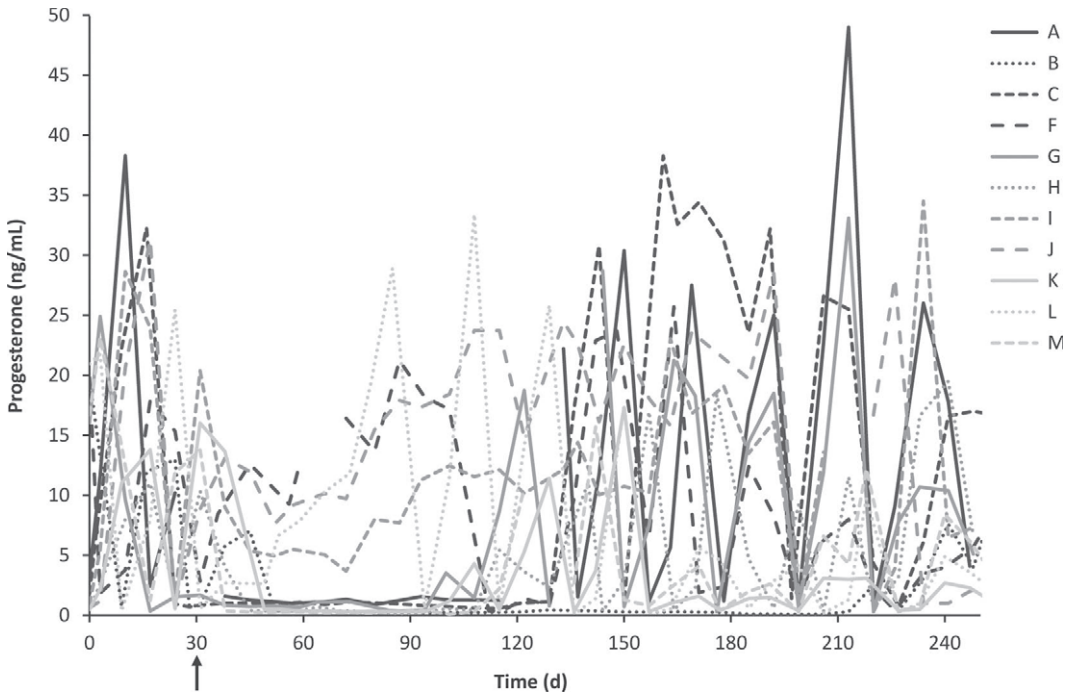

Figure 2. Plasma progesterone values of 11 cows (A through M) after 2 vaccinations (d 0 and d 30, arrow) with anti-GnRH vaccine (Bopriva, Zoetis Australia Ltd., West Ryde, Australia).

5, which increased above 10 and 15 ng/mL until wk 28 and 17, respectively. The plasma progesterone level of cow I returned to a fluctuating pattern after wk 28. In cow J, progesterone levels between 15 and 25 ng/mL were measured during wk 17 and 28. Cow L showed a continuous increase of the plasma progesterone level from wk 5 to 12 and reached a peak value of 28.9 ng/mL. The level of plasma progesterone concentration was positively correlated with the presence of a CL (Spearman r = 0.75; $P < 0.0001$).

Seven cows (A, B, C, F, H, I, J) showed fluctuating values of total plasma estrogen concentration during the study (data not shown), with peak values of 33.1 to 58.3 pg/mL, and minimal values below the detection limit. Cows K, L, and M showed fluctuating values until wk 11 after the first vaccination and then the values decreased below the detection limit until insemination, except for a very slight increase for cows L and M in wk 15 and 19, respectively. Cow G showed fluctuating values of total plasma estrogen concentration throughout the study, with very high peak values (102.0 pg/mL at wk 13).

Ovarian Ultrasonography

The number of class I follicles did not vary for 30 wk after the first immunization (Figure 3), whereas the number of class II follicles decreased between wk 7 and 17, although they were still present in some cows. Class III follicles were completely absent from wk 7 (±2 wk) to wk 16 (±3 wk) after the first vaccination (i.e., 3 wk after the booster) in all the cows except for cow G (Figure 4 a,b).

At the time of the first vaccination, a CL was present in 70% (8/11) of the cows. Four of the 11 cows developed a persistent CL over a maximum of 166 d after the second vaccination.

Figure 5 illustrates the correlation between GnRH antibody titers (d 17–97.5) and number of class III follicles; fewer class III follicles were present when GnRH antibody titers were high ($P < 0.0001$; phi coefficient = −0.461).

Pregnancy Diagnosis

Ten of 11 cows were confirmed pregnant 35 d after insemination following the Select-Synch protocol; 1 cow (J) was not pregnant at this time. In cow J, a CL on the right ovary and some class II follicles on both ovaries were observed, and the uterus showed no pathological findings. The cow was injected with 500 μg of cloprostenol i.m. (Estrumate, MSD Animal Health GmbH) on d 39 postinsemination and with 20 μg of buserelin i.m. (Receptal, MSD Animal Health GmbH) on d 41. Inseminations were performed on d 41 and 42 and she was confirmed pregnant 35 d later.

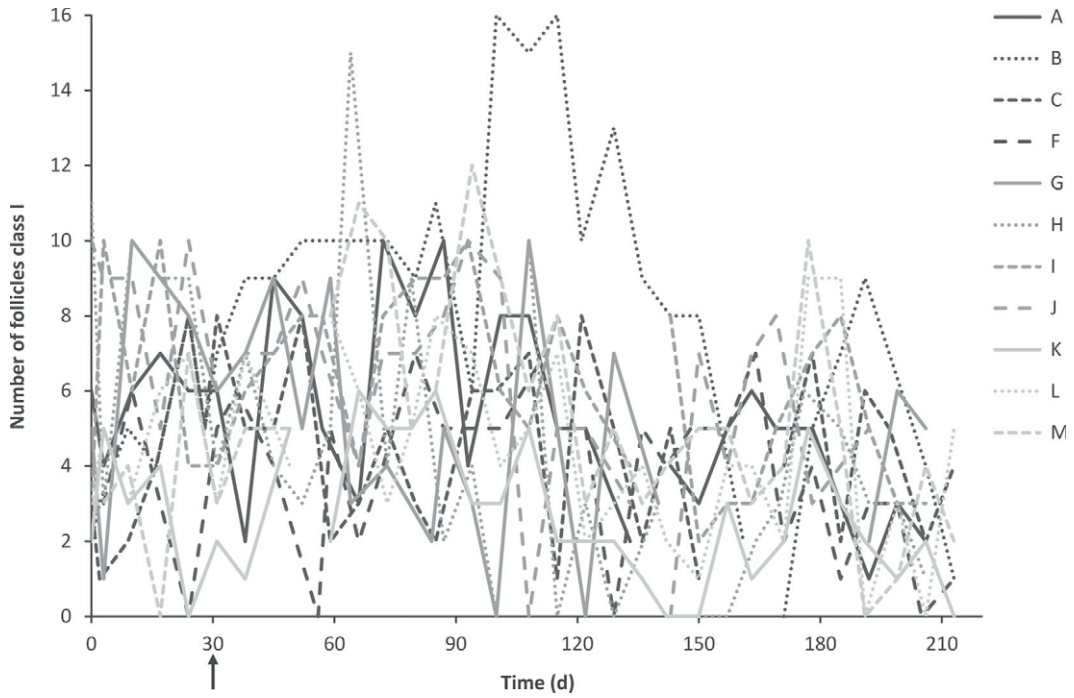

Figure 3. Number of class I follicles of 11 cows (A through M) after 2 vaccinations (d 0 and d 30, arrow) with anti-GnRH vaccine (Bopriva, Zoetis Australia Ltd., West Ryde, Australia).

Clinical Evaluation and Adverse Effects

No estrus behavior was observed in the GnRH-vaccinated cows even after anti-GnRH titers reached basal values and although class III follicles and the presence of a CL on the ovaries indicated resumption of reproductive cyclicity.

All cows treated with Bopriva showed a swelling at the injection site (varying in severity) and moderate to substantial local pain. In all animals, the local reactions subsided within 2 to 4 wk. A transient increase in rectal body temperature was apparent 24 h after the first (median; 25% and 75% quartiles: 39.2°C; 39.1°C, 40.3°C) and the second vaccination (39.5°C; 38.8°C, 40.4°C; Table 1). Heart rate (beats per min) increased after the first (88; 84, 100) and the second (88; 80, 90) vaccinations and returned to normal within 48 h after vaccination. Respiratory rate (breaths/min) increased after the first (34; 36, 56) and the second (32; 40, 48) vaccinations and returned to normal within 48 h postvaccination. No signs of apathy, reduced food intake, or decrease in milk production were observed. In 1 cow (J), a hydrometra was diagnosed 28 wk after the first vaccination and was successfully treated with 500 μg of cloprostenol i.m. (Estrumate, MSD Animal Health GmbH).

DISCUSSION

All cows showed similar patterns of GnRH antibody production after immunization, with a rapid onset of immune response and a peak 2 to 3 wk after the second vaccination. However, the maximal values of individual anti-GnRH antibodies varied greatly, due to the multistep involvements required for the immune system to establish antibodies to exposed antigens, as well as the individual variation in terms of the condition of the animals, their nutritional state, and a strong genetic component for major histocompatibility complex (Fluri et al., 2006).

Antibody titers >3,850 (detection limit) were found between 17 and 97.5 d after the first vaccination. This duration of effect is consistent with results in pubertal bull calves (Theubet et al., 2010; Janett et al., 2012a) but shorter than that observed in prepubertal bull calves (Janett et al., 2012b). The longer duration seen in prepubertal bull calves is most likely due to the vaccine resulting in a delay in the onset of puberty.

As expected, the number of class I follicles was not influenced by vaccination. Class I follicles in cattle are independent of gonadotropin (Campbell et al., 1995). The number of class II follicles was partly reduced, but class II follicles did not completely disappear after the second vaccination. In heifers, follicles with a diameter >5 mm are suppressed after vaccination against GnRH (Prendiville et al., 1995; Crowe et al., 2001). In our study, class III follicles were completely absent in 10 of 11 cows between 7 and 16 wk following 2 vaccinations of Bopriva. Cow G exhibited a low immune response to Bopriva as reflected in low GnRH antibody titers

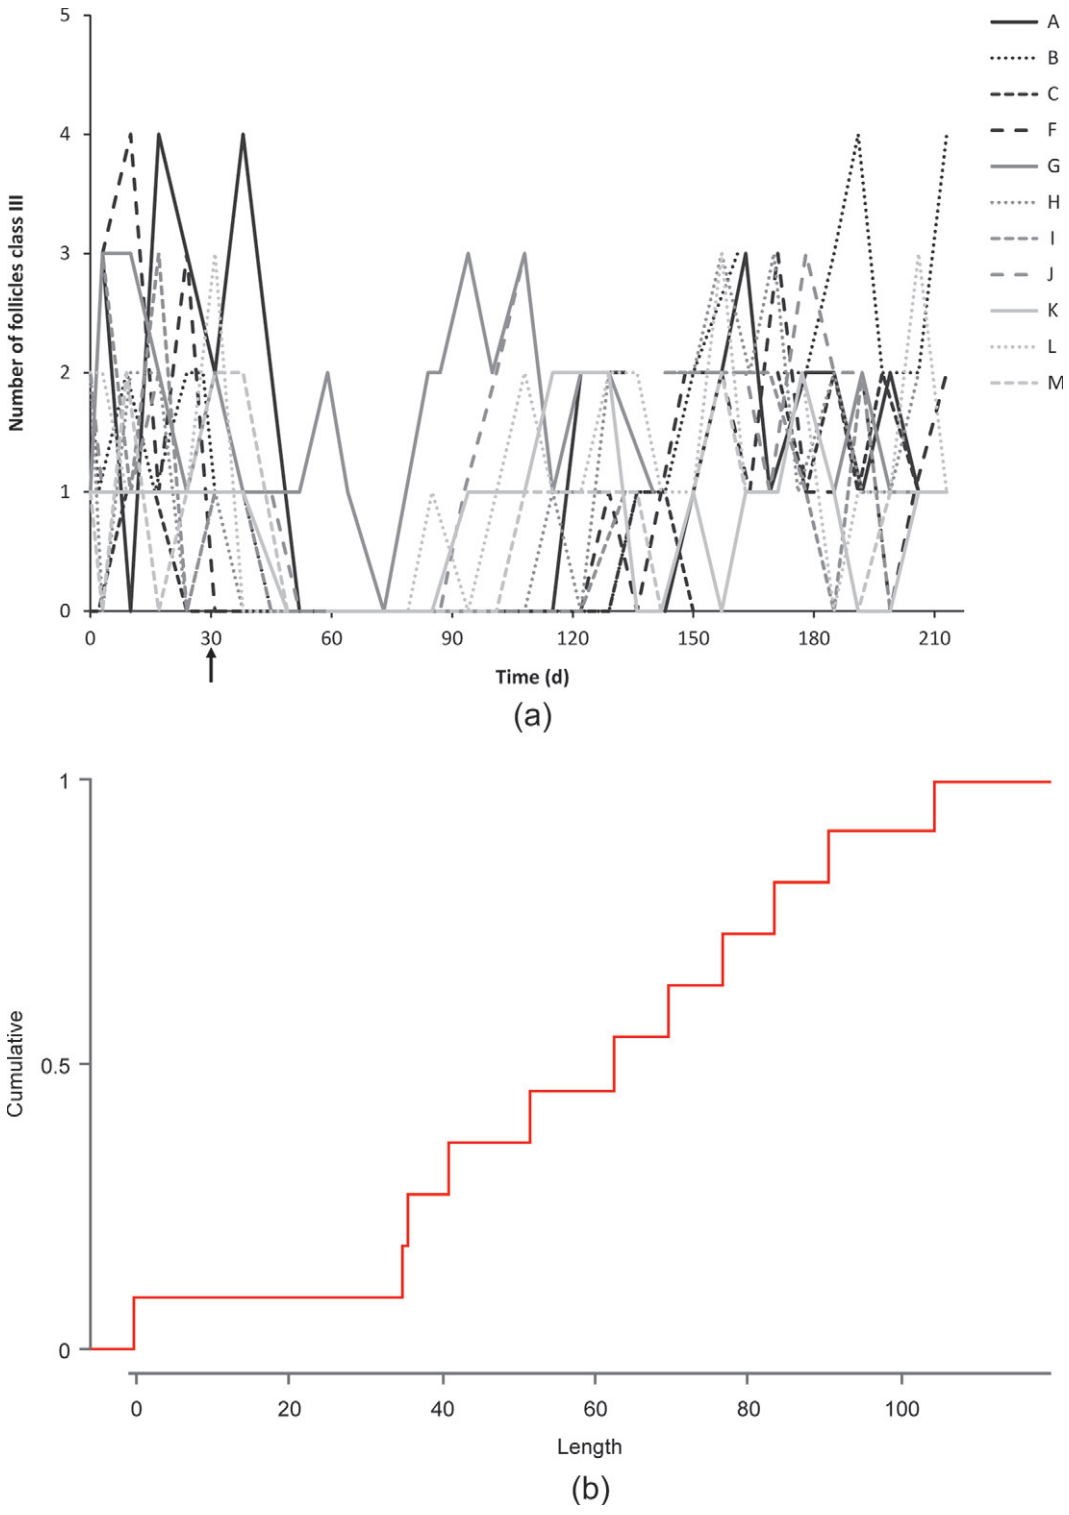

Figure 4. (a) Number of class III follicles of 11 cows (A through M) after 2 vaccinations (d 0 and d 30, arrow) with anti-GnRH vaccine (Bopriva, Zoetis Australia Ltd., West Ryde, Australia). These follicles were completely absent from wk 7 (±2 wk) to wk 16 (±3 wk) for all the cows except for cow G. (b) Survival analysis of class III follicles (empirical distribution, function of length in days of absence of class III follicles until class III follicles are present again). Color version available in the online PDF.

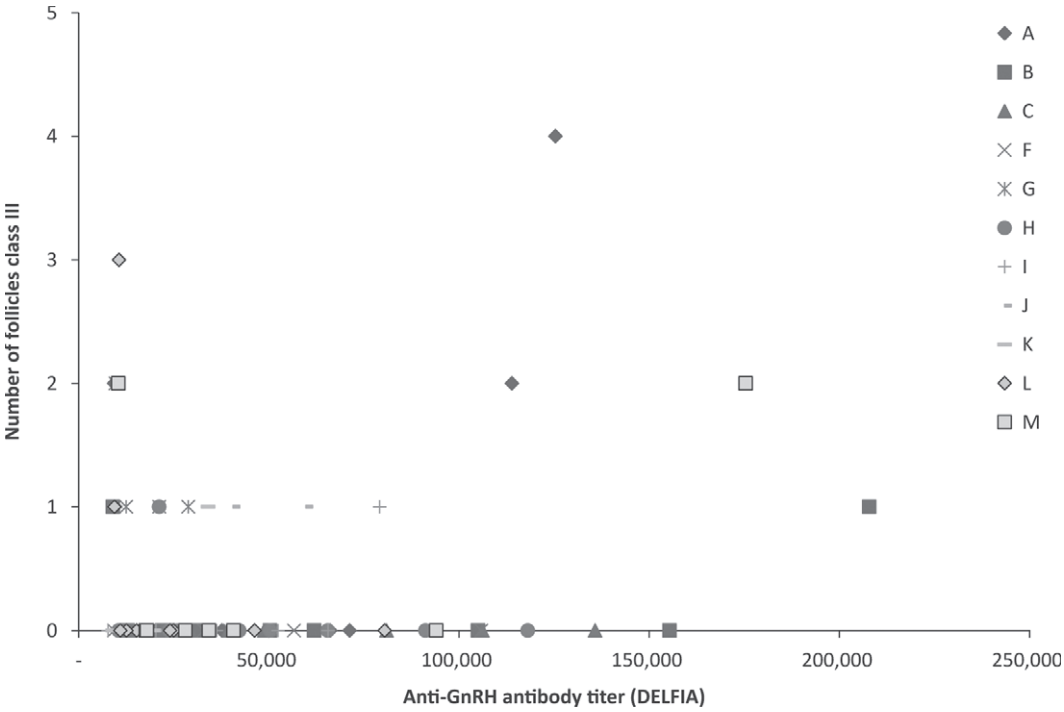

Figure 5. Association of class III follicles with GnRH antibody titer. DELFIA = dissociation-enhanced lanthanide fluorescence immunoassay.

Table 1. Temperature, heart rate, and respiration before vaccination (d 0) and on the 3 d following the first vaccination (1) with anti-GnRH vaccine (Bopriva, Zoetis Australia Ltd., West Ryde, Australia) and the second vaccination (2)

Trait	25% quartile	Median	75% quartile
Temperature (°C)			
d 0 (1)	38.1	38.4	38.4
d 1 (1)	39.1	39.2	40.3

d 2 (2)	30	32	52
d 3 (2)	28	35	42

and, subsequently, large follicle development was not suppressed. Earlier studies in cattle suggest that recruitment of follicles is likely to be FSH-dependent and that selection and growth of follicles above 7 to 9 mm in diameter is LH-dependent (Gong et al., 1996; Bao et al., 1997).

Plasma progesterone (e.g., estrus values vs. diestrus values) at the time of the first vaccination did not affect later values of plasma progesterone concentration during the study. Despite the production of GnRH antibodies, 4 cows showed a CL and a plasma progesterone concentration >1 ng/mL. Earlier studies in heifers and ewes (Hixon et al., 1975; Hughes et al., 1987) suggested that estradiol production from follicles could play a role in luteolysis; therefore, the suppression of follicle development could prolong the lifespan of a CL (Okuda et al., 2002). The lack of class III follicles might explain why no luteolysis occurred in some cows. In our study, the total plasma estrogen concentration was not affected by the production of GnRH antibodies. A good correlation exists between total estrogen and estradiol-17β (Mondal et al., 2006). Other studies in mares (Dalin et al., 2002; Imboden et al., 2006) and heifers (Prendiville et al., 1995) described a reduced estradiol-17β level after GnRH vaccination. Dalin et al. (2002) indicated that in mares, the estrus cycle stage at first immunization might have an influence on hormonal levels. Furthermore, in the study of Dalin et al. (2002), ovarian atrophy in mares did not correlate with cycle blockade. Among all parameters evaluated in our study, the suppression of class III follicles was the most reliable and easily detectable parameter for clinicians to predict the efficiency of the vaccine. Large follicles are almost always present in healthy cyclic cows because follicle growth occurs in waves (Lucy et al., 1992). In this study, the class III follicles were absent from wk 7 to 16 after the primary vaccination and cows entered anestrus approximately 3 wk after the booster injection. An important finding of the current study was that the immunization against GnRH was entirely reversible as shown by the return to basal levels of the GnRH antibody titer and with successful insemination of all the cows. These results confirm that Bopriva can be used in a safe manner in cows, as already seen in bull calves (Theubet et al., 2010; Janett et al., 2012a,b). In our study, the general condition and milk yield of cows were not disturbed by the vaccine, despite a short-term increase in rectal body temperature and a local reaction at the site of vaccination (data not shown). One noteworthy adverse effect was the hydrometra developed by cow J. This was the only cow needing 2 inseminations to become pregnant. The authors did not find any other case of hydrometra published in conjunction with the use of GnRH immunization. It is unclear whether it occurred causally or as a coincidence.

In addition to seasonal breeding systems, temporary immunization against GnRH could be used in seasonal alpine pasturing systems. Cows not pregnant during the seasonal alpine pasturing disturb the herd because of recurring estrus behavior. This is especially accentuated in the Swiss Hérens breed, which is raised for fighting and selected for dominance abilities (Plusquellec and Bouissou, 2001). Suppression of estrus during alpine pasturing is highly valued but, with the exception of intravaginal progesterone devices, currently no pharmaceuticals are permitted in Switzerland for production animals. Immunization against GnRH could be considered an animal-friendly solution for these cows and producers.

The cows in our study were not observed to be displaying estrus behavior until wk 30, when the Select-Synch protocol was started. In future studies, we plan to evaluate estrus behavior and return to cyclicity of cows in herds that include a bull. Alternatively to using a bull, heat detection patches could be used. Furthermore, a large clinical field study is planned, in which we will evaluate the influence of cycle stage at first and second vaccinations on characteristics of hormones and behavior.

ACKNOWLEDGMENTS

Evaluation of Somatic and Reproductive Immunotoxic Effects of the Porcine Zona Pellucida Vaccination

MATTHEW R. BARBER[1,2] AND RICHARD A. FAYRER-HOSKEN[1,2]*
[1]*Department of Large Animal Medicine, College of Veterinary Medicine, University of Georgia, Athens, Georgia 30602-7385*
[2]*Department of Physiology and Pharmacology, College of Veterinary Medicine, University of Georgia, Athens, Georgia 30602-7385*

ABSTRACT Immunological, immunocytochemical and fertility analyses were performed to determine the potential toxic side effects of porcine zona pellucida (pZP) vaccinations on target animals, including horses and dogs. The study was designed to determine the effect of antibodies, raised against highly purified pZP, on somatic tissues. Immunocytochemical studies performed with fixed tissues showed that rabbit anti-pZP antiserum did not crossreact with brain, heart, lung, kidney, liver, bladder, stomach, small intestine, large intestine, muscle, skin, spleen, pancreas, or lymph node of either the dog or horse. To determine the effect or oral intake on nontarget animals, female rabbits were fed a contraceptive vaccine containing pZP glycoproteins and the synthetic trehalose dicorynomycolate in drakeol (S-TDCM) adjuvant. Enzyme-linked immunoadsorbent assay (LISA) analyses showed that rabbits fed with the adjuvanted pZP proteins did not develop circulating anti-pZP IgG antibodies that crossreacted with pZP. Furthermore, fertility studies performed on rabbits fed with adjuvanted pZP revealed no significant differences in the number of embryos or stage of the embryos produced between the treated and control animals. Results of these studies suggest that the pZP vaccine delivered to dogs or horses in field studies have no recognizable somatic tissue effects. Moreover, there were no side effects on nontarget animals should they eat the vaccine. This substantiates field trials results about the safety of the pZP immunocontraceptive vaccine. *J. Exp. Zool. 286:641–646, 2000.* © 2000 Wiley-Liss, Inc.

The zona pellucida (ZP) is an extracellular matrix that surrounds the oocyte of all mammalian species. The ZP is composed of several families of acidic glycoproteins that exhibit biological and immunobiochemical variation among various species (Dunbar et al., ’91). These glycoproteins have been assigned several different roles, of which species-specific sperm–egg interaction has been most investigated (Shur, ’81; Shur and Hall, ’82; Florman and Wassarman, ’85; Bleil et al., ’88; Miller and Ax, ’90; Yurewicz et al., ’91, ’93). If the mechanism of interaction between the zona pellucida and sperm could be interrupted, this would be a nonhormonal method of contraception.

Total porcine zona pellucida (pZP) has been the most common ZP antigen used so far for immunocontraception because of its immunological antigenicity and crossreactivity with many mammalian species (Sacco ’77; Trounson et al., ’80; Hasegawa et al., ’85; Kirkpatrick et al., ’96; Fayrer-Hosken et al., ’97b; Barber et al, ‘98) and the availability of pig ovaries in relatively large amounts. Immunization with pZP has resulted in immunocontraception in many animal model systems (Tsunoda and Chang, ’76; Gwatkin et al., ’77; Gulyas et al., ’83; Sacco et al., ’83; Bamezai et al., ’86; Sacco, ’87; Dunbar, ’89; Kirkpatrick et al., ’92a; Willis et al., ’94). In most of these cases, pZP induced a loss of fertility while blood levels of the antibodies, usually IgG, remained high. Alterations in fertility have been recorded for monkeys (Sacco et al., ’83), horses (Liu et al., ’89), and multiple zoological species (Kirkpatrick et al., ’96).

Although some side effects of the pZP vaccine have been reported, the precise mechanisms of action are unclear. The anti-pZP antibodies have been shown to affect the cyclicity, ovarian structure, and follicular development in dogs (Mahi-Brown et al., ’82) and primates (Lou et al., ’96; Garza et al., ’98). In dogs, immunization of bitches with an uncharacterized pZP preparation led to

long-term changes in estrous cycles and aberrant steroid profiles (Mahi-Brown et al., '85). Baboons immunized with pZP showed greatly reduced number of antral follicles and a drop in the blood levels of estrogen (Dunbar et al., '89). Kirkpatrick et al. ('92b) inoculated 10 feral mares with pZP and monitored fertility effects. After 5 consecutive years of treatment, urinary estrogen levels were shown to become elevated as in estrus. However, the estral phase was never followed by a luteal or progesterone phase. Generally, in most species there are no clinically detectable side effects with short-term immunocontraception.

In our previous studies on equine immunocontraception (Willis et al., '94), we have shown the efficacy of using the new adjuvant, synthetic trehalose dicorynomycolate in Drakeol (S-TDCM was kindly provided by Dr. Terry Ulrick, RIBI Immunochem Research Inc., Billings, MT), with the pZP. Our results demonstrated a 12–24 month increase in anti-pZP titers, which were associated with infertility. In addition, our laboratory has reported an immunocytochemical study on ovarian tissues from the dog, cat, horse, and elephant (Barber et al., '98). These results revealed that the anti-pZP antibodies crossreacted with ovarian tissues, specifically the zona pellucida. A practical concern for field applications of contraceptive programs would be the somatic tissue effects on target animals and fate of stray pZP darts, particularly if the expelled adjuvanted-pZP is ingested by a nontarget species. This study was carried out to assess immunocytochemistry of somatic tissues in efforts to evaluate the vaccine's safety for dogs and horses. In addition, the possibility of fertility effects of orally fed, adjuvanted pZP vaccine, in rabbits (nontarget species) was investigated.

MATERIALS AND METHODS

Preparation of the pZP antigen

Porcine ovaries were collected from an abattoir and stored frozen at –20°C until processed. Briefly, the ovaries were minced and the oocytes were isolated by sequentially sieving through nylon meshes of decreasing pore sizes. The oocytes were homogenized in a glass homogenizer, and the solubilized zonae pellucidae glycoproteins were obtained by heating the solution at 73°C for 20 min. This was followed by centrifuging at 10,000*g* for 1 hr to precipitate unwanted proteins. The purified pZP protein in the supernatant was separated and lyophilized. Protein estimations were performed according to Peterson ('76).

Immunohistochemistry of equine and canine formalin fixed somatic tissues

Fresh somatic tissue from euthanized dogs and horses were obtained at necropsy from Department of Pathology, College of Veterinary Medicine, University of Georgia. Fourteen different somatic tissues were taken from both canine and equine carcasses. Ovaries, used for positive control sections, were obtained from spayed dogs from local area veterinary clinics, and horse ovaries were obtained from horses euthanized for nonreproductive reasons. Small blocks (1 cm^3) of tissue were fixed in neutral buffered formalin immediately after being removed from the animal and then embedded in paraffin. Three-micrometer-thick sections were cut with a microtome and adhered to slides.

Sections were heated in a 60°C oven for 20 min followed by two washes with xylene in order to remove all paraffin. The sections were then rehydrated through an ethanol series followed by incubation in a 9:1 methanol/H_2O_2 solution for 30 min to remove endogenous peroxidase. Nonspecific binding sites on the sections were blocked by incubating sections in 5% BSA dissolved in Tris buffered saline (TBS) containing 0.05% Tween 20 (TBST) overnight. Rabbits that had been vaccinated with highly purified pZP provided the source of the anti-pZP IgG. The serum was diluted 1:1000 with TBST and 200 µl were applied to the tissue sections and incubated for 1 hr in a wet chamber. Negative control sections were treated with a similarly diluted normal rabbit serum. Sections were washed twice with TBS after incubation with primary antibody followed by incubation with 200 µl of goat anti-rabbit IgG biotin conjugate at a 1:1000 dilution for 30 min in a wet chamber. After incubation, the sections were washed twice with TBS and then treated with Extravidin peroxidase (1:100 in TBST, Sigma Chemical, St. Louis, MO) for 30 min in a wet chamber. Tissue sections were washed twice with TBS and treated with diaminobenzidine (DAB) for 2 min. Color reaction was stopped with running distilled water followed by counterstaining with Mayer's hematoxylin. Sections were then dehydrated through an ethanol series and permanently mounted. Ovarian sections from both dog and horse were used as the positive control. These sections were treated as the stated above somatic tissues. Observations were made with a Zeiss Axioscope microscope at 40 and 100× magnification.

Additional canine stomach tissues sections were

treated with alkaline phosphatase enzyme and nitroblue tetrazolium chloride (NBT) and 5-bromo-4-chloro-3-indolyl-phosphate (BCIP) in 100 mM Tris buffer as the substrate in the place of horseradish peroxidase/DAB.

Oral administration of pZP

A 0.5 ml sample of blood for pretreatment serum antibody levels was collected from the marginal ear vein of each rabbit prior to dosing. The vaccine was prepared by mixing one part of S-TDCM with nine parts of phosphate buffered saline (PBS) containing 0.4% Tween-80 and pZP. The solution was mixed in a glass grinder with a Teflon pestle and then passed 10 times through a 25-gauge needle fitted to a 10 ml syringe. The white emulsion was introduced into the oral cavity of the rabbit with the open end of a French tom cat catheter. A treatment group of four adult New Zealand white female rabbits was fed with 400 μg of pZP per rabbit, whereas the control group of four adult New Zealand white females received the same volume of emulsion without the pZP.

Embryo production and collection

Four days after feeding the pZP, the rabbits were superovulated by injecting each rabbit with 75 IU of eCG intramuscularly. Seventy-two hours later, each rabbit was mated one to three times with a proven male and then given 150 IU human chorionic gonadotropin (hCG) intravenously. Blood samples were again collected for determining the possible presence of anti-pZP antibodies in the serum. The rabbits were killed by cervical dislocation 24-hr later. The embryos from the treated and control rabbits were flushed from the oviducts with warm PBS and immediately observed and evaluated for stage of cell division.

pZP antibody estimation in orally dosed rabbit

Anti-pZP antibody in the serum was estimated by a standard enzyme-linked immunoadsorbent assay (ELISA). Microtitration plates (Immulon-4, Dynatech Laboratories, Inc., Chantilly, VA) were coated with solubilized isolated pZP 92 μg/well) in carbonate buffer (100 mM sodium carbonate-bicarbonate, pH 9.0) and incubated at 4°C overnight. All subsequent incubations were carried out at room temperature. The wells were washed with TBS and blocked with 5% BSA for 24 hr. Triplicates of the preimmune serum and the anti-pZP serum were assayed at a dilution of 1:1,000. After incubating with 50 μl of the primary antibody for 2 hr, the plates were washed three times with TBS. Then a second antibody, alkaline phosphatase labeled goat anti-rabbit IgG, was added and incubated for 2 hr. The plates were then washed with TBS and the enzyme activity detected by adding *p*-nitrophenyl phosphate in bicarbonate buffer. After 30 min the reaction was stopped by adding 50 μl 3 M sodium hydroxide. The absorbance was read in an ELISA plate reader at 405 and 492 nm.

RESULTS

Immunohistochemistry of equine and canine fixed somatic tissues

The cross-reactivity of rabbit anti-pZP serum with canine and equine somatic tissues was determined in formalin fixed, paraffin embedded sections of brain, heart, lung, kidney, liver, bladder, stomach, small intestine, large intestine, muscle, skin, spleen, pancreas, and lymph node. For each tissue tested, with the exception of canine stomach tissue, there was no observable staining as compared to controls. In the canine stomach, the Parietal cells' intracytoplasmic granules did show staining with the peroxidase/DAB system in both treatment and control. But on subsequent treatment the cells' contents were negative for staining with alkaline phosphatase/NBT-BCIP enzyme system.

Oral administration of pZP

The sera collected from the four rabbits fed with pZP and the four control rabbits were tested for the presence of anti-pZP antibodies by the ELISA method. Several dilutions of the sera ranging form 1:10 to 1:1,000 were assayed. At each of the dilutions tested, the absorbance readings were not significantly different from those of the serum control rabbits. The readings in both treatment and control groups were the same as the control wells (i.e., without the primary antibody or the preimmune serum).

Effects of embryo production

The oviductal embryos from superovulated rabbits orally fed with pZP and the control rabbits were successfully collected. The embryos ranged from the one-cell to the six-cell stages (Table 1). In both the control and treatment groups, maximum number of embryos were observed at the four-cell stage, which is the appropriate stage 24 hr postbreeding. For each of the stages examined, the number of embryos in the treatment rabbits was not significantly different ($P < 0.05$) from the

number of the control rabbits as determined by a pooled *t*-test (Table 1).

DISCUSSION

The potential toxic effects of vaccination with pZP in a mammal include ovarian follicle damage, somatic organ damage, inhibition of circulating hormones, induction of neoplasia, or autoimmune disease. Immunocytochemical results from formalin fixed, paraffin-embedded somatic tissue showed that, in light microscopy, anti-pZP antibodies do not bind to brain, heart, lung, kidney, liver, bladder, stomach, small intestine, large intestine, muscle, skin, spleen, pancreas, and lymph node of either the dog or horse. False initial positive staining of the canine parietal cells with the peroxidase enzyme system was most likely caused by the highly acidic nature of the parietal cells themselves. Parietal cells are located in gastric mucosa of the stomach, which produce gastric juice consisting of hydrochloric acid and intrinsic factor. These cells produce HCl at a pH of 0.8. This is 3 million times the hydrogen ion concentration of arterial blood (Berglindh, '84; Malinowska and Sachs, '84). However, the false positive results were clarified by the alkaline phosphatase enzyme system, which demonstrated that there was no binding to the parietal cells by the pZP antibodies. These results, compared with the positive control ovarian sections that show that rabbit anti-pZP antibodies crossreact with ovarian tissue, clearly support the follicular specificity of anti-pZP antibodies. From the immunocytochemical data and the field vaccination trials in horses (Kirkpatrick et al., '96) and elephants (Fayrer-Hosken et al., '97a), it is clear that the systemic effects of the pZP vaccination are minimal. Furthermore, preliminary results on Western blots of equine luteinizing hormone and equine chorionic gonadotropin with anti-pZP antibodies show no crossreaction with the glycohormones (Fayrer-Hosken, unpublished results).

Although the vaccine is systemically safe, what are the effects on reproductive physiology? In field studies, horses vaccinated for more than three consecutive years with pZP and Freund's adjuvant (Kirkpatrick et al., '92b) showed some signs of decreased luteal activity defined by depressed progesterone levels. Studies of dogs showed long-term alterations in estrus cycles and abnormal steroid profiles (Mahi-Brown, et al., '85). In many other species, vaccination with various pZP preparations has caused erosion of the follicle pool, leading to infertility (Sehgal et al., '89; Upadhyay et al., '89; Grootenhuis et al., '96; Paterson et al., '96). Although these effects are acceptable in some forms of population control in which the animal should be sterilized (e.g., feral dogs and cats), this is unacceptable in wildlife conservation and ecology (Fayrer-Hosken et al., '97b). However, the possible deleterious effects on follicle populations in the immunocontraception of wildlife can be avoided by limiting the number of years of sequential pZP vaccination, or vaccinating annually, but in different regions of the ecosystem.

A remaining problem of population control with pZP would be the potential effect on the fetus. The primary consequence would be reduction or loss of fertility in female offspring. Anti-pZP antibodies are passed through the placenta and colostrum (Sacco et al., '81) in female mice immunized with pZP. However, the potential target of anti-pZP antibody effects, the pZP, is not developed in the fetal horse ovary (Deanesly, '75). Hence, the potential degradation of follicular reserved in the fetuses is extremely insignificant. Moreover, offspring of dams vaccinated in utero have been shown to be fertile (Kirkpatrick et al., '96).

In most wildlife immunocontraception studies, pZP is delivered remotely. Currently the primary modes of remote delivery are darts (Kirkpatrick et al., '96) and biobullets (Willis et al., '94). A practical consideration of the delivery vehicles is what happens to the contents if they miss their target. Adjuvanted pZP would be liberated, and one possible outcome would be the ingestion of the material by nontarget species. To test the effect of this eventuality, rabbits were dosed with a full dose of adjuvanted pZP. This single oral dose did not induce detectable titers in the female rabbits. In addition, there was no inhibition of fertility as reflected in the number and stage of embryos. From this data, the likelihood of there being any deleterious effects on reproduction from oral ingestion is nil. Thus, in a field situation of primary problem of uncollected darts would be mechanical.

Another concern with immunocontraception is

its effects on behavior and social structure, especially in herd animals like elephants, horses, and deer. This most extensive observations have been conducted in feral horse herds whose populations have been controlled by immunocontraception via pZP vaccination. Kirkpatrick and colleagues observed harem group fidelity and social hierarchy in mares and found no differences in these as compared with normal nonvaccinated mares (Kirkpatrick et al., '95). More investigation needs to be conducted on the behavior altering effects of pZP inoculation in other species as well as comparison of these effects, or the lack thereof, with the behavior effects of other forms of population control such as culling and relocation of animals.

The safety results of this study, along with other studies conducted on the practicality of zona pellucida proteins as an immunocontraceptive, provides encouragement to proceed with anti-pZP vaccination strategies. Based on the individual species under study, the vaccine delivery mechanism provides ecological control of populations.

An Economic Analysis of Alternative Fertility Control and Associated Management Techniques for Three BLM Wild Horse Herds

By John M. Bartholow

Executive Summary

Contemporary cost projections were computed for several alternative strategies that could be used by BLM to manage three wild horse populations. The alternatives included existing gather and selective removal methods, combined with potential contraceptive applications of varying duration and other potentially useful management techniques. Costs were projected for a 20-year economic life using the Jenkins wild horse population model and cost estimates from BLM that reflect state-by-state per horse removal, adoption, long-term holding, and contraceptive application expenses. Important findings include:

- Application of currently available 2-year contraceptives appears capable of reducing variable operating costs for wild horse populations by about 21% on average.
- Application of 3-year contraceptives, when fully tested and available, may be capable of reducing variable operating costs by about 27% on average.
- Combining contraceptives with modest changes to herd sex ratio (e.g., 55-60% males) can trim existing costs by about 31%.
- All savings are predicted to increase when contraception is applied in conjunction with the proposed removal policy that targets horses age zero to four, instead of zero to five.
- Reductions in herd size result in greater predicted variation in annual operating expenses for each herd, especially below about 200 animals, but are always at least ±20%.
- Because the horse program's variable operating costs only make up about one half of the total program costs (which include fixed and sunk costs), even with aggressive contraceptive management, total program costs could only be reduced by about 17%. This would still save about $7.7 million per year.
- None of the contraceptive options examined eliminated the need for long-term holding facilities over the 20-year period simulated, but the number of horses held may be reduced by about 23% with aggressive contraceptive treatment.
- Cost estimates are most sensitive to adoption age and per day holding costs.
- There are opportunities to improve both the population modeling software and the modeling processes used in assembling Herd Management Area environmental assessments.

Introduction

Managing wild horses (*Equus caballus*) as dictated by the Wild Free-roaming Horse and Burro Act of 1971 (as amended) has proven to be costly. Legislation has restricted options used to manage populations; sanctuary and adoption alternatives have been expensive and less than fully effective (U.S. General Accounting Office, 1990; Conover, 2002). Herds continue to grow, often at high rates (6% to 25% or more; Eberhardt and others, 1982; Wolfe, 1986). Budgetary limitations demand tough decisions on how to best minimize expenditures yet still meet legislated goals to maintain a "thriving natural ecological balance" and preserve existing multiple-use relationships, including rangeland health (U.S. General Accounting Office, 1990). Fertility control appears to be one option worth evaluating for cost effectiveness. It is viewed as humane (Reiter and others, 1999), safe and reversible (Kirkpatrick and Turner, 2002), and has been shown to successfully complement other methods of population control for wild horses (Garrott, 1991; Garrott and others, 1992; Gross, 2000; Hobbs and others, 2000).

BLM has maintained a database for state-by-state herd monitoring, census, selective removal, preparation and holding, adoption, compliance check, and other program costs. These new data have been used to compute estimates similar to those from Garrott and others (1992) for the early 1990s. In this paper, I update cost estimates using 2004 management expenses and currently available contraceptive technology for three specific BLM-managed wild horse populations. The three herds were chosen by BLM based on availability of data suitable for population modeling, and because they represented three different western states, different habitats, and herd sizes that characterize a majority of the managed populations.

Objectives

An economic analysis – with proposal costs weighed against anticipated benefits – is appropriate to examine differences between alternative courses of action where limited funds are invested in the public interest, i.e., is one investment more desirable than another? However, BLM's goal is herd management area reductions to clearly established appropriate management levels (AMLs), not to bring in revenue. This simplifies the objective to one of cost-avoidance. Alternatives explored include: (1) the status quo of selective removal, adoption, and sanctuary; (2) the frequency of gathers and how efficient they are in rounding up animals, (3) status quo plus several alternative contraceptive application scenarios, specifically the duration of the contraceptive agent, and (4) other potential management techniques, such as sex ratio manipulation through age- and sex-specific removal decisions.

It has been argued that contraceptive programs must be tailored for individual herds because small differences in reproductive biology and inherent population growth rates can have large influences on population dynamics (Kirkpatrick and Turner, 1986; Garrott, 1991), and because herd-specific data vary in quality (Wolfe, 1986). In addition, BLM tracks wild horse expenditures on a state-by-state basis for planning purposes because costs differ between states. Therefore this analysis has secondary objectives to examine multiple horse populations and perform appropriate sensitivity analyses to address the range of variability and flexibility inherent in herd management decision-making.

Specific Alternatives Analyzed

To address the issue of cost minimization in setting management guidelines for wild horse populations, several questions emerge as key within the confines of existing or proposed BLM policy guidelines:

- How often should horses be removed and/or treated with contraceptives?
- What sex and age horses are best to remove and/or treat with contraceptives?
- What other findings may be inferred from examination of simulation results (e.g., benefit: cost ratio for gather efficiency, general behavior of the HMA models)?
- Do the answers to the above questions depend strongly on the characteristics of individual herds or their locale?

Potentially, it would be easy to generate so many combinations of treatment alternatives that the results would prove cumbersome and would shift the focus away from valuable generalizations. Therefore, this analysis has concentrated on the following scenarios to help answer the questions posed above:

- Baseline Scenario – Existing "baseline" conditions as reflected in current gather policy (U.S. BLM, 2002). This is a regular 4-year gather with age-specific removal rates meant to mimic those shown in Figure 1. Age classes are removed in successive *tiers* as necessary to achieve the designated appropriate management level (AML), with age 0-5 horses removed first, followed by age 10+, and finally by age 6-9 animals.
- Alternative Baseline – Modification of the Baseline Scenario being considered as an update to the existing selective removal policy. Much of the existing selective removal process has yet to be fully institutionalized and may change to something like this scenario, which is the same as Baseline Scenario except Tier 1 includes age classes 0-4, Tier 2 remains 10+, and Tier 3 is 5-9. Contrasting with Figure 1, in the Alternative Baseline Scenario, 70 percent of Tier 3, if removed, is directed to the adoption pool, and 23% of age 4 animals end up in long-term holding.
- Gather Frequency Scenario G_i, where *i* represents regular gather interval in years (e.g., 2, 4, 6, or 8 years)
- Contraceptive Scenario C_d, where *d* represents duration of contraceptive in years (e.g., 2, or 3 years), defined more precisely with percent effectiveness in the first and subsequent years as shown in Table 1. Scenario 2-year-a represents values that have been used in some BLM Environmental Assessments, where Scenario 2-year-b represents values actually measured for one herd. However, scenario 2-year-c represents the most up-to-date estimates available. Contraceptives are assumed to be applied to all mares returned to the range. Note that it is considered to be the case, and the Jenkins model assumes, that if the vaccine does not produce infertility in the first year for a given mare, it would never be effective in subsequent years until retreatment.
- Sex Ratio Scenario S_m, where *m* represents the long-term sex ratio of males to females resulting from the selective removal process (e.g., 55% male to 45% female). Note that these sex ratios will usually not be given consistently. This is because the sex ratio is generated by long-term changes to sex- and age-class specific removal rates and could not be precisely predicted by specifying population model inputs.

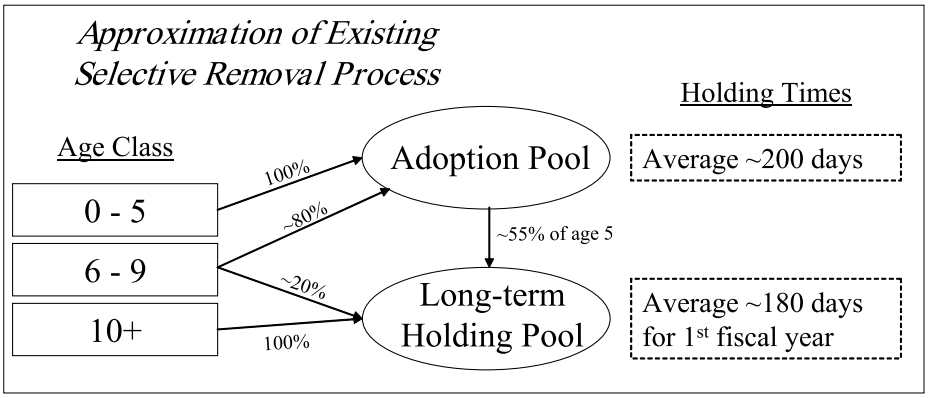

Figure 1. Approximation of existing selective removal policy (Baseline Scenario). Values are taken from Gather Policy & Selective Removal Criteria for Wild Horses, Instructional Memorandum No. 2002-095 (2/13/2002) and information provided by Ron Hall, BLM/NV (9/23/03).

Table 1. Annual effectiveness of existing and potential contraceptive treatments.

Nominal Duration	Effectiveness Year 1 (%)	Effectiveness Year 2 (%)	Effectiveness Year 3 (%)	Effectiveness Year 4 (%)	Effectiveness Year 5 (%)
2-year-a	80	50	0	0	0
2-year-b[1]	94	82	34	0	0
2-year-c[1]	94	82	68	0	0
3-year[2]	95	85	75	33	0

[1]Values taken from draft BLM Instruction Memorandum by Ron Hall (2003, personal communication 2004) reflecting results from the Clan Alpine (NV) HMA. 2-year-b represents a low range estimate and 2-year-c represents a high range estimate.
[2]Hypothetical values liberally extrapolated from 2-year efficacy rates.

- Gather Efficiency Scenario $E_{\%}$, where % represents percentage point change in 'normal' gather efficiency (i.e., if the given gather efficiency were 75%, a –5 would indicate 70% and a +10 would indicate 85%).
- As appropriate, combinations of the above scenarios have been considered. For example, 3-year Contraceptive/Sex ratio-55 would mean the combination of a 3-year contraceptive duration and 55 male:45 female sex ratio. Implicitly, all unspecified parameters would be the same as the baseline case.

Study Areas

The three wild horse populations chosen by BLM for this analysis were the Challis Herd Management Area (HMA) managed out of Challis Idaho; the McCullough Peaks HMA near Cody, Wyoming; and the Little Book Cliffs HMA close to Grand Junction Colorado. As will be seen later, costs and demographics for these three herds capture a large portion of the variability inherent in state-by-state cost differences.

The Challis herd has been managed exclusively by 'gate cut' gathers. Gate cut is not a representative sampling technique because it is dependent on the ease of capture and handling characteristics of corralled horses. Gate cut techniques likely over represent mares, foals, and younger horses in the gathered sample. In 2002, the herd size was estimated at approximately 271 horses with an annual growth rate of about 17%. Foals are included in the AML that is set to 185 animals post-removal. It is estimated that this herd has a foal sex ratio of 58 males:42 females.

The Little Book Cliffs herd is located about eight miles northeast of Grand Junction, Colorado, on 30,000 acres of public land. Many of these horses are descended from escaped domestic stock, but some may be of Spanish origin. This herd of about 150 horses receives periodic gathers and is already participating in an ongoing contraceptive research trial. All yearlings and 2-year-olds, half of those age 3 to 15, and all mares older than 15 that were captured at the 2002 roundup and returned to the range were primed with contraceptive agent porcine zona pellucida (PZP). Even though the Little Book Cliffs HMA is a herd currently undergoing research, this analysis is using it solely as a proxy for other populations with similar demographics. The simulations that explored this herd's response to contraceptive treatment were not meant to emulate the research protocols currently being applied.

The McCullough Peaks HMA is located about 20 miles east of Cody, Wyoming, covering 110,000 acres of open sagebrush prairie and badlands. The current wild horse population in the McCullough Peaks area is about 400 animals, with the AML set between 70 and 140 animals, not including foals. This herd, too, was chosen by BLM and USGS for additional study pertaining to fertility control, population census techniques, and so forth, but no contraceptives have yet been applied. Unlike the other two herds, McCullough Peaks requires Tier 2 aged horses to be removed to achieve its appropriate management level, and may be required by law to do so.

Methods

The analysis of each herd was completed using five main steps. There was nothing fundamentally difficult about this process except the rather rigorous bookkeeping involved.

Step 1. Organize Jenkins Model Input Data and Parameters for Each HMA

Data representative of each of the three HMAs were compiled and organized in a fashion suitable for the Jenkins wild horse population model (Jenkins, 2002). Much of the vital background and operational philosophy for the Jenkins model is given in Appendix A. Suffice it to say that the model attempts to mimic the on-the-ground gather, selective removal, and contraceptive application processes faithfully while including variability in both annual environmental conditions and individual animals. The model requires inputs describing what is known or estimated for survival and reproductive rates, as well as how removals and contraception may be handled. For the Challis HMA, data and modeling parameters were adapted from U.S. BLM Challis Field Office (2002), a task simplified because modeling for this HMA had already been assembled for the Jenkins model and I assumed it to be correct. Existing computer input files (or equivalent) were used for the other two populations, supplemented by information provided by the herd managers. Important demographic parameters and other data on the three herds are provided in Table 2. Note that for two of the herds, Challis and McCullough Peaks, the survival and foaling rates used were borrowed from other better-studied populations assumed to be similar to their counterparts. Complete listings for the baseline data set for the three herds are given in Appendix B.

Step 2. Exercise the Jenkins Model for Each Scenario

The Jenkins model was employed for each herd. Each scenario was run as a separate simulation using model input parameters to describe the various management actions that might be taken, contraceptive effectiveness, and so on. Like any model, there are deviations from reality, some addressed in Appendix D. Nonetheless, for this analysis I have assumed that the Jenkins model provides a reasonably accurate portrayal of possible futures important in choosing one cost minimization strategy over another.

Step 3. Estimate Dollar Value for Each Management Cost Component

Dollar values were estimated for each of the main gathering, treating, and selective removal expenditures, along with associated costs related to wild horse management. Most dollar figures were taken from the state-specific costs listed in Table 3. These costs represent FY 2004 values, but are assumed to increase 3% annually regardless of geographic area to parallel the inflation rate BLM uses for planning. Removal costs include all expenses of gathering and transport to adoption or holding facilities, averaged across all removed horses. Preparation and holding costs include freeze branding and required vaccinations. Adoption costs are largely administrative with follow-up compliance checks (site visits to adopted horses).

Costs for multi-year contraceptives are given in Table 4. The range of costs given for the various duration time-release pellets reflects their production method. Higher cost pellets are currently more reliable (and that cost was used in this analysis), but BLM's goal is to reduce the cost to below the lower cost values, on the order of $120 per applied dose. (Note: These cost estimates may not be applicable for herds undergoing research where a variety of protocols may be tried.) Several other potential costs were also considered in the analysis. It was assumed that the minimum gather cost was $10,000. This comes into play only if the number of animals removed times the appropriate per horse removal cost would be below $10,000. A $5,000 per year HMA census flight cost was applied for non-gather years to assess contraceptive treatment effectiveness and routine monitoring per the recommendation of Ron Hall (2003), and was applied only for contraceptive scenarios.

Table 2. Key demographic elements and other information for the three HMAs considered in this analysis. These values were set to generally mimic an existing or proposed Environmental Assessment (EA) for each HMA.

	Challis	Little Book Cliffs	McCullough Peaks
Cost state	ID	CO	WY
Initial sex ratio (% male)	46	46	46
Sex ratio at birth (% male)	58	50	57
Age 0-9 female survival (geometric mean %)	98	95	95
Age 0-9 male survival (geometric mean %)	93	97	95
Average foaling rate age 2-9 (%)	79	65	71
Gather trigger (# of horses)	253	150	140
Gather efficiency (%)	75	80	90
AML (# of horses)	185	90	100
AML includes foals?	Yes	No	No
AML requires Tier 2 removal	No	No	Yes
Released mares treated for contraceptive alternatives by age	0-1 year: 100%[1] 2-9 year: 50% 10+: 100%	0-4 year: 100%[1] 5-9 year: 75% 10+: 100%	0-4 year: 100%[1] 5-9 year: 75% 10+: 100%

[1]Note: After this report was finalized, a reviewer noted that no foals would ever be given contraceptives. This is true. However, a careful review of simulation results revealed that eliminating contraceptives for foals would make only a small difference for the three populations studied. The reason for this is that most gathered foals are removed for adoption instead of being released back to the herd and the foaling rate for yearlings and 2-year old mares is low compared with older aged mares. Should this analysis ever be updated, the models should incorporate this change.

Table 3. Summary of variable cost estimates for BLM wild horse management across states. Unusually high costs in each column may arise when they are averaged over a small number of horses. Cost estimates were taken from budget planning spreadsheet supplied by Linda Coates-Markle, BLM/MT (4/29/2003) as interpreted by Don Glenn, BLM/DC (6/17/2003) and Lili Thomas, BLM/NV (9/22/2003). NA means not applicable.

Management Office	Removal Cost (/horse; $)	Prep & Holding Cost (/horse/day; $)	Adoption Cost (/horse; $)	Compliance Check (/horse; $)	Comments
Arizona	345	2.80	318	50	
California	211	3.13	305	59	
Colorado	433	3.04	291	60	Little Book Cliffs
Eastern States	NA	7.66	361	46	
Idaho	285	2.10	396	18	Challis
Montana	450	13.99	500	150	
Nevada	460	3.11	510	66	
New Mexico	433	3.15	362	81	
Oregon	360	3.35	300	50	
Utah	434	4.72	367	50	
Wyoming	300	5.21	760	70	McCullough Peaks

Table 4. Estimated cost range for current 2-year contraceptive materials. Estimates derived from information supplied by Ron Hall (BLM/NV) and Linda Coates-Markle (BLM/MT) 9/23-30/2003.

Component	Cost Range
Primer (PZP and Freunds complete adjuvant)	$21.50
Time release booster doses (PZP and QA-21 adjuvant)	
1-month pellet	$28 – $37
3-month pellet	$31 – $40
12-month pellet	$65 – $95
Application	$20
TOTAL	$165.50 – $213.50

Since some scenarios call for contraceptives of longer duration, I received an estimate for applications having greater longevity. This estimate is given in Table 5 along with the more reliable estimate for the 2-year agent. These are the dollar costs used in this analysis.

Table 5. Estimated per horse costs for existing 2-year and hypothetical 3-year contraceptive materials and application used in this analysis. Cost for the 3-year agent is composed of the total cost of a 2-year agent plus additional 12-month time-release pellets (from Table 2). Estimates derived from Linda Coates-Markle (BLM/MT) 9/30/2003.

Contraceptive Duration	Estimated Cost per Horse
2 years	$214
3 years	$309

Step 4. Estimate Dollar Costs from Simulated Scenarios

The results of the Jenkins model simulations were summarized and converted to dollar expenses over a 20-year planning horizon. Twenty years was chosen because it is long enough (five complete 4-year gather cycles) to 1) reduce the uncertainty inherent in estimates of the initial age and sex structure, and 2) reveal most of the effects of variation in sex and age structure that would result over time from the variety of treatment options. Tallying the total expenditures required all cost estimates previously described, including which ages were eligible for adoption and how long adoptable and unadoptable horses are held (see Figure 1). All unadoptable horses (those that have not been successfully placed after three adoption attempts) were assumed to remain in holding facilities for the remainder of their natural life, estimated to be 25 years. In other words, the economic model became its own population model, in a manner of speaking, because it kept track of horses in life-long holding facilities. Results were summarized by software that computed the mean number of horses gathered, removed, and treated by sex and age class for each year of the 20-year simulations, along with average annual costs. In addition, the cost summarization step computed the likely annual variation in costs that would be expected as a result of the variability inherent in the Jenkins model. This step is explained in more detail in Appendix B.

Step 5. Conduct Sensitivity Analysis

The Jenkins simulation model captures environmental and demographic variability, but the uncertainty in cost estimates for the various management options remained to be explored. To accomplish this, a sensitivity analysis was performed for the three populations to see where opportunities for cost cutting might lie and which factors contribute most to the bottom line.

Results

A full suite of results for the Challis HMA is given in Table 6 and Figures 2-6. In general, the results confirm that a four-year gather cycle has been a good management decision without contraceptive intervention. Waiting longer between gathers has the potential to significantly increase annual costs because population sizes compound so rapidly (~10-20% annually). Interestingly, Figure 2 shows that there is not much cost difference between a 2- versus a 4-year gather cycle, or between a 6- versus an 8-year cycle, but a large difference between the 4-year and 6-year cycles.

Annual costs are far less sensitive to gather efficiency (Figure 3), at least in the small increments examined here, but are nicely responsive to seemingly modest changes in sex ratio (Figure 4). Removing fewer males and increasing the sex ratio of animals remaining on the range from about 51% to 57% male can dramatically reduce costs.

Contraceptive treatments are shown to be cost effective. Contraceptives alone (Figure 5) can reduce management costs for the Challis herd up to about $15,000 per year. The best estimate of 2-year efficacy (Figure 5, 2c) rivals the results from a 3-year agent. When combined with alterations to herd sex ratio (Figure 6), these treatments appear capable of reducing costs to about 65-70% of baseline.

Interestingly, the Alternative Baseline Scenario alone is not predicted to generate a significant cost savings for the Challis herd. This appears to be because the foaling rate for 5-year olds is so much higher than for 4-year olds, and though this alternative does reduce the total number of horses held in long-term facilities, the population growth rate is slightly higher so the number of horses gathered and removed must also be higher. However, as noted above, combinations of contraceptive treatment and sex ratio manipulation (e.g., 3-year contraceptives/Sex ratio-56% male and Alternative Baseline/3-year contraceptive/Sex ratio-56%) have the potential to reduce average annual costs by about 25-35%. This is an important conclusion.

Results for Little Book Cliffs and McCullough Peaks are given in Tables 7 and 8, respectively. I have not repeated the alternatives for gather frequency or efficiency because they provided no additional insight.

Aggregate results were examined to see what other information they provide. Figure 7 shows the relationship between the variability in annual costs and herd population size developed from a variety of scenarios examined. The apparent trend appears to be an L-shaped function of population size; at population sizes below about 200 animals, the variability in annual costs increases dramatically. This is probably an effect engendered by the demographic stochasticity inherent in the Jenkins model, i.e., random events applied to small numbers of animals foster greater variability in the results, with variation in population size translating into variation in expected annual costs. However, the results may simply be an artifact of dealing with three herds, one of which is smaller than, and has different parameters than, the other two.

Table 6. Summary of results for scenarios of the Challis HMA.

Scenario	Average Annual Cost ($)	Percent of Baseline Cost (%)	Median Annual Growth Rate (%)
Baseline	86,677	100.0	19.8
Alternative Baseline	85,814	99.0	20.4
2-year contraceptive-a	83,095	95.9	17.8
2-year contraceptive-b	75,415	87.0	16.1
2-year contraceptive-c	73,478	84.7	15.6
3-year contraceptive	72,156	83.2	14.9
2-year contraceptive-a/ Sex ratio-56	67,442	77.8	12.9
2-year contraceptive-c/ Sex ratio-56	60,687	70.0	11.7
3-year contraceptive-a/ Sex ratio-56	59,900	77.0	11.0
Alternative Baseline/3-year contraceptive/Sex ratio-56	57,136	65.9	11.4
2-year gather cycle	83,765	96.6	19.9
6-year gather cycle	145,474	167.8	20.8
8-year gather cycle	149,745	172.8	20.4
-5% gather efficiency	89,899	103.7	19.9
+5% gather efficiency	86,667	99.9	20.0
+10% gather efficiency	84,178	97.1	20.0
Sex ratio = 53.1% males	83,209	96.0	18.1
Sex ratio = 55.1% males	78,569	90.7	16.6
Sex ratio = 57.3% males	68,619	79.2	14.5

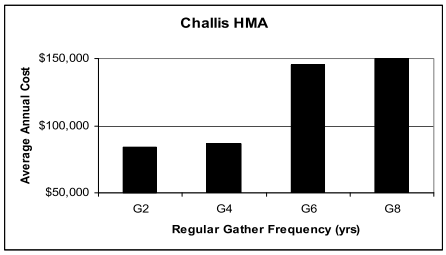

Figure 2. Annualized cost over a 20-year period for four gather frequencies for the Challis HMA (G-2, 4, 6, and 8 years, respectively).

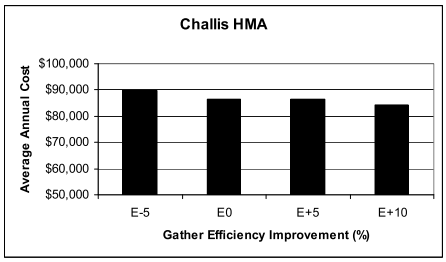

Figure 3. Annualized cost over a 20-year period for four gather efficiencies for the Challis HMA. Challis has an estimated baseline efficiency of 75%, so these scenarios represent 70, 75, 80, and 85% efficiencies, respectively.

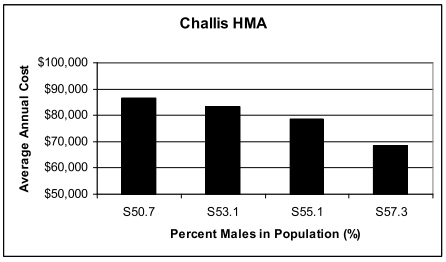

Figure 4. Annualized cost over a 20-year period for four resulting sex ratios for the Challis HMA (S-51, 53, 55, and 57% male, respectively).

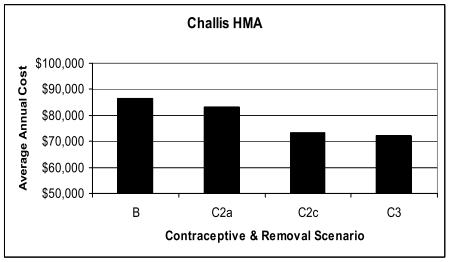

Figure 5. Annualized cost over a 20-year period for three contraceptive scenarios (2a,. 2c, and 30-year) compared to the baseline (B) for the Challis HMA.

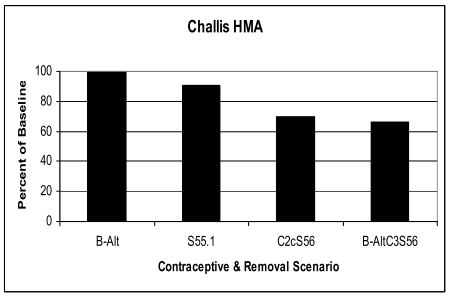

Figure 6. Percent of Baseline cost over a 20-year period for four scenarios: alternative baseline (B-Alt), 55.1% male, 2c with 56% male, and B-Alt with 3-year contraceptive and 55% males, respectively.

Table 7. Summary of results for scenarios of the Little Book Cliffs HMA.

Scenario	Average Annual Cost ($)	Percent of Baseline Cost (%)	Median Annual Growth Rate (%)
Baseline	50,766	100.0	12.9
Alternative Baseline	42,264	83.3	13.6
2-year contraceptive-a	46,230	91.1	9.6
2-year contraceptive-b	46,307	91.2	8.1
2-year contraceptive-c	37,596	74.1	6.9
3-year contraceptive	36,111	71.1	6.2
Sex ratio = 51.8% males	50,573	99.6	11.7
Sex ratio = 53.3% males	50,469	99.4	10.8
Sex ratio = 55.0% males	46,444	91.5	9.4
2-year contraceptive-a/ Sex ratio = 54% males	42,181	83.1	8.3
2-year contraceptive-c/ Sex ratio = 53% males	33,079	65.2	5.2
3-year contraceptive/ Sex ratio = 53% males	31,511	62.1	4.7
Alternative Baseline/ 3-year contraceptive/ Sex ratio = 53% males	28,128	55.4	5.1

Table 8. Summary of results for scenarios of the McCullough Peaks HMA.

Scenario	Average Annual Cost ($)	Percent of Baseline Cost (%)	Median Annual Growth Rate (%)
Baseline	16,8214	100.0	17.5
Alternative Baseline	150,836	89.7	17.5
2-year contraceptive-a	151,430	90.0	14.1
2-year contraceptive-b	137,295	81.6	11.2
2-year contraceptive-c	133,562	79.4	10.6
3-year contraceptive	109,197	64.9	10.0
Sex ratio = 60% males	157,759	93.8	14.5
Sex ratio = 61% males	145,534	86.5	12.2
Sex ratio = 63% males	138,669	82.4	10.0
2-year contraceptive-a/ Sex ratio = 63% males	130,136	77.4	8.4
2-year contraceptive-c/ Sex ratio = 64% males	118,241	70.3	6.3
3-year contraceptive/ Sex ratio = 63% males	118,497	70.4	5.9
Alternative Baseline/ 3-year contraceptive/ Sex ratio = 62% males	108,792	64.7	6.0

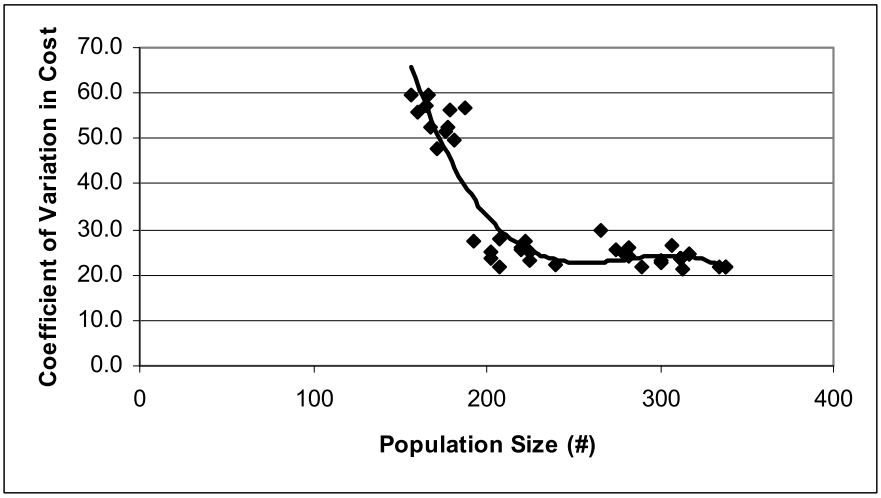

Figure 7. Apparent relationship between the variability in annual costs and herd population size developed from a variety of scenarios for the three populations examined. Trend line is 3rd order polynomial.

Figure 8 shows the relationship between the mean annual growth rate and percent of baseline scenario costs for the three populations combined. As growth rate declines through the application of various management and contraceptive options, the likelihood of reducing costs also declines. The variability (scatter) in results arises from the individual herd demographics and model-induced random variability. However, it seems apparent that when growth rates decline below about 10% annually, there is essentially a guarantee that costs will decline. Between 10 and 20% growth, large variability remains.

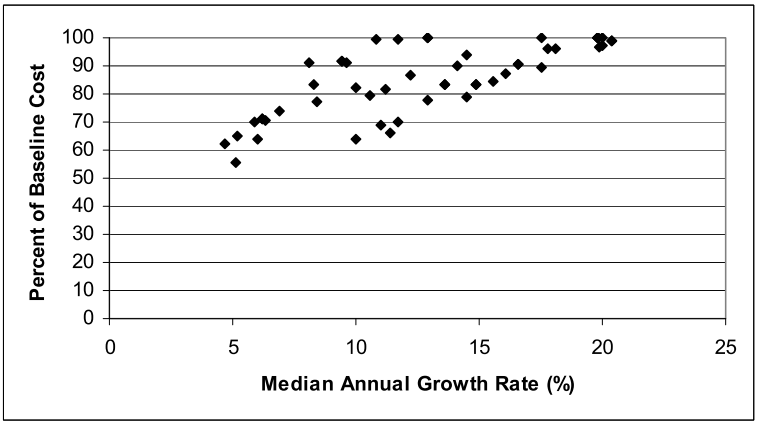

Figure 8. Relationship between mean annual growth rate and percent of the Baseline Scenario costs developed across all three populations examined.

Sensitivity Analysis for Cost Components and Related Factors

A basic sensitivity analysis was completed for the various elements that contribute to the cost estimates. This analysis tests how sensitive bottom line costs are to small changes in each of the contributing factors. The chart below (Figure 9) was generated by changing each cost and management factor ±10% and taking the ratio of the resulting cost fluctuation to the base cost of the 2-year Contraceptive Scenario-b for the Challis herd. Age class values were incremented up and down one age class – the minimum possible. (Because these age increments more closely represent a 20% change, their results have been divided by two to more closely reflect their relative impact.)

The results unsurprisingly indicate that the maximum age usually considered mostly adoptable (5 years) is the single largest influence on total costs. In other words, if this age were really four or six instead of five, there would be a large change in costs. Adoption age is followed by the average per day holding cost (*$/Unadoptable/day* = $5.21). Then comes a group of factors that have roughly equal sensitivity: the percent of age 5 horses that are adoptable (very much related to the maximum adoptable age), the number of days that horses are held prior to adoption (200 days), and the costs of adoption themselves. Costs related to contraceptives, treatment and off-year censuses, contribute little to the sensitivity, indicating that their cost is trivial compared with other management expenses. Four parameters have little or no effect: minimum gather cost, the maximum possible age of adoptable horses (10 years), the percentage of horses between age 5 and 10 (called *% of mid-ages* in Figure 9) that are adoptable (20%), and days unadoptable horses are held during their first year of removal (180 days). The two parameters dealing with age classes (*max age adoptable* and *% of mid-ages*) made no difference because none of these older aged animals needed to be removed to achieve the stated AMLs for the Challis herd.

Results of this form of sensitivity analysis for the other two herds were similar, but with some important differences. The holding cost (*$/Unadoptable/day)* was more important than the adoption age for the McCullough Peaks herd. This may not be surprising considering the high holding costs for this HMA given in Table 3. Likewise, the costs associated with adoption were somewhat less important for the Little Book Cliffs herd than the other two, again reflecting this herd's favorable adoption-related expenses.

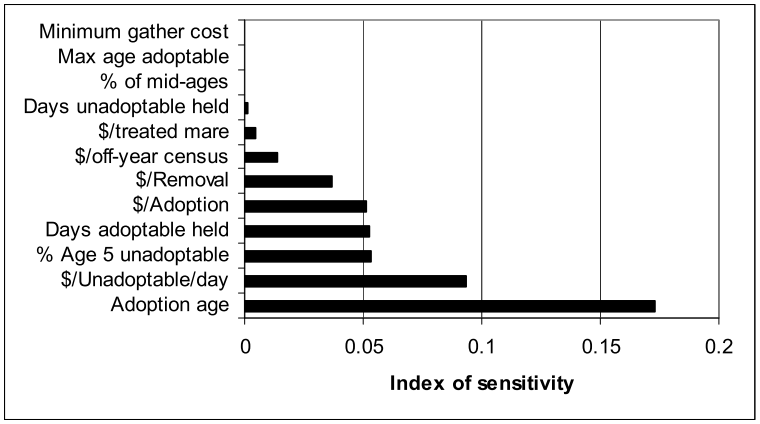

Figure 9. First order sensitivity analysis for management costs and other attributes for the Challis herd relative to the 2-year Contraceptive Scenario-b. The impact of adoption age has been divided by a factor of two to better represent its true relationship with the other factors.

Conclusions and Discussion

If all economists were laid end to end, they would not reach a conclusion.
– George Bernard Shaw

Results of this analysis have shown that when contraceptives are added to the gather-removal program, they are more cost effective than current or anticipated removal strategies that have no contraceptive component. When averaged over the variable costs anticipated with a regular 4-year gather (Figure 10), and depending on the herd and the aggressiveness of treatment, cost savings could range from 4 to 46%, averaging approximately 25%.

Populations controlled solely by gathers decline dramatically with each gather but increase rapidly between gathers. In contrast, populations controlled by contraceptives in conjunction with removals increase less rapidly. If sex ratio is also managed to increase males, even greater stability can result. Regardless of the management option, program costs always parallel population growth (Figure 10), agreeing with the findings of Gross (2000) and Garrott and others (1992).

A 4-year gather frequency appeared to be quite well matched with the demographic effects (and dollar costs) associated with 2-year contraceptive agents. However, if a viable 4-year agent becomes available, it would be wise to revisit the issue of gather frequency as it seems plausible that increasing the interval to five or more years may have economic benefits.

Comparison with Findings of Others

Garrott and others (1992) explored the impacts of alternative contraceptive management on wild horses in the early 1990s. They separated costs for wild horse management into three basic components: contract gather costs, contraceptive purchase and per mare application (including manufacture, implantation drugs and supplies, and

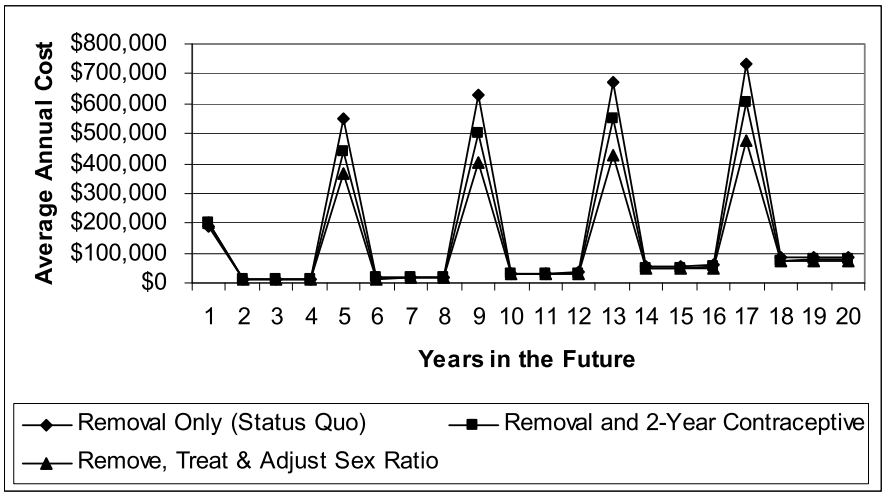

Figure 10. Example illustrating how periodic management expenses grow due to population growth, annual cost inflation, and holding of sanctuary horses for three possible scenarios.

veterinary services), and removal costs. They assumed all contraceptive applications would be associated with gathering as opposed to aerial darting for safety and logistic reasons. Adoption placement costs (including transportation, brand inspection, vaccinations and disease testing, branding, wrangler fees, age determination, administration, facility maintenance, and per day feeding) were more difficult to estimate. They broke costs down by age of horse since some age classes were considered adoptable while others were considered unadoptable, each having their own per horse cost. Like this analysis, Garrott and others (1992) simulated a variety of different herds, and considered more contraceptive alternatives than examined here. Their results were comparable, indicating that most variable program expenses are not related to contraceptive treatment per se, but rather remain associated with adoption program costs.

Others have pointed out that the cost-efficiency of contraceptive treatment for a species as long lived and with as high a reproductive rate as wild horses is extremely dependent on herd-specific demographics and management constraints (Garrott, 1991; Hobbs and others, 2000), and that contraception must be used in conjunction with an ongoing removal program (Gross, 2000). This example confirms that the current 22-month contraceptive agent within a 4-year gather cycle (2-year Contraceptive Scenario-c) can make an important difference in variable costs associated with management when gather efficiencies are typical (e.g., only 80%) and natural rates of increase are relatively high (Garrott, 1995). However, when combined with modest changes to the demographic structure of the population, such as altering the sex ratio to only a slight male bias, contraceptives may offer the possibility of far more substantive cost reductions.

It should be noted, however, that none of the contraceptive options considered in this analysis eliminate the need for long-term holding facilities. Collectively, the number of additional horses added to long-term holding is reduced by 23% over the simulated 20-year period with aggressive contraceptive treatment, yet only one of the three HMAs examined (McCullough Peaks) actually showed a decreasing number of horses added through the 20 years. The other two populations continued to increase the horses added to holding through time, albeit at rates 18-36% below the baseline scenario.

Putting the Results in Perspective

This analysis has explored methods of reducing costs through a combination of contraceptive and other potential management techniques. However, costs tabulated in the Results section should be considered *variable* costs because they arise from the variation in herd population dynamics and management strategy. In other words, the dollar values presented thus far are comparative variable costs that will accrue due to impending management decisions.

BLM also incurs certain *fixed* costs associated with the wild horse program that include all overhead (Washington and regional offices, many HMA monitoring costs, holding facility maintenance, etc.). The fixed costs could be assumed to continue more or less unchanged regardless of the specific gather and selective removal process, with the knowledge that some of these fixed costs, like annual monitoring, aerial censusing, and new or revised AML establishment, are subject to annual budgetary constraints. Portions of the fixed costs are 'sunk' costs that support the 20,000 wild horses currently residing in holding facilities. Like all fixed costs, these sunk costs have been ignored so far in this analysis because their presence (obligation) is the result of past decisions. Table 9 presents a summary of nationwide costs, both fixed and variable, for BLM's wild horse program.

As one can see, the variable costs represent slightly less than half (46%) of the aggregate costs. Results presented above have indicated that it might be reasonable to expect about a 38% annual decrease in variable costs if the most aggressive management methods were to be implemented. If these savings accrue solely to the variable side of the ledger, and if fixed/sunk costs remain the largest component of the overall wild horse program, even if variable costs were reduced by 38%, aggregate program costs would likely decrease by only 17%. Though it is probably best to couch the results of this analysis in relative terms, assuming that 17% is approximately correct for all herds combined, this would amount to about a $7.7 million annual savings in variable program costs in 2004 dollars. Significant changes to gather and selective removal procedures could alter the fixed cost structure (specifically labor and facility costs) such as completely closing an existing facility, further reducing costs. Sunk costs would be expected to decline through time if the number of unadoptable horses declines. These potential changes to overall program costs have not been considered in this analysis.

Table 9. Summary of nationwide fixed and variable cost estimates for BLM's wild horse program for FY2004. Cost estimates were summarized from budget planning spreadsheet supplied by Linda Coates-Markle, BLM/MT (4/29/2003) as interpreted by Don Glen, BLM/DC (6/17/2003) and Lili Thomas, BLM/NV (9/22/2003).

Cost Type	Factor	Expense	Total	Percent (%)
Fixed				
	Annual Monitoring	$219,912		
	Annual Censusing	$369,590		
	AML Establishment	$56,635		
	Labor	$8,862,197		
	Non-unit cost	$3,513,962		
	Long Term Holding Facilities	$6,387,500		
	==========	=========		
	Total Fixed Costs	$23,801,893		54
Variable				
	Selective Removal	$5,331,471		
	Prep & Holding	$12,046,381		
	Adoption	$2,713,550		
	Compliance Checks	$279,150		
	==========	=========		
	Total Variable Costs	$20,370,552		46
Fixed + Variable			$44,172,445	100

Uncertainty Inherent in Results

It is important to try to describe each of several major forms of uncertainty inherent in this analysis. *First* data quality for individual herd status (age and sex composition, fertility and survival rates, etc.) can vary widely. We must acknowledge that these horse populations are difficult and expensive to monitor, and our estimates of initial conditions and the various vital parameters are inaccurate (or indeed borrowed from other, better studied populations), but we must start with the information as best as it is currently understood. Fortunately, these data may be improved through time.

Second is forecasting. Population births and deaths are subject to the whims of animal and range conditions, predation, and other poorly understood population regulation mechanisms. In essence, the nature of the Jenkins population model used in this analysis automatically accounts for much of the uncertainty in initial conditions and lack of predictability of forecasts. As we have seen, this variability, as reflected in the coefficient of variation of annual costs, appears to be in the neighborhood of 20-30% annually for each HMA simulated. It may take many years to improve our estimates of this forecast uncertainty.

Third, there is the uncertainty in the BLM-derived estimates of expenses for each of the several cost components: gathering, selective removal, adoption, holding, contraceptive treatment, and population censusing. Costs vary through time and with the vagaries of local conditions. The cost summarization software automatically accounts for the uncertainty passed to it from the population model, but does not automatically incorporate uncertainty in the cost estimates, though this has been addressed to some degree through sensitivity analysis. Further, since this cost analysis has focused on variable program expenses, overhead costs have been treated as fixed costs and, along with 'sunk' costs (those costs originating from past decisions) such as the existing sanctuary inventory, have been summarized only to put the variable costs in perspective. There are obvious uncertainties in fixed costs that hinge on the practical life of all physical facilities (e.g., adoption corrals, fencing, etc.) and it is reasonable to assume that the 20-year time frame used in this analysis is long enough that new contraceptive techniques or agents may be available that change the complexion of the results presented here.

There is a bright side to some of this uncertainty. The computed coefficients of variation for costs are meant to be relevant for single populations. When considering the variation in costs that might arise program-wide,

it is reasonable to assume that the overall variance would be reduced. This is largely because gather schedules would presumably be staggered, but also because some populations would be increasing while others would be decreasing, with the 'average' expected to be less erratic, much like the behavior of a 'balanced' portfolio. One should never discount region-wide oscillations that might be due to widespread drought or other climatic oscillations (El Niño) that may provide broadly favorable or unfavorable habitat conditions over large geographic areas like the Intermountain West. On average though, variable program costs would not be expected to fluctuate more than about ±20% across all herds at the same time.

Research and Management Recommendations for BLM's Consideration

Sex Ratio Manipulation

Many of the environmental assessments that I reviewed, as well as some additional published literature (Berger, 1986), have recommended maintaining populations with 'natural' sex ratios that tend toward females, e.g., 40 males:60 females (e.g., U.S. BLM Worland Field Office 2000). Since sex ratio measured in the field results from the combined effects of sex ratio at birth and relative male:female survival and removal rates that vary from herd to herd, I believe that it may be problematic to characterize a 'natural' sex ratio, especially for a feral species undergoing active management.

In any event, this analysis has assumed no *a priori* constraint on the sex ratio resulting from any given management plan, and even though examining how changes to each HMA's sex ratio influenced cost was not the primary goal of this analysis, simulations revealed that only modest changes in herd sex structure could rival cost savings inherent in available contraceptive application techniques. When both contraceptives and sex ratio manipulation were combined, cost savings could be even more significant. Herds that have small groups of bachelor males that are difficult to gather may lend themselves easily to this paradigm, while other herds that have many small harems may prove more difficult and costly to manage favoring males. Further, there may be potential genetic concerns regarding sex ratios that favor males. Nonetheless, any implicit or explicit BLM policy recommending sex ratios inclined toward females should be reexamined in light of the results presented here.

Balancing Range Conditions with Population Size

The 20-year simulations used in this analysis often showed that any given management strategy might take several years to achieve relatively stable demographic characteristics for each herd. For example, Figure 11 is taken from one Jenkins model simulation for McCullough Peaks. This plot illustrates that the population size approaches stability after a few gather cycles. Recall that McCullough Peaks was simulated by removing animals from only Tiers 1 and 2. It may have reached its AML more quickly if Tier Three animals had also been immediately removed. However, the apparent delay in population reduction has management implications. One might be tempted to adjust the management strategy after only one or two gather cycles if the population did not appear to be responding (or management costs declining) as fast as considered desirable. Although removal decisions must always be made aided by good data and concrete management objectives, the results shown here also argue for patience in population management for these long-lived animals. In particular, a management option that removes only age 0-4 horses without any other age classes removed may result in a somewhat higher number of horses on the range initially, yet produce a satisfactory reduction over the long term. If the range is capable of sustaining a larger number of horses for several years, this more patient strategy could significantly help reduce long-term management and holding costs.

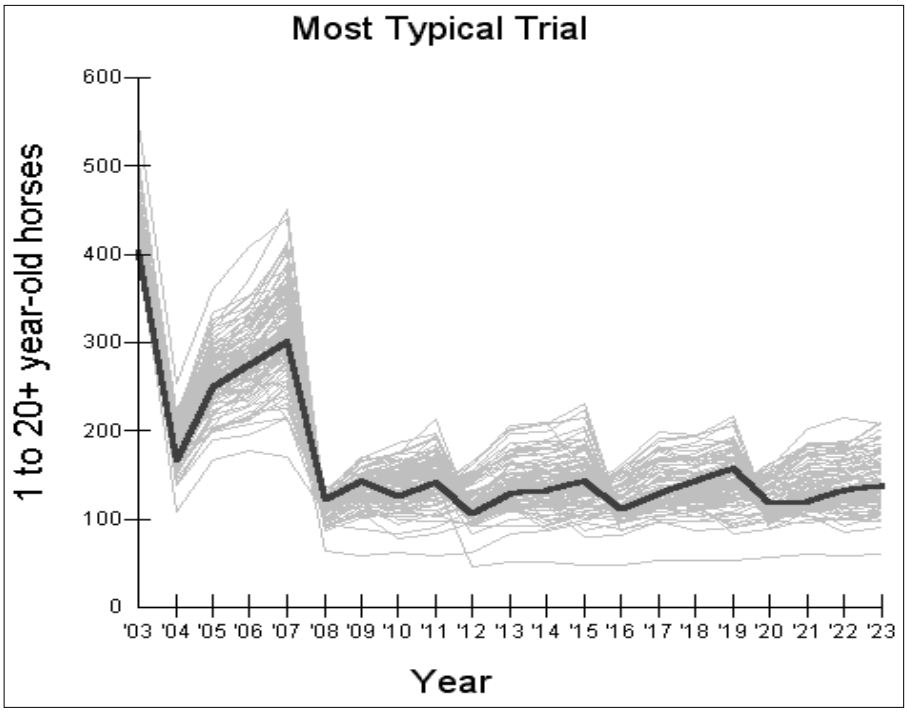

Figure 11. Example Jenkins model output for the McCullough Peaks HMA showing the total after-gather population size (minus foals since foals are not included in this AML) through a 20-year simulation. The light lines trace the 100 individual simulation trials and the heavy line traces the "most typical" result.

Population Modeling Software Improvements

Though modeling each wild horse herd with the Jenkins model is established BLM policy (U.S. BLM 2002), not all herds currently have such models. Even if the models have been assembled for a specific herd, these models may not necessarily reflect established selective removal guidelines, but instead be tailored toward previous removal practices. This analysis was not intended to be a critical assessment of the existing HMA models, but simply used what was available for the three herds examined here.

I have mentioned several areas where the Jenkins model might be improved to more faithfully represent the specific gather, selective removal, and contraceptive practices currently being used or contemplated as management decisions are fine-tuned (see Appendix D). I must admit that I do not have a good feel for whether modifications would significantly change the relative standing of the various scenarios examined here. My assumption is that simulation results would indeed differ, but that these differences would not actually change decisions based on those results, the ultimate form of sensitivity analysis. Nonetheless, it will be worthwhile to continually monitor where the model deviates from reality and test or upgrade it in response to perceived problems or improved data quality from research results.

Tom Hobbs and colleagues at Colorado State University are developing another individual-based modeling package. This software will contain a mathematical routine that will have the capability to suggest an 'optimum' gather, selective removal, and contraceptive management program for various herds, something that this current cost

analysis addressed only in a limited trial-and-error manner. When fully developed, the new software could be applied side-by-side with the Jenkins model to identify areas where each product might be improved.

Population Modeling Process Improvements

Results given in this analysis have seconded the findings of Garrott (1991) and Kirkpatrick and Turner (1986) that specific contraceptive prescriptions can depend strongly on individual herd population dynamics. Drawing on a large experience in big game population modeling in the West, I believe there will be a need to have one or more 'experts' to consistently apply whatever population model is used to evaluate HMA environmental assessments. Data gathering for each herd can be unique with subtle data quality issues. Modeling software, though ostensibly easy to use once you are familiar with its nuances, can produce very different results depending on exactly how the model structure is interpreted and applied for each herd. Though it will always be a good idea to have the herd managers closely involved in population modeling, such modeling will never be a day-to-day activity for them. These individuals often move from position to position, and applying the software will often receive only minimal attention. Filtering the HMA models through a specialist could 1) provide a level of quality control that may be necessary both in making cost effective long-term management decisions that can more easily respond to changing management directives, and 2) stand up to increasing scrutiny in our ever more sophisticated and litigious society. BLM should consider hiring an individual who can uniformly apply the appropriate population modeling software across the various herds, and assist and advise all of the herd managers in the uniform application of techniques. Further, it might be wise to encourage publication of modeling results in peer-reviewed journals to provide a solid foundation for scientific credibility.

Revised Cost Accounting

Because of the way BLM has tabulated removal costs, the base cost of gathering is averaged across all horses removed. Any management activity, like contraceptives, that results in an overall reduction of the number of horses that need to be removed to achieve the stated AML would likely end up with a higher cost per animal removed because all relatively invariant gather costs would be averaged across fewer horses. If, for example, gathering were used solely for a contraceptive treatment so effective that no horses were ever removed, the cost of the gather would not be accountable with BLM's current cost estimation procedure, at least as I have interpreted it. This is the reason why I included an estimate of the minimum gather cost.

Fortunately, sensitivity analysis has indicated that this is not likely to dramatically influence the results for many populations. Nonetheless, BLM may wish to partition total gather costs into two categories, one that would represent the base cost for a gather (to get the crew and equipment in place, construct fences and traps, permits, supplies, etc.) and specific per horse removal costs for marking, any veterinary services, and transport. This would support a cost accounting that more easily scales downward to reduced removal levels, a desirable target for the horse program.

Acknowledgments

This report could not have happened had it not been for many helping hands. Linda Coates-Markle (BLM) and Francis Singer (USGS) helped define the objectives, establish useful contacts, supplied interesting insights, and reviewed progress. Don Glenn, Ron Hall, and Lili Thomas (BLM) coached me on the details of BLM's cost estimates and how their existing processes worked. Tricia Hatle (BLM) and Linda Zeigenfuss (USGS), with help from Jim Dollerschell (BLM) and Gerald Thygerson (BLM retired), supplied Jenkins' HMA models or equivalent for the McCullough Peaks and Little Book Cliffs populations. Linda Zeigenfuss also helped tirelessly with numerous other data gathering and related activities. Stephen Jenkins (U. Nevada Reno) was generous with his time in coaching me in the use of his population modeling software, WinEquus. John Turner (Medical College of Ohio) supplied cost estimates for longer-term contraceptive treatments under development. Jason Ransom supplied

background information on two of the herds examined. Linda Zeigenfuss, Steve Jenkins, Francis Singer, Linda Coates-Markle and Al Kane (USDA) all provided excellent comments on the first draft of this document. Finally, I must acknowledge that this report would have been unnecessary if we had been able to devise a successful abstinence program for wild horses.

Appendix A. Using the Jenkins' WinEquus Software

General Description

A description of the Jenkins modeling software taken from selected portions of the WinEquus 'Help file' (Copyright 2002 by Jenkins and Veech, Version 1.4, April 2002 – used with permission) follows:

Overview

This is a population model for feral horses, designed to help you evaluate various management plans that might be considered for a particular area. The model uses data on average survival probabilities and foaling rates of horses to project population growth for up to 20 years. The model accounts for year-to-year variation in these demographic parameters by using a randomization process to select survival probabilities and foaling rates for each age class from a distribution of values based on these averages. This aspect of population dynamics is called environmental stochasticity, and reflects the fact that future environmental conditions that may affect horse populations can't be known in advance. Therefore each trial with the model will give a different pattern of population growth. Some trials may include mostly 'good' years, when the population grows rapidly; other trials may include a series of several 'bad' years in succession. The stochastic approach to population modeling uses repeated trials to project a range of possible population trajectories over a period of years, which is more realistic than predicting a single specific trajectory.

The model incorporates both selective removal and fertility treatment as management strategies. A simulation may include no management, selective removal, fertility treatment, or both removal and fertility treatment. You can specify many different options for these management strategies such as the schedule of gathers for removal or fertility treatment, the threshold population size which triggers a gather, the target population size following a removal, the ages and sexes of horses to be removed, and the effectiveness of fertility treatment.

To run the program, you must supply an initial age distribution (or have the program calculate one for you), annual survival probabilities for each age-sex class of horses, foaling rates for each age class of females, and the sex ratio at birth. Sample data are available for all of these parameters. You must also specify basic management options.

Population Data: Age-Sex Distribution

An important point about the initial age-sex distribution is that it is NOT necessarily the starting population for each of the trials in a simulation. This is because the program assumes that the initial age-sex distribution supplied on this form or calculated from a population size that you enter is not an exact and complete count of the population. For example, if you enter an initial population size of 100 based on an aerial survey, this is really an estimate of the population, not a census. Furthermore, it is likely to be an underestimate, because some horse will be missed in the survey. Therefore, the program uses an average sighting probability of about 90% (Garrott and others, 1991) to "scale-up" the initial population estimate to a starting population size for use in each trial. This is done by a random process, so the starting population sizes are different for all trials.

Contraceptive Efficacy

A set of parameters on the management options form called Percent Effectiveness of Fertility Control interacts with the contraception parameters to determine the actual reduction in reproduction in the population. For example, if effectiveness for the first year = 80% and 50% of released mares of each age class are treated, then only 40% of released mares in the population (80% x 50%) are actually infertile for the first year.

Contraceptive Parameters

Because of the way immunocontraceptives work (Turner and others, 1997), sterility in the first year really means that an effectively treated female will not produce a foal in the second foaling season after being treated. Mating in horses typically follows fairly soon after foaling. If gathers for treatment occur following mating, as the model assumes, then the female may already be pregnant and the immunocontraceptive won't cause her to abort the foal she is carrying. Instead, it will prevent fertilization during the mating season after this foal is born the following spring or summer, so will prevent foaling the spring or summer after that.

It may seem contradictory to remove 100% of 0 to 5 year-old horses [as an example] and at the same time treat 100% of 0 to 5 year-old mares. But remember that the contraception parameters are percentages of *released* mares to be treated. If the gather stops when the population has been reduced to the target level, then under these conditions no treated 0 to 5 year-old mares will be released. But it may be desirable to continue the gather after the population has been reduced to the target level, and treat and release extra females that are brought in. If your choice … is to continue the gather to treat females, and the removal and contraception parameters are as stated in the beginning of this paragraph, then until the target is reached all 0 to 5 year-old females (as well as males) will be removed as they are brought in. The gather will continue after the target is reached, and additional 0 to 5 year-old females gathered will be treated and released.

Environmental Stochasticity

For any natural population, mortality and reproduction vary from year to year due to unpredictable variation in weather and other environmental factors. This model mimics such *environmental stochasticity* by using a random process to increase or decrease survival probabilities and foaling rates from average values for each year of a simulation trial. Each trial uses a different sequence of random values, so gives different results for population growth. Looking at the range of final population sizes in many such trials will give you an indication of the range of possible outcomes of population growth in an uncertain environment.

How variable are annual survival probabilities and foaling rates for wild horses? The longest study reporting such data was done at Pryor Mountain, Montana by Garrott and Taylor (1990). Based on 11 years of data at this site, survival probability of foals and adults combined was greater than 98% in 6 years, between 90 and 98% in 3 years, 87% in 1 year, and only 49% in 1 year of severe winter weather. These values clearly aren't normally distributed, but can be approximated by a logistic distribution. This pattern of low mortality in most years but markedly higher mortality in occasional years of bad weather was also reported by Berger (1986) for a site in northwestern Nevada. Therefore, environmental stochasticity in this model is simulated by drawing random values from logistic distributions.

Because year-to-year variation in weather is likely to affect foals and adults similarly, this model makes foal and adult survival perfectly correlated. This means that when survival probability of foals is high, so is survival probability of adults, and vice versa. By contrast, you may adjust the correlation between survival probabilities and foaling rates to any value between -1 and +1. The default correlation is 0 based on the Pryor Mountain data and the assumption that most mortality occurs in winter and winter weather is not highly correlated with foaling-season weather.

WinEquus produces a variety of tables and graphs of simulation results. For this economic analysis, the WinEquus simulation results were saved to a text file that was subsequently read by a special-purpose program (see Appendix C) to calculate expected economic costs (and their variability) over a 20-year period.

Setting Jenkins Model Simulations for Economic Analysis

Following the lead of U.S. BLM Challis Field Office (2002) and the values or settings the Jenkins' WinEquus model uses by default if no other choice is made, the following 'switches' were used in all HMA model simulations. All other management switches or options varied depending on the specifics of each alternative evaluated and have been described in the main text.

- Simulations were run for 20 years (producing 21 years of simulation output) with 100 trials each (100 trials is the default)
- Gathering for removal occurred at regular 4-year intervals
- When fertility control was used:
    - Gathers for fertility control occurred regardless of population size
    - Gathers continued after removals to treat additional females to be released (default if the above condition is true. Note, however, that the percentage of females actually treated by age class depends on other model input.
- Scaling factors for annual variation:
    - survival probabilities = 1.00 (default)
    - foaling rates = 1.00 (default)
- Correlation between annual variation in survival probabilities and foaling rates = 0.00 (default)
- Initial population size is inexact but smoothed (default)
- Foal survival is not density dependent (default)
- Minimum age of sanctuary-bound horses: Not applicable (default)

The general procedure for each HMA model would be to 1) load the three relevant input files [initial sex and age structure, survival probabilities by sex and age class, and foaling rates by mare age class along with sex ratio of foals] making any change to the total estimated population size as necessary; 2) define each management option that consists of six parts: selective removal rates by sex and age class, contraceptive options, the 'gather when population exceeds' trigger, the 'reduce population to' level, whether or not foals are included in the AML, and percent of the population that can be gathered; 3) run the simulation model for 20 years using 100 trials each; 4)

examine the simulation results to make sure that AML was achieved; 5) save the results to a uniquely named text file designating each scenario; 6) record the median growth rate associated with that simulation; and 7) proceed to the cost estimation program.

Appendix B. Listings of Jenkins Model Parameters for the Three HMAs Analyzed

The following three tables present the basic parameters used in Jenkins' model simulations. Note, however, that the values in the columns titled "Initial Base Population" for males and females are actually randomly sampled values that assume that the user-specified model inputs are approximately 90% of the 'true' value. In addition, the log files incorrectly report that gathers do not continue after removals to treat additional females (Steve Jenkins, personal communication). This error has been corrected in these three tables.

Note: After this report was finalized, a reviewer noted that no foals would ever be given contraceptives. This is true. However, a careful review of simulation results revealed that eliminating contraceptives for foals would make only a small difference for the three populations studied. The reason for this is that most gathered foals are removed for adoption instead of being released back to the herd and the foaling rate for yearlings and 2-year old mares is low compared with older aged mares. Should this analysis ever be updated, the models should incorporate this change.

Table B.1. Challis Jenkins model log file for 2-year Contraceptive Scenario-a. Survival and foaling rates were borrowed from the Garfield Flat herd for BLM's modeling.

Age Class	Initial Base Population		Survival Probabilities		Foaling Rates	Percentages for Removals		Percentages for Fertility Treatment
	Females	Males	Females	Males		Females	Males	
foal	25	25	0.919	0.877	0.00	100%	100%	100%
1	12	10	0.996	0.950	0.00	100%	100%	100%
2	32	36	0.994	0.949	0.52	100%	100%	50%
3	16	16	0.993	0.947	0.67	100%	100%	50%
4	16	11	0.990	0.945	0.76	100%	100%	50%
5	9	10	0.988	0.942	0.89	100%	100%	50%
6	11	7	0.985	0.939	0.76	0%	0%	50%
7	10	5	0.981	0.936	0.90	0%	0%	50%
8	8	5	0.976	0.931	0.88	0%	0%	50%
9	3	5	0.971	0.926	0.91	0%	0%	50%
10-14	12	11	0.947	0.903	0.81	0%	0%	100%
15-19	9	4	0.870	0.830	0.82	0%	0%	100%
20+	3	2	0.591	0.564	0.75	0%	0%	100%

Sex ratio at birth: 58% males
Scaling factors for annual variation: survival probabilities = 1.00, foaling rates = 1.00
Correlation between annual variation in survival probabilities and foaling rates = 0.00

Management by removals and fertility control
Starting year is 2003
Gathering occurs at regular interval of 4 years
Initial gather year is 2003
Gathers for fertility treatment occur regardless of population size.
Gathers continue after removals to treat additional females.
Threshold population size for gathers is 253.
Target population size following removals is 185.
Foals are included in AML.
Percent of population that can be gathered = 75%.
Percent effectiveness of fertility control: year 1 is 80%, year 2 is 50%, year 3 is 0%, year 4 is 0%, year 5 is 0%.

Table B.2. Little Book Cliffs Jenkins model log file for 2-year Contraceptive Scenario-a. Survival and foaling data were not borrowed from any other herd.

Age Class	Initial Base Population		Survival Probabilities		Foaling Rates	Percentages for Removals		Percentages for Fertility Treatment
	Females	Males	Females	Males		Females	Males	
foal	11	11	0.919	0.936	0.00	100%	100%	100%
1	13	13	0.983	0.962	0.00	100%	100%	100%
2	7	9	0.935	0.948	0.04	100%	100%	100%
3	5	5	1.000	0.963	0.59	100%	100%	100%
4	6	8	0.968	0.957	0.58	100%	100%	100%
5	4	6	0.976	0.971	0.75	100%	100%	75%
6	4	4	0.985	0.962	0.83	0%	0%	75%
7	3	5	0.938	0.979	0.74	0%	0%	75%
8	3	3	0.879	1.000	0.81	0%	0%	75%
9	2	5	0.944	1.000	0.82	0%	0%	75%
10-14	8	9	0.970	0.983	0.64	0%	0%	100%
15-19	2	3	0.980	0.001	0.74	0%	0%	100%
20+	1	1	0.794	0.001	0.00	0%	0%	100%

Sex ratio at birth: 50% males
Scaling factors for annual variation: survival probabilities = 1.00, foaling rates = 1.00
Correlation between annual variation in survival probabilities and foaling rates = 0.00

Management by removals and fertility control
Starting year is 2003
Gathering occurs at regular interval of 4 years
Initial gather year is 2003
Gathers for fertility treatment occur regardless of population size.
Gathers continue after removals to treat additional females.
Threshold population size for gathers is 150.
Target population size following removals is 90.
Foals are excluded from AML.
Percent of population that can be gathered = 80%.
Percent effectiveness of fertility control: year 1 is 80%, year 2 is 50%, year 3 is 0%, year 4 is 0%, year 5 is 0%.

Table B.3. McCullough Peaks Jenkins model log file for 2-year Contraceptive Scenario-a. Survival and foaling rates applied by BLM were borrowed from the Granite Range herd.

Age Class	Initial Base Population		Survival Probabilities		Foaling Rates	Percentages for Removals		Percentages for Fertility Treatment
	Females	Males	Females	Males		Females	Males	
foal	20	5	0.917	0.917	0.00	100%	100%	100%
1	12	3	0.969	0.969	0.00	100%	100%	100%

10-14	29	54	0.951	0.951	0.85	0%	0%	100%
15-19	19	49	0.951	0.951	0.70	0%	0%	100%
20+	11	39	0.951	0.951	0.70	0%	0%	100%

Sex ratio at birth: 57% males
Scaling factors for annual variation: survival probabilities = 1.00, foaling rates = 1.00
Correlation between annual variation in survival probabilities and foaling rates = 0.00

Management by removals and fertility control
Starting year is 2003
Gathering occurs at regular interval of 4 years
Initial gather year is 2003
Gathers for fertility treatment occur regardless of population size.
Gathers continue after removals to treat additional females.
Threshold population size for gathers is 140.
Target population size following removals is 100.
Foals are excluded from AML.
Percent of population that can be gathered = 90%.
Percent effectiveness of fertility control: year 1 is 80%, year 2 is 50%, year 3 is 0%, year 4 is 0%, year 5 is 0%.

Appendix C. Program to Estimate Economic Costs from WinEquus Simulation Results

As mentioned in Appendix A, the Jenkins model was used to simulate the individual populations' alternative futures and the simulation results were written to a text file. A Microsoft VisualBasic program was constructed to read these results and calculate average yearly costs as well as overall average costs for a 20-year period. User-specified input to this program (Figure C.1) includes cost estimates for the individual components of the variable costs for each state.

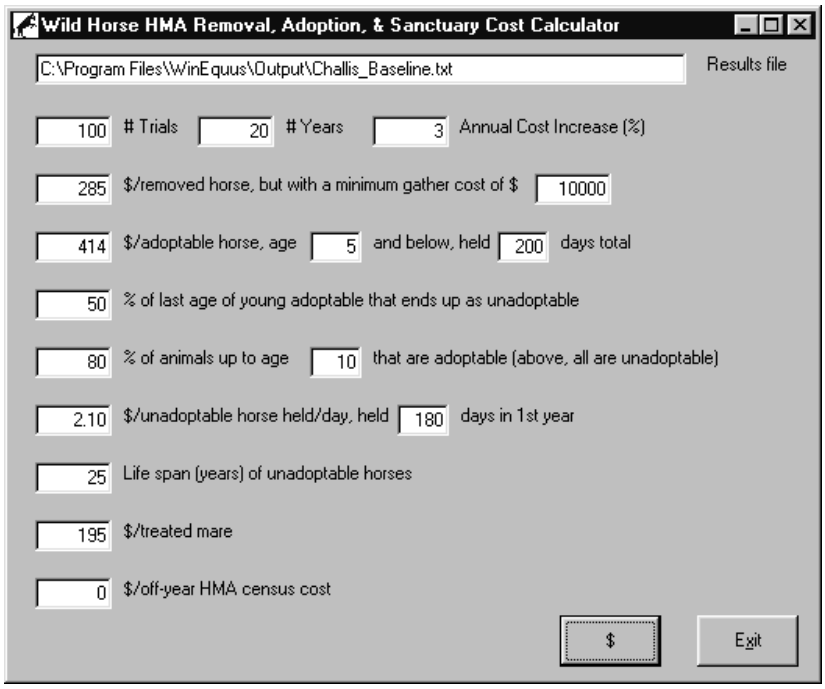

Figure C.1. Input costs and parameters for companion program to estimate costs of each specific simulation run with the Jenkins modeling software.

The number of *trials* and number of *years* are set to match the Jenkins model set-up. The number of trials and number of years captures both the variability inherent in stochastic simulation model and any population adjustments in age and sex structure that occur over about one horse life span. The *annual cost increase* adjusts all future expenditures for the rate of inflation. The *$/removed horse* reflects the cost of gathering and removal averaged across all removed horses. *Minimum gather cost* is just what it says, i.e., even if the number of gathered horses is small, there would be a minimum cost just to have a gather. The *$/adoptable horse* reflects the combined cost of adoption and compliance checks (Table 3). All horses up to the first age listed are assumed to be adoptable, except for the *% of last age of young adoptable that ends up as unadoptable*. In other words, a certain percentage of the oldest age class of adoptable animals (50% of age 5 animals in the above figure) is considered unadoptable. Adoptable animals are held for the first number of *days* listed prior to adoption. A *% of animals up to age* xx are also considered adoptable. Unadoptable animals accrue a cost of *$/unadoptable horse held/day*, are held *days in 1st*

year, and 365 days thereafter through their *life span*. Note that adoptable horses also accrue the same holding cost for the days they are held prior to adoption. Contraceptive application is reflected in the *$/treated mare* cost estimate. *$/off-year HMA census cost* reflects any additional costs involved with a contraceptive program in non-gather years (typically years 2 through 4), such as flight costs to assess treatment effectiveness and perform other routine monitoring (Hall, 2003). This last item would be zero except for scenarios involving contraceptive treatment.

The program reads the simulation results, averaging the costs for each year over the number of trials for which the software was run, and then summarizes the results across all simulation years. The output from this program looks like that shown in Table C.1.

Table C.1. Example output from cost estimator program for Challis 2-year Contraceptive Scenario-a.

```

The economic model output contains the name of the Jenkins model simulation results file and echoes the input values used. *Expenses* are inflation-adjusted values and *CV* is the coefficient of variation, i.e., the percent that expenses might be expected to vary annually given the variability reflected in the stochastic population model. The CV value is calculated as one standard deviation from the mean value for the year divided by that mean value. The remaining values listed (population size, sex ratio, number gathered, number treated, number removed, number adopted, number unadoptable, number held, and number dying) also represent annual averages, rounded to the nearest animal. The *mean* values listed near the bottom are averages across the number of years, except for those associated solely with gathering (population size, sex ratio, number gathered, number treated, number removed, number adopted, number unadoptable), which are averaged across the number of gathers. Finally, the program

provides the percentage of the mean annual expense attributable to the total cost of adoptions, long-term holding, and contraceptive treatment.

Scanning the values listed in Table C.1 above, one can usually see how the population is adjusting through time to the management strategy implemented in the population modeling software. It is also a useful way to assess whether the selective removal rates specified in the Jenkins model have been effective in reaching the specified herd-specific AML – if foals are included in the AML.

Appendix D. Caveats to this Analysis

In conducting any sort of analysis that pretends to forecast the future, there are numerous caveats that should be mentioned. It is the author's considered opinion that none of the items listed below should be regarded as truly significant in interpreting the main conclusions of this analysis; they merely serve to document and inform any subsequent analysis, and point to opportunities for additional research.

Practical ecological and management problems such as preservation and regulation of wild horse populations can be addressed with quantitative tools such as models. A model is nothing more than a mathematical caricature of the real world. Models can be excellent tools for developing a better understanding of the way things work and the expected effects of certain management interventions, but they typically do not -- indeed cannot -- fully capture all the possible variability inherent in the system under study. Models are therefore compromises between available data and complete understanding (Akcakaya and others, 1997).

There are several particular areas where the Jenkins model may not fully capture biological processes or current management practices. One deviation from reality is the model's view that horses gathered and removed approximate a sample of the population. As one reviewer pointed out, gathers are not likely to be a random sample, but instead probably over represent mares, foals, and younger horses due to their relative 'gatherability'. Small, scattered groups of bachelor males are likely underrepresented in the gather because they can be elusive. The full ramifications of this *lack* of bias in the model are unknown and need further work. Another limitation deals with the application of specified sex- and age-specific removal 'rates'. This is a two-pronged issue. Removal rates can be set too low to actually achieve the target AML and, because of the model's implementation, it can be difficult to tell whether or not the AML has actually been achieved under all conditions simulated, especially if foals are not included in the AML. Related to this, the current selective removal policy's three-tiered age removal guidelines can be difficult to emulate with the existing Jenkins software because the specified removal rates are applied as if the animals are being run through a random removal process. That is, each animal is handled in a random order and either removed or returned to the field. The software does not, as an example, first remove all Tier One animals, followed by Tier Two and then Three only as necessary. One can approximate the three-tiered policy using a trial-and-error approach, but this can be tedious and cannot be changed during a multi-year simulation period. Fortunately, if the software can reach AML solely by removing Tier 1 animals – as seemed to be the case for two of populations studied here, all is well. In the case of McCullough Peaks, Tier Two removals were needed, and even then it took several years to truly achieve its AML (see previous Figure 11). Herds with significant numbers of older aged animals might pose additional modeling problems. Finally, there is a small lack of fidelity in the Jenkins model's representation of age classes. The last three age classes in the software are aggregates (10-14, 15-19, and 20+). I assumed that unadoptable horses in these age categories were 12, 17, and 22 years old, respectively, when calculating how long they would remain in long-term holding.

Because of randomness inherent in Jenkins model simulations, running exactly the same scenario a second time is guaranteed to produce slightly different results. Changing a parameter and re-running the software will also produce different results both because of chance phenomena in the model and the parameter change itself. This has implications when interpreting the results, occasionally making it difficult to unilaterally assign effects to causes, especially when counter-intuitive or questionable predictions arise from small input changes. This phenomenon could perhaps be minimized if more simulation trials were used, but it also mimics difficulties with real-world experiments.

It would be prudent to address whether the three populations examined here are truly representative of horse herds larger than those simulated. It is my opinion that the estimates of relative cost savings of contraceptive alternatives are not likely to change much for larger herds. I say this because these dynamics are fundamentally governed by the relative ratio of survival and foaling rates that, in combination with removal strategy, controls the effective population growth rate. However, I have not actually tried to confirm these conclusions by simulating larger populations.

Additional caveats to this analysis include: (1) I have not accounted for any potential compensatory reproductive stimulus after a contraceptive has worn off (Garrott and Taylor, 1990) or any increase in longevity of treated mares (Garrott and others, 1991). (2) This analysis did not consider any effects on genetic integrity,

cumulative risks to population persistence, or herd social/behavioral effects. It was assumed that these considerations were already reflected in the establishment of each herd's AML. However, the particular method of achieving an AML (such as using fertility control) can influence the minimum projected population size, an important factor in ensuring genetic integrity. (3) This analysis did not factor in any density dependent survival or reproduction because it was assumed that each population's AML was well below estimates of range carrying capacity. (4) There are some inaccuracies inherent in the cost-accounting model when percentages are applied to a small number of removed animals, such as to divide an age class into adoptable or unadoptable animals. (5) There are other small deviations from reality inherent in the cost accounting model. In the existing baseline situation (as depicted in Figure 1), slightly more males than females are moved from the adoption pool to the long-term holding pool due to difficulty of handling or other problems that tend to make these males more unadoptable (see Godfrey and Lawson 1986). (6) This analysis was not intended to cover other generalities of managing populations with contraceptives such as those provided by Garrott and Siniff (1992), Gross (2000) or Hobbs and others (2000).

Economic analysis is not a substitute for judgment. Judgment will continue to play a role in assessing values, uncertainties, and elements that do not lend themselves to quantification. Economic analysis is but one component of the whole decision making process. Economic analysis assumes rational behavior, which can be both a strength and a weakness. There are likely to be many other intangibles: socio-political acceptability (Boyles, 1986; Berger 1986; Berger, 1991), legality, income-distributional effects, and potential environmental aspects. I have not done a full-blown *net benefit to society* analysis. For example, I have not considered costs of decreased grazing by domestic livestock and wildlife on horse range, potential increased siltation of streams if horse populations were higher, maintenance of fences and other improvements, nor the 'subsidy' that may be received by some individuals participating in the adoption program (Godfrey, 1979). In addition, I have not included the costs of research into contraceptive application and follow-up, a necessary component of any large-scale undertaking.

Management and Conservation Article

Economic Benefit of Fertility Control in Wild Horse Populations

JOHN BARTHOLOW,[1] *United States Geological Survey (Retired), Fort Collins Science Center, 2150 Centre Avenue, Building C, Fort Collins, CO 80526-8118, USA*

ABSTRACT I projected costs for several contraceptive treatments that could be used by the Bureau of Land Management (BLM) to manage 4 wild horse (*Equus caballus*) populations. Potential management alternatives included existing roundup and selective removal methods combined with contraceptives of different duration and effectiveness. I projected costs for a 20-year economic life using the WinEquus© wild horse population model and state-by-state cost estimates reflecting BLM's operational expenses. Findings revealed that 1) currently available 2-year contraceptives in most situations are capable of reducing variable operating costs by 15%, 2) experimental 3-year contraceptives may be capable of reducing costs by 18%, and 3) combining contraceptives with modest changes to herd sex ratio (e.g., 55–60% M) could trim costs by 30%. Predicted savings can increase when contraception is applied in conjunction with a removal policy that targets horses aged 0–4 years instead of 0–5 years. However, reductions in herd size result in greater variation in annual operating expenses. Because the horse program's variable operating costs make up about half of the total program costs (which include other fixed costs), contraceptive application and management can only reduce total costs by 14%, saving about $6.1 million per year. None of the contraceptive options I examined eliminated the need for long-term holding facilities over the 20-year period simulated, but the number of horses held may be reduced by about 17% with contraceptive treatment. Cost estimates were most sensitive to the oldest age adoptable and per-day holding costs. The BLM will experience significant cost savings as carefully designed contraceptive programs become widespread in the wild horse herds it manages. (JOURNAL OF WILDLIFE MANAGEMENT 71(8):2811–2819; 2007)

DOI: 10.2193/2007-064

KEY WORDS Bureau of Land Management, contraceptive, *Equus caballus*, feral horses, modeling, porcine zona pellucida (PZP), reproduction, sex ratio.

Recent management of wild horses in the western United States has been governed by the Wild Free-roaming Horses and Burros Act of 1971 (Public Law 92–195), as amended. Management has typically been achieved by the Bureau of Land Management (BLM) by rounding up each herd about every 4 years and removing selected animals from the range to attain herd-specific population goals known as appropriate management levels (AMLs). Under 2003 BLM policies and guidelines, young horses (age 0–5 yr), which have a higher probability of being adopted, are removed first to achieve the AML. If necessary, older horses (≥10 yr) compose a second tier of removals, followed by horses aged 6–9 (tier 3). All young horses and most middle-aged horses that have been removed enter a pool from which private adoptions are encouraged. All other horses removed to achieve population goals are maintained in long-term holding facilities for the remainder of their natural lives (Fig. 1).

Management of these herds has been costly. Legislation has restricted the options that can be used to manage populations; sanctuary and adoption alternatives have been expensive and less than fully effective because of the long-term care requirements (U.S. General Accounting Office 1990, Conover 2002), and herds continue to grow, often at high rates (6–25% or more annually; Eberhardt et al. 1982, Wolfe 1986). Budgetary limitations demand tough decisions on how best to minimize expenditures yet still meet legislated goals to maintain a "thriving natural ecological balance" and preserve existing multiple uses including rangeland health (U.S. General Accounting Office 1990:9). Fertility control has been proposed as one option but has not been thoroughly evaluated for expected cost-effectiveness. Fertility control is generally viewed as humane (Reiter et al. 1999), is safe and reversible (Kirkpatrick and Turner 2002), and has been shown to successfully complement other methods of population control for wild horses (Garrott 1991, Garrott et al. 1992, Gross 2000, Hobbs et al. 2000).

The BLM maintains a state-by-state database on the costs of herd monitoring, population estimates, selective removal, preparation and holding, adoption, compliance checking, and other program activities. With this database, I estimated costs of several management alternatives using 2004 management expenses for available or reasonably foreseeable contraceptive technology for 4 BLM-managed wild horse populations in a manner similar to that of Garrott et al. (1992). My specific objective was to identify the expected effectiveness and costs for a limited set of contraceptive options in the face of variable, state-by-state management expenses representing BLM's 2003 management policies.

STUDY AREA

The 4 wild horse populations chosen by BLM for this analysis were the Challis Herd Management Area (HMA) near Challis, Idaho, USA; the McCullough Peaks HMA near Cody, Wyoming, USA; the Pryor Mountain Wild Horse Range north of Lovell, Wyoming, USA; and the Little Book Cliffs HMA near Grand Junction, Colorado, USA. Each herd had a different management history, discrete population goals, and unique demographic attributes with accompanying data reliability issues.

The Challis herd occupied a large area (323,749 ha) of

[1] *E-mail: JohnB@Webaccess.Net*

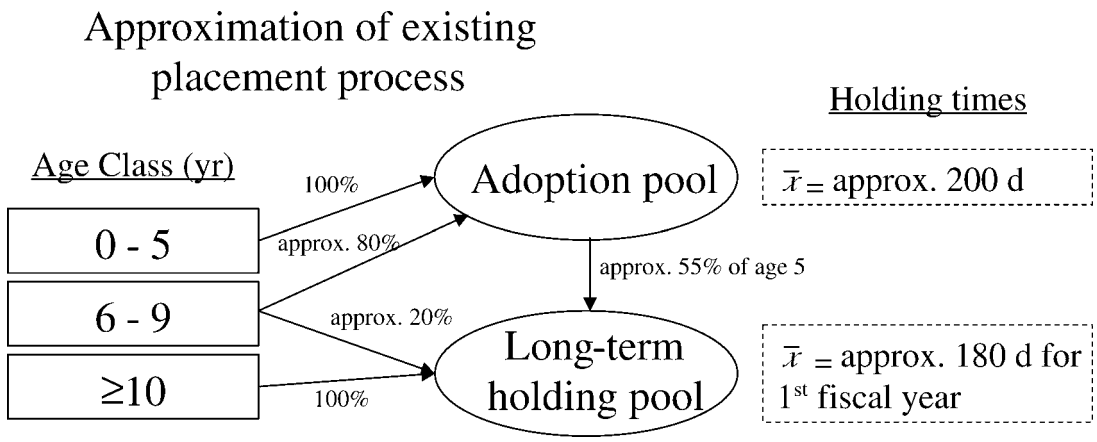

Figure 1. Approximation of existing selective removal and placement policy (baseline scenario) for the Bureau of Land Management's wild horse program in the western United States. For example, 100% of any 0-year-old to 5-year-old horses removed from the range to achieve the target population size are placed in the adoption pool. I obtained values from Bureau of Land Management instructional guidance representative of 2003 procedures.

mostly public land that included many livestock grazing allotments. In 2002, the herd size was estimated at approximately 271 horses, growing at about 17% annually. Rangeland and aquatic system health goals dictated a postremoval population goal of 185 animals, including young-of-the-year.

The Little Book Cliffs herd was located on 12,140 ha of public land. This herd of about 150 horses was rounded up periodically and had been the subject of ongoing contraceptive research. All yearlings and 2-year-old females, half of those aged 3–15 years, and all females >15 years that were captured at the 2002 roundup and returned to the range were primed with the contraceptive agent porcine zona pellucida (PZP). Though the Little Book Cliffs HMA was undergoing research during my study, I used it as a proxy for other populations with similar demographics. Simulations were not meant to emulate research protocols currently being applied.

The McCullough Peaks HMA occupied 44,515 ha of open sagebrush (*Artemisia tridentata*) prairie and badlands. The wild horse population was about 150 animals, with the AML set between 70 animals and 140 animals, excluding young-of-the-year. Contraceptives had only recently been applied to this herd. Unlike the other herds, McCullough Peaks had more older-age horses (tier 2) removed to achieve its AML.

The Pryor Mountain Wild Horse Range occupied 15,378 ha of multi-jurisdictional lands along the border of Montana and Wyoming. This mostly arid range supported 100–200 freely roaming wild horses. Harsh winters and abundant predators likely limited the number of older animals and contributed to variable, intermittently high young-of-the-year mortality. Conflicting perspectives stimulated research on several issues germane to management of this herd, including vegetation dynamics and population genetics (Singer and Schoenecker 2000). Fertility control research began on the Pryor Mountain herd in 2001, with contraceptives applied via remote darting after an initial roundup. Darting, which delivered an initial primer and annual booster, can take place over time, ultimately reaching 100% of the females targeted for contraceptives. Though BLM had managed this herd somewhat differently from the others, I included it in this analysis because of its unique demography. For tractability, I treated the Pryor Mountain herd in a manner parallel to the other 3 herds and assigned it management costs representative of Montana because these costs most closely represent the Pryor-specific program costs estimated by BLM.

METHODS

Population Model

I extracted data for each herd from BLM records, supplemented as necessary with information provided by herd managers (Table 1). I then conducted simulations using WinEquus© (Version 1.4; Jenkins 2002) for each herd. This sex- and age-based model mimics roundup, selective removal, and contraceptive applications against a backdrop of random variability in both annual environmental conditions and individual animal mortality and reproductive status. The model requires an initial age and sex distribution, age-specific survival and foaling rates, young-of-the-year sex ratio, and rules governing how removals and contraception alternatives are simulated. Each random model trial results in a different pattern of population growth, at times producing runs of good and bad years.

I ran each scenario as a separate stochastic simulation using model input parameters that control the various assumptions or management actions that might be taken. I ran all simulations for 20 years and repeated them for 100 trials each (Fig. 2). I chose the model's default simulation assumptions: 1) there is no correlation between annual variation in survival probabilities and foaling rates, 2) initial population size and structure are treated as inexact (slightly variable in each trial) and smoothed by the model, and 3) young-of-the-year survival is density independent. I simulated each scenario by the appropriate combination of 6 model parameters: selective removal rates by sex and age class, efficacy of contraceptive agent (if applied), threshold population size triggering a roundup, target population size

Table 1. Key demographic and other information for the 4 wild horse herd management areas I assessed in the western United States. Values are representative of 2004 data.

Attribute	Herd management area			
	Challis	Little Book Cliffs	McCullough Peaks	Pryor Mountain
Cost state	ID	CO	WY	MT

following removal, whether young-of-the-year were included in the AML, and percentage of the population that can be rounded up. The WinEquus model calculated growth rates as the geometric average of year-to-year changes in population size, excluding any management removals.

Specific Alternatives Analyzed

Population management alternatives that I explored using WinEquus included 1) the status quo of selective removal, adoption, and sanctuary; 2) changing the frequency of roundups and how efficient roundups are; 3) status quo plus a variety of alternative contraceptive application scenarios, specifically varying the duration of the contraceptive agent; and 4) sex ratio manipulation through age- and sex-specific removal rates. I modeled the following limited set of scenarios:

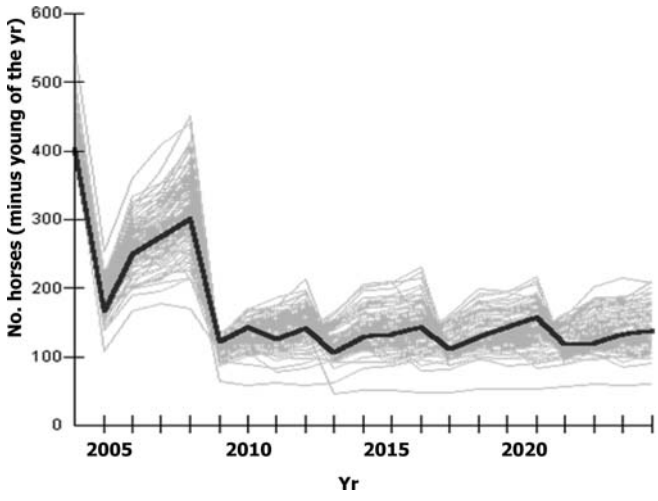

Figure 2. Example WinEquus model output for the McCullough Peaks Herd Management Area in Wyoming showing the total postroundup population size of wild horses (minus young-of-the-yr, because they are not included in the target population size) through a 20-year simulation beginning in 2004. Light lines trace the 100 individual simulation trials and the heavy line traces the median (most typical) result.

1. *Baseline.*—Management conditions as reflected in BLM's recent roundup policy, including a regular 4-year roundup cycle with age-specific placement rates (Fig. 1). Age classes are removed in successive age-specific tiers to achieve the designated AML for each herd, with 0-year-old to 5-year-old horses removed first, followed by ≥10 year olds, and finally 6-year-old to 9-year-old animals.
2. *Alternative baseline.*—An alternative to the Baseline Scenario being considered by BLM in which the first tier of removals targets age classes 0–4 years, tier 2 remains ≥10 years old, and tier 3 is 5–9 years old. In the Alternative Baseline Scenario, 70% of tier 3, if removed, is directed to the adoption pool and 23% of 4-year-old animals end up in long-term holding, in contrast with Figure 1.
3. *Roundup frequency.*—Scenarios representing regular intervals of every 2 years, 6 years, or 8 years.
4. *Contraceptive.*—Scenarios representing either a 2-year or 3-year contraceptive agent defined more precisely with percent effectiveness in the first and subsequent years (Table 2). I assumed that if a contraceptive proved ineffective in the first year for a given female, it would never be effective in subsequent years until re-treatment.
5. *Sex ratio.*—Scenarios representing reductions in the percentage of males removed across all targeted age classes. Normally, if an age class is subject to removals, a herd-specific percentage of animals of both sexes is targeted for that removal. In these scenarios, I reduced male removals by 10%, 20%, and 30%, resulting in more females removed to satisfy herd size goals.
6. *Roundup efficiency.*—Scenarios representing changes in

Table 2. Estimated treatment cost and annual effectiveness of existing 2-year and potential 3-year contraceptive treatments I used in analysis of 4 wild horse herds in the western United States. Costs include both contraceptive materials and application. Effectiveness in this context refers to the percentage of treated females that do not give birth. All values are representative of 2004.

Nominal duration (yr)	Cost/F ($)	Effectiveness yr 1 (%)	Effectiveness yr 2 (%)	Effectiveness yr 3 (%)	Effectiveness yr 4+ (%)
2[a]	214	94	82	34	0
3[b]	309	95	85	75	0

[a] Effectiveness values reflect preliminary results from the Clan Alpine Horse Management Area in NV (R. Hall, Bureau of Land Management, personal communication).

[b] I extrapolated hypothetical effectiveness values from 2-yr effectiveness rates. Cost of 3-yr agent is cost of 2-yr agent plus additional 12-month time-release pellets.

the estimated efficiencies for the 4 herds. I varied the nominal roundup efficiency by −5%, +5%, and +10%.

7. I also considered a limited set of combinations of the above scenarios.

Estimating Dollar Values

I estimated costs for each of the main expenses (i.e., roundup, treating, and selective removal) along with other miscellaneous management expenses from the state-specific costs compiled by the BLM (Table 3). These costs represented 2004 values, but I assumed they increased 3% annually regardless of geographic area to approximate inflation. Removal costs included all expenses of roundup and transport to adoption or holding facilities, averaged across all removed horses. Preparation and holding costs included operational and labor expenses for freeze-marking, health care, required vaccinations, feed, and facility maintenance. Adoption costs were largely administrative, including follow-up site visits to adopted horses to assess compliance with adoption policies.

Multiyear contraceptive costs I used in this analysis were provided by the BLM (L. Coates-Markle, BLM, personal communication). The BLM gave a range of costs associated with the 2-year contraceptive. Though costs are likely to decline in the future, I chose the more expensive estimate provided, $214 per horse, to be conservative.

I also considered several other costs in the analysis. I assumed a minimum roundup cost of $15,000 for the Pryor Mountain HMA and $10,000 for the other 3 herds, reflecting higher costs for the Pryor herd. This minimum applies only if the number of animals removed times the appropriate per horse removal cost is below the minimum. For each contraceptive scenario, I also assumed a flight cost of $5,000/year/HMA (R. Hall, BLM, personal communication) to estimate contraception effectiveness.

I summarized the results of WinEquus simulations and converted them to dollar expenses over a 20-year planning horizon. I chose 20 years because it is long enough (5 complete 4-yr roundup cycles) to reduce the uncertainty inherent in estimates of the initial age and sex structure and to reveal most of the effects of change in sex and age structure that would result over time from the variety of treatment options simulated. To tally the total expenditures, I summed all costs previously described, including which age groups were eligible for adoption and how long adoptable and unadoptable horses were projected to be held (Fig. 1). I assumed all unadoptable horses would remain in holding facilities for the remainder of their natural lives, estimated to be 25 years. I summarized cost estimates by computing the mean number of horses rounded up, removed, and treated by sex and age class for each year of the 20-year simulations, along with average annual costs and the coefficient of variation in annual costs.

First-Order Sensitivity Analysis

The WinEquus simulation model incorporates environmental and demographic stochasticity, but the uncertainty in cost estimates and sensitivity of other management options was unknown. To examine this, I performed a first-order sensitivity analysis for the 4 populations to see where opportunities for cost cutting might be found and which factors contributed most to the estimated costs. I conducted

the sensitivity analysis by varying each cost (e.g., cost/adopted horse) by ±20% and each age class category ±1 year class, one parameter at a time, and then calculating the ratio of the resulting cost fluctuation to the base cost of the 2-year contraceptive scenario.

RESULTS

The alternative baseline scenario proved to be more expensive than the baseline scenario for the Challis and Pryor Mountain herds, 102% and 111%, respectively (Table 4). For these 2 herds, the alternative baseline resulted in an average of 1–2 additional horses held in long-term facilities with attendant costs. Costs were reduced for the Little Book Cliffs and McCullough Peaks herds under the alternative baseline, 98% and 99%, respectively (Table 4).

In the remove-only scenarios, adjusting the herds' sex ratio by removing fewer males was always successful at reducing management costs, with the −30% male removal scenarios resulting in 10–24% cost reductions on average and corresponding reductions in median annual growth rate depending on the herd. Resultant sex ratios for these most extreme simulations were generally in the range of 52–57% males as opposed to baseline conditions that were 46% males for 3 of the herds. The McCullough Peaks HMA was an exception, because the sex ratio increased over time to 65% males (Table 4).

Either a 2-year or 3-year contraceptive application was effective in reducing management costs by 12–20% for 3 of the herds; the Pryor Mountain HMA was an exception because of its comparatively slow growth rate and higher costs. In fact, as simulated, the contraceptive scenarios reduced the Pryor Mountain growth rate below zero. None of the herds would benefit by delaying the regular 4-year roundup frequency to 6 years or 8 years in combination with a 2-year contraceptive, although reducing the period to 2 years could reduce costs 26–55% in all but the Pryor Mountain herd because of its low growth rate and high costs compared with the other herds. A 2-year roundup cycle combined with contraceptive treatment precludes reproduction by even more of the youngest females.

Annual costs were sensitive to roundup efficiency, although increasing the efficiency 5–10% only resulted in decreasing costs by about 10%. The Pryor Mountain herd remained a notable exception. The estimated coefficient of variation in average annual costs differed among the herds. McCullough Peaks and Challis had the lowest variability in costs, averaging 25%. Little Book Cliffs variability was higher at 56%, and Pryor Mountain annual variability was almost 100%.

Finally, the 3-year contraceptive application combined with either adjusting the sex ratio or modifying the age classes targeted for the adoption program were the most cost-effective treatments across all herds, with reductions up to 29% for Challis, 32% for Little Book Cliffs, 31% for McCullough Peaks, and 31% for Pryor Mountain. Though not shown in Table 4, the more effective a scenario was at reducing costs, the smaller the average annual population size over all simulation trials. However, the consequence of smaller population sizes was typically an increase in the coefficient of variation in annual costs. In other words, the smaller the population, the more inherent variability in annual growth rates (a function of the stochasticity in

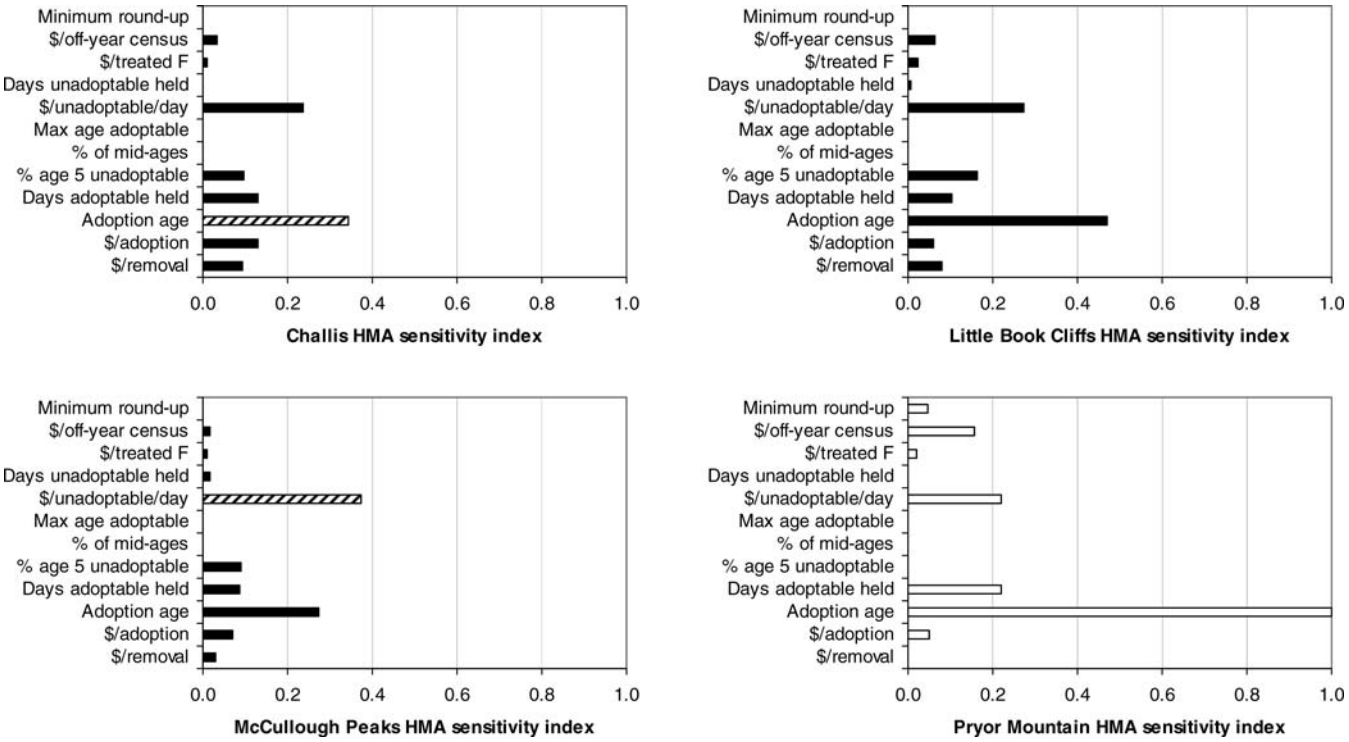

Figure 3. First-order sensitivity analysis for management costs and other attributes for the 4 wild horse herd management areas (HMA) in the western United States relative to the 2-year contraceptive scenario. Hatched bars indicate potential to be more cost-effective than the baseline alternative using data indicative of 2004 costs. Empty bars for Pryor Mountain signify that all contraceptive alternatives can be more expensive than the baseline within the sensitivity range examined.

WinEquus) and the greater the expected fluctuation in management costs. This trend was more evident in the alternative roundup interval and alternative efficiency of roundup scenarios than in the sex ratio adjustment or contraceptive alternatives.

The sensitivity analysis modeled how responsive bottom-line costs were to changes in each contributing factor (Fig. 3) relative to the 2-year contraceptive. The maximum age considered adoptable (5 yr) generally had the largest influence on total costs, indicating that if BLM were successful in placing more 6-year-old animals, costs could be reduced substantially. Adoption age was followed by the average per-day holding cost, a factor that actually exceeded maximum age adoptable for the McCullough Peaks herd because of its high holding costs (Table 3). Other factors (e.g., % of 5-yr-old horses that are unadoptable, no. of d that horses are held prior to adoption, and actual cost of adoption) had approximately equal and low sensitivity indices relative to the other factors. Costs related to contraceptive treatment, minimum roundup costs, and costs of off-year population estimates were insensitive because they were inconsequential compared with other management expenses.

In summary, contraceptive treatment added to the status quo roundup and removal program was predicted to be cost-effective for wild horse herds except for those herds with low growth rates. Depending on the herd and the effectiveness of treatment, operational cost savings projected ranged from 12% to 20% compared with baseline estimates. When combined with other actions that adjust age- and sex-specific removal rates, cost savings could increase to around 30% for all herds, even those like the slowly growing Pryor Mountain herd. Populations controlled solely by roundup declined markedly with each roundup (Fig. 2) but typically increased rapidly between them. In contrast, modeled populations controlled by contraceptives in conjunction with removals grew much less rapidly. Increasing the male sex ratio further reduced the growth rate, resulting in greater stability.

DISCUSSION

Contraceptive Effectiveness

All contraceptive options I simulated were effective at reducing costs for at least 3 of the herds studied. However, it should be noted that none of the contraceptive options I considered were projected to eliminate the need for long-term holding facilities. In total, the number of horses added to long-term holding was reduced by 17% over the simulated 20-year period with the most effective contraceptive treatment, yet only the McCullough Peaks HMA actually showed a decreasing number of horses held through the 20 years. Little Book Cliffs and Challis continued to increase the horses added to holding through time, albeit at rates 6–36% below the baseline scenario. Instead, contraceptive treatment would likely reduce the number of horses that must be removed in total, with attendant cost reductions in the number of adoptions and total holding costs. Overall, proportionate costs were predicted to shift

Table 5. Nationwide fixed and variable cost estimates for the Bureau of Land Management's wild horse program, 2004.

Cost type	Factor	Expense ($)	Total ($)	% of total

[a] AML = appropriate management levels.

from 73% related to adoption and 27% related to holding in the baseline case to 56% for adoption, 30% for holding, and 14% for contraceptive treatment in the most effective contraceptive scenarios.

Sex Ratio Manipulation

Some published literature (Berger 1986), as well as many unpublished wild horse environmental assessments, recommend maintaining populations with natural sex ratios inclined towards females (e.g., 40 M:60 F). Because sex ratio measured in the field results from the combined effects of young-of-the-year sex ratio, relative male:female survival, and removal rates that vary from herd to herd, it may be problematic to characterize a natural sex ratio, especially for a species undergoing such active management. My analysis assumed no a priori constraint on sex ratio resulting from management. Herds that have small groups of bachelor males that are difficult to round up may lend themselves easily to such a management strategy, whereas other herds that have many small harems may prove more difficult and costly to manage favoring males. Although I did not assess any potential genetic or behavioral ramifications of management favoring a male-dominated herd structure, it is clear that changing sex ratios could be significant in determining program costs.

Balancing Range Conditions with Population Size

The 20-year simulations typically showed that any management strategy might take several roundup cycles to achieve relatively stable demographics. For example, take the McCullough Peaks herd I examined (Fig. 2). I simulated this herd by removing animals from both tiers 1 and 2. A herd manager might be tempted to adjust the management strategy by also removing tier 3 animals after only 1 or 2 roundup cycles if the population (and costs) did not appear to fall as quickly as expected (i.e., if the population trajectory were near the upper extent of some of the traces on the graph). Although removal decisions must always be made using the best available data and be guided by management objectives, the results shown here argue for patience in population management for these long-lived ungulates. In particular, a management option that removes only 0-year-old to 4-year-old horses may result in a larger number of horses on the range initially, yet achieve the desired herd reduction goal over the long term. If the range is capable of sustaining a larger number of horses for several years, a patient approach could significantly reduce long-term management and holding costs.

Program-Wide Costs

My analysis explored methods of reducing costs through a combination of contraceptive and other potential management techniques. However, the costs I tabulated should be considered variable costs because they arise from variation in herd population dynamics and management strategies.

The BLM also incurs certain fixed costs associated with the wild horse program's overhead (e.g., WA and regional offices, many HMA monitoring costs, holding facility maintenance, support for the 20,000 wild horses currently residing in holding facilities). The fixed costs might be assumed to continue essentially unchanged regardless of the specific roundup and selective removal process, with the knowledge that some fixed costs, like annual monitoring, aerial population estimation, and new or revised AML establishment, are subject to annual budgetary constraints. These fixed costs have been ignored so far because they are the result of past decisions.

The BLM provided nationwide costs, both fixed and variable, for its wild horse program (Table 5). Variable costs represent slightly less than half (46%) of the aggregate costs. Results from the WinEquus model indicated that one might expect an annual decrease in variable costs of about 30% if the most effective management methods were implemented (Table 4). If these savings accrued solely to the variable side of the ledger, and if fixed costs remained stable, aggregate program costs would likely decrease by only about 14%. Characterizing the results of this analysis in relative terms, assuming that a 30% reduction is approximately correct for all herds combined, would amount to a $6.1

million annual savings in variable program costs in 2004 dollars.

Fixed costs might be expected to decline through time if the number of unadoptable horses declines. Other changes to roundup and selective removal procedures, such as completely closing an existing sanctuary facility, could alter the fixed-cost structure (specifically labor and facility costs), further reducing costs. I did not consider such potential changes to overall program costs in this analysis.

Comparison with Findings of Others

Garrott et al. (1992) explored the impacts of alternative contraceptive management on wild horses in the early 1990s. Similar to this analysis, Garrott et al. (1992) simulated a variety of different herds and considered more contraceptive alternatives than those examined here. Their results were comparable to mine, indicating that most variable program expenses are not related to contraceptive treatment per se, but instead are associated with adoption program costs. Similarly, Garrott (1995) showed that a 2-year contraceptive agent applied on a 4-year roundup cycle can make a large difference in variable costs associated with management when roundup efficiencies are around 80% and natural rates of increase are comparatively high. In my analysis, program costs always paralleled population growth regardless of the management option; this is consistent with the findings of Gross (2000) and Garrott et al. (1992).

Others have pointed out that the cost-efficiency of contraceptive treatment for a long-lived and highly productive species is extremely dependent on herd-specific demographics, management constraints, and data quality (Kirkpatrick and Turner 1986, Wolfe 1986, Garrott 1991, Hobbs et al. 2000) and that contraception must be used in conjunction with an ongoing removal program (Gross 2000). Although I made no attempt to optimize a specific management alternative for any of the 4 herds I examined, this analysis confirms that contraceptive programs must be tailored for individual herds, given differences in reproductive biology and inherent population growth rates.

Analysis Uncertainty

These simulations contain several forms of uncertainty. First, estimates of initial conditions and vital parameters are likely inaccurate, and in some cases I borrowed values for one herd from better studied herds assumed to be similar. Second, uncertainty due to range conditions, predation, and other poorly understood regulatory mechanisms is accounted for by WinEquus but results in the predicted variation in annual herd management costs of 20–30%. Such high variability likely means that it is difficult to distinguish precisely among many cost estimates. Although it would be possible to run more model trials to better estimate central tendencies, doing so would only result in a reduction of statistical uncertainty rather than actual uncertainty. Third, the BLM-derived estimates of expenses for each of the several cost components are uncertain. Costs vary through time and with the vagaries of local conditions. Further, new contraceptive techniques or agents will likely become available within 20 years. If, for example, a contraceptive were perfected that could extend the nominal efficacy well beyond 3 years, projected cost savings would mount accordingly. However, it seems likely that the program-wide cost variance would be less than the 20–30% herd level variance because some herds would be increasing whereas others would be decreasing. Nonetheless, it would be wise to consider the possibility of region-wide synchronous oscillations accompanying climatic variation that might provide favorable or unfavorable habitat conditions throughout the Intermountain West.

Analysis Limitations

Practical ecological and management problems can be addressed with models, but models are merely mathematical abstractions of the real world. Models can help develop a better understanding of the way things work and predict outcomes of specific management interventions, but they never capture the full variability and complexity inherent in the real world. WinEquus may not always faithfully represent management practices used in some herds. The model assumes that horses captured and removed approximate a random sample of the herd structure, but in reality, depending on the size of the herd, the number of animals that need to be removed, and other factors that effect roundup efficiency, females and younger animals may be overrepresented in the roundup.

As always, additional caveats extend beyond the modeling domain. This analysis did not account for any potential compensatory reproductive stimulus after $\geq$1 year of being spared from the energetic demands of pregnancy and lactation (Garrott and Taylor 1990) or any potential increase in longevity of treated adult females (Garrott et al. 1991), nor did I consider any effects on genetic integrity, cumulative risks to population persistence, or any herd social–behavioral effects. I assumed that these considerations were already reflected in the establishment of each herd's AML. This analysis did not factor in any density-dependent survival or reproduction because I assumed that each population's AML is set well below levels that would normally impact survival or population growth. For any given horse population, there are many intangibles such as the public acceptability of BLM management activities (Berger 1986, 1991; Boyles 1986) and other potential environmental ramifications. For example, I did not consider costs of decreased or increased grazing by domestic livestock and wildlife on range quality, potential decreased siltation of streams if horse populations were lower, or any secondary effects associated with the adoption program (Godfrey 1979).

MANAGEMENT IMPLICATIONS

Using the most recently available demographic and cost data for 4 widely dispersed wild horse herds, this analysis has shown that WinEquus is capable of discriminating the economic implications of a variety of management prescriptions and that prudent, patient contraceptive applications are likely to result in cost savings up to 30% for

BLM's wild horse management program. Model results clearly illustrate that the most significant cost savings accrue only when 2-year or 3-year contraceptives are combined with removals that explicitly raise the proportion of males above 50%. As herd demographic data and contraceptive techniques improve, or accepted BLM management guidance evolves, additional modeling can be used to tailor management strategies for each herd, potentially resulting in even greater cost savings.

ACKNOWLEDGMENTS

I extend thanks to many, including L. Coates-Markle, D. Glenn, R. Hall, L. Thomas, T. Hatle, J. Dollerschell, and D. Bolstad (BLM), G. Thygerson (BLM, retired), L. Zeigenfuss (United States Geological Survey [USGS]), S. Jenkins (University of Nevada, Reno), and A. Kane (United States Department of Agriculture). J. Roelle and K. Schoenecker (USGS) provided many helpful comments on an early draft of this manuscript, which is an update and condensation of investigations funded by BLM (Bartholow 2004). F. Singer (USGS, deceased) deserves great credit for initiating and encouraging this work.

Mares
IgG isotypes

ABSTRACT

SpayVac® is an immunocontraceptive vaccine based on porcine zona pellucida (pZP) antigens and uses a patented liposome formulation (VacciMax™ or DepoVax®). It has delivered single-dose, long-lasting (4–10 years) immunocontraception in several species. Previous studies have demonstrated a positive correlation between levels of pZP antibodies produced and contraceptive effect; however, individual mares that were consistently infertile did not necessarily have the highest antibody titers. The objective of this study was to identify potential differences in specific immunoglobulin G (IgG) isotype responses among mares treated with SpayVac (VacciMax formulation) to improve our understanding of vaccine efficacy and potential management applications. We analyzed serum samples collected 1, 2 and 4 years post-vaccination from mares in another study that were continuously infertile or had foaled at least once during the 4-year period ($n = 14$ each). Additional samples from the continuously infertile mares were collected 5 years post-vaccination. A fluorescent bead-based assay was used to distinguish IgG isotype responses against pZP. IgG1 antibodies were generally higher in the infertile compared to the fertile mares, but only IgG4/7 antibodies were significantly higher in infertile mares during years 1 and 2 post-vaccination ($p < 0.05$). Interestingly, IgG4/7 isotype levels were significantly higher during year 5 compared to year 4 in the continuously infertile mares ($p < 0.02$). SpayVac's ability to preferentially stimulate IgG4/7 antibodies may contribute to its long-term immunocontraceptive efficacy, and measuring IgG4/7 isotypes may help differentiate effectively contracepted mares from those that may need additional vaccination.

1. Introduction

The Bureau of Land Management (BLM) is responsible for managing feral horse (*Equus caballus*) and burro (*E. asinus*) populations on public lands, and horse numbers are currently estimated to be around 75,000 [pers. comm. Dean Bolstad, 7/17/17]). This far exceeds the appropriate management level of 26,715 [1]; and maintaining horses in off-range facilities costs the BLM millions of dollars annually [2]. Immunocontraceptive vaccines have the greatest potential to help BLM maintain horse populations at appropriate management levels; however, vaccines must have multi-year efficacy to be both technically feasible and cost-effective.

Two main classes of contraceptive vaccines have been developed based on gonadotropin-releasing hormone (GnRH) and porcine zona pellucida (pZP) antigens. It is presumed that pZP immunocontraception has fewer side effects compared to GnRH vaccines (like GonaCon™), because GnRH receptors are located in a variety of tissues in addition to reproductive organs, including the nervous system [3], bladder [4], and heart [5]. Antibody occupation of ZP receptors is thought to disrupt sperm binding [6–8], which normally initiates the acrosome reaction and subsequent fertilization [9]. ZonaStat-H is a pZP vaccine currently used in horses; however, it requires a booster 3–4 weeks after the initial inoculation and subsequent annual boosters to maintain contraceptive efficacy [10]. PZP-22 uses time-release pellets to obviate the need for boosters; however, it has a reported efficacy of up to 22 months [11], which is still not ideal for BLM [12].

SpayVac® is a pZP vaccine that uses a unique liposome technology and has delivered single-dose, long-lasting (4–10 years)

immunocontraception in a variety of species including fallow deer (*Dama dama*) [13], grey seals (*Halichoerus grypus*) [14], and horses [15]. SpayVac comes in two formulations: VacciMax™ is a water-in-oil emulsion, and DepoVax® is first lyophilized and then components are resuspended in oil prior to injection. A study by Killian et al. [15] demonstrated pregnancy rates of 0%, 17%, 17% and 17%, respectively, 1–4 years after treatment of mares with a single SpayVac VacciMax dose (400 μg pZP; n = 12) administered in the neck compared to 75%, 75%, 88% and 100% for untreated mares. Bechert et al. [16] demonstrated that 3–4 months post-vaccination with SpayVac VacciMax or DepoVax (200 μg pZP) administered in the neck, 93% of treated mares (n = 14) ceased cycling as evidenced by significantly lower serum concentrations of progesterone ($p < 0.025$) and smaller ovaries with fewer follicles ($p < 0.001$), while other organ systems were unaffected. The U.S. Geological Survey (USGS), and the U.S. Department of Agriculture, Animal and Plant Health Inspection Service initiated field trials with SpayVac in mares (200 μg pZP in DepoVax [n = 30] and VacciMax [n = 30] SpayVac formulations administered in the rump) and found that pregnancy rates for the VacciMax treatment group were significantly lower ($p < 0.001$) compared to controls for 3 years following the single injection [12].

However, results from this last study were not as robust as expected, given earlier results from both Bechert et al. [16] and Killian et al. [15]. For example, the fertility rate for the SpayVac VacciMax group (n = 30) was 13%, 47%, and 43% compared to 100%, 98%, and 100% in controls for years 1, 2 and 3 post-vaccination, respectively. The relationship between antibody titer, measured by a pZP ELISA, and fertility was also not clear, because individual mares that were consistently infertile did not necessarily have the highest antibody titers [12]. Previous studies have demonstrated a positive correlation between levels of pZP antibodies produced and contraceptive effect [10,17], and similarly in the Roelle et al. study [12], antibody titers within 50–60% of the positive reference serum appeared to effectively contracept 90–95% of the mares.

Wagner [18] reviewed different horse immunoglobulin (Ig) antibody classes (e.g., IgG, IgM, IgA, IgE) as well as IgG isotypes, which are more numerous in horses (IgG1-IgG7) compared to other mammalian species [19]. IgG is the predominant antibody class in equine serum and the major component of humoral immunity. After stimulation with specific antigens, B-cells are activated and, with the help of T-cells, develop into antibody producing plasma cells. After successful antigen stimulation or vaccination, long-lived plasma cells produce large amounts of high-affinity IgG antibodies. These antibodies, depending on their immunoglobulin subclass or isotype, can neutralize antigens or pathogens. The latter is a key function of many protective vaccines, and it has been suggested that "different IgG isotypes should be considered in developing therapeutic antibodies" [20].

The SpayVac VacciMax formulation, when administered to rabbits, created a significantly greater antibody response compared to that produced by alum-adjuvant vaccines, and this enhanced response was correlated with an increased number of antigen-specific plasma cells in the bone marrow [21]. SpayVac may similarly stimulate increased production of plasma cells in mares. Various mechanisms potentially responsible for maintenance of pZP antibody titers in mares are discussed in Bechert et al. [16], but the role different IgG isotypes may play with respect to SpayVac has not been considered.

Lewis et al. [22] analyzed different effector functions of the seven equine IgG isotypes, including complement activation, IgG-receptor binding and affinity to different bacterial cell-wall proteins. Their work suggested that equine IgG1, IgG4 and IgG7 isotypes are most capable of mediating all of these effector functions and most likely have a better neutralizing capacity compared to IgG3 and IgG5. The remaining two equine IgG2 and IgG6 isotypes are only weak immune mediators. Some of the objectives of the Roelle et al. [12] study were to: 1) evaluate the contraceptive efficacy of SpayVac over several breeding seasons, and 2) determine serum pZP antibody titers. The objective of this study was to identify potential differences in specific IgG isotype responses among mares treated with SpayVac VacciMax in the Roelle study and improve our understanding of vaccine efficacy and potential management applications.

2. Materials and methods

2.1. Vaccine preparation

Immunovaccine, Inc. (IMV; Halifax, Nova Scotia, Canada) obtained frozen pig ovaries from Sioux-Preme Packing Company (Sioux Center, IA), isolated pZP, and prepared the vaccine as previously described by Brown et al. [23]. Purified pZP was incorporated in phosphate buffered saline (PBS; pH 7.4) at a final concentration of 200 μg per dose. Lipids containing lecithin and cholesterol at a ratio of 10:1 (0.2 g lecithin and 0.02 g cholesterol/dose; Lipoid, Newark, NJ) were added to the pZP solution to form multilamellar liposomes. Modified Freund's Adjuvant (MFA; Calbiochem, La Jolla, CA) was added to half of the prepared pZP-liposome mixture to form a water-in-oil (aqueous) emulsion (1:1, v/v; 1 mL/dose). The second half of the prepared pZP-liposome mixture was lyophilized (non-aqueous) and then reconstituted with MFA for a final deliverable dose volume of 0.5 ml. Vehicle control vaccines were produced as described above without the addition of the pZP antigen (0.5 mL/dose). All vaccines and control doses were shipped to USGS for the Roelle et al. study in individual syringes kept frozen on dry ice.

2.2. Animals

The captive breeding trial was initiated in 2011 at a BLM wild horse and burro adoption facility near Pauls Valley, OK [12]. The study's protocol was approved by the USGS Animal Care and Use Committee in Fort Collins, CO. Mares were maintained in 12-ha pastures and fed bermudagrass (*Cynodon* sp.) *ad libitum* and alfalfa hay at approximately 6.4 kg/animal/day. Protein/fat supplements and trace mineralized salt blocks were also provided, and annual prophylactic vaccines and anthelmintics were administered by BLM personnel (see Roelle et al. [12] for details).

Ninety mares (4–7 years of age) were randomly assigned to one of three experimental groups (SpayVac VacciMax vaccine, SpayVac DepoVax vaccine, and control; n = 30 each), and mixed treatment groups were maintained on three separate pastures. On 30 March 2011, all injections were administered by hand in the left rump during restraint in a padded hydraulic squeeze chute. Mares had opportunities to breed with stallions starting in June 2011 (approximately 2 months after vaccination), with a new stallion being introduced every 2 weeks on a rotation schedule that allowed each stallion to rest at least 2 weeks between sessions.

As described by Roelle et al. [12], 10-mL blood samples were collected from each mare at the time of vaccination (in March) as well as several other time points. All samples were used to determine pZP antibody titers, and blood samples collected in December 2011, and January and November 2013 were also analyzed to quantify pregnant mare's serum gonadotropin (PMSG) and estrone sulfate. Mares were considered to be pregnant if any one of the following three criteria were positive: 1) elevated hormone levels (PMSG >600 mIU/mL or estrone sulfate >20 ng/mL), 2) positive transrectal ultrasound or palpation exams, or 3) observations of nursing foals (mares were observed in each pasture for at least 2 h per day 3 days per week).

2.3. Samples

The fertility rates in the control group (n = 30) were 100% and 96.7% for year one and two, respectively, compared to 16.7% in the SpayVac DepoVax treated group (n = 30) during the first year ($p < 0.001$) and 75.9% during the second year (n = 29) [12]. Because the performance of this vaccine during the second year was so poor, BLM decided to drop the DepoVax treatment group from the study. In contrast, the fertility rate in the SpayVac VacciMax treated mares was 13.3%, 46.7%, and 43.3% for 2012, 2013 and 2014, respectively (n = 30 each year), compared to 100%, 96.7%, and 100% for the control group ($p < 0.001$ [12]). Half of the mares vaccinated with SpayVac VacciMax in 2011 were still infertile 4 years later (15 of 30). We analyzed serum samples collected 1, 2 and 4 years post-vaccination (7 March 2012, 6 March 2013, 3 February 2015) from mares that were continuously infertile or had foaled at least once during the 4-year period (14 complete sample sets from each group were available for comparative analysis in our study). We also analyzed serum collected on 24 February 2016 from 14 of 15 continuously infertile mares.

2.4. Laboratory analyses

2.4.1. Determination of pZP antibody titers by ELISA

IMV technicians determined pZP antibody titers as a percentage of a positive reference serum using an enzyme-linked immunosorbent assay as described by Roelle et al. [12]. Briefly, pZP antigen (1 μg/mL, prepared in-house) was used to coat 96-well polystyrene microtiter plates (Bio-Rad, Hercules, CA) prior to incubation overnight at 4° C. Plates were washed with a Tris wash buffer (Tris-buffered saline/Tween-20) and blocked with 3% gelatin (Bio-Rad) for 30 min at 37° C. Following another wash, a standard horse serum sample as well as unknown samples were added to the wells prior to incubation at 4° C overnight. Unknown and positive reference serum samples were diluted to 1/25,000 and each sample was added to the plates in triplicate. Plates were washed and a secondary antibody (Protein G [Calbiochem] conjugated to alkaline phosphatase enzyme) was added to each well at a dilution of 1/1000 prior to incubation for 1 h at 37° C. Plates were washed, a substrate solution containing 4-nitrophenyl phosphate disodium salt hexahydrate (Sigma-Aldrich Chemie GmbH, Buchs, Switzerland) was added at a concentration of 1 mg/mL, and plates were then incubated for 1 h at 37° C. A microtiter plate reader (ASYS Hitech GmbH, Eugendorf, Austria) measured the absorbance of each well at a wavelength of 405 nm. Absorbance values from the triplicate wells were averaged for each sample and expressed as a percentage of the average absorbance of the positive reference sample. The positive reference sample was considered to have a titer of 100% and came from a female previously vaccinated with SpayVac in a separate study and determined to have a strong, pZP-specific antibody response.

2.4.2. Determination of pZP antibody values by a fluorescent bead assay

Purified pZP antigen (from IMV) was coupled to fluorescent bead 33 (Microspheres; Luminex Corporation, Austin, TX) as previously described in detail by Wagner and Freer [18]. In brief, 5×10^6 activated beads were used for coupling of 300 μg pZP antigen. After coupling, the beads were re-suspended in blocking buffer (PBS with 1% [w/v] BSA and 0.05% [w/v] sodium azide) and incubated for 30 min. The beads were washed three times in PBS with 0.1% (w/v) BSA, 0.02% (v/v) Tween 20 and 0.05% (w/v) sodium azide (PBS-T), counted and stored in the dark at 2–8 °C.

For the assay, all serum samples were diluted at 1:100 in blocking buffer immediately before the assay was started. Five control serum samples from healthy mares not vaccinated with SpayVac were included as controls in each assay run. Wells containing blocking buffer were included as background controls. Using a Biotek ELx50 plate washer (Biotek Instruments Inc., Winooski, VT), PBST (PBS with 0.02% [v/v] Tween 20) was dispensed to all Millipore Multiscreen HTS plate wells (Millipore, Danvers, MA), and aspirated after soaking the plate for 2 min. Then 50 μl of the diluted serum samples, control sera, or blocking buffer were added to the plate wells. Beads coupled with pZP were vortexed and sonicated for 20 s, and 50 μl of bead solution containing 5×10^3 pZP beads were added to each well. The plates were covered to protect the beads from light and were incubated at room temperature with shaking for 30 min. Plates were then washed five times using the Biotek ELx50 plate washer. For total Ig detection, 50 μl of a biotinylated goat anti-horse IgG (H + L) antibody (Jackson Immunoresearch Laboratories, West Grove, PA) was added to each plate at a 1:5000 dilution in blocking buffer. The plates were incubated and washed again as previously described. Subsequently, 50 μl of streptavidin-phycoerythrin (PE; Invitrogen, Carlsbad, CA) was added to each well at a dilution of 1:100 in blocking buffer. Plates were incubated for another 30 min as described above. Finally, the plates were washed by adding 100 μl of blocking buffer to each well, and then the plates were covered and placed on a shaker for 15 min to re-suspend the beads. The assay was then analyzed in a Luminex 200 instrument (Bio-Rad Laboratories, Inc., Philadelphia, PA) using BioPlex Manager 6.1 software (Bio-Rad, Hercules, CA). The data were reported as median fluorescent intensities (MFI).

2.4.3. Anti-pZP IgG isotype detection

For IgG isotype detection, the fluorescent bead-based assay setup was conducted as described above, but detection antibodies used were different. Instead of biotinylated goat anti-horse IgG (H + L) antibody measuring total IgG, biotinylated monoclonal antibodies to IgG1 (CVS45), IgG4/7 (CVS39), IgG5 (clone 416), or IgG6 (clone 267) were added to the plates. All four IgG detection antibodies were used at previously determined optimal dilutions of 1:500 (IgG1), 1:1000 (IgG4/7), or 1:100 (IgG5 and IgG6). Monoclonal antibodies against equine IgG1 and IgG4/7 were described by Sheoran et al. [24], and antibodies to IgG5 and IgG6 were described by Keggan et al. [25].

2.5. Statistical analysis

D'Agostino and Pearson normality tests indicated that most antibody values were not normally distributed. All anti-pZP antibody measurements were thus compared by repeated-measures ANOVAs with Sidak post tests between the fertile and infertile groups. For comparing anti-pZP antibody values between years 4 and 5 in the infertile group, a Wilcoxon matched-pairs test was used. *P*-values <0.05 were considered significant. The statistical analyses were performed and the graphs were created using GraphPad Prism 6 for Mac OS X, version 6f.

3. Results

3.1. Fertility

Of the 15 SpayVac VacciMax treated mares that remained infertile for 4 years post-vaccination in the Roelle et al. study [12], 12 were still infertile 5 years post-vaccination (February 2016) and 3 had become pregnant. The 15 other SpayVac VacciMax treated mares that had conceived or foaled at least once during the initial 4 years post-vaccination were no longer being monitored.

3.2. Antibodies against pZP as measured by ELISA and fluorescent bead assay

The pZP antibody titers for the first 4 years post-vaccination from the Roelle et al. study [12] are illustrated in Fig. 1A. Serum pZP antibody values obtained by ELISA showed a trend towards increased pZP antibodies in the infertile group during the first year, which did not reach significance. The same serum samples from years 1, 2 and 4 were measured in the newly developed pZP fluorescent bead-based assay (Fig. 1B; $n = 14$ per group). Similar to the ELISA assay, the bead-based assay was initially used to analyze all serum antibodies against pZP independent of their isotype. By analyzing the sera in the bead-based assay, anti-pZP antibodies were clearly elevated in infertile mares in years 1 and 2 (both $p < 0.001$), and still showed a trend towards increased antibody values in the infertile group in year 4 post-vaccination (Fig. 1B).

3.3. IgG isotype responses against pZP

The fluorescent bead assay was then used to distinguish IgG1, IgG4/7, IgG5, and IgG6 isotype responses against pZP (Fig. 2). IgG1 antibodies showed a trend towards higher anti-pZP IgG1 values in the infertile compared to the fertile mares; however, the differences did not reach significance at any of the three observation time points (Fig. 2A). IgG4/7 responses were most similar to the total anti-pZP antibody response (Fig. 1B) and resulted in increased anti-pZP IgG4/7 values in years 1 and 2 ($p < 0.05$) post-vaccination. During year 4, anti-pZP IgG4/7 antibodies in infertile mares still had a trend towards higher antibody values compared to the fertile mares, but this did not reach statistical difference anymore (Fig. 2B). Interestingly, IgG4/7 isotype levels were significantly higher during year 5 compared to year 4 in the continuously infertile mares ($p = 0.0166$; $n = 14$; Fig. 3). In contrast, anti-pZP IgG5 and IgG6 values were low overall in both groups (Fig. 2C and D).

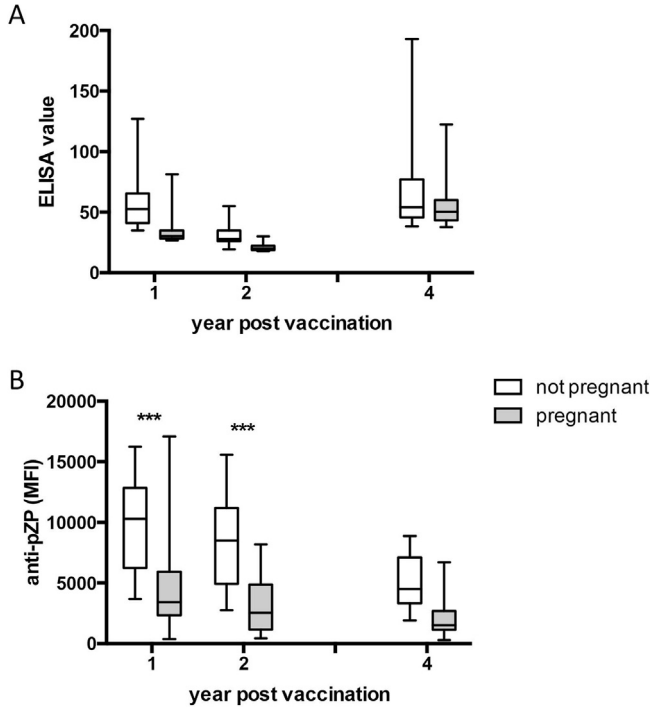

Fig. 1. Comparison of ELISA (A) and fluorescent bead-based assay (B) to measure serum pZP antibodies in mares 1, 2, and 4 years post-vaccination with a single dose of SpayVac VacciMax ($n = 14$ each) depicted as median, 25 and 75 percentiles, and ranges (extended bars). Asterisks indicate significant differences between antibody values in the fertile and infertile groups (p-value *** <0.001).

4. Discussion

To optimize application of SpayVac to free-ranging herds of horses, a better understanding of how the vaccine affects the immune system and results in contraception would be helpful. A variety of internal physiologic factors can influence an animal's ability to mount an immune response (e.g., age, pregnancy, nutrition, and other environmental factors) [26]. The primary mediators of adaptive immune function are B and T lymphocytes as well as antibodies; however, dendritic cells (DCs) control T-cell activation [27], and regulate antigen-specific immunity [28]. DCs arise primarily from the bone marrow and serve as an interface between the body and its environment by patrolling the dermis and epidermis (e.g., Langerhans cells), and mucosal membranes [29]. They can initiate T-effector cell, cytolytic, or suppressive immune responses, as well as production of cytokines like IL-12 [30]. “Dendritic cells act as nature's adjuvants for regulating antigen-specific immunity … and elicit T-cell memory, a critical goal of vaccination” [28]. Immature DCs take up antigen, and after this, or exposure to pro-inflammatory cytokines (e.g., TNFα and IL-1β), they transform into mature DCs. Maturation involves a significant cytoplasmic reorganization that brings MHC class II loaded with antigenic peptides to the cell surface, chemokine receptors remodel to facilitate movement to lymphoid organs, and membrane folds expand as “dendritic” processes in lymph nodes to increase opportunities for T-cell interaction [30,31]. Key to DCs' effectiveness is their movement into lymph nodes after maturation. The main lymph node homing chemokine receptor (CCR7) needs to be expressed by DCs for successful migration through peripheral lymph vessels [32]. There are also other mediators of DC migration to lymph nodes, including CCR8, which facilitates the migration of monocyte- (but not skin-derived) DCs to lymph nodes [33].

Dendritic cells form clusters with antigen-specific T-cells in lymph nodes to promote the immune response [27]. DCs present antigenic peptides to T-cells via MHC class I and II complexes. Activated T-cells can subsequently induce B-cells to proliferate and mature into memory B-cells and plasma cells, which produce large amounts of antibodies. Cytokines produced by T-cells also directly affect B-cells to enhance Ig secretion and isotype switching [30]. T follicular helper (T_{FH}) CD4 cells in lymph nodes are required for production of antibodies by plasma cells; however, *circulating* (T_{FH}) CD4 cells were recently identified, and it was proposed that these cells might further facilitate immune memory by seeding new germinal cell reactions in other lymphoid tissues [34].

Vaccine efficacy can be improved by enhancing antigen capture and processing by immature DCs, DC maturation, and migration to the lymph nodes [28]. Adjuvants can help condition the site of injection by causing tissue inflammation, which enhances DC migration to lymph nodes [32], and a failure of DCs to migrate to lymph nodes can exacerbate local immune responses because DCs release pro-inflammatory mediators and attract other leukocytes [35]. The liposomes in SpayVac may themselves serve as immunological adjuvants [36]. VacciMax created a significantly greater humoral response in rabbits compared to that produced by alum-adjuvant vaccines, and this response was correlated with an increased number of antigen-specific plasma cells in the bone marrow [21]. Plasma cells originate in lymph nodes, enter the bloodstream, and travel to the bone marrow where they can form a stable long-lived population of fully differentiated cells, especially after reactivation of memory B-cells during a secondary immune response [37]. Both Bechert et al. [16] and Roelle et al. [12] reported

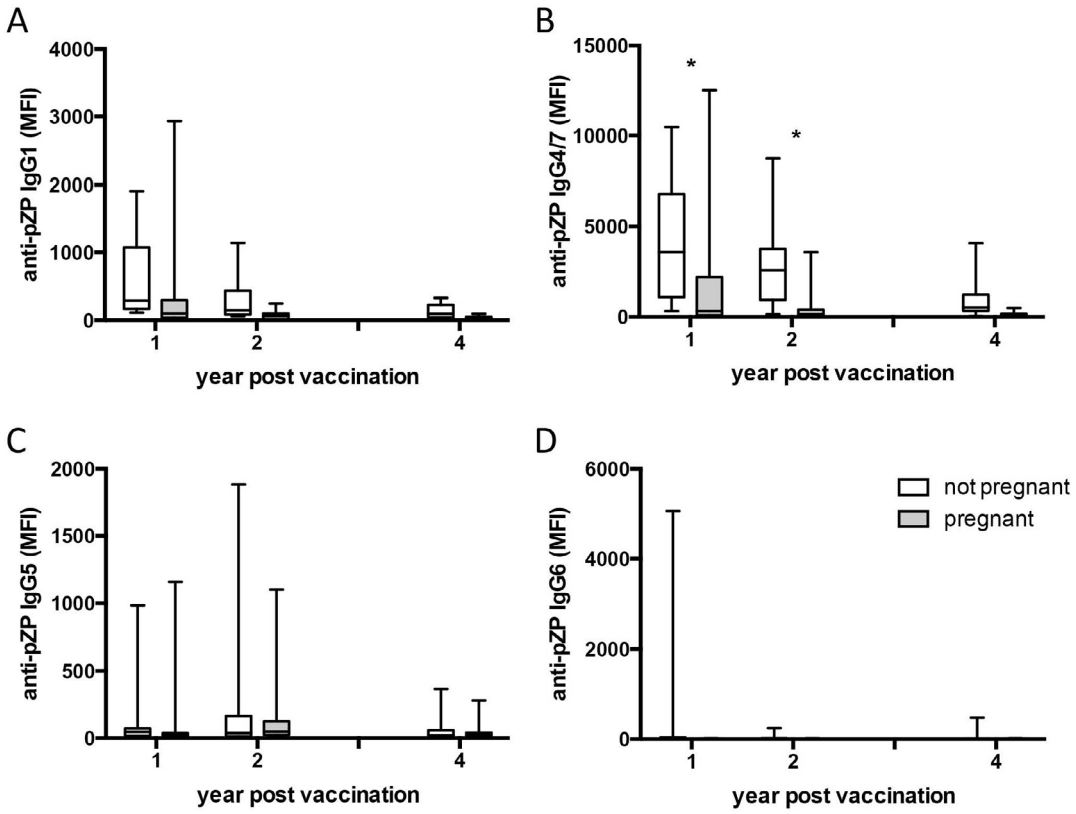

Fig. 2. Anti-pZP IgG isotypes in serum samples collected 1–4 years post-vaccination with SpayVac VacciMax, evaluated by different fluorescent bead-based assays for IgG1 (A), IgG4/7 (B), IgG5 (C), and IgG6 (D). *P*-values (* <0.05) show differences between fertile and infertile groups (n = 14 each).

vacillating reactions at the SpayVac injection site over a period of months, and this could be initiating the secondary immune response.

A variety of cells have been shown to support plasma cell populations in the bone marrow, including eosinophils [38] and most recently regulatory T cells [39]. Furthermore, regulatory T-cells modulate the activation of DCs [40], and DCs are required for regulatory T-cell homeostasis [41]. DCs are organized into perivascular clusters in the bone marrow, which include mature B lymphocytes (e.g., terminally differentiated B-cells or long-lived plasma cells) and T lymphocytes (e.g., $CD4^+$ and $CD8^+$ T cells); and removal of these bone marrow stroma cells resulted in a significant loss of mature B-cells [42]. pZP antibody titers remained consistently elevated for 7 years in African elephants (*Loxodonta africana*) given a single injection of SpayVac [43], and grey seals vaccinated with a single-dose of SpayVac [14] maintained high titers for at least 10 years (Robert Brown, personal communication). SpayVac formulations seem to support maturation and longevity of dendritic and plasma cells in bone marrow.

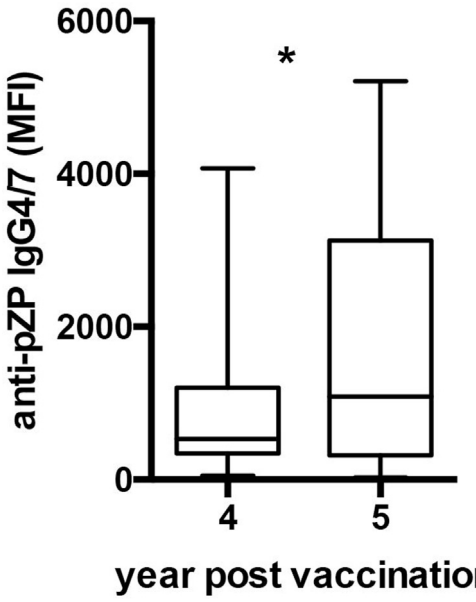

Fig. 3. Anti-pZP IgG4/7 isotypes values in serum of the infertile mares in years 4 and 5 post-vaccination (n = 14 each) with SpayVac VacciMax (p = 0.0166).

Antibody occupation of ZP receptors is thought to disrupt sperm binding [6–8], which normally initiates the acrosome reaction and subsequent fertilization [9]. However, the ZP is also involved in intercellular communication between the oocyte and surrounding granulosa cells [44]. Bechert et al. [16] and subsequently Joone et al. [45] reported significantly smaller ovaries and fewer follicles in pZP-vaccinated mares; and absence of estrous cyclicity likely contributes to infertility. This may be due to a non-specific immune response to an ovarian cellular component in the vaccine [46], or immune-mediated disruption of folliculogenesis [47]. Contamination with a non-ZP ovarian protein is possible (reviewed by Bechert and Fraker [44]) and supported by the finding that recombinant ZP vaccines do not have the same contraceptive effect [48,49]. Species-specific differences in response to pZP vaccination are reviewed by Joone et al. [49], and are likely due to differences in ZP structure and glycosylation [50]. Adverse effects on ovarian function have been described in a number of species receiving pZP vaccinations,

including hamsters (*Mesocricetus auratus*) [51], dogs (*Canis lupus familiaris*) [52], rabbits (*Oryctolagus cuniculus*) [53], white-tailed deer (*Odocoileus virginianus*) [54], sheep (*Ovis aries*) [46], and primates (*Macaca radiate*) [55]. Nonetheless, pZP antibody titers above a certain threshold level are clearly linked to infertility in a variety of species [10,17].

Equine IgG1, IgG4, and IgG7 isotypes are capable of mediating all of these effector functions and most likely have a better neutralizing capacity compared to the remaining four equine IgGs [22]. IgG1 and IgG4/7 antibodies are typically involved in responses to viral infection [56–59] or intracellular bacteria [3,60], while IgG3 and IgG5 isotypes are induced after nematode infection [61], tetanus vaccination or during allergic responses of the horse [62,63]. In this study, mares that were continuously infertile post-vaccination had higher levels of IgG4/7 compared to mares that foaled at least once. Although the exact mechanisms of the immune response against pZP antigen still needs to be unraveled, it likely induced a Th1 type immune response leading to the development of mainly IgG1 and long-lasting IgG4/7 antibodies as previously described for some other vaccines [64]. It is not clear why IgG4/7 antibody values increased in the infertile group during year 5 compared to year 4. It is possible that the length of time samples were in storage or multiple thaw/freeze cycles led to an artificial decrease in sera pZP antibody concentrations prior to year 5.

The fluorescent bead-based assay clearly enhanced the analytical sensitivity and linear detection range of pZP antibody detection compared to the ELISA, resulting in more pronounced differences in IgG concentrations between fertile and infertile SpayVac-treated mares. The advantages of fluorescent bead-based assays have also been reported previously for other analytes [18,65–67]. The bead-based assay also allowed for antibody isotyping, which identified anti-pZP IgG4/7 as the primary equine isotypes mediating the long-term contraceptive immune response. This assay could eventually be used as a management tool to identify effectively contracepted mares based on established cut-off values for anti-pZP IgG4/7.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.

Funding

Anti-IgG5 and IgG6 monoclonal antibodies, described in this article, were developed with funding from the Agriculture and Food Research Initiative (Grant #2005-01812; the U.S. Veterinary Immune Reagent Network) supported by the USDA National Institute of Food and Agriculture, and were further characterized with funding from the same agency (Grant #2015-67015-23072; Equine Immune Reagents: development of monoclonal antibodies to improve the analysis of immunity in horses).

Acknowledgments

Anti-IgG1 and IgG4/7 monoclonal antibodies were a kind gift of Dr. Paul Lunn (North Carolina State University). We thank Butch Roelle and colleagues for sharing their data and mare serum samples with us and for collecting additional serum samples in February 2016 for this study.

CHAPTER 1—INTRODUCTION

GENERAL

The Bureau of Land Management (BLM) is responsible for the protection, management and control of wild free-roaming horses and burros (WH&B). Under the Wild Free-Roaming Horses and Burros Act (WFRHBA), WH&B are considered an integral part of the national system of public lands in the areas where they were found in 1971. The BLM's goal is to manage healthy WH&B populations on healthy rangelands. To achieve this goal, the BLM designates Herd Management Areas (HMAs) for the long-term maintenance of WH&B herds and collects data about the animals and their habitat. The BLM also prescribes management to assure WH&B populations are in balance with other uses of the public lands and that a thriving natural ecological balance (TNEB) is achieved and maintained. Activities are carried out with the objective of maintaining free-roaming behavior and at the minimum feasible level of management necessary to attain the objectives identified in approved land use plans (LUPs) and Herd Management Area Plans (HMAPs).

1.1 PURPOSE

This handbook describes the authorities, objectives, policies and procedures that guide the management of WH&B on the public lands administered by the BLM.

1.2 OBJECTIVE

The objective of this handbook is to provide guidance for the protection, management and control of WH&B in accordance with the 1971 WFRHBA, as amended, and the implementing regulations in 43 Code of Federal Regulations (CFR) 4700.

CHAPTER 2—LAND USE PLANNING

GENERAL

Section 202(a) of the 1976 Federal Land Policy and Management Act (FLPMA) requires the Secretary to develop, maintain, and when appropriate revise LUPs that provide (by tracts or areas) for the use of the public lands. The responsible BLM official shall follow the established LUP procedures in 43 CFR 1600, associated BLM manual sections and policy for fulfilling the planning requirements prescribed in the statute.

LUPs are the basis for every on-the-ground management decision that the BLM makes. LUPs establish goals and objectives (desired outcomes), identify the management actions needed to achieve the desired outcomes, and identify allowable uses of the public lands.

2.1 LAND USE PLAN DECISIONS

LUP planning requirements for the WH&B program are applicable to all BLM LUP documents, including Management Framework Plans (MFPs) and Resource Management Plans (RMPs).

2.1.1 Comparability Consideration

Under 43 CFR 4700.0-6(b), WH&B shall be considered comparably with other resource values in the formulation of LUPs. This means WH&B are to be considered in the same manner as other resource values (e.g., cultural, historic, scenic, rangelands, timber, and minerals). WH&B are a resource value, as opposed to a land use (e.g., livestock grazing or timber harvest).

2.1.2 Herd Areas

Herd areas (HAs) are limited to areas of the public lands identified as habitat used by WH&B at the time that the WFRHBA passed (December 15, 1971). When preparing a LUP, identify the HAs (in whole or in part) which will not be managed as HMAs and explain the reasons they will not be managed for WH&B.

HA boundaries can be adjusted through a LUP when the current boundary does not correctly portray where WH&B were found in 1971 based on well-documented historical data. Existing herd areas where all animals were privately-owned (claimed during the claiming period) shall be dropped from HA status in a LUP.

Under 43 CFR 4710.2 and to assure transparency regarding the disposition of HAs, the authorized officer shall permanently maintain a record regarding the location of all HA boundaries and explanations of any changes in field office (FO) files.

2.1.3 Herd Management Areas

HMAs shall be designated in those HAs within which WH&B can be maintained over the long term in LUPs. For each HMA designated within the planning area, the LUP should identify the following:

- The HA(s) that contain the HMA.

- The initial and estimated herd size that could be managed while still preserving and maintaining a TNEB and multiple-use relationships for that area.

- The guidelines and criteria for adjusting herd size.

LUPs should also identify:

- The HMAs to be managed for non-reproducing wild horses to aid in controlling on the range population numbers and the criteria for their selection (16 United States Code (USC) § 1333(b)(1)). See Chapter 4 (Population Management). Examples of criteria that could be used to select HMAs for management of non-reproducing wild horses include: no special or unique herd characteristics, low ecologic condition, limited public land water, and reliance on private water.

- The management tools to control population size within AML and to extend (reduce) gather frequency.

2.1.4 Herd Areas Not Designated as HMAs

Where appropriate, the LUP may include decisions not to manage WH&B in all or a part of an HA. An example is intermingled and unfenced private lands within HAs where the landowners are unwilling to make them available for WH&B use, or the animals present at that time were later found to be claimed domestic horses (or burros). Another example would be where essential habitat components (forage, water, cover and space) are unavailable or insufficient to sustain healthy WH&B and healthy rangelands over the long term.

2.1.5 Changes to HA or HMA Boundaries

Decisions to change HA boundaries, to designate HMAs for the maintenance of WH&B, or to remove all or a portion of an area's designation as an HMA must be made through a LUP amendment, revision or new RMP (43 CFR 4710.1 and H-1601-1: Land Use Planning Handbook).

HMA boundaries may be changed within HAs through the LUP process to facilitate WH&B management or mitigate unacceptable impacts to other resources.

An area may lose its designation as an HMA when WH&B cause unacceptable impacts to other resource values, or conditions change and one or more of the four essential habitat components are not present in sufficient quantities to sustain WH&B use over the long term. Similarly, if conditions change, all or part of an HA may be reconsidered for designation as an HMA through LUP. See Chapter 3 (Habitat Management).

2.1.6 Wild Horse and/or Burro Ranges

An HMA may be considered for designation as a WH&B Range to be managed principally, but not necessarily exclusively, for WH&B. Criteria for consideration as a WH&B Range should include the presence of one or more of the following: unique herd characteristics, outstanding viewing opportunities, unique landscape, or significant historical or cultural features (H-1601-1: Appendix D). The authorized officer, currently only the Director or Assistant Director (AD) (refer to BLM Manual 1203: Delegation of Authority), may establish a WH&B Range after a full assessment of the impact on other resources through the LUP process.

2.2 GRAZING AUTHORIZATIONS WITHIN HMAs

Domestic horses and burros may not graze under permits or leases within HMA boundaries (43 CFR 4710.5(b)). If necessary to provide habitat for WH&B, to implement herd management actions, or to protect WH&B from disease, harassment or injury, the authorized officer may close areas of the public lands to grazing use by all or a particular kind of livestock (43 CFR 4710.5(a)).

Closure to livestock grazing may be temporary or permanent (43 CFR 4710.5(c)). Prior to issuing a final decision to permanently close an area to livestock grazing use, a LUP amendment should be completed. Completion of site-specific environmental analysis and issuance of a proposed and final decision pursuant to 43 CFR 4160 (2005) is also required.

2.3 OTHER PERMITTED ACTIVITIES

2.3.1 Commercial Recreation Use

Proposals for commercial recreational use of the public lands should be evaluated through the appropriate BLM permitting process. Permits should stipulate the safeguards necessary to protect the health and welfare of WH&B, particularly before, during and immediately following the peak foaling period (e.g., generally March – June). See Chapter 4 (4.4.4).

Proposals for motor vehicle racing, air racing, or other potentially intrusive activities have potential to harass or harm WH&B. Permit authorizations should contain provisions to minimize impacts to WH&B from these activities. Should adequate safeguards prove impractical, permits should not be approved (refer to BLM Manual Section 2930 and H-2930-1: Recreation Permit Administration).

2.3.2 Energy and Minerals Exploration and Development

The health and welfare of WH&B should be considered during project planning for hard-rock mining or oil and gas exploration and development; non-mineral sales such as gravel; or wind or solar energy development proposals. Specific mitigation measures will be identified through a site-specific environmental analysis and decision process in accordance with the 1969 National Environmental Policy Act (NEPA). Mitigation measures will be implemented through applicable permits.

2.4 LAND USE PLAN GOALS AND OBJECTIVES

LUPs normally contain general habitat and population management goals and objectives. LUPs may also include the management requirements or actions necessary to make progress toward attainment of Land Health Standards and to preserve and maintain a TNEB and multiple-use relationship on the public lands.

2.4.1 Habitat and Population Management

Habitat or population management and monitoring objectives regarding the management of a specific HMA or complex of HMAs are normally identified in a Herd Management Area Plan (HMAP) rather than a LUP.

2.5 IMPLEMENTATION DECISIONS

Implementation decisions make progress toward achieving LUP goals and objectives and may include:

- Establishing or adjusting appropriate management levels (AMLs) based on monitoring and evaluation, including the population range within which the herd size will be allowed to fluctuate.
- Identifying and setting objectives for herd composition, animal characteristics and habitat development needs (e.g., HMAPs).
- Specific habitat improvement projects (e.g., construction, modification, or removal of fences; water development construction/reconstruction or removal; or re-vegetation projects).
- Site-specific population management actions (e.g., decisions to gather/remove excess WH&B, apply fertility control, or adjust age or sex ratios).

2.5.1 Appropriate Management Level (AML) Adjustments

AML may be adjusted (either up or down) through a site-specific environmental analysis and decision process (NEPA). An analysis under NEPA is also required to establish a population range (upper and lower limit) for AMLs initially established as a single number. Development of a LUP amendment or revision is not generally required.

2.5.1.1 AMLs Established in LUPs

- When AML is established in a LUP, follow the process outlined in the LUP to adjust AML.

- When the LUP does not outline a process for AML adjustment, the LUP may need to be amended or revised to adjust AML.

2.5.1.2 AMLs Established through Implementation Decisions

See Chapter 4 (4.2.2).

2.5.2 Herd Management Area Plans

Herd Management Area Plans (HMAPs) are prepared under 43 CFR 4710.3-1. HMAPs establish short- and long-term management and monitoring objectives for a specific WH&B herd and its habitat. HMAPs also identify the actions to be taken to accomplish herd and habitat management objectives. An HMAP assists the authorized officer in tracking progress toward achieving LUP goals.

HMAPs tier to and must be in conformance with the applicable LUP. If the proposed management strategy is not consistent with the LUP, then the LUP should be amended, or the proposal should be modified or rejected.

HMAPs may be prepared for a single HMA or a complex of adjacent HMAs where animal interchange occurs. When two or more jurisdictions have management responsibility for portions of a single HMA or an HMA complex, BLM will designate one field office with the lead responsibility for development of the HMAP and management of the HMA or complex. When a WH&B herd is dependent on the habitat within a BLM HMA and an adjacent U.S. Forest Service (USFS) Wild Horse Territory (WHT), the agencies should jointly determine lead responsibility for development of the HMAP and management of the herd and habitat.

2.6 NOTICES, CONSULTATIONS AND HEARINGS

2.6.1 Agency Consultation and Public Involvement

See BLM Manual Section 4710.25.

2.6.2 Hearings

See BLM Manual Section 4740.3.

CHAPTER 3—HABITAT MANAGEMENT

GENERAL

Habitat for WH&B is composed of four essential components: forage, water, cover, and space. These components must be present within the HMA in sufficient amounts to sustain healthy WH&B populations and healthy rangelands over the long term. If they are not present in sufficient amounts, the authorized officer should consider amending or revising the LUP to remove the area's designation as an HMA. If the decision is made to return a designated HMA to HA status, the total population of WH&B should then be gathered and removed. See BLM Manual Section 4710.3.

A recurring pattern of WH&B movement out of the HMA to access forage, water, or thermal or hiding cover is an indication that year-long WH&B use cannot be sustained. If one or more of the key habitat components is missing, the HMA should be considered as unsuitable for year-long use. In these situations, the authorized officer should consider removing the area's designation as an HMA through LUP. An exception would be two or more HMAs which adjoin and are managed as a complex of HMAs, or HMAs which adjoin USFS WHTs that can be managed as a complex.

3.1 FORAGE (VEGETATION)

Forage (vegetation) is one of the essential components of WH&B habitat. The authorized officer should determine whether vegetation provides sustainable forage (and cover) for the animals. Vegetation should be managed within each HMA in a manner that achieves and maintains a TNEB and assures significant progress is made toward achieving the Standards for Land Health and other site-specific or landscape-level objectives.

3.2 WATER

An adequate year-round quantity and quality of water must be present in the HMA to sustain WH&B numbers within AML. If baseline information concerning access to and availability of water does not exist, then a public land water inventory should be conducted.

If privately-owned water is essential to sustaining WH&B populations within HMAs, cooperative agreements with the owners or acquisition of water rights should be considered. If agreement cannot be achieved with private water owners, or if public land water cannot be developed and maintained, one of the following should occur:

- AML should be adjusted based on the available public land water within the HMA boundary.

- The authorized officer should amend or revise the LUP to remove the area's designation as an HMA.

3.3 COVER (VEGETATION) AND SPACE

The terrain and vegetation are needed to provide WH&B with escape (hiding) cover and shelter from the prevailing weather. (Vegetation also provides sustainable forage. See 3.1 above). WH&B require sufficient space to allow the herd to move freely between water and forage within seasonal habitats. Cover and space are interrelated. If the HMA has barriers preventing free movement of WH&B throughout the HMA or between forage and water, it would not have sufficient cover and space. Barriers can be natural (e.g., rock rims, rivers) or human-induced (e.g., fences, highways).

3.4 HABITAT IMPROVEMENT PROJECTS

3.4.1 Nonstructural Improvements

Nonstructural improvement projects such as seeding, prescribed fire, emergency fire rehabilitation or shrub and tree removal have potential to increase the forage available for WH&B use and to improve habitat conditions. They may also cause grazing animals to concentrate their use within the project area. As a result, it may be necessary to close these areas to grazing until vegetation management objectives are achieved.

Before making the decision to exclude an area from grazing use, the authorized officer should first take a hard look at alternatives to fencing. These alternatives could include:

- Reduce WH&B populations to the AML lower limit.
- Reduce WH&B to a number below the AML lower limit (based on the available forage and water).
- One of the above, in combination with closing the area to domestic livestock use (in whole or in part).
- Use of mineral supplements to modify distribution.
- Restrict or eliminate access to selected water sources.

If the authorized officer determines fence construction is necessary, the fences should be designed to maintain WH&B access to critical water sources. Fences should then be removed once objectives have been achieved.

3.4.2 Structural Improvements

Construct and maintain structural improvement projects (e.g., fences, cattle guards, or water developments) in a manner that protects the wild, free-roaming nature of WH&B and provides for normal herd distribution and movement as well as genetic interchange.

While some projects might increase the forage, cover, or water available for WH&B, others might negatively impact individual animals or entire populations:

- Fences and cattle guards might restrict seasonal WH&B movement or use of critical escape (hiding) or thermal cover, key spring-summer-fall-winter use areas, or critical water sources.

- Water development projects might encourage use outside the HMA or concentrate use in sensitive areas.

Existing projects that negatively impact WH&B should be considered for removal or modification through coordinated activity plans. Proposed projects should be analyzed and mitigation proposed to minimize adverse impacts to WH&B where possible.

3.4.2.1 Existing Fences and Cattle Guards

Existing fences and cattle guards with negative impacts to WH&B should be reviewed to determine:

- If the project is still needed; or
- Whether the project can be modified to minimize impacts to WH&B.

Possible fence or cattle guard modifications could include:

- Make fences open-ended allowing WH&B movement around the ends.
- Construct large gates or sections of "let-down" fence, or consider the use of electric take-down fence where feasible, to allow movement when fences are not needed for livestock control.
- Weld rebar strips between cattle guard grates; or
- Replace the cattle guard with a gate, if possible.

3.4.2.2 Proposed Fences and Cattle Guards

Fencing within an HMA should be done only after the impacts are carefully analyzed through the NEPA process. If fences and cattle guards are essential for proper resource management, they should be constructed with particular attention to location and design. Avoid locating fences across migration routes, to prevent WH&B (or livestock) concentration, or the unintended trapping or death of WH&B.

3.4.1.3 Existing Water Developments

Consistent with resource management objectives, existing projects may be modified to provide WH&B with access to water through one or more of the following methods:

- Piping water to a trough away from the source.
- Piping water to a trough outside an exclosure.
- Retaining a portion of the source outside the exclosure.

3.4.1.4 Proposed Water Developments

Water sources may be excluded from use by WH&B to protect the water source, the associated riparian area, and to maintain or improve the quality and quantity of water. Where possible, projects should be designed to provide WH&B with access to water as described in 3.4.1.3 above.

Fences constructed in proximity to major WH&B water sources and smaller riparian pastures or exclosures should be constructed with a top rail composed of pipe or wooden poles. The top rails provide a visual barrier to prevent WH&B from entering the exclosure and becoming trapped. Project design may also consider the use of specialized gates (e.g., finger gates) to allow any WH&B entering an exclosure to exit safely.

Reservoirs and similar water sources should be designed and maintained with gently sloping (rather than steep) sides to avoid trapping foals.

Where WH&B are, or may become, dependent upon mechanically provided water, the authorized officer shall assure that alternative sources of known and accessible water are available to WH&B in the event of a system failure of a well, storage tank, pipeline, trough, or float device.

Actions to assure water is available to WH&B may include:

- Entering into Cooperative Range Improvement Agreements (Form 4120-6) whose terms and conditions require water to be made available to WH&B and wildlife.

- Using WH&B program funding (in whole or part) for construction and/or maintenance of a well, spring development, catchment, pond, or other permanent water improvement providing WH&B with access to water on public land.

- Acquiring the necessary water rights in order to provide and maintain access to water sources. Refer to BLM Manual 7250 (Water Rights).

CHAPTER 4—POPULATION MANAGEMENT

GENERAL

Under the 1971 WFRHBA, WH&B are to be managed in a manner designed to achieve and maintain a thriving natural ecological balance and protect the range from the deterioration associated with WH&B overpopulation.

4.1 MANAGEMENT REQUIREMENTS

4.1.1 Self-Sustaining

WH&B shall be managed as self-sustaining populations of healthy animals in balance with other uses and the productive capacity of their habitat. Some selected HMAs may be managed for non-reproducing wild horses to aid in controlling on-the-range population numbers (see 4.5.4).

4.1.2 Free-Roaming Behavior

In accordance with 43 CFR 4700.0-6(c), management activities affecting WH&B shall be undertaken with the goal of maintaining free-roaming behavior.

4.1.3 Constraints on Management

Management of WH&B on the public lands is limited to herd areas (HAs), consistent with the WFRHBA (16 USC § 1339) which states: “Nothing in this Act shall be construed to authorize the Secretary to relocate wild free-roaming horses or burros to areas of the public lands where they do not presently exist.”

Consistent with 43 CFR 4710.3-1, herd management areas (HMAs) shall be established for the maintenance of WH&B herds. In delineating each HMA, the authorized officer shall consider the appropriate management level for the herd, the habitat requirements of the animals, and the relationships with other uses of the public and adjacent private lands, and the constraints contained in § 4710.4.

4.1.4 Minimum Feasible Level of Management

As required in 43 CFR 4710.4, management shall be at the minimum level necessary to attain the objectives identified in approved LUPs and HMAPs.

1. Limit population management actions by:

    a. Establishing AML as a population range within which herd size will be allowed to fluctuate.

    b. Evaluating HMAs that require frequent emergency or nuisance removals due to inadequate habitat (e.g., limited availability of forage or water) for the possible removal of the area’s designation as an HMA through LUP.

2. It is not consistent with management at the minimal level to provide supplemental feed or rely on water developments that require frequent maintenance. It may, however, be appropriate to provide water in temporary emergency situations.

4.1.5 Thriving Natural Ecological Balance (TNEB)

Consistent with 43 CFR 4700.0-6, WH&B shall be managed in balance with other uses and the productive capacity of their habitat (i.e., WH&B will be managed to achieve and maintain a thriving natural ecological balance (TNEB) and multiple use relationships on the public lands).

The WFRHBA requires the BLM to manage horses in a manner that is designed to achieve and maintain a thriving natural ecological balance on the public lands (16 USC § 1333(a)). *See also Animal Protection Institute of America*, 109 IBLA 112, 115 (1989) ("…the 'benchmark test' for determining the suitable number of wild horses on the public range is 'thriving natural ecological balance'…") (*Dahl v. Clark*, 600 F. Supp. 585, 594 (D. Nev. 1984)).

To achieve a TNEB on the public lands, WH&B should be managed in a manner that assures significant progress is made toward achieving the Land Health Standards for upland vegetation and riparian plant communities, watershed function, and habitat quality for animal populations, as well as other site-specific or landscape-level objectives, including those necessary to protect and manage Threatened, Endangered, and Sensitive Species (TES). WH&B herd health is promoted by achieving and maintaining TNEB.

4.2 ESTABLISHING THE APPROPRIATE MANAGEMENT LEVEL

4.2.1 AML Definition

The appropriate management level (AML) shall be expressed as a population range within which WH&B can be managed for the long term. AMLs previously established as a single number will be modified to include an upper and lower limit. For reporting purposes, the upper limit of the AML range will be used.

AML applies to the number of adult wild horses or burros to be managed within the population and does not include current year's foals. All WH&B one year of age and older are considered adults (a foal is considered one year of age on January 1 of the year following its birth).

The AML upper limit shall be established as the maximum number of WH&B which results in a TNEB and avoids a deterioration of the range. This number should be below the number that would cause rangeland damage (refer to *Animal Protection Institute of America v. Nevada BLM*, 118 IBLA 63, 75, (1991)).

The AML lower limit shall normally be established at a number that allows the population to grow (at the annual population growth rate) to the upper limit over a 4-5 year period, without any interim gathers to remove excess WH&B. Some HMAs may require more frequent removals to maintain population size within AML. For HMAs that require more frequent gathers, the authorized officer should consider management options which would either extend the gather

cycle or broaden the AML range; amend or revise the LUP to remove the area's designation as an HMA; or manage the HMA for non-reproducing wild horses.

4.2.2 Establishing or Adjusting AML

An interdisciplinary and site-specific environmental analysis and decision process (NEPA) with public involvement is required to establish or adjust AML.

4.2.2.1 Establishing AML

When establishing AML, the analysis shall include an in-depth evaluation of intensive monitoring data or land health assessment. Intensive monitoring data shall include studies of grazing utilization, range ecological condition and trend, actual use, and climate (weather) data. Population inventory, use patterns and animal distribution should also be considered. A minimum of three to five years of data is preferred. Progress toward attainment of other site-specific and landscape-level management objectives should also be considered. See Appendix 3 (AML Establishment and Adjustment).

4.2.2.2 Evaluation and Adjustment of AML

In-depth AML evaluations should be completed when review of resource monitoring and population inventory data indicates the AML may no longer be appropriate. The following should be considered when evaluating AML:

- Changes in environmental conditions which may have occurred since the AML was established. Changing environmental conditions could include drought, wildfires, noxious weed infestations, effect of varying numbers of WH&B on forage utilization or range ecological condition/trend, an increase or decrease in the available forage, changes in livestock management, etc.

- The presence of any newly listed Threatened, Endangered or Sensitive Species (TES).

- Any additional resource monitoring, population inventory or other relevant data collected since AML was established.

For additional information refer to Appendix 3 (AML Establishment and Adjustment) and BLM Manual Section 4720.3.

4.2.3 WH&B Animal Unit and Animal Unit Month

Wild horses, one year of age or older, count as one (1) Animal Unit (AU) and burros one year of age and older count as 0.5 AU. One Animal Unit Month (AUM) is the amount of forage necessary to sustain one adult horse or two adult burros for one month (or approximately 800 pounds of air dried forage).

4.2.4 Forage Allocations for WHB

The amount of forage available to allocate to WH&B shall be determined through in-depth evaluation of resource monitoring data and following a site-specific environmental analysis and decision process. Forage for WH&B (AUMs) is allocated based on the AML upper limit.

4.3 DETERMINATION OF EXCESS

Before issuing a decision to gather and remove animals, the authorized officer shall first determine whether excess WH&B are present and require immediate removal. In making this determination, the authorized officer shall analyze grazing utilization and distribution, trend in range ecological condition, actual use, climate (weather) data, current population inventory, wild horses and burros located outside the HMA in areas not designated for their long-term maintenance and other factors such as the results of land health assessments which demonstrate removal is needed to restore or maintain the range in a TNEB.

The term "excess animals" is defined as those animals which must be removed from an area in order to preserve and maintain a thriving natural ecological balance and multiple-use relationship in that area (16 USC § 1332(f)(2)). This definition underscores the need to remove excess animals before damage to the range begins to occur.

4.4 PARAMETERS FOR POPULATION MANAGEMENT

4.4.1 Age Structure and Sex Ratio

Age structure and sex ratio influence herd health, social interactions, and population growth rates of reproducing WH&B herds. A herd's age structure and sex ratio may have been altered by previous selective removal policies or natural mortality and should be estimated from the best available data (e.g., capture records, preparation records, and final gather reports). Most populations will have representatives from each age class, and rapidly growing populations will have a greater proportion of younger WH&B. WH&B populations will produce roughly equal numbers of males and females over time.

In order to maintain the desired age structure and sex ratios, consider retaining male and female animals from each age group (0-4, 5-9, 10-15, 15+ years of age) following a removal operation. If specific age structure and sex ratio objectives are not established for an HMA or complex of HMAs, a desired post-gather age structure and sex ratio should be established during the pre-gather planning and analysis process. These objectives should be consistent with the selective removal criteria outlined in BLM Manual Section 4720.33 and the AML lower limit.

The authorized officer should consider alternatives which would manage WH&B herds for a sex ratio with a female component of less than or equal to 50 percent, to reduce population growth rates and extend the gather cycle. Opportunities to manage sex ratios as a tool to slow population growth rates are discussed later in this chapter.

4.4.2 Selective Removal

Selective removal and release of animals back to the range should be conducted to achieve AML, and the age structure and sex ratio objectives established for the specific HMA or complex of HMAs. In the absence of specific age structure or sex ratio objectives for the HMA or complex, see BLM Manual Section 4720.33.

4.4.3 Population Growth Rates

Population growth rates represent the net difference between births and deaths over time. Population growth rates can be highly variable and influenced by habitat quality, forage production, water availability and other factors. Data from recent gathers and population estimates derived from aerial surveys are used to determine population growth rates. The annual growth rate from Year 1 to Year 2 is calculated as follows:

Population on 2/28 (Year 2) – Population on 2/28 (Year 1)
÷ Population on 2/28 (Year 1) ×100 = Percent Annual Growth Rate

The same formula can be used to calculate growth over a period of several years (e.g., between aerial population surveys which are normally conducted at 3-4 year intervals).

Significant variation from historical growth rates may indicate that either immigration into the HMA or migration out of the HMA is occurring.

4.4.4 Foaling Period

Foaling period can be documented for each population (individual HMA or HMA complex) through direct observation. The capture of wild horses by using a helicopter to herd the animals is prohibited during the foaling period, which is defined as six weeks on either side of the peak of foaling to assure that young foals are mature enough to be able to remain with their band during gather activities. This period is generally March 1 to June 30 for most wild horse herds. Helicopters may be used year-round in the removal of burros. See BLM Manual Section 4740.1.

The capture of wild horses and burros by using bait (e.g., food, water, salt or sexual attraction) to lure animals into a trap may be used year-round.

Population surveys or distribution flights involving fixed-wing aircraft may be conducted during the foaling period. The use of helicopters for these activities during this time should be evaluated on a case-by-case basis.

4.4.5 Gathers and Gather Cycles

The gather cycle is the interval between gathers. Gather frequency is a function of the AML range, population growth rates and other environmental factors. Once AML is achieved, gathers to remove excess WH&B should be planned to occur at intervals of approximately 4 to 5 years to maintain population size within AML.

4.4.6 Genetic Diversity

Reproducing WH&B herd health is dependent, in part, on maintaining desirable genetic diversity (avoiding inbreeding depression).

4.4.6.1 Baseline Genetic Diversity

Baseline genetic diversity will be determined for all WH&B herds. Once a baseline is established, additional samples will be collected to reassess genetic diversity every other gather (e.g., every 6-10 years). If testing indicates diversity is less than desired, the herd should be reassessed more frequently (e.g., every gather).

In the past, genetic diversity was assessed by evaluating blood samples from the herd. Hair samples are now used to assess genetic diversity. Procedures for collecting and processing WH&B hair samples are described in Appendix 1 (Genetics Data and Hair Sample Collection Instructions). A report assessing genetic diversity is developed for each set of samples from an HMA.

Baseline data can be compared between adjacent HMAs to determine if the WH&B herd is isolated, or if genetic material is being exchanged between reproducing herds as part of a larger population of WH&B. Movement of WH&B from one HMA to another may enhance genetic diversity.

4.4.6.2 Interpreting Genetics Data

Measures of individual animal and population-wide genetic diversity are based on the number of individuals sampled within each HMA or complex. The most important measure of genetic diversity is Observed Heterozygosity (Ho). The observed heterozygosity is a measure of how much diversity is found, on average, within individual animals in a WH&B herd and is insensitive to sample size, although the larger the sample, the more robust the estimate.

Population-wide measures for the presence of genetic variants and the effective number of alleles provide information about changes in a herd's diversity, now and in the future. Other measures provide a comparison of the herd's genetic similarity to domestic horse breed types. All measures are compared to values derived from domestic horse breeds and to WH&B herds which have already been sampled.

Values below the mean for feral populations are an indication that the WH&B herd may have diversity issues. Herds with observed heterozygosity values that are one standard deviation below the mean are considered at critical risk. For DNA-based (hair) samples this value is 0.66, and the value is 0.31 for blood samples.

Few herds sampled to date show values below the feral mean. Those with values below the feral mean tend to be herds with small population size, which are the most at-risk for inbreeding. There is no specific diversity value that is a clear indicator of imminent inbreeding risk. The lower the genetic variation, the greater the risks for inbreeding-related impacts to the WH&B

herd. Mitigation to address or resolve genetic diversity concerns should be considered using the recommendations in the genetics report as a starting point.

4.4.6.3 Herd Size

A minimum population size of 50 effective breeding animals (i.e., a total population size of about 150-200 animals) is currently recommended to maintain an acceptable level of genetic diversity within reproducing WH&B populations (Cothran, 2009). This number is required to keep the rate of loss of genetic variation at 1 percent per generation. Animal interchange between adjacent HMAs with smaller population sizes may reduce the need for maintaining populations of this size within each individual HMA. Research has not yet established a recommended minimum breeding herd size for burros.

4.4.6.4 Management Actions

If the recommended minimum wild horse herd size cannot be maintained due to habitat limitations (e.g., insufficient forage, water, cover and/or space) or other resource management considerations (e.g., T&E species), a number of options may be considered as part of an appropriate site-specific NEPA analysis to mitigate genetic concerns:

- Maximize the number of breeding age wild horses (6-10 years) within the herd.
- Adjust the sex ratio in favor of males to increase the number of harems and effective breeding males.
- Introduce 1-2 young mares every generation (about 10 years), from other herds living in similar environments.

If wild horse herd size in small, isolated HMAs is so low that mitigation is not feasible, consideration should be given to managing the HMA for non-reproducing wild horses or to removing the area's designation as an HMA through LUP.

4.4.7 Herd Social Structure

Some management actions (e.g., sex ratio adjustments to favor stallions) may affect social structure and herd interactions (e.g., band size).

4.4.7.1 Wild Horses

The social structure of most wild horse herds consists of breeding and bachelor bands. Breeding bands or harems usually consist of a dominant stallion, lead or dominant mare(s), a group of breeding mares, and associated foals and yearlings. Most wild horses breed and foal in the spring of the year. Bachelor bands consist of various aged males that either have not yet established their own harem or have lost their mares. The composition of bachelor bands varies considerably throughout the year. In most breeding bands, male foals leave the band at 1 or 2 years of age and generally join bachelor bands.

Although wild horse bands tend to use the same habitat areas (home ranges) from year to year, they are not territorial and do not defend preferred habitat areas. As a result, bands often graze

and water near each other, and there may be movement of mares between bands. This, in combination with the periodic displacement of the dominant stallion and removal or death of other horses, results in a very fluid social structure in most herds. These factors are beneficial in enhancing genetic diversity.

4.4.7.2 Wild Burros

Wild burros do not form breeding bands. There are no strong individual bonds other than jenny-foal relationships. Wild burros present themselves as single animals, all-male groups, all-female groups, jenny-foal groups, or mixed groups. All of the groups are variable and their composition may change at any time. This loose social structure, where all animals are potential breeding partners, maximizes genetic diversity in small or dispersed burro populations.

Some of the older jacks establish a breeding territory but do not prevent other males from entering this area unless there is an estrous female present. It is common for males to roam freely throughout their habitat and breed upon encountering an estrous female. Large male groups may form in the vicinity of an estrous female, and it is normal for the jenny to have multiple breeding partners.

In dispersed populations in a desert environment, breeding efficiency increases as the population densities increase. As daily temperatures increase and water availability decreases, more and more animals will gather around the remaining available water sources. These areas become important areas for maximizing breeding efficiency. This temporary or seasonal increase in population density increases the chance for males to encounter estrous females. Thus, although breeding occurs year-round, increased breeding and foaling may occur during this period of time.

4.5 POPULATION CONTROLS

The authorized officer may consider a number of population control methods to achieve and maintain WH&B population size within AML.

4.5.1 Natural Population Controls

The rate at which WH&B herd sizes naturally increase or decrease is affected by a number of factors, including the nutritional value of the forage consumed, weather, disease, and predation. Experience gained in managing WH&B and other large herbivores indicates that soil, vegetation, and water resources are almost always severely damaged before these factors negatively affect population growth rates. Human intervention may be necessary when these factors, acting alone or in combination, do not exert sufficient influence to maintain WH&B population size within AML.

4.5.2 Gather and Removal

When the authorized officer has determined that excess WH&B exist, gathers to capture and remove the animals immediately or as soon as possible are required. For additional information, refer to BLM Manual Section 4720 (Removal) and 43 CFR 4720.1, 4740.1 and 2.

4.5.3 Reduce Population Growth Rates

During gather or herd management area planning, the authorized officer should consider a range of alternatives to reduce population growth rates and extend the gather cycle for all wild horse herds with annual growth rates greater than or equal to 5 percent. Alternatives may include but are not limited to: use of fertility control, adjustments in the sex ratio in favor of males, a combination of fertility control and sex ratio adjustment, and management of selected HMAs for non-reproducing wild horses. Additional management alternatives (tools) may be considered in the future, pending further research (see Chapter 8).

4.5.3.1 Use of Fertility Control as a Tool to Slow Population Growth Rates

a. Use of Porcine Zona Pellucida (PZP). There are two forms of the conventional PZP agent:

- The 1-year agent, delivered as a liquid primer injection and follow-up booster one month later; additional boosters must be injected annually by hand or by darting to continue treatment.

- The 22-month agent that includes the same primer shot as the one-year agent as well as a second injection of three time-release pellets (1-, 3- and 12-month pellets) to booster the vaccine over a 12-month period of time.

Foaling rates of 6 percent in Year One, 14 percent in Year Two and 32 percent in Year Three following treatment compared with 54 percent foaling in untreated controls have been reported for PZP-22 (Turner, 2007). Maximum effectiveness is not achieved unless mares are treated during a 3-4 month window prior to foaling. Research has shown that the best time to apply PZP is during the winter gather season (i.e., November-February).

The use of PZP, under an investigational exemption held by the Humane Society of the United States, requires treated mares to be physically marked (freeze branded) or readily identifiable in order to be compliant with FDA requirements. Application is limited to individuals specifically trained to handle, mix, and administer the product. Post-treatment monitoring in accordance with the Standard Operating Procedures (SOPs) is required.

As part of an appropriate environmental analysis, the authorized officer will analyze the use of the 22-month PZP vaccine in all wild horse herds, particularly those where: (1) the annual herd growth rate is greater than 5 percent and (2) the post-gather herd size is 50 animals or greater. Fertility control will be most effective when treatment of 50-90 percent of all breeding-age mares within the herd is possible using application in conjunction with gathers or remote delivery (darting). Our current understanding is that to maximize treatment effects, at least 90 percent of all mares should be treated.

The authorized officer should apply the 22-month PZP vaccine to all release mares when the NEPA analysis supports its use. In herds where sex ratio adjustments are made, fertility control may be implemented in combination with sex ratio adjustments to further reduce population growth rates.

b. Increased Use of PZP. One option to slow population growth rates (and reduce the number of excess wild horses removed) would be to gather selected HMAs and apply PZP-22 every 2 years. Because PZP does not totally eliminate reproduction, some excess horses may need to be removed from treated herds over time. Implementation should generally be limited to HMAs that have had high gather efficiencies (i.e., a high percentage of the actual population is captured). Because 70-90 percent of the breeding-age mares may need to be treated to effectively reduce population growth rates, 80-100 percent of the actual population may need to be captured.

c. Remote Application of PZP. Remote application of the 1-year formulation of PZP is problematic, as it is very difficult to approach most wild horses closely enough to allow darting (i.e., follow-up treatment). Remote application of PZP-22 is not possible at the present time since the pellets must be administered by hand injection.

   Remote application of the 1-year PZP agent may be considered for herds where individual horses can be identified (consistent with FDA requirements) and are approachable. Remote application is limited to individuals specifically trained to administer the product by darting.

4.5.3.2 Adjust Male/Female Sex Ratios

The authorized officer should consider alternatives which would manage WH&B herds for a sex ratio with a female component of less than or equal to 50 percent, as this reduces the population growth rate and extends the gather cycle. See Chapter 4 (4.4.1).

Adjusting sex ratios to favor males is another possible management tool which should be considered when the suppression of herd growth rate is desired. This management option should be considered in HMAs and complexes where the low end of AML is greater than 150 animals. Implementation of sex ratio adjustments is most feasible during maintenance gathers (4-5 years after AML is achieved). Sex ratio adjustments may be accomplished by shifting the overall sex ratio to favor males by (1) releasing greater numbers of stallions post-gather or (2) releasing geldings back to their home range following castration. Adjusting the sex ratio so that males comprise 60-70 percent of the adult herd could be considered.

Herd dynamics may change somewhat with adjustments in sex ratios. An increase in the proportion of stallions may have a greater impact when water resources are limited and bands are more concentrated.

Though additional information is needed, geldings are likely to have fewer impacts on the herd's social structure than would an increase in the proportion of stallions. Based on anecdotal observations, geldings released back to their home range: (1) tend to remain near where they were released (with adequate forage and water), (2) form small bachelor groups rather than join

with a reproducing band, (3) maintain better body condition than the herd average because they are sexually inactive, (4) live longer in comparison to sexually active horses, and (5) were easy to recapture (many have been recaptured and released several times).

Post-treatment monitoring should be conducted to observe behavior of individual animals and the herd during the first breeding season following treatment. Monitoring should be designed to determine whether bachelor stallions or geldings interfere with breeding harems, and whether there is increased competition for forage or water. Monitoring should also be designed to determine if the bachelor geldings form bands or intermix with the breeding population and whether band size changes with a greater proportion of stallions. This monitoring information will be used to determine if sex ratio adjustment is an effective population management technique that should be continued.

If post-treatment monitoring indicates that initial introductions of geldings or a greater proportion of stallions have resulted in negative impacts to breeding harems, mitigation could include removal of the additional stallions or geldings in whole or in part, no further introductions of stallions or geldings during future gathers, or release of a larger proportion of mares during the next gather. The need for post-treatment monitoring will decrease as the effectiveness of sex ratio adjustments as a tool to slow population growth rates is determined.

4.5.4 Manage Selected HMAs for Non-Reproducing Wild Horses

Under the WFRHBA (16 USC § 1333(b)(1)), the authorized officer may determine whether AML should be achieved by removal of excess animals, or if options such as sterilization or natural population controls should be implemented. Consistent with this authority, some selected HMAs may be managed for non-reproducing wild horses to aid in controlling on the range population numbers.

4.5.4.1 Manage HMAs for Non-Reproducing Wild Horses

LUPs should identify the HMAs to be managed for non-reproducing wild horses and the criteria for their selection. Completion of additional site-specific environmental analysis, issuance of a decision, and providing opportunity for administrative review under 43 CFR Part 4.21 may also be necessary.

Actual on-the-ground implementation would be influenced by gather efficiency and it may take several gathers to work toward an HMA with non-reproducing wild horses. Animals would be gathered to the extent possible and sterilized for return to the range, or removed. A safe, effective and humane means to sterilize stallions is castration, but a safe, effective and humane means to sterilize females has not yet been perfected. Therefore, initial efforts should focus on returning sterilized males to the HMA of origin. Sterilized males from HMAs with similar environments may be added as long as population size remains within AML. Care should be taken to ensure they are introduced and located near other animals in areas with good water and forage.

4.5.4.2 Manage Reproducing and Non-Reproducing Wild Horses in Selected HMAs

In selected HMAs with large AMLs, management of both reproducing and non-reproducing wild horses could be considered. As an example, non-reproducing wild horses could be geldings released back to their home range HMA following castration. Post-treatment monitoring and/or mitigation would be conducted as discussed in 4.5.3.2 above.

4.6 PRIORITIES FOR GATHER AND REMOVAL

When removal of excess WH&B from the range is necessary, gathers shall be prioritized in the following order:

- Emergencies
- Court Orders
- Nuisance animals (public health and safety)
- Impacts to threatened, endangered, or sensitive species (TES)
- WH&B located outside the HMA in areas not designated for their long-term maintenance
- Landowner request
- To achieve and maintain population size within AML
- Coordinate gathers across State, District and/ or Field Office boundaries and conduct gathers jointly whenever possible to improve gather efficiency and implementation of other population control measures such as application of fertility control and sex ratio adjustments.

4.7 NATIONAL GATHER SCHEDULE

A National Gather Schedule is developed annually based on the need to remove excess WH&B to achieve or maintain AML and the available funding and facility space. Situations that may require adjustments to the National Gather Schedule are: (1) Emergencies and (2) Escalating Problems.

4.7.1 Escalating Problems

Escalating problems are defined as conditions that deteriorate over time. The key indicator is a decline in the amount of forage or water available for WH&B use, which result in negative impacts to animal condition and rangeland health. Causal factors are normally drought or animal numbers in excess of AML. These situations can be detected in advance and are managed through the normal planning process. See BLM Manual Section 4720.21.

4.7.2 Emergencies

Emergencies generally are unexpected events that threaten the health and welfare of a WH&B population and/or their habitat. Examples of emergencies include fire, insect infestation, disease, or other events of a catastrophic and unanticipated nature. Immediate action is normally required. For some emergency actions, it may be appropriate to use alternative means or

procedures to comply with NEPA (see BLM NEPA Handbook, H-1790-1: National Environmental Policy Act Handbook, Chapter 2.3 Emergency Actions). If timeframes permit, a gather plan environmental assessment should be prepared prior to WH&B removal. If this is not possible, emergency actions should be documented and a report prepared after resolution of the problem. Public notification can be addressed through a press release. See BLM Manual Section 4720.22.

4.8 POPULATION MODELING

Version 3.2 of the Winn Equus population model developed by Dr. Steven Jenkins will be used during gather or herd management area planning to analyze and compare the effects of proposed wild horse management. The model is not designed for use on burros.

The model's primary purpose is to analyze and compare the effects of the proposed action (and alternatives) on population size, average population growth rate, and average removal number. Possible management alternatives or strategies may include, but are not limited to:

- Proposals to gather/remove excess animals, with or without fertility control.
- Proposals involving various gather cycles.
- Proposals to make adjustments in sex ratios.
- Proposals to manage all or a portion of a herd as a non-reproducing population.
- Proposals for gate-cut or selective removal gather.
- No Action.

Another objective of the modeling is to identify whether any of the alternatives would be likely to "crash" the population based on a number of stochastic factors (varying environmental conditions).

Use of the Win Equus population model requires the following:

- **Gather Planning:** Run the model for 10 years and 100 trials; select and display the most typical trial.
- **Herd Management Area Planning:** Run the model for 20 years and 100 trials; select and display the most typical trial.
- **Adjustment of Sex Ratios:** Select 100 percent gather for mares and adjust (decrease) the gather percentage for studs to achieve the desired post-gather sex ratio.
- **Results Analysis:** Drop the highest trial and the lowest trial and analyze and compare the remaining trials.

4.9 HUMANE DESTRUCTION

The BLM authorized officer will euthanize or authorize the euthanasia of a wild horse or burro when any of the following conditions exist:

1. Displays a hopeless prognosis for life.

2. Is affected by a chronic or incurable disease, injury, lameness or serious physical defect (includes severe tooth loss or wear, club feet, and other severe acquired or congenital abnormalities).

3. Would require continuous treatment for the relief of pain and suffering in a domestic setting.

4. Is incapable of maintaining a Henneke body condition score greater than or equal to 3, in its present environment.

5. Has an acute or chronic illness, injury, physical condition or lameness that would not allow the animal to live and interact with other horses, keep up with its peers or maintain an acceptable quality of life consistently or for the foreseeable future.

6. A State or Federal animal health official orders the humane destruction of the animal(s) as a disease control measure.

7. Exhibits dangerous characteristics beyond those inherently associated with the wild characteristics of wild horses and burros.

    a. Dangerous animals are defined as those horses or burros that are unusually aggressive and pose an unacceptable risk of injury to humans or other animals.

    b. Unusually dangerous horses or burros possess characteristics that are not desirable to breed into the wild herd.

    c. It is also reasonable to conclude that an average adopter could not humanely care for the animal.

CHAPTER 5—INVENTORY AND MONITORING

GENERAL

The authorized officer is required to identify, plan, collect and analyze the resource monitoring data necessary to prepare resource management plans, plan amendments, gather plans, herd management area plans or other associated environmental documents through which WH&B management decisions are made.

Inventory (monitoring) shall be completed in order to determine:

- If an overpopulation of WH&B exists and action is needed to remove the excess animals.
- WH&B AMLs; and,
- If AMLs should be achieved by removal of the excess animals or other appropriate means.

Monitoring data is needed to support AML establishment and decisions to remove excess WH&B. Various rulings from the Interior Board of Land Appeals (IBLA) underscore the need to base WH&B management decisions on the results of monitoring.

5.1 HABITAT MONITORING

The primary purpose of habitat monitoring is to collect the resource data necessary to:

- Make a determination of excess animals (i.e., support the need to gather and remove excess wild horses or burros).
- Establish or adjust AML.
- Develop or revise HMAPs.
- Evaluate conformance with Land Health Standards, LUP goals and objectives, or other site-specific or landscape-level objectives.

Collection of habitat monitoring data should be coordinated with other resource programs (e.g., range, watershed, wildlife) to maximize efficiency and minimize duplication.

Appendix 2 (Habitat Monitoring References) provides a list of BLM Technical References that can assist in planning for, and collection and evaluation of monitoring data. BLM Technical References can be found at: http://www.blm.gov/nstc/library/techref.htm

5.1.1 Annual Monitoring

Annual monitoring objectives include:

- Determine whether or not forage and water is adequate to support the animals in a healthy condition through the remainder of the year.
- Assess and evaluate animal condition.

To achieve these objectives, monitoring efforts should focus on the following:

- Evaluate current year's forage production and water flows.
- Evaluate/measure use, map patterns of use and monitor seasonal distribution/movement.
- Evaluate WH&B body condition.

Data collection to accomplish the above could include:

1. Photographs and Field Inspection Notes. Document observations on current year's growing conditions (average, below average or above average precipitation and soil moisture); plant phenology (are plants maturing earlier or later than normal); and forage production and water flows (average, below normal, above normal). When taking photographs, label each photograph with the date and the location to facilitate re-photographing the area in the future.

2. Use Mapping. Map utilization of current year's growth. Where possible, document forage utilization by WH&B in rest pastures or prior to livestock use. Where separation of use by type of animal is not possible, map total utilization at the end of the season. Use the information collected to identify and establish key areas, determine distribution, and seasonal use areas. If mapping utilization of the HMA on an annual basis isn't possible, focus monitoring on measuring utilization at key areas used by WH&B within the HMA on an annual and continuing basis.

3. Utilization. Estimate the proportion of annual forage production used by herbivores (WH&B, domestic livestock, wildlife, and insects).

4. Residual Vegetation or Stubble Height, Woody Species Use or Streambank Alteration. Measuring stubble height, use on woody species, and the degree of streambank utilization occurring annually (especially in rest pastures or prior to livestock use) may also be helpful in documenting resource impacts associated with WH&B use.

5. Grazing Use Records. Summarize the actual grazing use (animal unit months of forage) by livestock, WH&B, and wildlife by unit or pasture for the year.

6. Weather Data. Document information on temperature, precipitation, and growing conditions.

7. Animal Condition. Using the Henneke Body Condition Scoring (BCS) system, document the number of animals seen, where they were observed, and their BCS class. Document average group size (e.g., animals are concentrating in large groups or scattered, small groups, evidence of lameness, or other possible animal health concerns). This information may be used to assist in the evaluation of TNEB within the HMA.

When collected, data should be filed in the 4710-Herd Management case file and cross-referenced to the applicable rangeland management or other resource monitoring files.

5.1.2 Long-Term Monitoring

The objective of long-term monitoring is to determine whether management is resulting in significant progress toward attaining Land Health Standards, other applicable site-specific or landscape-level objectives, or changes in range ecological condition and trend (up, stable or downward). Data are typically collected by an interdisciplinary team of resource specialists in preparation for a formal and detailed evaluation of current management and its effect on resource conditions.

5.1.2.1 Ecological Sites

Rangeland landscapes are divided into ecological sites for the purposes of inventory, evaluation and management. Each site is defined and described by the Natural Resources Conservation Service (NRCS) based on climate, geology, soils, vegetation and other environmental factors. An ecological site is also described based on its ability to produce and support a characteristic plant community (i.e., kind, amount, and proportion of natural vegetation). Ecological site descriptions can be used to evaluate current management and to identify the potential effects in range ecological conditions or trends that could be expected from proposed changes in WH&B management. Ecological site descriptions for each Major Land Resource Area (MLRA) are available from NRCS. If an area has not yet been inventoried by NRCS, an interdisciplinary team of resource specialists will use the best available data to identify the ecological sites in the HMA.

5.1.2.2 Riparian Areas

Properly functioning riparian areas produce abundant forage, important habitats for fish and wildlife, and improve water quality and quantity. Functional-at-risk riparian areas have one or more attributes which place them at risk of deterioration, while nonfunctional riparian areas are unable to capture sediment, enhance infiltration, recharge aquifers or dissipate high energy flows. Assessments of proper functioning condition can be used to identify issues, establish objectives, and propose and evaluate changes in WH&B management.

5.1.2.3 Key Areas

Key areas are selected to monitor changes in range ecological condition or trend across representative areas within the HMA or complex which may result from current WH&B management. Key areas may be selected to represent a particular plant community or a specific ecological site. They should also be selected to represent ecological conditions and trends, utilization or use patterns, seasonal distribution, and resource production within the HMA or complex.

Long-term monitoring within key areas may include measurements of frequency, production, and cover (canopy cover, foliar cover, ground cover and basal cover). Plots are generally read at intervals of 5-10 to 15-20 years.

5.1.2.4 Key Species

Key plant species are selected for forage utilization studies. Key species are important forage species within plant communities that can indicate changes in resource conditions resulting from WH&B management. More than one key species may be selected, depending on management objectives.

Key forage species are used to indicate the allowable degree of forage utilization on a key area which promotes attainment of attaining vegetation management objectives. They may be identified during land use planning, or result from habitat management objectives established during site-specific planning efforts such as herd management area planning.

5.1.3 Integrated (Interdisciplinary) Resource Monitoring Plans

Development of integrated (interdisciplinary) resource monitoring plans can help assure that the data needed to support WH&B management decisions is collected in an effective and efficient manner. Resource monitoring plans should identify the following:

- **Who** (The resource specialty responsible for data collection, i.e., WH&B specialist, range specialist, etc.).
- **What** (Data to be collected).
- **When** (Time of year data should be collected and how often).
- **Where** (Location(s) for data collection, i.e., location and documentation of key areas).
- **Why (**The specific monitoring objective).
- **How** (Methods to be used).

Also refer to Appendix 4 (Table 4.2).

5.2 POPULATION MONITORING

An accurate and current assessment of WH&B health and condition, as well as population size, growth rate, and distribution, is needed for proper WH&B management. At a minimum, population surveys should be conducted every 2 years whenever possible, and within 6-12 months prior to establishing the need to gather and remove excess WH&B.

5.2.1 Population Estimation

WH&B population size should be estimated primarily by aerial survey. See BLM Manual Section 4710.45.

1. Aerial surveys will be conducted and documented using standardized sampling methods and procedures. Survey methods (types of aircraft and techniques) should utilize the most effective and cost-efficient techniques for the specific HMA or complex.

2. To permit comparison with prior data and detect population trends, aerial surveys should be conducted during the same time of the year, using the same or similar type of equipment, methodology, and personnel.

3. The following data should be should be recorded during aerial surveys:

   - HMA name and number
   - State/District or Field Office
   - Survey date
   - Observer(s) name
   - Weather conditions
   - Type of aircraft used
   - Altitude
   - Flight time
   - Time of day
   - Survey method (direct count, simultaneous double-count, mark-resight, etc.)
   - Flight path, number and location of animals seen in GPS/GIS data format
   - Number of adults, number of foals
   - Basic herd health and condition information
   - Basic information about range, forage or water conditions, wildlife, or livestock use, etc.

4. In areas where gather efficiencies have been historically low or WH&B range widely, a post-gather survey should be conducted in the 6-12 months following gather completion to obtain a more accurate estimate of the number of WH&B left on the range.

5. Monitoring WH&B distribution is critical in identifying seasonal use areas, determining movement patterns and identifying areas for habitat monitoring. While seasonal distribution may vary over the years, movement is normally related to the abundance and quality of the forage, climate, weather patterns, and availability of water.

6. The HMA monitoring file shall contain a permanent record of data collected during the aerial surveys and the results should be entered into the Wild Horse and Burro Program System (WHBPS) and the local GIS data base.

5.2.2 Herd Condition and Health Monitoring During Gathers

The condition class of individual horses should be evaluated and documented during gathers using the Henneke Body Condition Scoring System (refer to H-4760-1: Compliance Handbook).

1. Data should also be collected on age structure and sex ratio. This information can be used to evaluate the effects of the management actions on herd health and condition.

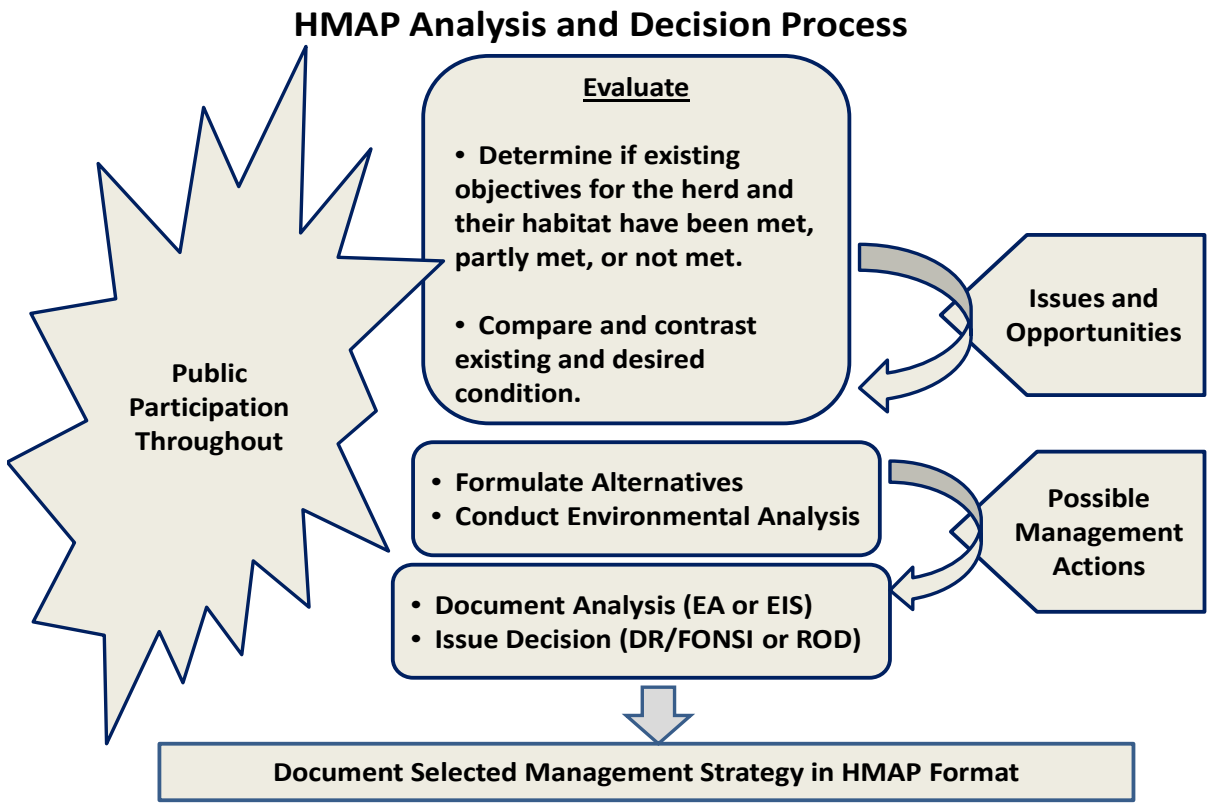
2. Estimate the number of WH&B left on the range (number remaining ungathered) following each gather.

3. Other data that may be collected during gather operations include: parasite load, disease (from blood samples), percentage of pregnant mares (through analysis of blood or fecal samples), and/or the effects of fertility control.

4. The incidence of albinism, parrot mouth, club feet, severely crooked legs or other physical deformities should also be documented and the subject animals removed from the population when possible. The incidence of these traits should be minimized within individual herds over time.

CHAPTER 6—HERD MANAGEMENT AREA PLANNING

GENERAL



Herd Management Area Plans (HMAPs) identify and set objectives for WH&B herds and their habitat. HMAPs are prepared with public involvement through a site-specific environmental analysis and decision process (NEPA). During the NEPA process, the environmental impacts associated with a range of alternative management strategies for the WH&B herd and its habitat is analyzed.

The approved HMAP outlines the selected management actions, together with the management and monitoring objectives which, when implemented, would make progress toward achieving land health standards, LUP goals/objectives, and other relevant objectives.

6.1 HMAP ANALYSIS AND DECISION PROCESS

An overview of the HMAP analysis process is provided in Figure 6.1. Also refer to Appendix 4 (Herd Management Area Planning) for additional information.

Figure 6.1
Overview of the HMAP Analysis and Decision Process

6.1.1 Evaluate Current Management

The first step in the HMAP analysis process should generally be to evaluate existing management. At the conclusion of the management evaluation, a report will be prepared and made available to the public for a 30-day review and comment period (public scoping). To facilitate public review, the document will be posted on the state, district or field office web page.[1] The management evaluation report is not a decision subject to administrative appeal.[2] Rather, the report documents the key issues identified as a result of the management evaluation. A range of the possible management alternatives (Proposed Action and Alternatives) that would address or resolve the identified issues may also be identified. The range of alternative may be expanded as a result of scoping comments.

Key steps in the management evaluation process include:

1. Review existing goals and objectives for the herd and its habitat and determine whether these have been met, partly met, or not met. Incorporate a summary of the rationale supporting BLM's determination in the evaluation report.

2. Compare and contrast the existing and desired condition for the herd and its habitat. Refer to the information in Chapter 3 (Habitat Management) and Chapter 4 (Population Management) as a starting point for the analysis.

3. Document the gaps (or differences) between the current and desired conditions. These differences represent the issues to be addressed and resolved (i.e., the purpose and need for action).

4. Identify the possible management actions that could be implemented in response to the identified issues.

5. Formulate a range of alternative management strategies for the herd and its habitat from the list of possible management actions (Proposed Action and Alternatives). Each alternative considered should meet the purpose and need for action and respond to the identified issues in whole or in part.

6. Finalize the management evaluation report and provide it to the public for a 30-day review and comment period (i.e., public scoping).

6.1.2 Conduct and Document the Site-Specific Environmental Analysis

As a next step, conduct and document the interdisciplinary, site-specific analysis of potential impacts that could result from implementation of the No Action (generally defined as "Continue

[1] If an Environmental Impact Statement (EIS) is prepared, scoping will be conducted following issuance of a Federal Register Notice.

[2] Once the HMAP decision is made, the Evaluation Report is part of the administrative record for that decision.

Existing Management" for HMAP development and analysis), the Proposed Action, and other action alternatives. Refer to H-1790-1: National Environmental Policy Act Handbook.

Though it may be appropriate in some instances to prepare an Environmental Impact Statement (EIS), normally an environmental assessment (EA) is prepared to document and analyze an HMAP decision. The section below provides guidance about how an HMAP EA may be structured.

6.1.2.1 Preparing the HMAP Environmental Assessment (EA)

1. Introduction. Limit the information included in the "Introduction" section of the EA to the minimum needed to allow the reader to understand the existing situation. Include a brief description of the HMA and its location, and the AML (and when/how it was established). Describe the purpose and need for the Proposed HMAP. Identify the relevant issues, summarize the results of public scoping, and document how the BLM used the comments in preparing the preliminary environmental assessment. Tier the analysis to applicable decisions in the LUP.

2. Proposed Action and Alternatives. Each alternative considered in detail in the EA shall meet the purpose and need for action and respond to the identified issues to varying degrees. The range of alternatives considered will include a No Action Alternative (i.e., Continue Existing Management) and the Proposed Action (Proposed HMAP). Other alternatives should be developed in response to the purpose and need and the identified issues, as appropriate.

   Each alternative will describe the strategy to be used to manage the herd and its habitat over the long-term, together with the associated management, monitoring and implementation objectives. In formulating the alternative management strategies, various management tools may be considered to protect, control and manage WH&B populations and their habitat. For example, consider differing gather seasons or methods, various tools to slow population growth, or various habitat improvement tools, projects or techniques.

3. Management Objectives and Actions. Management objectives and actions may differ by alternative. This section of the EA would summarize the objectives and actions specific to each alternative.

   For each alternative specify: (a) the proposed habitat and population management objectives, (b) the associated management actions (e.g. implementation objectives), and (c) the proposed monitoring objectives. These objectives and actions should conform to and be consistent with LUP goals.

   a. SMART Objectives. Well-written objectives should be specific, measurable, achievable/attainable, reasonable/relevant and trackable within a specified timeframe (SMART):

1) Specific: Specifies what and where.
2) Measurable: Identifies the amount of change expected; desired change can be measured or observed.
3) Achievable/Attainable: Realistic for the specific site conditions.
4) Reasonable/Relevant: Limited in scope, within the BLM's control and influence, measures results (not activities).
5) Trackable/Timeframe: Identifies where the activity will occur, short- and long-range targets, as well as interim steps and a plan to monitor progress.

b. Habitat Objectives. Habitat objectives may involve vegetation, trend or key area objectives for upland vegetation or riparian plant communities within the HMA or complex or objectives to maintain or improve the wild, free-roaming behavior of the population. Site-specific objectives to improve habitat conditions (e.g., forage or water) may also be established.

Examples of SMART Objective(s)

- ❒ Improve riparian condition from functioning at-risk (FAR) in 1998 to properly functioning condition (PFC) by decreasing utilization from heavy to moderate within a ½ mile circumference of Bird Spring.
- ❒ Adjust sex ratios from 40 percent studs and 60 percent mares in 2010 to 60 percent studs and 40 percent mares by 2014.

c. Population Objectives. These objectives would establish a framework for management of the WH&B herd over the longer term. Objectives could include when and how AML would be adjusted in the future, or when and how the population within the HMA would be gathered. Among other population management parameters, objectives may be identified for desired age structure and sex ratio, animal condition, phenotype, genetic diversity, population growth rate, or selective removal criteria. These objectives may be based on historical attributes or other management considerations.

d. Monitoring Objectives. As necessary, identify a monitoring objective that would measure the progress made toward achieving proposed habitat or population management objectives.

e. Implementation Objectives (Management Actions). Implementation objectives are management actions that, when implemented, are expected to make progress toward attaining the proposed habitat or population management objectives. These could include application of fertility control, adjustment of sex ratios to favor males, or other actions to slow population growth, management actions to assure genetic diversity or achieve the desired sex ratio or age structure for the WH&B herd, or range improvement projects.

4. Description of the Affected Environment and Environmental Impacts

   a. General Description of the Affected Environment. This section of the EA should include a concise general description of the HMA or HMA complex. Voluminous material may be included in the EA appendix. Maps, tables, charts or graphs may also be useful in summarizing or displaying relevant information. Information could include:

      1) General information about the HMA or complex's size, location, acres of public land or other land ownership, general description of topography, elevation, climate, and dominant vegetation.

      2) A summary of the WH&B herd's history using best available data. This could include the probable origin of the WH&B population, identification of the general type of WH&B historically occupying the HMA, any interchange between this herd and adjacent HMAs, known genetic diversity (observed heterozygosity or Ho) and any introductions of WH&B from another HMA.

      3) A brief discussion of any historic adjustments that have been made in the HA/HMA boundary, and the name and date of the decision document(s) used to initiate those adjustments. Maps or descriptions of HA/HMA boundaries may also be included.

      4) Initial forage allocations together with the existing AML range. The name and date of any decision document(s) used to establish or adjust AML along with a brief description of the causal factors leading to the change.

      5) Any population and habitat management actions or events that have impacted herd size including scheduled, emergency or nuisance animal gathers, application of fertility control, and the occurrence of catastrophic events such as extended drought or wildfire.

      6) A concise list of applicable LUP decisions that affect the HA/HMA, including any constraints on WH&B distribution and management (voluminous information can be included in an appendix to the EA).

      7) A list of applicable Land Health Standards (these may be included in an appendix to the EA or an internet address can be provided if they are available on the internet).

      8) Brief descriptions of other resource values and uses relative to the management of WH&B, as appropriate. This could include: authorized and/or actual livestock use, TES species and their habitat, Wilderness, Wilderness Study Areas (WSAs), etc.

b. Description of the Affected Environment and Environmental Impacts. For each element of the human environment that has the potential to be affected by the Proposed Action or alternatives, describe the existing situation (affected environment). Also describe the direct and indirect impacts to these resources that could result from implementation of the Proposed Action and Alternatives.

5. Cumulative Impacts. The National Environmental Policy Act (NEPA) regulations define cumulative impacts as impacts on the environment that result from the incremental impact of the Proposed Action when added to other past, present, and reasonably foreseeable future actions, regardless of what agency or person undertakes such actions (40 CFR 1508.7). Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time.

   In assessing the cumulative impacts associated with preparation of a proposed HMAP, first define the area of potential effect—cumulative impacts will be evaluated within the area of potential effect.

   Next define the issues and resource values identified during scoping that are of major importance (in accordance with the 1994 BLM *Guidelines for Assessing and Documenting Cumulative Impacts*, the cumulative impacts analysis should be focused on only those issues and resource values identified during scoping that are of major importance).

6. Public Review and Comment. The HMAP environmental assessment shall be made available to the public for a 30-day review and comment period by posting on the state/district or field office web page. See H-1790-1 for instructions if an EIS has been prepared.

7. Finalize the HMAP EA. Soliciting public comments obligates reviewers to give fair consideration to the input received. Summarize the results of public review and comment and document how the BLM used the comments in finalizing the environmental assessment.

6.1.2.2 Prepare the Decision Record and Finding of No Significant Impact (FONSI) or an EIS and Record of Decision (ROD)

Based on the analysis of potential environmental consequences, the authorized officer will determine whether to prepare an EIS or issue a Decision Record (DR) and "Finding of No Significant Impact" (FONSI). A FONSI documents why implementation of the selected alternative will not result in environmental impacts that significantly affect the quality of the human environment. The DR identifies the authorized officer's final decision and is a separate and subsequent document to the FONSI. See H-1790-1 for additional information.

If an EIS has been prepared, due to the potential for significant environmental impacts, the authorized officer's final decision will be documented in a Record of Decision (ROD).

6.1.2.3 Prepare the HMAP

As a final step and to facilitate on-the-ground implementation, document the selected management strategy, together with the habitat and population management, monitoring and implementation objectives in HMAP format. The HMAP shall be included as an attachment to the authorized officer's final decision.

The approved HMAP should include the following components:

- **Introduction.** Briefly introduce or summarize the relevant background information (repetition of detailed information incorporated in the NEPA document is not required in the approved HMAP).

- **Management Strategy.** Summarize the selected management strategy as outlined in the EA together with the site-specific habitat and population objectives and management actions established to accomplish the objectives.

- **Monitoring and Evaluation Plan** (refer to 6.1.2.3.1).

- **Tracking Log/Project Implementation Schedule** (refer to 6.1.2.3.2).

6.1.2.3.1 Resource Monitoring Plan/Schedule

The HMAP shall include a resource monitoring plan and schedule that will be used to facilitate the timely and effective completion of habitat and population monitoring. The plan should identify the specific monitoring item, the methodology to be used, the resource specialty needed to complete the monitoring (e.g., field office WH&B specialist, rangeland management specialist, wildlife biologist, etc.), where and when monitoring should occur, as well as any actions to be taken to adjust or adapt management as needed and appropriate pending monitoring results. The plan should include both habitat and population monitoring components. See Appendix 4 (Table 4.2).

6.1.2.3.2 Tracking Log/Project Implementation Schedule

The HMAP will include a tracking log and project implementation schedule to facilitate and monitor plan implementation. The tracking log may be developed in a tabular format, and will list the selected habitat and population management actions (what), the entity responsible for implementation (e.g. who -- BLM, USFS, volunteer groups, etc), and define where, when, and how often the action is to be completed. Columns to document the date the action was completed and/or implemented and for any remarks (e.g. project numbers from BLM's Rangeland Improvement Project system, etc) should also be included. See Appendix 4 (Table 4.3).

6.2 HMAP MONITORING AND EVALUATION

Resource (habitat and population) monitoring data should be analyzed periodically to determine whether minor adjustments in management are needed (adaptive management). Periodic evaluations are conducted to assure HMAP implementation is on track and to gauge progress toward achieving the selected habitat and population management and other relevant objectives. Refer to the process outlined in 6.1.1.

The goals for HMAP monitoring and evaluation are twofold: (1) to track implementation of the management actions/decisions outlined in the HMAP (implementation monitoring); and (2) to collect the data/information necessary to evaluate the effectiveness of those decisions (effectiveness monitoring).

1. Implementation Monitoring. Implementation monitoring tracks implementation of the selected management actions. It answers the question "Did we do it?" To assure selected management actions are being implemented in a timely manner, annual review is recommended.

2. Effectiveness Monitoring/HMAP Evaluation. Plan evaluation is the process of periodically reviewing the HMAP to determine if it is effective in making progress toward or accomplishing the approved habitat and population management objectives (plan evaluation typically occurs at intervals of 5, 10 or 15-20 years). Effectiveness monitoring answers the question "Did it work?"

   The HMAP shall also be evaluated to determine: (1) whether management goals and objectives are still appropriate or need to be revised, and (2) whether progress is being made toward achieving the goals and objectives, or additional management actions are needed (adaptive management). Evaluation of the HMAP could also be completed in conjunction with land health assessment.

   Evaluations that highlight the need for substantial changes may require consultation with interested public as well as appropriate NEPA analysis and documentation prior to implementation.

6.3 4710 CASE FILE

A 4710-Herd Management Area file shall be established for individual HMAs or complexes. The case file should include (but is not limited to) the following:

- A copy of the HMAP.
- HMA and HA maps.
- The associated NEPA and BLM decision documents (or a cross-reference to those documents).
- Any correspondence pertaining to HMA management.
- Aerial survey results.

- Field inspection reports and monitoring data (or a cross-reference to the applicable rangeland management or other case files).
- Information on habitat improvement projects (or a cross-reference to the applicable rangeland management or other case files).
- Final gather reports.
- Fertility control reports, if applicable.
- Results from periodic HMAP evaluations.

Additional 4710 case files may be created if the number and type of monitoring studies is large and varied (e.g. 4710-1, 4710-2, etc).

Relevant data and information should also be entered in a timely manner into WHBPS, as appropriate.

HA/HMA maps and a record of the HA/HMA history should be included in the 4710 HMA file. However, the HA and HMA boundaries delineated in the State GIS data base and provided to the National Coordinator for upload into the National Data Set serve as the official record. Any future changes to HA or HMA boundaries should be documented in the State GIS data base as well as in the HMAP file.

CHAPTER 7—DECISIONS AND APPEALS

7.1 DECISIONS

Implementation decisions form the basis for approval of on-the-ground management actions. When implemented, these actions further the incremental progress toward achieving LUP goals and objectives, Standards for Land Health, or other site-specific habitat or population management objectives. If proposed management is not in conformance with the LUP, the proposal shall be modified or rejected, or the LUP shall be amended or revised.

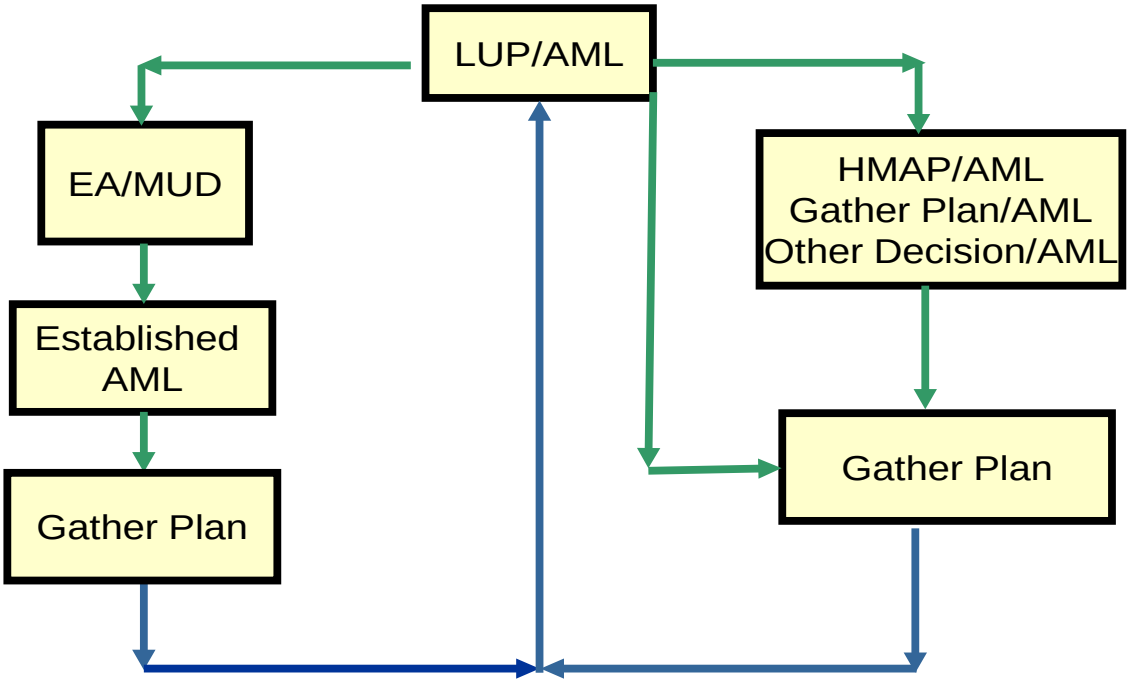
WH&B implementation decisions can include:

- Establishing or adjusting AML
- Developing HMAPs
- Population management actions
- Habitat improvement projects

Program-specific procedures must be followed when issuing a decision. WH&B implementation decisions can be made in a variety of ways and administrative review (appeal) requirements may vary based on the decisions made (Figure 7.1).

Figure 7.1
Decisions and Appeals Process

An Overview



Authority	43 CFR 4770.3(c)	43 CFR Part 4.21
Decision Type	Decisions to Gather/Remove Excess WH&B	AML, HMAP or Project Decisions
Effective Date	• *Emergency Removal Decisions:* make effective upon issuance. • *TNEB Removal Decisions:* make effective on a date specified in the decision *(*e.g., 31-76 days prior to proposed gather start).	Effective the day after the appeal period expires (i.e., 31 days) unless a petition for stay is filed.
Administrative Review Timeframe	Appeals and petitions for stay must be filed within 30 days of the date of the decision.	
Implementation Timeframe	Unless a petition for stay is granted, the gather and removal may proceed as outlined in the authorized officer's decision.	The authorized officer's decision may be implemented immediately if the Appeals Board either denies the petition for stay or fails to act on it within 45 calendar days of the expiration of the time for filing a notice of appeal.

* AML decisions issued as MUDs are heard by a OHA/ALJ and are not implementable until OHA has ruled.

7.1.1 AML Decisions

AML decisions determine the maximum number of WH&B to be managed in the HMA that results in a TNEB and avoids a deterioration of the range. Decisions to establish or adjust AML or establish a population range if the AML was initially set as a single number, can be made in a number of ways (refer to Figure 7.2).

Figure 7.2
AML Decisions

AML decisions are generally implementation decisions as compared to LUP decisions. All AML decisions must meet the following criteria:

1. AML is set based on in-depth analysis of site-specific resource monitoring data including grazing utilization, trend in range condition, actual use and climatic factors (i.e., AML is not set based on administrative convenience or single surveys); and

2. Guidelines and criteria for adjusting herd size are included. Refer to *Dahl v. Clark*, 600 F. Supp. 585 (D. Nev. 1984); *Animal Protection Institute*, 117 IBLA, 208, 219 (1990); and *Animal Protection Institute*, 109 IBLA 112, 118 (1989).

AML decisions may also be made through:

- Issuance of WH&B (single-use) decisions.

- Issuance of multiple-use decisions (MUDs, which allocate forage for domestic livestock, wildlife and WH&B).
- As a part of HMAP decisions.
- As part of gather/removal plan decisions.

AML is not generally established or adjusted as part of the gather planning (NEPA) process due to the in-depth and complex nature of the analysis required. Complexity also increases if allocation of the available forage for use by wildlife, livestock and WH&B will be made concurrently (e.g., MUDs).

If the authorized officer elects to formally review AML as part of the same environmental document which evaluates the proposed removal, the AML decision should be separated from the gather/removal decision. This may be accomplished by issuing separate Decision Records:

1. Gather/removal decision.
2. AML decision.

Separation of the two decisions is desirable because there are different rules governing the timing and appeals process for those decisions:

- Under 43 CFR 4770.3(c), the authorized officer can make decisions to remove wild horses or burros from public or private lands effective upon issuance or on a date specified in the decision, where removal is needed to preserve or maintain a thriving ecological balance and maintain a multiple use relationship.

- The authorized officer does not have similar authority with respect to issuing AML decisions, which, if no petition for stay is filed, become effective on the day after the expiration of the appeals period. See 43 CFR § 4.21(a)(2).

7.1.2 Gather/Removal Decisions

Prior to removing WH&B from public lands, the authorized officer must make a determination, based on current information, that excess animals are present and their removal is necessary to restore a TNEB and multiple-use relationship. BLM's authority to remove excess animals from public lands is found in 16 USC § 1333(b)(2) of the WFRHBA (as amended). This provision requires the BLM to immediately remove the animals upon determination that excess WH&B exist, so as to achieve appropriate management levels, restore a thriving natural ecological balance, and protect the range from the deterioration associated with the overpopulation.

In making the determination that excess WH&B are present and require immediate removal, the authorized officer will analyze current information including grazing utilization and distribution, trend in range ecological condition, actual use, climate (weather) data, current population inventory, WH&B located outside the HMA in areas not designated for their long-term maintenance and other factors which demonstrate removal is needed to restore or maintain the range. Justifying a removal based on nothing more than the established AML is not acceptable.

7.1.2.1 Environmental Analysis (Gather Plans)

The following tools can be used to focus the discussion during the site-specific environmental analysis conducted for Gather Plans:

1. Limit the analysis to that needed to determine the potential impacts associated with the Proposed Action and Alternatives, including No Action. Refer to H-1790-1 for a detailed discussion of the appropriate components of a NEPA analysis.

2. Tier the analysis to LUPs, HMAPs, or other relevant decision documents, as appropriate.

3. Incorporate previous analysis or decisions by reference (e.g., reference to previous AML decisions, HA/HMA boundary decisions, etc), as appropriate.

These tools allow reference to the information without the need to either include the documents in whole or in part, or to restate the information in voluminous detail.

7.1.2.2 Decision Record (Gather Plan)

Unless an emergency situation exists, gather/removal decisions shall be issued 31-76 days prior to the proposed gather start to provide an opportunity for administrative review of the authorized officer's decision to be completed. The Decision Record (DR) for Gather Plans that are documented in an environmental assessment should:

1. Summarize the substantive comments received and describe how BLM used these comments to finalize the environmental assessment. See 7.2 for additional information.

2. In accordance with 43 CFR 4770.3(c):

   - The authorized officer will issue gather decisions effective upon a date established in the decision in situations where removal is required by applicable law, or is necessary to preserve or maintain a thriving natural ecological balance and multiple use relationship.

   - When an emergency situation exists, and timeframes permit, a Gather Plan EA should be prepared and the decision should be made effective upon issuance. See BLM Manual Section 4720.36.

3. Cite the regulatory authority upon which the decision is based.

4. Explain the timeframe and procedures for filing an appeal.

5. Describe the procedures for requesting a stay of the action under 43 CFR 4.21.

7.1.3 Other Management Decisions

Other management decisions may include:

- Approval of HMAPs that establish site-specific population or habitat objectives or actions.
- Project-specific decisions (i.e., water development construction or reconstruction, etc.).

These decisions are made following site-specific environmental analysis (NEPA) with public involvement and are subject to administrative review (appeal) under 43 CFR 4.21.

7.1.4 Actions Excluded from Further NEPA Documentation

Certain actions may be categorically excluded from NEPA analysis (refer to H-1790-1, Chapter 4, Categorical Exclusions). Other actions may have already been adequately analyzed through NEPA and a Determination of NEPA Adequacy (DNA) may be prepared.

Before conducting a new NEPA analysis for a proposed Gather Plan, existing NEPA documentation should be reviewed to determine if it is adequate (i.e., review previous Gather Plan EAs together with the associated Decision Records and Findings of No Significant Impact). Changes in numbers of WH&B since the previous gather that result in changes in forage utilization, use patterns, and/or ecological conditions and trends, or changing environmental conditions such as drought, wildfire, noxious weed infestations, and others, may require that a new NEPA analysis be conducted.

If the existing NEPA documentation appears to be adequate, consult with the Office of the Solicitor to determine whether the issuance of a DNA may be appropriate.

7.2 PUBLIC INVOLVEMENT

The authorized officer may conduct public scoping. See H-1790-1, Chapter 6.3.

The authorized officer will provide the public 30 days to review and comment on the NEPA document, typically an Environmental Assessment that documents and analyzes the environmental effects of the BLM's Proposed Action.

The authorized officer shall make Gather Plan EAs and DNAs available to interested individuals, groups, and agencies for a 30-day review and comment period, except when an emergency situation exists. The NEPA document(s) identified in the DNA (e.g., the EA and Finding of No Significant Impact (FONSI)) will also be made available to the public for information.

The authorized officer should consider substantive comments and summarize how they were addressed in the NEPA document or DNA for the Gather Plan. This summary should be presented in the NEPA document, the DNA, or the decision document. See H-1790-1, Chapter 6.9 for additional information.

Possible options for responding to substantive comments include:

- Modifying one or more of the alternatives.
- Developing and evaluating additional alternatives.
- Supplementing, improving, or modifying the analysis.
- Making factual corrections.
- Explaining why the comments do not warrant further agency response, citing cases, authorities or reasons to support the BLM's position.

When an EIS has been prepared, follow the guidance provided in H-1790-1, Chapter 9.

7.3 APPEALS (ADMINISTRATIVE REVIEW)

Any party who is adversely affected by a final decision of the authorized officer may file an appeal and request a stay of the action. WH&B decisions are subject to administrative review (appeal) and remedies under the provisions of 43 CFR 4.21, 4.410, and 4770.3.

As a general matter, WH&B decisions will not become effective during the time in which a person adversely affected may file a notice of appeal. Unless a petition for a stay pending appeal is filed together with a timely notice of appeal, these decisions will become effective on the day after the expiration of the time during which a person adversely affected may file a notice of appeal (generally 31 days from the decision date). If a petition for stay pending appeal is filed together with a timely notice of appeal, a decision will become effective immediately if:

- The stay request is denied; or,
- The Interior Board of Land Appeals fails to act on the petition for a stay within 45 days from the date of the decision.

Under certain circumstances, however, the authorized officer may make decisions to gather/remove excess wild horses or burros effective upon issuance or on a date specified in the decision. See 43 CFR 4770.3(c).

Under the authority provided in 43 CFR 4770.3 (c), the authorized officer may make decisions to gather/remove excess wild horses or burros effective upon issuance or on a date specified in the decision.

When issued under this authority, the gather may be implemented unless a stay is granted or a Federal Court enjoins the gather.

7.3.1 AML Decisions

AML decisions are subject to administrative review:

1. When administrative review of multiple-use decisions (MUD) is requested, BLM may ask to combine the wild horse decision with the grazing decision for review by an administrative law judge (ALJ) in the Office of Hearings and Appeals (OHA).

2. Wild horse decisions are subject to administrative review by the Interior Board of Land Appeals (IBLA) in accordance with 43 CFR 4.21 and 4.410.

7.3.2 Gather/Removal Decisions

The authorized officer has the authority to make decisions to gather and remove excess WH&B effective upon issuance or on a date specified in the decision when removal is court ordered or is needed to preserve a thriving natural ecological balance and multiple use relationship.

Any party who is adversely affected by the authorized officer's final decision may file an appeal and/or request a stay of the action with the Interior Board of Land Appeals (IBLA). The appeal and/or request for stay must be filed within 30 days from the date of the decision and in accordance with the regulations found at 43 CFR 4.411(a).

7.3.3 HMAP or Other Management Decisions

AML, HMAP, or other management decisions are subject to administrative review through the IBLA under provisions of 43 CFR 4.21 and 4.410. Under this authority, decisions **cannot** be implemented effective upon issuance or on a date specified in the decision.

A notice of appeal must be filed in the office of the authorized officer within 30 days from the date of the decision. See 43 CFR 4.411.

CHAPTER 8—RESEARCH

GENERAL

Direction to conduct research is contained in the WFRHBA, 16 U.S.C. § 1333(b)(2)(C)(3), and the Strategic Plan for Management of Wild Horses and Burros on Public Lands (1992). In late 2000, the Midcontinent Ecological Science Center of the U. S. Geological Survey (USGS) was charged with developing a strategic research plan for the management of WH&B. The purpose of the strategic planning process was to:

- Review past progress and identify problems that could be addressed with research.
- Set broad research goals central to the BLM's mission for WH&B management.
- Establish specific, time-bound, measurable research goals, and strategies to achieve them.
- Evaluate the progress towards those goals at set time periods, and to readjust the planning as needed.

There had been no previous prioritization of the BLM's WH&B research and management needs, and no effort to develop a strategy for fulfilling those needs within a specified time period. The strategic planning process was designed to fill this void.

8.1 STRATEGIC RESEARCH PLAN

The Strategic Research Plan for Wild Horse and Burro Management identified research priorities to include health and handling, fertility control, population estimation and modeling, genetic conservation, habitat assessment and setting population goals. The components of fertility control and population estimation have been implemented and research is being conducted. Genetic diversity of WH&B herds is being evaluated. Other research projects may be initiated as needed to support the management of WH&B. Research results will be used to improve management practices within the WH&B program.

8.1.1 Development

The Strategic Research Plan was a joint effort between the USGS, the BLM, the Animal and Plant Health Inspection Service (APHIS), and the U.S. Department of Agriculture (USDA). The plan was developed over a period of 2 years with input from 39 subject area experts representing 11 universities, 3 Federal agencies (BLM, USGS, APHIS), and two State wildlife agencies.

The USGS took the lead role in planning and coordinating meetings of the expert committees and in drafting the Strategic Plan based on committee and agency input. Assisting in this effort were the BLM's National WH&B Research Coordinator and equine health experts from APHIS.

Principal input from the USGS was focused on topics of contraception, aerial population estimation, population modeling, and genetics. Principal input from APHIS was focused on topics of disease and animal health monitoring and surveillance.

Advice and input has also come from BLM including managers and specialists assigned to the WH&B program, the National WH&B Advisory Board, and WH&B staff in the Washington Office. Advice and input was also provided by the BLM Director's Science Advisory Committee, and from seven topic-specific advisory panels that were convened by the USGS.

8.2 RESEARCH REQUESTS

A National Research Advisory Team exists to review research proposals, monitor research project progress, update the Strategy as necessary, and provide recommendations to the WH&B Division Chief. The Research Advisory Team has been formed with equal participation by the BLM (BLM's National WH&B Research Coordinator), the USGS, and APHIS.

All requests for research and/or research proposals pertaining to the Wild Horse and Burro program, whether generated from the field or through field-related contacts, are to be directed to the Research Advisory Team for review. This Team is also available to assist field offices with the development of research proposals. Proposal format and submission should be coordinated through the National WH&B Research Coordinator. Proposals will be reviewed on an as-needed basis and recommendations for funding will be made directly to the WH&B Division Chief.

8.3 RESEARCH PROJECTS

8.3.1 Fertility Control

An effective, safe, and cost-effective fertility control agent is an essential tool in the management of wild horses. A Fertility Control Field Trial Plan has been developed and field research is underway for two components of the Plan: (1) Individual-Based Trials and (2) Population-Based Trials. Over the last decade, BLM research efforts in fertility control have been focused on PZP (Porcine zona pellucida) and the development of time-release pellets to extend the effectiveness of PZP. PZP has proven effective in reducing foaling rates, the population impacts of which are presently being determined.

8.3.2 Other Possible Fertility Control Tools

Other possible fertility control tools that could potentially be considered in the future include:

- Spaying mares.
- Vasectomizing studs.
- Use of IUDs.
- Use of GonaCon™.
- Use of SpayVac™.
- Use of other fertility control agents or sterilants.

8.3.2.1 Spaying (Mares)

Spaying mares involves major abdominal surgery, is risky, and requires good post-operative care. Spaying mares could be considered in the future if safe, effective and humane surgical methods and post-operative care procedures can be perfected for use on wild horses.

8.3.2.2 Vasectomies (Stallions)

Performing vasectomies on stallions is not a widely practiced procedure within veterinary medicine. Post-vasectomy, it is expected that studs would retain their stud-like behavior. By contrast, gelding studs (castration) is a routine veterinary procedure in both domestic and wild horses. However, geldings lose their stud-like behavior after a few months.

Vasectomized studs would be expected to continue to cover mares and keep them in a harem, but eventually most mares would be bred by an intact stallion. If this continued over several estrous cycles it could lead to extended foaling seasons and potentially an increase in foal mortality. Research shows that at 15-33 percent of foals are sired by non-harem stallions, making it unlikely that fertility control focused on males would be effective in slowing population growth (Bowling and Touchberry 1990, Kaseda and Kahlil 1996, Asa 1999). Further research is needed to perfect a safe technique for performing vasectomies in stallions and demonstrate whether this approach will reduce population growth rates.

8.3.2.3 Use of IUDs

Pilot studies using coil-type intrauterine devices (IUDs) and glass balls or marbles as IUDs have failed to demonstrate a long-lasting effect on conception in mares. In both instances, mares "slipped" the devices and became pregnant soon thereafter. The application of IUDs is further complicated by the difficulties associated with identifying a time window for application when mares are not pregnant.

8.3.2.4 Use of GonaCon™

GonaCon™ is an experimental fertility control vaccine that is being developed for potential use as a management tool for deer. Tests of the GnRH vaccine are ongoing in several States and countries, involving a wide range of wildlife and feral species, including horses. A research study conducted with estray horses in Nevada suggests GonaCon™ will reduce foaling rates for 1 year following treatment. At present, the effectiveness of GonaCon™ as a fertility control agent beyond one year appears similar to or less than that of PZP-22, suggesting limited potential for use of the product to reduce population growth rates over a longer period of time.

8.3.2.5 Use of SpayVac™

SpayVac™ is an experimental fertility control vaccine using PZP antigens and a novel liposome technology. It is easy to handle and administer. A single vaccination with SpayVac™ has maintained a high level of contraception throughout a 4-year study with estray horses in Nevada. However, there is currently no regulatory approval for the management or investigational use of

SpayVac™ through the EPA or FDA, and the product is not currently commercially available. SpayVac™ may have potential for use as an effective, longer-lasting fertility control agent in the future and could offer an alternative to spaying mares. However, additional research would be needed before it could be used on a population-management basis.

8.3.3 Population Estimation and Setting Population Goals

Aerial surveys rarely detect all WH&B within an HMA. As a result, population estimates must be developed using correction factors to account for WH&B not identified during the census. At present, research is being conducted on two techniques (simultaneous double-count and photo mark-resight) that will allow use of such correction factors.

8.3.4 Other Research

In the future, research may be conducted in other areas identified as research priorities, depending on need and funding. When other research needs are identified or research projects are proposed, they will be reviewed and evaluated by the National WH&B Research Advisory Team and recommendations will be made to the WH&B Division Chief.

GLOSSARY OF TERMS

Activity Plan – Examples of activity plans include Herd Management Area Plans (HMAPs) and Allotment Management Plans (AMPs). These plans lead to implementation decisions that usually describe multiple projects or management actions and apply best management practices to make progress toward attainment of Land Use Plan (LUP), Land Health Standards, or other resource objectives.

Adaptive Management – WH&B management is adjusted as indicated based on the results of monitoring and evaluation.

Adult Wild Horse – WH&B 1 year of age and older are considered adults. A foal is considered 1 year of age on January 1 of the year following its birth.

Adult Breeding Population - Wild horses within a population that are 1 year of age and older.

Aerial Survey – A method of counting WH&B using an aircraft. Aerial survey allows the BLM to obtain estimates of WH&B population size with associated confidence intervals.

Animal Unit (AU) - Wild horses 1 year of age and older count as 1 AU and burros 1 year of age and older count as 0.5 AU.

Animal Unit Month (AUM) – The amount of forage (approximately 800 pounds of air dried forage) necessary to sustain one adult horse or two burros for one month.

Appropriate Management Level (AML) - The number of adult horses or burros (expressed as a range with an upper and lower limit) to be managed within an HMA. Forage for WH&B (AUMs) is allocated based on the AML upper limit.

AML Range – The number of adult WH&B within which herd size will be allowed to fluctuate.

AML Upper Limit – The maximum number of WH&B that results in a thriving natural ecological balance (TNEB) and avoids a deterioration of the range. This number should be somewhere below the number that would cause damage to the range (refer to 118 IBLA 75).

AML Lower Limit – The number that allows the population to grow to the AML upper limit over 4-5 years, without the need for gathers to remove excess WH&B in the interim.

Authorized Officer – Any employee of the BLM to whom authority has been delegated to perform the duties described in this Handbook (refer to BLM Manual 1203 for a further explanation of delegation of authority).

Census – A complete count of the total WH&B population within an area. Because aerial surveys do not usually detect all WH&B within an HMA, a true census is usually not possible. Better population estimates are developed using correction factors to account for WH&B not seen during the survey (i.e., sightability correction factors).

Considered Comparably - During the LUP process, WH&B are considered in the same manner as other resource values (e.g., cultural, historic, scenic, rangelands, timber, and minerals).

Emergency – An unexpected event that threatens the health and welfare of a WH&B population and/or its habitat. Examples include fire, insect infestation, disease or other events of a catastrophic and unanticipated nature.

Escalating Problems - Conditions that deteriorate over time. The key indicators are a decline in the amount of forage or water available for WH&B use, with negative impacts to rangeland health and, ultimately, animal condition. Causal factors are normally drought and/or animal numbers in excess of AML. These situations can be detected in advance and are managed through the normal planning process.

Evaluation (LUP Evaluation) – The process of reviewing the land use plan and periodic plan monitoring reports to determine whether the decisions and NEPA analysis are still valid and whether the plan is being implemented.

Evaluation (HMAP Evaluation) – Periodic review of herd management area plans (HMAPs) to determine if the selected management practices were implemented as planned (answers the question "Did we do it?") and whether or not the plan is effective in making progress toward established habitat and population management objectives (answers the question "Did it work?").

Excess Animals – Wild, free-roaming horses or burros which have been removed or which must be removed from in order to preserve and maintain a thriving natural ecological balance and multiple-use relationship in an area.

Fertility Control – A tool to decrease fertility and which, when implemented, reduces (slows) population growth rates and extends the gather cycle.

Free-Roaming – WH&B are able to move without restriction by fences or other barriers within a HMA.

Goal – A broad statement of a desired outcome.

Genetic Diversity – The absence of inbreeding depression as monitored through an established baseline and periodic reassessment. This represents an expression of the genetic health of an individual animal or the population.

Herd (Reproducing) – One or more stallions and their mares and foals.

Herd Area (HA) - Geographic areas of the public lands identified as habitat used by WH&B at the time the WFRHBA was enacted (12/15/1971).

Herd Management Area (HMA) – May be established in those HAs within which WH&B can be managed for the long term. HMAs are designated through the LUP process for the

maintenance of WH&B herds. In delineating each HMA, the authorized officer shall consider the appropriate management level (AML) for the herd, the habitat requirements of the animals, the relationships with other uses of the public and adjacent private lands, and the constraints contained in 43 CFR 4710.4.

Herd Management Area Plan (HMAP) – An HMAP establishes management actions and short- and long-term management and monitoring objectives for a specific WH&B herd and its habitat. HMAPs assist the authorized officer in tracking progress toward achieving LUP goals. They are prepared under authority of 43 CFR 4710.3-1. An HMAP can be prepared for an individual HMA or a complex of HMAs.

Implementation Decision – Decisions that make progress or take action toward achieving LUP goals and objectives.

Implementation Plan – Refer to Activity Plan above.

Land Use Plan (LUP) – LUPs provide (by tracts or areas) for the use of public lands. LUPs are prepared in accordance with established land use planning procedures in 43 CFR 1600 and pursuant to FLPMA. They establish goals and objectives (desired outcomes), identify the management actions needed to achieve the desired outcomes, and identify the allowable uses of the public lands.

Manage Principally but not Exclusively – An HMA may be considered for designation as a wild horse or burro range when there is significant public value present, such as unique characteristics in a herd or an outstanding opportunity for public viewing. These HMAs may be managed principally, but not exclusively, for wild horse or burro herds.

Minimal Feasible Level of Management - The minimum number of habitat or population management tools or actions necessary to attain the objectives identified in approved LUPs and HMAPs for a HMA or HMA complex.

Monitoring – The process of collecting and analyzing the data necessary to evaluate existing management and determine whether progress is being made toward attaining established habitat and population management goals and objectives.

Non-Reproducing Wild Horses – An HMA composed, in whole or in part, of sterilized wild horses (either stallions or mares) to aid in controlling on the range population numbers.

Objective(s) – A description of the desired outcome of a management decision. Objectives are specific, measurable, achievable/attainable, reasonable/relevant, and progress can be quantified within established timeframes for achievement (SMART).

Plan Monitoring – The process of tracking land use plan implementation, including collecting and assessing the data or information necessary to evaluate the effectiveness of land use planning decisions.

Population Growth Rates – Represent the net effect of births and deaths in any given year. The BLM reports annual population numbers as of February 28th.

Range – The amount of land necessary to sustain an existing herd or herds of wild free-roaming horses and burros, which does not exceed their known territorial limits.

Resource Management Plan – see LUP above.

Self-Sustaining – The ability of reproducing herds of wild horses and burros to maintain themselves in a healthy condition and to produce healthy foals.

Standards for Land Health – Standards are statements of physical and biological condition or degree of function required for healthy sustainable rangelands. Achieving or making significant progress towards these functions and conditions is required of all uses of public lands. Historical data, when available, should be utilized when assessing standards.

Standard Operating Procedures – The Bureau follows standardized methods of operation which have been developed over time to assure the safe, effective, and humane handling and treatment of WH&B.

Thriving Natural Ecological Balance (TNEB) – WH&B are managed in a manner that assures significant progress is made toward achieving the Land Health Standards for upland vegetation and riparian plant communities, watershed function, and habitat quality for animal populations, as well as other site-specific or landscape-level objectives, including those necessary to protect and manage Threatened, Endangered, and Sensitive Species.

Utilization – The portion of annual forage production that has been consumed by herbivores (WH&B, domestic livestock, wildlife, and insects). The term is also used to refer to the pattern of such use.

WH&B Range – A HMA which meets the special criteria defined in H-1601-1, Land Use Planning Handbook. These include unique herd characteristics, viewing opportunities, unique landscape, significant public demand or other reasons. WH&B Ranges are managed principally, but not necessarily exclusively, for WH&B.

Wild Free-Roaming Horses and Burros – All unbranded and unclaimed horses and burros that use public lands within 10 contiguous Western States as all or part of their habitat, or that have been removed from these lands by the authorized officer, or have been born of wild horses or burros in authorized BLM facilities, but have not lost their status under the WFRHBA (16 USC § 1332 (f)).

APPENDIX 1 - Genetics Data and Hair Sample Collection Instructions

Analysis of DNA to determine genetic diversity of wild horse and burro (WH&B) herds is currently being done using hair samples rather than blood samples. Unless there is a previously recognized concern regarding low genetic diversity in a particular herd, it is not necessary to collect genetic information at every gather. Typical herds should be sampled every other gather. A new baseline does not need to be established through hair analysis if blood analysis has already been completed. Please follow the instructions below for collecting hair samples. Call BLM's National WH&B Research Coordinator if you have any questions.

While it is preferable to sample release horses, you may sample removed horses if necessary. In complexes or HMAs where separate breeding populations are suspected, WH&B in each distinct population should be sampled separately. Do not mix samples from different horses or different breeding populations. The minimum sample size is 25 animals or 25 percent of the post-gather population, not to exceed 100 animals per population. Samples should be collected from males and females in the same approximate ratio as the population. Animals of any age class may be sampled. Burros should be sampled in the same manner as horses.

1. You will need one plain white paper envelope (a white #10 business envelope works best) for each horse. DO NOT use plastic or zip-lock bags and DO NOT use plastic coated envelopes or envelopes with windows in them.

2. Hair samples must be obtained by pulling the hair out by the root NOT cutting or shaving it off the horse. This is because the DNA is in the root follicle not the hair itself. Mane hair will work, but for foals or young horses you may need to obtain tail hair. Please submit about 30 hairs per animal. A bundle of 30 hairs is about the diameter of a pencil.

The easiest way to pull a good sample is to grasp a bundle of hair and wrap it around a clean mane comb or hoof pick. Holding the bundle close to the neck, pull **straight out** firmly. Foal hair is more brittle and tends to break off. If you are having trouble getting hair with the root attached try obtaining a tail hair sample instead.

(James Sturdivant – The Jockey Club, modified with permission)

3. Check that you have the hair roots or hair bulbs attached to the hair at the base. They look, and feel like little bumps on the end of each hair.

Keep the hair in a loose bundle pointed in one direction or twist it together and place it in an envelope. You can cut off excess hair and leave only a few inches with the hair root attached to put in the envelope if that is easier.

4. Seal the envelope and **write the sample number on the envelope.**

Also write the sample number, color, sex and age of the horse on the data collection sheet. If animals cannot be aged in years, at a minimum record adult, yearling or foal. Be sure to keep stray hairs out of the comb and off your clothes so they don't contaminate the next sample.

Please NOTE: it is best to sample when the hair is dry. If you need to sample when it is raining or the horses are wet, then DO use zip-lock bags for each sample AND keep the samples cool not frozen (refrigerate, then ship the samples with cold packs).

Please fill out the top of the form completely, including the HMA name, HMA number and the date the sample was collected.

Within 3 days after hair collection, send a copy of the data collection form to:

Attn: Research Coordinator, National Program Office-Reno

FEDEX the samples, to arrive on a weekday not the weekend **with the Data Collection Sheet to Dr. Gus Cothran, address below:**

APPENDIX 3 - AML Establishment and Adjustment Process

AML decisions determine the number of WH&B to be managed within an HMA or complex of HMAs. AML is expressed as a population range with an upper and lower limit. The AML upper limit is the number of WH&B which results in a TNEB and avoids a deterioration of the range. The AML lower limit is normally set at a number that allows the population to grow to the upper limit over a 4-5 year period, without any interim gathers to remove excess WH&B. See Chapter 4.

A multi-tiered analysis process should be used to establish and adjust the appropriate management level (AML) of WH&B.

- ❒ **Tier One**: determine whether the four essential habitat components (forage, water, cover and space) are present in sufficient amounts to sustain healthy WH&B populations and healthy rangelands over the long-term.

- ❒ **Tier Two**: determine the amount of sustainable forage available for WH&B use.

- ❒ **Tier Three**: determine whether or not the projected WH&B herd size is sufficient to maintain genetically diverse WH&B populations (i.e., avoid inbreeding depression).

Should the Tier One analysis determine that one or more of the essential habitat components is insufficient to maintain a healthy WH&B population and healthy rangelands; the authorized officer should consider amending or revising the LUP to remove the area's designation as an HMA.

Tier 1

Determine if the four essential habitat components (forage, water, cover, and space) are present in sufficient amounts to sustain healthy WH&B populations and healthy rangelands over the long-term. In making this determination, the most limiting factor(s) within the HMA should be considered. In some HMAs, the most limiting factor may be:

- The water available for WH&B use.
- The limited habitat available for WH&B use on either the summer or winter range, in HMAs with seasonal ranges.
- The naturally occurring, low productive capability of the dominant ecological sites.
- The low ecological status of key WH&B use areas.
- Low annual rainfall or extended periods of drought.

The essential habitat components must be located on public lands within the HMA boundary. If forage or water located on private lands within the HMA is needed to maintain healthy WH&B populations, a written agreement with the private landowner allowing use by WH&B is required. In the absence of private landowner agreement, the forage and water on private lands is not available for use by WH&B and may not be included when establishing or adjusting AML.

Forage

The amount of forage available for WH&B use is expressed in animal unit months (AUMs). One AUM is defined as the amount of forage necessary to sustain one adult horse or two adult burros for one month (or approximately 800 pounds of air dry forage). Twelve AUMs of forage are needed to support one wild horse or two adult burros for one year.

As a **starting point**, the amount of sustainable forage available for WH&B use may be determined based on the results of utilization monitoring and use pattern mapping for the years evaluated. A determination of forage availability should not be based on the results of only one year's monitoring data. A minimum of three to five years of monitoring data is preferred. This is because forage production can vary substantially from year to year based on the timing and amount of precipitation received, among other factors. Under the same level of grazing, use pattern mapping may indicate light to moderate utilization during above normal precipitation years, yet indicate heavy or severe utilization during below normal precipitation years.

The nature of the forage (i.e., perennial vs. annual) should also be considered. While annual forage may be available to support WH&B use during years with normal or above normal precipitation, it may be greatly reduced during below average precipitation years. As a result, annual forage is not typically used to support or justify WH&B numbers within a HMA. Within perennial ranges, the production of perennial species may also be greatly reduced during drought, and the production of annual grasses and forbs may be largely absent.

The flexibility to remove WH&B in below average forage years, or to move the animals to another area, can be constrained by funding, contractor capability, facility space, or animal behavior. To prevent range damage or adverse impacts to animal health, the upper limit of AML for WH&B should be established in consideration of the most limiting forage (or water) production years.

Other Considerations

1. Situations in which the Land Health Standards are achieved but population inventory indicates more WH&B are present than expected. These situations may indicate additional forage is present to support use by higher numbers of WH&B, wildlife, or livestock, consistent with LUP guidance.

2. Situations in which deteriorated land health conditions exist but population inventory indicates the number of WH&B is the same or lower than expected. These situations may indicate there is less forage available to support the existing use by WH&B, wildlife, or livestock, and that a reduction in the allowable use may be needed, consistent with LUP guidance.

The number of WH&B which can be sustained based on the available forage is determined in **Tier Two.** To determine if there is sufficient forage to sustain long-term WH&B:

- Analyze utilization data, use pattern mapping, and/or production, ecological site condition (ESI), trend, frequency, precipitation (weather), and indicators of land health.

- Determine the AUMs of actual use by WH&B for each of the evaluation years. (Calculate the AUMs of actual WH&B use based on population estimates derived from aerial surveys. You can also project actual use by WH&B using previous population estimates together with herd's average annual population growth rate.)
- Identify key WH&B use areas (distribution). Calculate carrying capacity on the basis of the key use areas (primary range).

Water

The amount of water available for WH&B use is generally based on public, natural waters (i.e., water occurring on private lands is not considered unless a written agreement with the private landowner is obtained). Water availability during drought conditions is also considered. Sufficient water for WH&B must be available during drought to achieve and maintain a thriving natural ecological balance and multiple use relationship on the public lands.

In determining the amount of water available for WH&B use, a thorough inventory of the available public, natural water resources is needed. Developed and man-made waters should also be inventoried if they are available for WH&B use (i.e., BLM holds the necessary water rights and WH&B access to the water can be depended upon over the long-term). The water resources inventory should include the name, location, and flow (in gallons per minute or cubic feet per second). Wild horses require a minimum of 10 gallons of available water per animal per day (15 gallons per day is not unusual during the hot, dry summer months) while burros require about 5 gallons available per animal per day. The analysis of available water should also be based on the most limiting season of the year (i.e., generally summer when flows are reduced).

Cover and Space

A recurring pattern of WH&B movement out of the HMA to access forage, water, or thermal or hiding cover is an indication the HMA cannot sustain year-long WH&B use. If one or more of the key habitat components is missing, the HMA should be considered as unsuitable for year-long use by WH&B. In these situations, the authorized officer should consider amending or revising the LUP to remove the area's designation as an HMA. An exception would be two or more HMAs which adjoin and are managed as a complex of HMAs, or HMAs which adjoin Forest Service wild horse territories (WHT) that can be managed as a complex.

The results of the **Tier One** analysis may be summarized in a simple table (see example Table 3.1 below). The table should be followed by a detailed description of the analysis and the rationale used in making the determination that a key habitat component either is (or is not) sufficient to support healthy WH&B populations and healthy rangelands over the long-term.

Table 3.1
Sufficient Forage, Water, Cover and Space

HMA	Forage		Water		Cover		Space	
	Sufficient	Insufficient	Sufficient	Insufficient	Sufficient	Insufficient	Sufficient	Insufficient
HMA 1	X			X	X		X	
HMA 2		X		X	X		X	
HMA 3	X			X	X		X	

Tier 2

Determine the AUMs of sustainable forage available for WH&B use. Based on the desired level of utilization, propose an AML for WH&B (expressed as a range with an upper and lower limit).

Forage availability should be determined based on in-depth analysis of rangeland monitoring data. As a first step, monitoring data should be reviewed to determine if Land Health Standards or other site-specific vegetation management objectives are being met. If standards and objectives are being met, WH&B population estimates are then examined to determine the range in number of WH&B using the HMA during the evaluation years. The upper values are used to establish AML when no land health issues occur.

In HMAs where Land Health Standards or other objectives are not being achieved, WH&B use should be examined to determine if this level of use has contributed to or is the causal factor for the standards or objectives not being met (or only partly met). When standards or objectives are not being met and WH&B use is a contributing (or causal) factor, AML is proposed based on the estimated number of WH&B present relative to the level of forage utilization that is occurring (i.e., AML would be established at a number below that which has contributed to the standards or objectives not being met). The need for frequent emergency removals of WH&B due to lack of forage and/or water or the emigration of WH&B out of the HMA due to population size or concentration levels may also be a consideration in proposing AML for WH&B.

The sustainable forage (carrying capacity) available for WH&B use within a HMA is determined pending detailed analysis of utilization data and use pattern mapping for all users. For each evaluation year, determine the following: (1) weighted average utilization, (2) potential carrying capacity, and (3) the proposed carrying capacity. An example for the Mojave Desert ecosystem follows.

Example – Determining Sustainable Forage Available for WH&B Use (Mojave Desert Ecosystem)

The following example can be used to assist with establishing and/or adjusting AML for WH&B use. To determine if there is sufficient forage to sustain long-term WH&B use, analysis of utilization data, use pattern mapping, and/or production, ecological site condition, trend, frequency or other indicators of rangeland health is necessary.

Selection of Allowable Use Criteria

The recommended allowable utilization by all herbivores under year-round use within the Mojave Desert ecosystem is 25-35 percent of the current year's forage production.

WH&B use will be limited to 25 percent of current year's production on key vegetation species as measured at seed dissemination for these species.

Rationale: Within the Mojave Desert ecosystem, allowable use levels of 25 percent are recommended for areas in poor ecological condition or for areas grazed during the growing season. Allowable use levels of 35 percent are recommended for areas in good ecological condition or for areas grazed during the dormant season. Allowable use is established at 25 percent for this HMA due to year-round grazing by WH&B as well as a number of areas in poor ecological condition.

Determine Weighted Average Forage Utilization

Deriving a weighted average utilization from use pattern maps generally provides a more representative picture of the forage use that has occurred throughout the HMA and leads to a more accurate estimate of carrying capacity. To derive a weighted average utilization for the HMA, determine the number of acres within the HMA which received moderate, heavy or severe utilization for each evaluation year.[3] Refer to BLM Technical Reference 4400-7 for additional information.

The weighted average use is calculated by multiplying the number of acres by the mid-point of the utilization category (example: moderate use is classified as 41-60 percent, therefore, 50 percent is the mid-point used in the calculation).

Data used in the example carrying capacity analysis outlined below includes: utilization data, use pattern mapping data, actual livestock use information, and WH&B population estimates.

[3] To protect rangeland health over the long-term, consider WH&B use only on the primary range when deriving a weighted average utilization. Primary range is defined as the areas which animals (WH&B) prefer to use when management is limited (refer to Glossary of Terms Used in Range Management, 4th Edition, Published by Society for Range Management, 1998). Secondary range is defined as range which is not ordinarily used until the primary range has been overused. Therefore, areas receiving slight or light use or that are unused should not be considered when deriving a weighted average utilization.

Weighted Average Utilization =

(Moderate use acres*50 percent) + (Heavy use acres*70 percent) + (Severe use acres*90 percent)

Analyze the total acres of moderate, heavy, and severe use.

1995 $\frac{(19639*50\text{ percent}) + (34351*70\text{ percent})}{53{,}990}$ = 63 percent

1996 $\frac{(8023*50\text{ percent}) + (48957*70\text{ percent}) + (9885*90\text{ percent})}{66{,}865}$ = 71 percent

1997 $\frac{(3081*50\text{ percent}) + (22888*70\text{ percent})}{25{,}969}$ = 68 percent

1999 $\frac{(5627*50\text{ percent}) + (3696*70\text{ percent})}{9{,}323}$ = 58 percent

2000 $\frac{(4344*50\text{ percent}) + (4386*70\text{ percent})}{8{,}730}$ = 60 percent

2002 $\frac{(5627*50\text{ percent}) + (3696*70\text{ percent})}{9{,}323}$ = 58 percent

2004 $\frac{(4395*50\text{ percent}) + (7933*70\text{ percent})}{12{,}328}$ = 63 percent

The example below demonstrates the impact of variable precipitation (and forage production) on actual forage utilization and the desired carrying capacity.

Potential Carrying Capacity =

Average use in AUMs (of cattle or horse use)*25 percent Allowable Use Objective
Weighted Average Utilization

Year	Average Use (AUMs)		Effective Precipitation
1995	3000 AUMs*25 percent / 63 percent	= 1190 AUMs	Above Average
1996	600 AUMs*25 percent / 71 percent	= 211 AUMs	Severe Drought
1997	444 AUMs*25 percent / 68 percent	= 163 AUMs	Severe Drought
1999	600 AUMs*25 percent / 58 percent	= 259 AUMs	Severe Drought
2000	1440 AUMs*25 percent / 60 percent	= 600 AUMs	Slightly Below Average
2002	1632 AUMs*25 percent / 58 percent	= 703 AUMs	Average
2004	3576 AUMs*25 percent / 63 percent	= 1419 AUMs	Well Above Average

Proposed Carrying Capacity =

In the example above, the carrying capacity would be set in consideration of the driest years in order to prevent damage to the range or adverse impacts to animal health.

211 (1996) +163 (1997) +259 (1999) +600 (2000) +703AUMs (2002) = 387 AUMs
5 (# years of data)

Proposed AML =

387 AUMs (Desired Carrying Capacity) = 32 cattle or wild horses
12 months

Or:

$$\frac{\text{387 AUMs (Desired Carrying Capacity)}}{\text{6 months}} = 65 \text{ burros}$$

***Discussion*:**

- Allocation of the forage between WH&B, wildlife and domestic livestock would be made after site-specific NEPA analysis is completed.

- In the example above, the upper limit of the AML range for wild horses was calculated by dividing the proposed carrying capacity for the HMA (expressed in AUMs) by 12 months.

- The upper limit of the AML range for burros was calculated by dividing the proposed carrying capacity for the HMA by 6 months (an adult burro is equivalent to only 0.5 AU).

- The lower limit of the AML range would be determined based on the herd's average annual growth rate (i.e., the lower limit will normally be set at a number that allows the herd to grow to the upper limit over a 4-5 year period without the need for gathers to remove excess WH&B in the interim).

Tier 3

Determine whether or not the WH&B herd size proposed in Tier Two is sufficient to maintain genetically diverse WH&B populations (i.e., avoid inbreeding depression). To avoid inbreeding depression in wild horse populations, a minimum herd size of 50 effective breeding animals (a total population size of about 150-200 animals) is recommended. An effective breeding size for burro herds has not yet been determined.

If the herd size proposed in Tier Two is not sufficient to maintain genetically diverse WH&B populations, determine if there is WH&B interchange between the HMA and other adjacent HMAs or WHTs and whether this interchange would be sufficient to maintain genetic diversity (avoid inbreeding depression). Genetic diversity baseline or monitoring information can be used to evaluate whether WH&B interchange between HMAs is occurring.

If the proposed herd size is less than 150 animals and the HMA is isolated with limited potential for WH&B egress/ingress, possible management actions which could be considered as part of an appropriate site-specific NEPA analysis could include:

1. Removing the area's designation as an HMA through LUP and returning it to HA status.
2. Maximizing the number of breeding age WH&B in the herd (animals age 6-10 years).
3. Adjusting the sex ratio to favor males to encourage formation of additional breeding harems.
4. Introducing 1-2 young mares from outside the HMA every generation (about every 10 years). Introduced animals should come from herds living in similar environmental conditions.

Documentation

The results of the multi-tiered analysis should be documented in an HMA (AML) Evaluation Report. The completed report should be provided to the affected and interested public for a 30-day review and comment period (e.g., public scoping). The management evaluation report is not a decision subject to administrative appeal. However, once the decision is made, the Evaluation Report is part of the administrative record for that decision.

Following public scoping, a site-specific environmental analysis should be completed to analyze the environmental impacts associated with the Proposed AML and any alternatives. As part of the environmental analysis, summarize the results of public scoping and document how BLM used the comments in preparing the environmental assessment (or EIS).

Based on the analysis of potential environmental impacts, the authorized officer will determine whether to prepare an Environmental Impact Statement (EIS) or issue a Decision Record and Finding of No Significant Impact (FONSI). A FONSI documents why implementation of the selected AML will not result in environmental impacts that significantly affect the quality of the human environment. Or, if an EIS has been prepared, the authorized officer's decision will be documented in a Record of Decision.

Administrative Review

AML decisions are subject to administrative review (appeal) pursuant to 43 CFR Part 4.

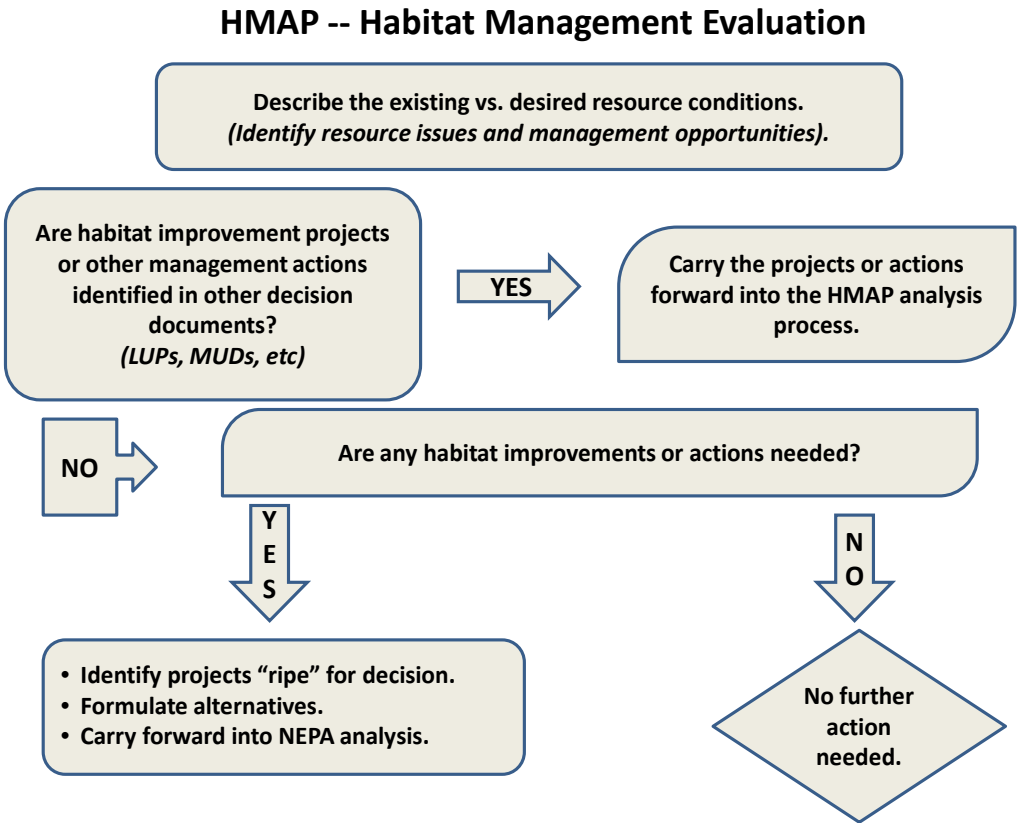
APPENDIX 4 - Herd Management Area Planning

Herd management area plans (HMAPs) establish the management actions and the short and long-term management and monitoring objectives for WH&B herds and their habitat. Once established with public involvement through site-specific NEPA analysis and decision, the objectives guide management of the HMA or complex over the life of the plan.

Management Evaluation

Typically, the first step in the HMAP analysis process should be to evaluate existing management. The existing vs. the desired condition of the both the herd and its habitat are examined during the evaluation. Refer to Figures 4.1 and 4.2.

Figure 4.1
Habitat Management Evaluation



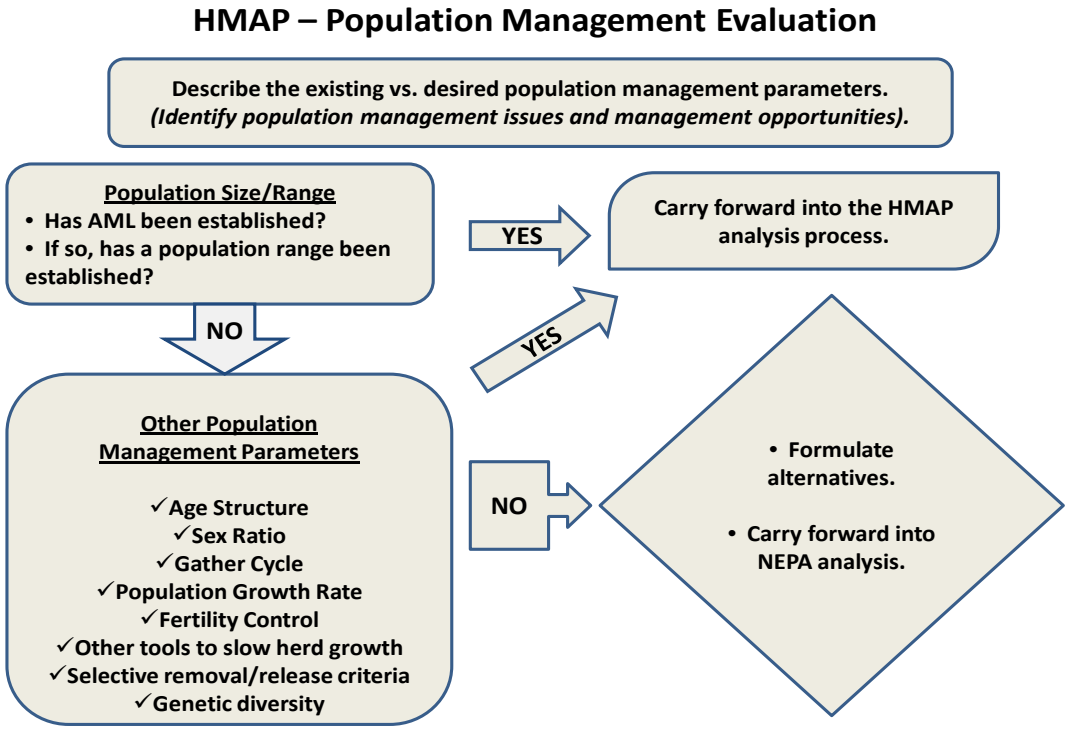


Figure 4.2
Population Management Evaluation

At the conclusion of the management evaluation, a report is prepared and provided to the public for a 30-day review and comment period (public scoping). The management evaluation report is not a decision subject to administrative appeal. Rather, the report documents the key issues identified as a result of the management evaluation. A range of the possible management alternatives (Proposed Action and Alternatives) which could address/resolve the identified issues may also be identified.

NEPA Analysis and Decision
The next step in the HMAP analysis process would be to analyze the potential environmental consequences which could result from implementation of the Proposed Action or Alternatives through completion of a site-specific environmental analysis (NEPA).

To prepare a concise environmental assessment (EA), site-specific management, monitoring and implementation objectives can be displayed in a tabular format within the environmental assessment. Refer to the example which follows.

Example – Documentation of the No Action Alternative in the HMAP EA

Alternative One: No Action Alternative, Continue Existing Management
Under Alternative 1 (No Action), the HMA would continue to be managed as a range of 150-250 wild horses as follows:

- The sex ratio of the animals released back to the range following future gathers would be about 34 percent males and 64 percent females.
- Existing monitoring, including utilization, forage condition, water availability, animal health and periodic population estimates and sampling for genetic diversity (inbreeding) would occur.
- AML would be adjusted, as needed, based on in-depth analysis of resource monitoring data.
- Fertility control would be applied to mares released back to the range following future gathers.

Table 4.1
No Action Alternative (Continue Existing Management) in HMAP Format

Management Objective(s)	Monitoring Objective(s)	Implementation Objective(s)
A. Control Population Numbers Manage the wild horse population within the established AML range to protect the range from the deterioration associated with overpopulation.	Aerially estimate populations a minimum of once every 3-4 years. Determine population number and average annual herd growth rate.	Schedule gathers to remove excess wild horses when (1) the population reaches or exceeds the AML upper limit (about every 3 years), or (2) when forage utilization exceeds 50 percent of current year's growth in ½-2/3 of the key areas; or (3) when animal health/condition is at risk.
B. Assure Land Health Limit utilization by all herbivores to 50 percent of the current year's above ground primary production for key grasses and 45 percent for key shrubs and forbs.	• Locate key monitoring areas within the HMA. • Establish baseline trend studies using the frequency sampling procedures outlined in the (cite applicable BLM Technical Reference or Handbook). • Measure utilization at key areas and complete use pattern mapping annually.	Re-adjust AML or identify management actions to address resolve land health issues, as needed/appropriate, based on results of land health monitoring.

Based on the analysis of potential environmental consequences, the authorized officer will determine whether to prepare an EIS or issue a Decision Record and FONSI.

HMAP
As a final step and to facilitate on-the-ground implementation, the selected management strategy (selected alternative), together with the habitat and population management, monitoring and implementation objectives are documented in HMAP format. The HMAP is included as an attachment to the authorized officer's final decision.

HMAP Format

1. Introduction. Briefly summarize the relevant background information.

2. Selected Management Alternative. Briefly summarize the selected management strategy/alternative as outlined in the EA, together with the site-specific habitat and population management objectives and management actions.

3. Monitoring and Evaluation Plan.

4. Project Tracking and Implementation Schedule.

The Monitoring Plan and Tracking Log/Project Implementation Schedule may also be prepared in a tabular format. See the examples which follow.

Table 4.2
Example -- Monitoring Plan

Item	How	Who	When	Actions to Take (Adaptive Management)
Population Management Monitoring				
Manage wild horse populations within the established AML range.	Aerial survey flights following established protocols. Simultaneous double count method or other approved protocol pending population estimation research results & recommendation.	FO WH&B Specialist	Aerial population estimates a minimum of every 3 years, i.e., 2010, 2013, etc.	Schedule gathers to remove excess wild horses when (1) the population reaches or exceeds the AML upper limit (about every 3 years), or (2) when forage utilization exceeds 50 percent of current year's growth in ½-2/3 of the key areas; or (3) when animal health/condition is at risk.
Habitat Management Monitoring				
Limit utilization by all herbivores to 50 percent of the current year's above ground primary production for key grasses and 45 percent for key shrubs and forbs.	Measure utilization at key areas and complete use pattern mapping annually.	FO WH&B Specialist	Annually (October)	Re-adjust AML or identify management actions to address resolve rangeland health issues, as needed/appropriate, based on results of rangeland health monitoring.

Table 4.3
Example – Tracking Log/Project Implementation Schedule

Description	Who	Where	When	Completed	Remarks
Population Management Actions					
Schedule gathers to remove excess wild horses when the population reaches/exceeds AML, utilization exceeds allowable limits, or animal health/condition is at risk.	BLM	(Name) HMA	About every 3 years (2010, 2013, etc)		
Habitat Management Actions

WILD HORSE AND BURRO COMPREHENSIVE ANIMAL WELFARE PROGRAM

PIM 2021-002
Permanent Instruction Memorandum

December 18, 2020

In Reply Refer To:
4700 (260) P

EMS TRANSMISSION 12/18/2020
Permanent Instruction Memorandum No. 2020- 002

To: All Headquarters Officials and Field Office Officials

Attn: State and Center Directors

From: Assistant Director, Resources and Planning

Subject: Wild Horse and Burro Comprehensive Animal Welfare Program

Program Area: Wild Horse and Burro Program

Purpose: The purpose of this Permanent Instruction Memorandum (PIM) is to re-affirm the Bureau of Land Management's (BLM's) longstanding commitment to ensure the humane treatment of wild horses and burros (WHB) in all on-range and off-range management activities through the Comprehensive Animal Welfare Program (CAWP). The humane treatment of wild horses and burros outlined in this policy reiterates the BLM's longstanding practices but also provides additional clarification to BLM employees. This PIM consolidates current humane practices, incorporates the existing Standard Operating Procedures (SOPs) outlined in Attachments 1 and 2 to ensure humane care and handling of the animals, and increases transparency concerning the humane treatment of wild horses and burros.

Policy/Action: The BLM is committed to continue protecting animal welfare and providing humane care and treatment to WHBs both on and off the range. Consistent with long-standing policies and practices, the handling and treatment provided by the BLM, its contractors, and its partners is based on compassion and concern for the animals' well-being at all times. Animals are managed and cared for to optimize animal condition, health, and safety.

All state, district, and field offices will continue to comply with the WHB CAWP policy within their jurisdiction at all times. The WHB CAWP policy includes:

1. CAWP Standards for Wild Horse and Burro Gathers (Attachment 1): These standards include requirements for trap and temporary holding facility design, capture and handling, transportation, and care after capture. The standards are also incorporated into helicopter gather contracts as specifications for performance.
2. Training for gather operations: All BLM staff associated with gather operations (incident commanders, contracting officer representatives, project inspectors, public affairs officials, and law enforcement officers) and contractor crews are required to complete online training annually for CAWP – Gathers (BLM-TC-4700-13), which is available through DOI Talent.
3. CAWP Standards for Off-Range Corral Facilities, Transportation, and Adoption/Sale Events (Attachment 2): This includes requirements for holding of animals in off-range corrals, transportation, and adoptions/sales events. These SOPs are incorporated into off-range corral contracts as specifications for performance.
4. Training for the Care, Handling, and Transportation of Wild Horses and Burros at off-range corrals and adoption/sales events: All personnel, including contractors and partners involved in the care, handling, and transportation of wild horses and burros at off-range

CAWP STANDARDS OFF RANGE CORRAL TRANSPORT ADOPTION SALE EVENTS (PDF / 364 KB)

FISCAL YEAR

2021

corrals and adoption/sale events are required to complete online training annually. Development of this training will begin following issuance of this PIM.

5. CAWP Standards and SOPs (to be developed) for animals on the range, in off-range pastures, and public off-range pastures: All personnel, contractors, and partners involved in management of WHBs on the range, in off-range pastures, or public off-range pastures are required to complete online training annually following the development of these guidelines and SOPs.

The purpose of this PIM is to continue to ensure that the humane care and treatment of WHBs remains the priority for the BLM, its contractors, and its partners. The BLM will continue to use the best available science, husbandry, and handling practices applicable for WHBs. Whenever possible, the BLM will make improvements to its practices while also meeting planned objectives in accordance with current BLM policy, SOPs, as well as contractual and cooperative agreement requirements. The CAWP will be reviewed periodically by WHB program leadership and modified as necessary to strengthen public trust, transparency, and effectiveness in assuring the humane care and treatment of the WHBs.

The authorized officer is the primary party responsible for immediately addressing any actions that are inconsistent with the CAWP. Consistent with applicable BLM delegation of authority manuals, the authorized officer may delegate responsibility to an alternate individual. The authorized officer should promptly notify the employees, contractors, and partners of actions that are not compliant with the CAWP and correct all issues immediately. It is the responsibility of all individuals engaged in actions throughout the WHB program to implement all aspects of the CAWP.

The WHB CAWP Coordinator will lead the implementation, development, and modification of all aspects of the CAWP, including those developed to date as well as future components of the CAWP.

Timeframe: This policy is effective immediately.

Budget Impact: This PIM codifies long-standing policy, practice, and guidance to include mandatory annual training and reporting requirements for BLM personnel, contractors, and partners associated with gather operations. The cost for the required training is approximately $100 per person per year. This PIM also formalizes SOPs for off-range holding, adoptions, sales, and transportation of excess WHB. When fully developed, the CAWP program implementation, oversight, data compilation, and reporting requirements will require an additional 12 to 18 work months per year.

Background: Public Law-195, Wild Free-Roaming Horses and Burros Act of 1971 (as amended) and 43 CFR 4700.0-2 provide the authority for a CAWP for WHB.

This CAWP policy provides a comprehensive approach to long-standing policies and practices within the BLM WHB program. Despite these policies and practices, the BLM has been criticized by some animal protection organizations on its handling and care of wild horses and burros, especially during the gathering activities and transitioning of the horses from public lands to off-range facilities. Some of the criticisms include concerns as to the transportation conditions of the horses, facility design, environmental conditions, handling practices, and nutrition. Similar to policies adopted by other organizations in agricultural and animal research industries, this PIM establishes a framework to ensure there are programs in place to verify humane care and handling of animals. It provides transparency on how the animals are assured humane care and proper handling. This framework seeks to confirm that the WHB program is conducted in a humane and caring manner.

The CAWP for WHB consolidates and highlights the BLM policies, procedures, and ongoing commitment to protect animal welfare; provides training for employees, contractors, and partners on animal care and handling, and implements assessment tools to evaluate adherence to the CAWP SOP by the agency, contractors, and partners.

Manual/Handbook Sections Affected: This PIM affects policies in BLM Manual/Handbooks H-4700-1 “Wild Horse and Burro Management” and H-4750-2 “Adoption of Wild Horses and Burros”.

Coordination: This PIM was coordinated among HQ-100, HQ-200, HQ-260, HQ-600, Deputy State Directors, WHB State Leads, APHIS Veterinarian, WHB Facility Managers, and WHB Specialists.

Contact: If you have any questions, please contact the Wild Horse and Burro Division Chief, at 866-468-7826 or wildhorse@blm.gov.

STANDARDS

Standard Definitions

Major Standard: Impacts the health or welfare of WH&Bs. Relates to an alterable equipment or facility standard or procedure. Appropriate wording is "must," "unacceptable," "prohibited."

Minor Standard: unlikely to affect WH&Bs health or welfare or involves an uncontrollable situation. Appropriate wording is "should."

Lead COR = Lead Contracting Officer's Representative

COR = Contracting Officer's Representative

PI = Project Inspector

WH&Bs = Wild horses and burros

I. FACILITY DESIGN

A. Trap Site and Temporary Holding Facility

1. The trap site and temporary holding facility must be constructed of stout materials and must be maintained in proper working condition, including gates that swing freely and latch or tie easily. (**major**)
2. The trap site should be moved close to WH&B locations whenever possible to minimize the distance the animals need to travel.(minor)
3. If jute is hung on the fence posts of an existing wire fence in the trap wing, the wire should be either be rolled up or let down for the entire length of the jute in such a way that minimizes the possibility of entanglement by WH&Bs unless otherwise approved by the Lead COR/COR/PI. (minor)
4. Fence panels in pens and alleys must be not less than 6 feet high for horses, 5 feet high for burros, and the bottom rail must not be more than 12 inches from ground level. (**major**)

5. The temporary holding facility must have a sufficient number of pens available to sort WH&Bs according to gender, age, number, temperament, or physical condition. (**major**)
    a. All pens must be assembled with capability for expansion. (**major**)
    b. Alternate pens must be made available for the following: (**major**)
        1) WH&Bs that are weak or debilitated
        2) Mares/jennies with dependent foals
    c. WH&Bs in pens at the temporary holding facility should be maintained at a proper stocking density such that when at rest all WH&Bs occupy no more than half the pen area. (minor)
6. An appropriate chute designed for restraining WH&Bs must be available for necessary procedures at the temporary holding facility. This does not apply to bait trapping operations unless directed by the Lead COR/COR/PI. (**major**)
7. There must be no holes, gaps or openings, protruding surfaces, or sharp edges present in fence panels or other structures that may cause escape or possible injury. (**major**)
8. Padding must be installed on the overhead bars of all gates and chutes used in single file alleys. (**major**)
9. Hinged, self-latching gates must be used in all pens and alleys except for entry gates into the trap, which may be secured with tie ropes. (**major**)
10. Finger gates (one-way funnel gates) used in bait trapping must be constructed of materials approved by the Lead COR/COR/PI. Finger gates must not be constructed of materials that have sharp ends that may cause injuries to WH&Bs, such as "T" posts, sharpened willows, etc. (**major**)
11. Water must be provided at a minimum rate of ten gallons per 1000 pound animal per day, adjusted accordingly for larger or smaller horses, burros and foals, and environmental conditions, with each trough placed in a separate location of the pen (i.e. troughs at opposite ends of the pen). Water must be refilled at least every morning and evening. (**major**)
12. The design of pens at the trap site and temporary holding facility should be constructed with rounded corners. (minor)

13. All gates and panels in the animal holding and handling pens and alleys of the trap site must be covered with materials such as plywood, snow fence, tarps, burlap, etc. approximately 48" in height to provide a visual barrier for the animals. All materials must be secured in place.(**major**)

    These guidelines apply:

    a. For exterior fences, material covering panels and gates must extend from the top of the panel or gate toward the ground.(**major**)
    b. For alleys and small internal handling pens, material covering panels and gates should extend from no more than 12 inches below the top of the panel or gate toward the ground to facilitate visibility of animals and the use of flags and paddles during sorting. (minor)
    c. The initial capture pen may be left uncovered as necessary to encourage animals to enter the first pen of the trap. (minor)

14. Non-essential personnel and equipment must be located to minimize disturbance of WH&Bs. (**major**)
15. Trash, debris, and reflective or noisy objects should be eliminated from the trap site and temporary holding facility. (minor)

B. Loading and Unloading Areas

1. Facilities in areas for loading and unloading WH&Bs at the trap site or temporary holding facility must be maintained in a safe and proper working condition, including gates that swing freely and latch or tie easily. (**major**)
2. The side panels of the loading chute must be a minimum of 6 feet high and fully covered with materials such as plywood or metal without holes that may cause injury. (**major**)
3. There must be no holes, gaps or openings, protruding surfaces, or sharp edges present in fence panels or other structures that may cause escape or possible injury. (**major**)
4. All gates and doors must open and close easily and latch securely. (**major**)

5. Loading and unloading ramps must have a non-slip surface and be maintained in a safe and proper working condition to prevent slips and falls. Examples of non-slip flooring would include, but not be limited to, rubber mats, sand, shavings, and steel reinforcement rods built into ramp. There must be no holes in the flooring or items that can cause an animal to trip. (**major**)
6. Trailers must be properly aligned with loading and unloading chutes and panels such that no gaps exist between the chute/panel and floor or sides of the trailer creating a situation where a WH&B could injure itself. (**major**)
7. Stock trailers should be positioned for loading or unloading such that there is no more than 12" clearance between the ground and floor of the trailer for burros and 18" for horses. (minor)

II. CAPTURE TECHNIQUE

A. Capture Techniques

1. WH&Bs gathered on a routine basis for removal or return to range must be captured by the following approved procedures under direction of the Lead COR/COR/PI. (**major**)
   a. Helicopter
   b. Bait trapping
2. WH&Bs must not be captured by snares or net gunning. (**major**)
3. Chemical immobilization must only be used for capture under exceptional circumstances and under the direct supervision of an on-site veterinarian experienced with the technique. (**major**)

B. Helicopter Drive Trapping

1. The helicopter must be operated using pressure and release methods to herd the animals in a desired direction and should not repeatedly evoke erratic behavior in the WH&Bs causing injury or exhaustion. Animals must not be pursued to a point of exhaustion; the on-site veterinarian must examine WH&Bs for signs of exhaustion. (**major**)

2. The rate of movement and distance the animals travel must not exceed limitations set by the Lead COR/COR/PI who will consider terrain, physical barriers, access limitations, weather, condition of the animals, urgency of the operation (animals facing drought, starvation, fire, etc.) and other factors. (**major**)
    a. WH&Bs that are weak or debilitated must be identified by BLM staff or the contractors. Appropriate gather and handling methods should be used according to the direction of the Lead COR/COR/PI. (**major**)
    b. The appropriate herding distance and rate of movement must be determined on a case-by-case basis considering the weakest or smallest animal in the group (e.g., foals, pregnant mares, or horses that are weakened by body condition, age, or poor health) and the range and environmental conditions present. (**major**)
    c. Rate of movement and distance travelled must not result in exhaustion at the trap site, with the exception of animals requiring capture that have an existing severely compromised condition prior to gather. Where compromised animals cannot be left on the range or where doing so would only serve to prolong their suffering, euthanasia will be performed in accordance with BLM policy. (**major**)
3. WH&Bs must not be pursued repeatedly by the helicopter such that the rate of movement and distance travelled exceeds the limitation set by the Lead COR/COR/PI. Abandoning the pursuit or alternative capture methods may be considered by the Lead COR/COR/PI in these cases. (**major**)
4. When WH&Bs are herded through a fence line en route to the trap, the Lead COR/COR/PI must be notified by the contractor. The Lead COR/COR/PI must determine the appropriate width of the opening that the fence is let down to allow for safe passage through the opening. The Lead COR/COR/PI must decide if existing fence lines require marking to increase visibility to WH&Bs. (**major**)
5. The helicopter must not come into physical contact with any WH&B. The physical contact of any WH&B by helicopter must be documented by Lead COR/COR/PI along with the circumstances. (**major**)
6. WH&Bs may escape or evade the gather site while being moved by the helicopter. If there are mare/dependent foal pairs in a group being brought to a trap and half of an identified pair is thought to have evaded capture, multiple attempts by helicopter may

be used to bring the missing half of the pair to the trap or to facilitate capture by roping. In these instances, animal condition and fatigue must be evaluated by the Lead COR/COR/PI or on-site veterinarian on a case-by-case basis to determine the number of attempts that can be made to capture an animal.(**major**)

7. Horse captures must not be conducted when ambient temperature at the trap site is below 10ºF or above 95ºF without approval of the Lead COR/COR/PI. Burro captures must not be conducted when ambient temperature is below 10ºF or above 100ºF without approval of the Lead COR/COR/PI. The Lead COR/COR/PI will not approve captures when the ambient temperature exceeds 105 ºF. (**major**)

C. Roping

1. The roping of any WH&B must be approved prior to the procedure by the Lead COR/COR/PI. (**major**).
2. The roping of any WH&B must be documented by the Lead COR/COR/PI along with the circumstances. WH&Bs may be roped under circumstances which include but are not limited to the following: reunite a mare or jenny and her dependent foal; capture nuisance, injured or sick WH&Bs or those that require euthanasia; environmental reasons such as deep snow or traps that cannot be set up due to location or environmentally sensitive designation; and public and animal safety or legal mandates for removal. (**major**)
3. Ropers should dally the rope to their saddle horn such that animals can be brought to a stop as slowly as possible and must not tie the rope hard and fast to the saddle so as to intentionally jerk animals off their feet. (**major**)
4. WH&Bs that are roped and tied down in recumbency must be continuously observed and monitored by an attendant at a maximum of 100 feet from the animal. (**major**)
5. WH&Bs that are roped and tied down in recumbency must be untied within 30 minutes. (**major**)
6. If the animal is tied down within the wings of the trap, helicopter drive trapping within the wings will cease until the tied-down animal is removed. (**major**)
7. Sleds, slide boards, or slip sheets must be placed underneath the animal's body to move and/or load recumbent WH&Bs. (**major**)

8. Halters and ropes tied to a WH&B may be used to roll, turn, position or load a recumbent animal, but a WH&B must not be dragged across the ground by a halter or rope attached to its body while in a recumbent position. (**major**)
9. Animals captured by roping must be evaluated by the on-site/on-call veterinarian within four hours after capture, marked for identification at the trap site, and be re-evaluated periodically as deemed necessary by the on-site/on-call veterinarian. (**major**)

D. Bait Trapping

1. WH&Bs may be lured into a temporary trap using bait (feed, mineral supplement, water) or sexual attractants (mares/jennies in heat) with the following requirements:
   a. The period of time water sources other than in the trap site are inaccessible must not adversely affect the wellbeing of WH&Bs, wildlife or livestock, as determined by the Lead COR/COR/PI. (**major**)
   b. Unattended traps must not be left unobserved for more than 12 hours. (**major**)
   c. Mares/jennies and their dependent foals must not be separated unless for safe transport. (**major**)
   d. WH&Bs held for more than 12 hours must be provided with accessible clean water at a minimum rate of ten gallons per 1000 pound animal per day, adjusted accordingly for larger or smaller horses, burros and foals and environmental conditions. (**major**)
   e. WH&Bs held for more than 12 hours must be provided good quality hay at a minimum rate of 20 pounds per 1000 pound adult animal per day, adjusted accordingly for larger or smaller horses, burros and foals. (**major**)
      1) Hay must not contain poisonous weeds, debris, or toxic substances. (**major**)
      2) Hay placement must allow all WH&Bs to eat simultaneously. (**major**)

III. WILD HORSE AND BURRO CARE

A. Veterinarian

1. On-site veterinary support must be provided for all helicopter gathers and on-site or on-call support must be provided for bait trapping. (**major**)

2. Veterinary support must be under the direction of the Lead COR/COR/PI. The on-site/on-call veterinarian will provide consultation on matters related to WH&B health, handling, welfare, and euthanasia at the request of the Lead COR/COR/PI. All decisions regarding medical treatment or euthanasia will be made by the on-site Lead COR/COR/PI. (**major**)

B. Care

1. Feeding and Watering
    a. Adult WH&Bs held in traps or temporary holding pens for longer than 12 hours must be fed every morning and evening with water available at all times other than when animals are being sorted or worked. (**major)**
    b. Water must be provided at a minimum rate of ten gallons per 1000 pound animal per day, adjusted accordingly for larger or smaller horses, burros and foals, and environmental conditions, with each trough placed in a separate location of the pen (i.e. troughs at opposite ends of the pen). . (**major**)
    c. Good quality hay must be fed at a minimum rate of 20 pounds per 1000 pound adult animal per day, adjusted accordingly for larger or smaller horses, burros and foals. (**major**)
        i. Hay must not contain poisonous weeds or toxic substances. (**majo**r)
        ii. Hay placement must allow all WH&Bs to eat simultaneously. (**major**)
    d. When water or feed deprivation conditions exist on the range prior to the gather, the Lead COR/COR/PI should adjust the watering and feeding arrangements in consultation with the onsite veterinarian as necessary to provide for the needs of the animals. (minor)
2. Dust abatement
    a. Dust abatement by spraying the ground with water must be employed when necessary at the trap site and temporary holding facility. (**major**)

3. Trap Site
    a. Dependent foals or weak/debilitated animals must be separated from other WH&Bs at the trap site to avoid injuries during transportation to the temporary holding facility. Separation of dependent foals from mares must not exceed four hours unless the Lead COR/COR/PI authorizes a longer time or a decision is made to wean the foals. (**major**)
4. Temporary Holding Facility
    a. All WH&Bs in confinement must be observed at least once daily to identify sick or injured WH&Bs and ensure adequate food and water. (**major**)
    b. Foals must be reunited with their mares/jennies at the temporary holding facility within four hours of capture unless the Lead COR/COR/PI authorizes a longer time or foals are old enough to be weaned during the gather. (**major**)
    c. Non-ambulatory WH&Bs must be located in a pen separate from the general population and must be examined by the BLM horse specialist and/or on-call or on-site veterinarian as soon as possible, no more than four hours after recumbency is observed. Unless otherwise directed by a veterinarian, hay and water must be accessible to an animal within six hours after recumbency.(**major**)
    d. Alternate pens must be made available for the following: (**major**)
        1) WH&Bs that are weak or debilitated
        2) Mares/jennies with dependent foals
    e. Aggressive WH&Bs causing serious injury to other animals should be identified and relocated into alternate pens when possible. (minor)
    f. WH&Bs in pens at the temporary holding facility should be maintained at a proper stocking density such that when at rest all WH&Bs occupy no more than half the pen area. (minor)

C. Biosecurity

1. Health records for all saddle and pilot horses used on WH&B gathers must be provided to the Lead COR/COR/PI prior to joining a gather, including: (**major**)
   a. Certificate of Veterinary Inspection (Health Certificate, within 30 days).
   b. Proof of:
      1) A negative test for equine infectious anemia (Coggins or EIA ELISA test) within 12 months.
      2) Vaccination for tetanus, eastern and western equine encephalomyelitis, West Nile virus, equine herpes virus, influenza, *Streptococcus equi*, and rabies within 12 months.
2. Saddle horses, pilot horses and mares used for bait trapping lures must not be removed from the gather operation (such as for an equestrian event) and allowed to return unless they have been observed to be free from signs of infectious disease for a period of at least three weeks and a new Certificate of Veterinary Examination is obtained after three weeks and prior to returning to the gather. (**major**)
3. WH&Bs, saddle horses, and pilot horses showing signs of infectious disease must be examined by the on-site/on-call veterinarian. (**major**)
   a. Any saddle or pilot horses showing signs of infectious disease (fever, nasal discharge, or illness) must be removed from service and isolated from other animals on the gather until such time as the horse is free from signs of infectious disease and approved by the on-site/on-call veterinarian to return to the gather. (**major**)
   b. Groups of WH&Bs showing signs of infectious disease should not be mixed with groups of healthy WH&Bs at the temporary holding facility, or during transport. (minor)
4. Horses not involved with gather operations should remain at least 300 yards from WH&Bs, saddle horses, and pilot horses being actively used on a gather. (minor)

IV. HANDLING

A. Willful Acts of Abuse

1. Hitting, kicking, striking, or beating any WH&B in an abusive manner is prohibited. (**major**)
2. Dragging a recumbent WH&B without a sled, slide board or slip sheet is prohibited. Ropes used for moving the recumbent animal must be attached to the sled, slide board or slip sheet unless being loaded as specified in Section II. C. 8. (**major**)
3. There should be no deliberate driving of WH&Bs into other animals, closed gates, panels, or other equipment. (minor)
4. There should be no deliberate slamming of gates and doors on WH&Bs. (minor)
5. There should be no excessive noise (e.g., constant yelling) or sudden activity causing WH&Bs to become unnecessarily flighty, disturbed or agitated. (minor)

B. General Handling

1. All sorting, loading or unloading of WH&Bs during gathers must be performed during daylight hours except when unforeseen circumstances develop and the Lead COR/CO/PI approves the use of supplemental light. (**major**)
2. WH&Bs should be handled to enter runways or chutes in a forward direction. (minor)
3. WH&Bs should not remain in single-file alleyways, runways, or chutes longer than 30 minutes. (minor)
4. Equipment except for helicopters should be operated and located in a manner to minimize flighty behavior . (minor)

C. Handling Aids

1. Handling aids such as flags and shaker paddles must be the primary tools for driving and moving WH&Bs during handling and transport procedures. Contact of the flag or paddle end of primary handling aids with a WH&B is allowed. Ropes looped around the hindquarters may be used from horseback or on foot to assist in moving an animal forward or during loading. (**major**)

2. Electric prods must not be used routinely as a driving aid or handling tool. Electric prods may be used in limited circumstances only if the following guidelines are followed:
    a. Electric prods must only be a commercially available make and model that uses DC battery power and batteries should be fully charged at all times. (**major**)
    b. The electric prod device must never be disguised or concealed. (**major**)
    c. Electric prods must only be used after three attempts using other handling aids (flag, shaker paddle, voice or body position) have been tried unsuccessfully to move the WH&Bs. (**major**)
    d. Electric prods must only be picked up when intended to deliver a stimulus; these devices must not be constantly carried by the handlers. (**major**)
    e. Space in front of an animal must be available to move the WH&B forward prior to application of the electric prod. (**major**)
    f. Electric prods must never be applied to the face, genitals, anus, or underside of the tail of a WH&B. (**major**)
    g. Electric prods must not be applied to any one WH&B more than three times during a procedure (e.g., sorting, loading) except in extreme cases with approval of the Lead COR/COR/PI. Each exception must be approved at the time by the Lead COR/COR/PI. (**majo**r)
    h. Any electric prod use that may be necessary must be documented daily by the Lead COR/COR/PI including time of day, circumstances, handler, location (trap site or temporary holding facility), and any injuries (to WH&B or human). (**major**)

V. TRANSPORTATION

A. General

1. All sorting, loading, or unloading of WH&Bs during gathers must be performed during daylight hours except when unforeseen circumstances develop and the Lead COR/CO/PI approves the use of supplemental light. (**major**)

2. WH&Bs identified for removal should be shipped from the temporary holding facility to a BLM facility within 48 hours. (minor)
    a. Shipping delays for animals that are being held for release to range or potential on-site adoption must be approved by the Lead COR/COR/PI. (**major**)
3. Shipping should occur in the following order of priority; 1) debilitated animals, 2) pairs, 3) weanlings, 4) dry mares and 5) studs. (minor)
4. Planned
5. transport time to the BLM preparation facility from the trap site or temporary holding facility must not exceed 10 hours. (**major**)
6. WH&Bs should not wait in stock trailers and/or semi-trailers at a standstill for more than a combined period of three hours during the entire journey. (minor)

B. Vehicles

1. Straight-deck trailers and stock trailers must be used for transporting WH&Bs. (**major**)
    a. Two-tiered or double deck trailers are prohibited. (**major**)
    b. Transport vehicles for WH&Bs must have a covered roof or overhead bars containing them such that WH&Bs cannot escape. (**major**)
2. WH&Bs must have adequate headroom during loading and unloading and must be able to maintain a normal posture with all four feet on the floor during transport without contacting the roof or overhead bars. (**major**)
3. The width and height of all gates and doors must allow WH&Bs to move through freely. (**major**)
4. All gates and doors must open and close easily and be able to be secured in a closed position. (**major**)
5. The rear door(s) of the trailers must be capable of opening the full width of the trailer. (**major**)
6. Loading and unloading ramps must have a non-slip surface and be maintained in proper working condition to prevent slips and falls. (**major**)

7. Transport vehicles more than 18 feet and less than 40 feet in length must have a minimum of one partition gate providing two compartments; transport vehicles 40 feet or longer must have at least two partition gates to provide a minimum of three compartments. (**major**)
8. All partitions and panels inside of trailers must be free of sharp edges or holes that could cause injury to WH&Bs. (**major**)
9. The inner lining of all trailers must be strong enough to withstand failure by kicking that would lead to injuries. (**major**)
10. Partition gates in transport vehicles should be used to distribute the load into compartments during travel. (minor)
11. Surfaces and floors of trailers must be cleaned of dirt, manure and other organic matter prior to the beginning of a gather. (**major**)

C. Care of WH&Bs during Transport Procedures

1. WH&Bs that are loaded and transported from the temporary holding facility to the BLM preparation facility must be fit to endure travel. (**major**)
    a. WH&Bs that are non-ambulatory, blind in both eyes, or severely injured must not be loaded and shipped unless it is to receive immediate veterinary care or euthanasia. (**major**)
    b. WH&Bs that are weak or debilitated must not be transported without approval of the Lead COR/COR/PI in consultation with the on-site veterinarian. Appropriate actions for their care during transport must be taken according to direction of the Lead COR/COR/PI. (**major**)
2. WH&Bs should be sorted prior to transport to ensure compatibility and minimize aggressive behavior that may cause injury. (minor)
3. Trailers must be loaded using the minimum space allowance in all compartments as follows: (**major**)
    a. 12 square feet per adult horse.
    b. 6.0 square feet per dependent horse foal.
    c. 8.0 square feet per adult burro.
    d. 4.0 square feet per dependent burro foal.

4. The Lead COR/COR/PI in consultation with the receiving Facility Manager must document any WH&B that is recumbent or dead upon arrival at the destination. (**major**)
    a. Non-ambulatory or recumbent WH&Bs must be evaluated on the trailer and either euthanized or removed from the trailers using a sled, slide board or slip sheet. (**major**)
5. Saddle horses must not be transported in the same compartment with WH&Bs. (**major**)

VI. EUTHANASIA OR DEATH

A. Euthanasia Procedure during Gather Operations

1. An authorized, properly trained, and experienced person as well as a firearm appropriate for the circumstances must be available at all times during gather operations. When the travel time between the trap site and temporary holding facility exceeds one hour or if radio or cellular communication is not reliable, provisions for euthanasia must be in place at both the trap site and temporary holding facility during the gather operation. (**major**)
2. Euthanasia must be performed according to American Veterinary Medical Association euthanasia guidelines (2013) using methods of gunshot or injection of an approved euthanasia agent. (**major**)
3. The decision to euthanize and method of euthanasia must be directed by the Authorized Officer or their Authorized Representative(s) that include but are not limited to the Lead COR/COR/PI who must be on site and may consult with the on-site/on-call veterinarian. (**major**)
4. Photos needed to document an animal's condition should be taken prior to the animal being euthanized. No photos of animals that have been euthanized should be taken. An exception is when a veterinarian or the Lead COR/COR/PI may want to document certain findings discovered during a postmortem examination or necropsy. (minor)
5. Any WH&B that dies or is euthanized must be documented by the Lead COR/COR/PI including time of day, circumstances, euthanasia method, location, a

description of the age, gender, and color of the animal and the reason the animal was euthanized. (**major**)

6. The on-site/on-call veterinarian should review the history and conduct a postmortem physical examination of any WH&B that dies or is euthanized during the gather operation. A necropsy should be performed whenever feasible if the cause of death is unknown. (minor)

B. Carcass Disposal

1. The Lead COR/COR/PI must ensure that appropriate equipment is available for the timely disposal of carcasses when necessary on the range, at the trap site, and temporary holding facility. (**major**)
2. Disposal of carcasses must be in accordance with state and local laws. (**major**)
3. WH&Bs euthanized with a barbiturate euthanasia agent must be buried or otherwise disposed of properly. (**major**)
4. Carcasses left on the range should not be placed in washes or riparian areas where future runoff may carry debris into ponds or waterways. Trenches or holes for buried animals should be dug so the bottom of the hole is at least 6 feet above the water table and 4-6 feet of level earth covers the top of the carcass with additional dirt mounded on top where possible. (minor)

CAWP

REQUIRED DOCUMENTATION AND RESPONSIBILITIES OF LEAD COR/COR/PI

Required Documentation

Section	Documentation
II.B.5	Helicopter contact with any WH&B.
II.C.2	Roping of any WH&B.
III.B.3.a and III.B.4.b	Reason for allowing longer than four hours to reunite foals with mares/jennies. Does not apply if foals are being weaned.
III.C.1	Health status of all saddle and pilot horses.
IV.C.2.h	All uses of electric prod.
V.C.4	Any WH&B that is recumbent or dead upon arrival at destination following transport.
VI.A.5	Any WH&B that dies or is euthanized during gather operation.

Responsibilities

Section	Responsibility
I.A.10	Approve materials used in construction of finger gates in bait trapping
II.A.1	Direct gather procedures using approved gather technique.
II.B. 2	Determine rate of movement and distance limitations for WH&B helicopter gather.
II.B.2.a	Direct appropriate gather/handling methods for weak or debilitated WH&B.
II.B.3	Determine whether to abandon pursuit or use other capture method in order to avoid repeated pursuit of WH&B.
II.B.4	Determine width and need for visibility marking when using opening in fence en route to trap.
II.B.6	Determine number of attempts that can be made to capture the missing half of a mare/foal pair that has become separated.
II.B.7	Determine whether to proceed with gather when ambient temperature is outside the range of 10°F to 95°F for horses or 10°F to 100°F for burros.
II.C.1	Approve roping of any WH&B.
II.D.1.a	Determine period of time that water outside a bait trap is inaccessible such that wellbeing of WH&Bs, wildlife, or livestock is not adversely affected.
III.A.2	Direct and consult with on-site/on-call veterinarian on any matters related to WH&B health, handling, welfare and euthanasia.

III.B.1.e	Adjust feed/water as necessary, in consultation with onsite/on call veterinarian, to provide for needs of animals when water or feed deprivation conditions exist on range.
III.B.4.c	Determine provision of water and hay to non-ambulatory animals.
IV.C.2.g	Approve use of electric prod more than three times, for exceptional cases only.
V.A.1	Approve sorting, loading, or unloading at night with use of supplemental light.
V.A.2.a	Approve shipping delays of greater than 48 hours from temporary holding facility to BLM facility.
V.C.1.b	Approve of transport and care during transport for weak or debilitated WH&B.
VI.A.3	Direct decision regarding euthanasia and method of euthanasia for any WH&B; may consult with on-site/on-call veterinarian.
VI.B.1	Ensure that appropriate equipment is available for carcass disposal.

PROPOSED CAWP COMPONENTS FOR OFF-RANGE CORRAL FACILITIES, TRANSPORTATION, AND ADOPTION EVENTS **22**

PREFACE

The Bureau of Land Management (BLM) estimates that 58,150 wild horses and burros (WH&Bs) are roaming on BLM-managed rangelands in 10 Western states, based on the latest data available, compiled as of March 1, 2015. Wild horses and burros have virtually no natural predators and their herd sizes can double about every four years. As a result, the agency must remove thousands of animals from the range each year to control herd sizes.

The Bureau of Land Management manages many off-range corral facilities throughout the U.S. The primary mission of the off-range corral facilities is to act as a holding and preparation facility that accepts WH&Bs from gather/removal operations and prepares them for adoption to the public or placement into off-range pastures. As of November 2015, there are 16,182 WH&Bs in off-range corral facilities.

The design of each facility is organized to handle large numbers of WH&Bs with pens, corrals, alleys, and loading/unloading areas that facilitate animal movement. There are multiple pens and corrals to sort animals for compatibility and care upon arrival to the facility. Each pen or corral offers all animals continuous water accessibility and quality feed on a daily basis.

The BLM strives to place horses removed from the range into private homes that provide quality care. Horses placed in off-range corral facilities are made available to the public for adoption or sale at adoption events held throughout the U.S. and through the BLM's Adopt or Sales Program (http://www.blm.gov/wo/st/en/prog/whbprogram/adoption_program/schedule.html). The off-range corral facility transitions WH&Bs to hay diets, performs necessary vaccinations and deworming procedures, provides hoof care and may train WH&Bs. Other WH&Bs, due to age, temperament, or other factors, may not be adopted or sold and subsequently are placed in off-range pastures. These facilities are designed to provide unadoptable wild horses with humane life-long care in a natural setting off the public rangelands. There are approximately 46,016 WH&Bs being cared for in off-range pastures (November 2015). All WH&Bs residing in both off-range corral facilities and off-range pastures, like those roaming Western public rangelands, are protected by the BLM under the 1971 Wild Free-Roaming Horses and Burros Act, as amended.

The BLM has been criticized by the public and animal protection organizations on their handling and care of wild horses and burros especially during the gathering activities and transitioning of the horses from public lands to off-range facilities. Some of the issues include the transportation conditions of the horses, facility design, environmental conditions, handling practices, and nutrition. Agricultural and research animal industries have developed assessment or auditing programs to verify humane care and handling of their industry's animals. These industries are performing both internal and 3rd-party audits for animal welfare to assure their stakeholders and provide transparency on how these animals are provided care and proper handling. Assessment programs based on standards have multifaceted benefits in providing education to employees and assurance to societal entities that their programs are responsible for properly handling and providing care for the animals. An assessment welfare program reported routinely to the public will increase transparency concerning the humane treatment of BLM's WH&Bs, as recommended by the 2008 US Government Accountability Office.

STANDARDS

Deficiency Definitions

Major Deficiency: impacts welfare of WH&Bs; usually is a procedure. Appropriate wording is "must," "unacceptable," "prohibited."

Minor Deficiency: a reporting deficiency (lack of, not enough detail) or involves an uncontrollable situation. Appropriate wording is "should."

WH&Bs = Wild horses and burros

SECTION 1.

OFF-RANGE CORRAL FACILITY STANDARDS

I. FACILITY PERSONNEL

A. Facility management establishes and implements standards of care, treatment, and handling of WH&Bs, and communicates expectations to all personnel to ensure the humane care and treatment of all WH&Bs at the facility. (**major**)

B. The facility must have employees with training, skills, and experience to observe, move, and handle the WH&Bs on the facility. (**major**)

C. The facility must have personnel that can properly maintain the working chute systems and facility infrastructure to provide for the safe housing, movement, and processing of the WH&Bs. (**major**)

D. The facility should be staffed by appropriate office staff for record maintenance and recording. (minor)

II. FACILITY DESIGN

A. Facilities must be operated in a manner to provide a safe, clean and supportive environment for all WH&Bs. (major)

B. WH&Bs must be allowed to exist in an undisturbed environment unless being prepared for health procedures, identification, adoption events, or transportation. (major)
C. All WH&Bs must have adequate space to move freely within a pen enclosure. (major)
D. The facility must have a sufficient number of pens available to sort WH&Bs according to sex, age, temperament, health status, or physical condition as needed. (major)
E. Facility fences, gates, alleys, tubs, and working chutes must be constructed of stout materials and must be maintained in proper working condition. (major)
F. Fences in pens, alleys, and working chute systems must be not less than 6 feet high for horses, 5 feet high for burros, and the bottom rail must not be more than 12 inches from ground level. (major)
G. Fences must be of stout design and be maintained in proper condition with no holes, gaps, or sharp edges which could result in WH&Bs being injured. (major)
H. All WH&Bs within a pen must have adequate dry space to rest. (major)
I. Ground surfaces in pens must be maintained to promote drainage, reduce wet ground conditions, and allow for routine manure removal. (major)
J. Watering systems in WH&B holding pens must provide unlimited access to clean water appropriate for livestock at all times. (major)
K. Feeding areas must be accessible to all WH&Bs in the enclosure and maintained as a dry area without excessive manure accumulation. (major)
L. An appropriate squeeze chute maintained in proper working order must be available for safely restraining WH&Bs for necessary procedures at the facility including hoof trimming. (major)
M. Facilities must provide access to shade and shelter (wind breaks) in pens designated for compromised animals needing special care (i.e., injured or weak animals). Additional provisions for shade and shelter (wind breaks) will be evaluated and determined by managers as appropriate for their region, the function of their facility and the condition of the animals under their care. (major)

N. Shelter structures should be designed or constructed to reduce the risk for injury of the WH&Bs and maintained to avoid excessive manure and mud. (minor)

III. RECEIVING WILD HORSES AND BURROS

A. Loading and Unloading Facilities

1. Facilities in areas for loading and unloading WH&Bs must be maintained in a safe and proper working condition, including gates and doors that swing freely and latch or tie easily as designed. (**major**)
2. The side panels of the loading chute must be a minimum of 6 feet high and covered with materials such as plywood or metal without holes that may cause injury. (**major**)
3. There must be no holes, gaps or openings, protruding surfaces, or sharp edges present in fence panels or other structures that may cause escape or possible injury. (**major**)
4. Loading and unloading ramps must have a non-slip surface and be maintained in a safe and proper working condition to prevent slips and falls. Examples of non-slip floors would include, but not be limited to, rubber mats, sand, shavings, and steel reinforcement rods or rough surfaces built into the ramp. There must be no holes in flooring or items that cause an animal to trip. (**major**)
5. Trailers must be properly aligned with loading and unloading chutes and panels with no gaps between the chute/panel and floor or sides of the trailer creating a situation where a WH&B could injure itself. (**major**)
6. Stock trailers should be positioned for loading and unloading such that there is no more than 12" clearance between the ground and floor of the trailer for burros and 18" for horses. (minor)

B. Receiving Procedures

1. All unloading of WH&Bs must be performed during daylight hours except when unforeseen circumstances develop and the Authorized Officer approves of the use of supplemental light. (**major**)

2. At the time of unloading, WH&Bs must be inspected by facility personnel to look for signs of infectious disease, sickness or injury and take appropriate steps if these conditions are observed. (**major**)
3. Any WH&B needing immediate veterinary attention must be identified and separated as necessary for examination, and a consultation with a veterinarian must be conducted within 4 hours. (**major**)
4. An authorized, properly trained, and experienced person, as well as euthanasia equipment and supplies, must be available immediately following unloading in the event that the emergency euthanasia of an animal is required. Euthanasia must be done in compliance with BLM Euthanasia policy. (**major**)
5. The receiving Authorized Officer must document any WH&B that is recumbent or dead upon arrival at the destination. (**major**)
6. Reporting of animals received from gather operations or from another BLM facility must be done in compliance with BLM policy. (**major**)
7. WH&Bs received from a gather must remain segregated from resident animals at the facility until a negative test for Equine Infectious Anemia (EIA) can be confirmed. (**major**)
8. Newly arrived WH&Bs must immediately be provided hay and water upon unloading. (**major**)
9. When WH&Bs are received from gather operations or from another facility, the receiving facility should unload them in a manner to minimize stress. (minor)
10. WH&Bs should be penned with WH&Bs of like age, sex, and temperament. (minor)
11. Newly arrived WH&Bs should be observed for signs that they may have difficulty transitioning to hay in a domestic setting. (minor)

IV. CARE OF WILD HORSE AND BURROS

A. Veterinarian

1. Routine presence by an on-site or on-call veterinarian must be provided at each facility with records of those visits maintained at the facility. (**major**)
2. A veterinarian must be available to collect and submit blood samples for Equine Infectious Anemia (EIA) testing and rabies immunization. (**major**)
3. Health care protocols must be in accordance with Program guidelines and accepted by the facility veterinarian for preventive health care procedures (vaccinations, deworming, hoof trimming, freeze marking). Medical treatments will be prescribed by or performed under the supervision of a veterinarian. Surgical procedures will only be performed by a veterinarian. (**major**)
4. WH&B deaths in a facility should be discussed with the facility veterinarian to review the probable causes of death. (minor)
5. If multiple animals die due to a related cause or unknown cause(s), a post-mortem examination or necropsy should be performed by the facility's on-call or on-site veterinarian to identify the cause of death where possible. Laboratory testing should be performed when possible to aid in determining the cause of death or related underlying factors that may be present when these are not readily apparent during the gross examination. (minor)
6. If a series of unexplained deaths occurs, facility quarantine measures must be considered with input from the attending veterinarian until the cause has been determined or when indicated until adequate bio-security measures are in place to prevent the spread of disease. Coordination with State and/or Federal Animal Health Officials in consultation with the attending veterinarian must be done if this occurs. (**major**)

B. Bio-Security

1. Authorized Officers must consult with the on-site or on-call veterinarian(s) to establish and review biosecurity and health care decisions. (**major**)

2. Newly arrived WH&Bs from gather operations must not be co-mingled with resident animals at the facility. (**major**)
3. Pens should be provided to segregate sick, infectious, injured, or weak WH&Bs from other healthy individuals in the facility when possible. (minor)
4. Hazardous or infectious biological waste (i.e., sharps, needles, blood samples, etc.) must be properly disposed in labeled containers. (**major**)
5. Working chute and tub systems should be routinely cleaned and disinfected to reduce the risk of disease transmission, especially after moving contagious WH&Bs through the system. (minor)

C. Feed and Water

1. Quality hay must be provided daily to WH&Bs in the amount of 2-3% of their body weight per day. **(major)**
2. Fresh, clean water appropriate for livestock must be accessible to WH&Bs located in holding pens at all times. (**major**)
3. Water troughs and watering systems must be checked daily to ensure they are clean and operating correctly. (**major**)
4. Feeding sites must allow all WH&Bs within a pen simultaneous access to hay. (**major**)
5. Newly arrived WH&Bs from gather operations may be fed grass hay and transitioned to alfalfa. (minor)
6. Salt and/or mineral blocks should be provided in holding pens at all times. (minor)
7. Supplemental feeds should be provided to address the nutritional needs of the WH&Bs, if needed. (minor)

D. Preparation Procedures

1. Facilities must identify individual WH&Bs and maintain inventories in accordance with BLM policy. This includes unmarked WH&Bs as well as those provided a freeze-mark. **(major)**
2. Facilities must conduct Equine Infectious Anemia (EIA) testing and apply freeze-marks within 30 days of receiving WH&Bs, unless directed by the facility veterinarian when age or physical condition requires a delay. (**major**)

3. WH&Bs receiving a freeze-mark must be recorded on the animal preparation record using the approved Signalment Key. (**major**)
4. Foals born in the facility should be freeze-marked no earlier than 3 months of age. (minor)
5. WH&Bs must be evaluated daily by facility personnel to identify animals in poor body condition, poor hoof condition, injured, or in need of veterinary evaluation/treatment, and/or supplemental feeding. (**major**)
6. Facilities must adhere to the current BLM vaccination policy. (**major**)
7. Foals must be tested for EIA and vaccinated when weaned or at 6 months of age. (**major**)
8. Hoof trimming must be performed twice per year at minimum or as necessary to maintain hooves in a proper condition. (**major**)
9. Castration of stallions and jack burros must be performed by a veterinarian using general anesthesia. If a surgical plane of anesthesia is not reached initially animals must be re-dosed or the procedure postponed until the problem can be resolved. (**major**)
10. Stallions and jack burros should be castrated as soon as approved by the on-site veterinarian for the procedure in accordance with BLM policy. (minor)
11. WH&Bs being prepared for freeze-marking, blood collection, vaccination, hoof trimming, sorting, and other care treatments should be handled to minimize stress and injuries (minor).

E. Euthanasia Procedures

1. The decision to euthanize and method of euthanasia must be directed by the Authorized Officer(s) who may consult with the on-site/on-call veterinarian. (**major)**
2. Euthanasia must be done in compliance with BLM Euthanasia policy. (**major**)
3. An authorized, properly trained, and experienced person, as well as euthanasia equipment and supplies, must be available at off-range corral facilities in the event that the emergency euthanasia of an animal is required. (**major**)

4. Any WH&B that dies or is euthanized must be documented including the circumstances, freeze brand ID if present, a description of the age, sex, color of the animal and the reason the animal was euthanized. A death record must be entered into the WHBPS. (**major**)
5. If an animal is euthanized due to an unknown cause, a post-mortem examination or necropsy should be performed by the facility's on-call or on-site veterinarian to identify the cause of death where possible. Laboratory testing should be performed when possible to aid in determining the cause of death or related underlying factors that may be present when these are not readily apparent during the gross examination. (minor)

F. Carcass Disposal

1. The Authorized Officer must ensure that appropriate procedures are in place for the timely disposal of carcasses when necessary at off-range corral facilities. (**major**)
2. Disposal of carcasses must be in accordance with applicable state and local laws. (**major**)

V. HANDLING WILD HORSES AND BURROS

A. Willful Acts of Abuse

1. Hitting, kicking, or beating any WH&Bs in an abusive manner is prohibited. **(major)**
2. Dragging a recumbent WH&Bs without a sled, side board or slip sheet is prohibited. Ropes used for moving the recumbent animal must be attached to the sled, slide board, or slip sheet. (**major**)
3. There should be no deliberate driving of WH&Bs into other animals, closed gates, panels, or other equipment. (minor)
4. There should be no deliberate slamming of gates and doors on WH&Bs. (minor)
5. There should be no excessive noise (e.g., constant yelling) or sudden activity causing WH&Bs to become unnecessarily flighty, disturbed or agitated. (minor)

B. General Handling

1. All sorting, loading or unloading of WH&Bs must be performed during daylight hours except when unforeseen circumstances develop and the Authorized Officer approves of the use of supplemental light. (**major**)
2. Halters and ropes tied to a WH&B may be used to roll, turn, position, or load a recumbent animal, but a WH&B must not be dragged across the ground by a halter or rope attached to its body while in a recumbent position. (**major**)
3. WH&Bs should be moved into and out of pens in a manner that will minimize stress and injury. (minor)
4. When possible, WH&Bs should be allowed to move at their own pace to new pens or sorting/handling locations. (minor)
5. WH&Bs should be handled to enter runways or chutes in a forward direction. (minor)
6. Any unattended WH&Bs or a single WH&B should not remain in single-file alleyways, runways or chutes longer than 30 minutes. (minor)
7. No equipment should be operated in such a manner as to cause flighty behavior or injury to WH&Bs. (minor)

B. Handling Aids

1. Handling aids such as flags and shaker paddles must be the primary tools for driving and moving WH&Bs during handling and transport procedures. Contact of the flag or paddle end of primary handling aids with a WH&B is allowed. Ropes looped around the hindquarters may be used from horseback or on foot to assist in moving an animal forward or during loading. **(major)**
2. Electric prods must not be used routinely as a driving aid or handling tool. Electric prods may be used in limited circumstances only if the following guidelines are followed:
    a. Electric prods must only be a commercially available make and model that uses DC battery power with batteries fully charged at all times. (**major**)
    b. The electric prod device must never be disguised or concealed. (**major**)

c. Electric prods must only be used after three attempts using other handling aids (flag, shaker paddle, voice or body position) have been tried unsuccessfully to move the WH&Bs. (**major**)
d. Electric prods must only be picked up when intended to deliver a stimulus; these devices are not constantly carried by the handlers. (**major**)
e. Space in front of an animal should be available for the WH&B to move forward prior to application of the electric prod. (**major**)
f. Electric prods must never be applied to the face, genitals, anus, or underside of the tail of a WH&B. (**major**)
g. Electric prods must not be applied to any one WH&B more than three times during a procedure (e.g., sorting, loading) except in extreme cases with the approval of the Authorized Officer. Each exception must be approved at the time by the Authorized Officer. (**major**)

SECTION 2.

TRANSPORTATION STANDARDS TO ANOTHER OFF-RANGE CORRAL FACILITY, OFF-RANGE PASTURE, ECO-SANCTUARY OR ADOPTION EVENT

I. LOADING AND UNLOADING FACILITIES

A. Facilities in areas for loading and unloading WH&Bs must be maintained in a safe and proper working condition, including gates and doors that swing freely and latch or tie easily as designed. (**major**)

B. The side panels of the loading chute must be a minimum of 6 feet high and covered with materials such as plywood or metal without holes that may cause injury. (**major**)

C. There must be no holes, gaps or openings, protruding surfaces, or sharp edges present in fence panels or other structures that may allow escape or cause possible injury. (**major**)

D. Loading and unloading ramps must have a non-slip surface and be maintained in a safe and proper working condition to prevent slips and falls. Examples of non-slip floors would include, but not be limited to, rubber mats, sand, shavings, and steel reinforcement rods or rough surfaces built into the ramp. There must be no holes in flooring or items that cause an animal to trip. (**major**)

E. Trailers must be properly aligned with loading and unloading chutes and panels with no gaps between the chute/panel and floor or sides of the trailer creating a situation where a WH&B could injure itself. (**major**)

F. Stock trailers should be positioned for loading and unloading such that there is no more than 12” clearance between the ground and floor of the trailer for burros and 18” for horses. (minor)

II.CARE OF WILD HORSES AND BURROS DURING TRANSPORT PREPARATION PROCEDURES

A. WH&Bs being transferred to another off-range corral facility, off-range pasture, eco-sanctuary or adoption event must have a current negative EIA test, be in a state of health appropriate for a Certificate of Veterinary Inspection (CVI), and be accompanied by appropriate paperwork as required by the laws of the receiving state. **(major)**

B. WH&Bs being transferred to another off-range corral facility, off-range pasture, eco-sanctuary or adoption event must be fit to endure the travel. (**major**)

    1. WH&Bs that are non-ambulatory, blind in both eyes, or severely injured must not be loaded and shipped unless it is to receive immediate veterinary care or euthanasia (**major**)

    2. WH&Bs that are weak or debilitated must not be transported without the approval of Authorized Officer in consultation with the on-site veterinarian. Appropriate actions for their care during transport must be taken according to the Authorized Officer. (**major**)

C. WH&Bs being transferred to another off-range corral facility, off-range pasture, eco-sanctuary, or adoption event must be sorted prior to shipping to ensure compatibility and minimize aggressive behavior that may cause injury during transport. (**major**)

D. Except for exceptional circumstances including but not limited to trap site adoptions, WH&Bs being offered for adoption should have received primary and booster vaccinations as well as deworming medications prior to adoption. (minor)

II. VEHICLES

A. Straight deck trailers or stock trailers must be used for transporting WH&Bs to another off-range corral facility, off-range pasture, eco-sanctuary or adoption event. **(major)**

    1. Two-tiered or double deck trailers are prohibited. **(major)**
    2. Transport vehicles for WH&Bs must have a covered roof containing them such that WH&Bs cannot escape. **(major)**

B. WH&Bs must have adequate headroom during loading and unloading and must be able to maintain a normal posture with all four feet on the floor during transport without contacting the roof. **(major)**

C. The width and height of all gates and doors must allow WH&Bs to move through freely. **(major)**

D. All gates and doors must open and close easily and be able to be secured in a closed position. **(major)**

E. Loading and unloading ramps of vehicles must have a non-slip surface and be maintained in a safe and proper working condition to prevent slips and falls. Examples of non-slip flooring would include, but not be limited to, rubber mats, sand, shavings, and steel reinforcement rods built into ramp. There must be no holes in the flooring or items that can cause an animal to trip. **(major)**

F. Transport vehicles more than 18 feet and less than 40 feet in length must have a minimum of one partition gate providing two compartments; transport vehicles 40 feet or longer must have at least two partition gates to provide a minimum of three compartments. **(major)**

G. Partition gates in transport vehicles should be used to distribute the load into compartments during travel. (minor)

H. All partitions and panels inside of trailers must be free of sharp edges or holes that could cause injury to WH&Bs. **(major)**

I. The inner lining of all trailers must be strong enough to withstand failure by kicking that would lead to injuries. **(major)**

J. Surfaces and floors of trailers must be cleaned of dirt, manure and other organic matter prior to the beginning of a shipping event, and must have non-skid material on the trailer floor, such as, wood shavings, rubber non-skid mats etc. **(major)**

III. TRANSPORT PROCEDURES

A. WH&Bs must be loaded at the following rates: **(major)**

1. 12 square feet per adult horse.
2. 6.0 square feet per dependent horse foal.
3. 8.0 square feet per adult burro or yearling horse.

4. 4.0 square feet per dependent burro foal

B. Planned drive time from off-range corral facility to another off-range corral facility, off-range pasture, eco-sanctuary, or adoption must not exceed 24 hours without unloading. (**major**)

C. Trucking companies or haulers must be provided directions and contact phone numbers for the facility or adoption location. **(major**)

D. A transportation event that is longer than 24 hours will require unloading and a minimum rest period of 8 hours with access to hay and water prior to being re-loaded and sent to the final destination. **(major**)

E. While in transit, WH&Bs must be observed by the transport driver a minimum of once every 8 hours. **(major)**

F. Non-ambulatory or recumbent WH&Bs must be evaluated on the trailer and either euthanized or removed from the trailers using a sled, slide board or slip sheet. (**major**)

G. WH&Bs should not be allowed to remain standing on straight-deck and stock trailers while not in transport for a combined period of greater than three (3) hours. (minor)

IV. RECEIVING PROCEDURES

See Section 1. Off-range Corral Standards, Part III. B. 1-5 and 8-11.

SECTION 3.

ADOPTION EVENT STANDARDS

I. ADOPTION EVENT PERSONNEL

A. BLM establishes and implements standards of care, treatment, and handling of WH&Bs, and communicates expectations to all personnel to ensure the humane care and treatment of all WH&Bs at the adoption event. **(major)**

B. The adoption event must have employees with training, skills, and experience to observe, move, and handle the WH&Bs at the event. **(major)**

C. The adoption event must have maintenance staff that can properly maintain the facilities to provide for the safe housing, movement, and processing of the WH&Bs. **(major)**

II. SATELLITE FACILITY DESIGN

A. All satellite facilities must be operated in a manner to provide a safe, clean and supportive environment for all WH&Bs. **(major)**

B. The satellite facility must have a sufficient number of pens available to sort WH&Bs according to sex, temperament, or physical condition as needed. (**major**)

C. The satellite facility's fences, gates, alleys, and working chutes must be constructed of stout materials and must be maintained in proper working condition. (**major**)

D. Fences in adoption pens, alleys, and working chute systems must not be less than 6 feet high for horses and 5 feet high for burros. (**major**)

E. Adoption pen fences must be of stout design and must be maintained in proper condition with no holes, gaps, or sharp edges that could result in WH&Bs being injured. (**major**)

F. Watering systems in WH&B adoption holding pens must provide unlimited access to clean water appropriate for livestock at all times. (**major**)

G. Adoption pen feeding areas must be accessible to all WH&Bs in the pen at the same time. (**major**)

H. Ground surfaces in adoption pens should promote drainage to reduce wet ground conditions. (minor)

I. WH&Bs in pens at the satellite facility should be maintained at a stocking density such that when at rest all WH&Bs occupy no more than half the pen area. (minor)

III. CARE OF WILD HORSES AND BURROS RECEIVED AT SATELLITE FACILITIES

A. Provisions to provide care by a veterinarian in a timely manner on-site, on call, or by transporting an animal to a veterinarian must be made in advance**. (major)**

B. Provisions for medical care (treatments including euthanasia if necessary) at adoption events will be made in accordance with BLM policy and carried out as described above for preparation facilities (Section 1. Off-range Corral Facility Standards, Part IV. A. 1-6). (**major**)

C. WH&Bs must be sorted upon arrival at adoption events into pens with animals of appropriate age and temperament such that animals can promptly begin a period of rest, eating, and drinking with limited disturbance. **(major)**

D. All WH&Bs must have adequate space to move freely within an adoption facility pen. **(major)**

E. WH&Bs, to the greatest extent possible, must be allowed to exist in an undisturbed environment after arriving at an adoption facility until the adoption event begins. **(major)**

F. Quality hay must be provided to WH&Bs in the amount of 2-3% of their body weight per day upon unloading following transport and daily during the adoption event. **(major)**

G. WH&Bs at adoption events may be supplemented with feed or water supplements to address the stress of transport. (minor)

H. WH&Bs will be sorted during the adoption event in a manner to reduce stress and opportunity for injury. (minor)

I. WH&Bs transported for more than 12 hours to an adoption event should be allowed a rest period of 5 hours or more prior to formal viewing by the adopting public. (minor)

IV. EUTHANASIA PROCEDURES AT SATELLITE FACILITIES

See Section 1. Off-range Corral Facility Standards, Part IV. E. 1-4.

V. CARCASS DISPOSAL AT SATELLITE FACILITIES

See Section 1. Off-range Corral Facility Standards, Part IV. F. 1-2.

VI. HANDLING WILD HORSES AND BURROS AT SATELLITE FACILITIES

A. Willful Actus of Abuse

See Section 1. Off-range Corral Facility Standards, Part V. A. 1-5

B. General Handling

See Section 1. Off-range Corral Facility Standards, Part V. B. 1-7

C. Handling Aids

See Section 1. Off-range Corral Facility Standards, Part V. C. 1-2

Abstract: This report describes the successful use of a gonadotropin-releasing hormone (GnRH) vaccine to suppress ovarian steroidogenic activity and to treat hemorrhage and anemia associated with reproductive tract pathology in a 59-year-old Asian elephant (*Elephas maximus*). The Repro-BLOC® GnRH vaccine was administered subcutaneously as a series of 4 boosters of increasing dose from 3 to 30 mg of recombinant ovalbumin-GnRH fusion protein given at variable intervals after initial vaccination with 3 mg protein. Efficacy was confirmed over a year after initial vaccination based on complete ovarian cycle suppression determined by serum progestagen analyses. Estrous cycle suppression was associated with a significant increase in GnRH antibody binding and subsequent decrease in serum luteinizing hormone and follicle-stimulating hormone concentrations. Ultrasonographic examinations of the reproductive tract documented a reduction in uterine size and vascularity after immunization. The hematocrit level normalized soon after the initial intrauterine hemorrhage, and no recurrence of anemia has been detected. No substantive adverse effects were associated with GnRH vaccination. The results indicate that GnRH vaccination in elephants shows potential for contraception and management of uterine pathology in older elephants.

Key words: Contraception, elephant, *Elephas maximus,* gonadotropin-releasing, progestagen, vaccine.

INTRODUCTION

Ovarian function in elephants is similar to that in other mammals and is controlled by secretion of the pituitary gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), presumably under the influence of hypothalamic gonadotropin-releasing hormone (GnRH).[4,5] In general, FSH is responsible for stimulating ovarian follicular growth and development and for the production of estrogens, whereas LH induces ovulation, formation of the corpus luteum, and production of progestagens.[6,25] Elephants are unique in having the longest documented mammalian estrous cycle, of 13–17 wk, and exhibiting two successive waves of follicular development that culminate in two distinct LH surges, with only the second inducing ovulation.[8,9,35]

One documented problem of older female elephants and other long-lived species in captivity is termed asymmetric reproductive aging.[24,28] In the wild, most adult female elephants are either pregnant or lactating; they experience comparatively few reproductive cycles in their lifetime. In captive Asian elephants, primarily nulliparous females over 30 yr of age or those that have not calved within a 10- to 15-yr period, numerous reproductive tract pathologies develop.[24,27–29,44] For example, older Asian elephants often develop endometrial hyperplasia and/or multiple leiomyomata (benign myometrial tumors).[1,27–29,44,45,57] Periodic mucohemorrhagic vaginal discharge can result from these pathologic alterations. These specific conditions have not been reported in wild Asian elephants. Because older cycling cows appear to be particularly susceptible, it has been speculated that continuous steroid hormone (estrogens and/or progestagens) exposure associated with ovarian cyclicity of nonbred females has a negative and cumulative effect on reproductive health and urogenital tract integrity.[1,24,28] To prevent these pathologies from developing, treatments to shut down ovarian activity should be considered if a female is not intended for breeding.

GnRH vaccines have been designed to stimulate the production of anti-GnRH antibodies that

block binding of endogenous GnRH to gonadotrope receptors in the pituitary gland. This action inhibits the release of FSH and LH from the anterior pituitary, thereby causing the cessation of ovarian steroidogenic activity and reproductive cyclicity. Immunization against GnRH has been used successfully to suppress ovarian function in a number of domestic, laboratory, wildlife, and livestock species.[3,10,18,22,23,30,31,36,42,49,55] The primary structure of the decapeptide GnRH is largely conserved in mammals, but by itself is not immunogenic.[23,46] The vaccine in this study was developed by using a recombinant ovalbumin-GnRH fusion protein, marketed under the trade name Repro-BLOC® (Amplicon Vaccine, LLC, Pullman, Washington 99163, USA).[11,20,33,51,56] The adjuvant is a combination of Freund's incomplete adjuvant with a synthetic cytosine guanine oligodeoxynucleotide that mimics the immunostimulatory effects of bacterial deoxyribonucleic acid because of its relatively high content of unmethylated cytosine guanine dinucleotides.[10,11]

This case report describes the use of Repro-BLOC to suppress ovarian cyclicity to prevent hemorrhage and anemia associated with reproductive tract pathologies in an older female Asian elephant at the National Zoological Park. To date, to the authors' knowledge, there are no published reports on the use of GnRH vaccination to control reproductive activity in female elephants. Possible benefits of using this approach to address problems associated with asymmetric reproductive aging as well as for contraception in elephants are discussed.

CASE REPORT

The subject was a 59-yr-old, approximately 3,300 kg, female Asian elephant who had been at the Smithsonian Institution's National Zoological Park for 46 yr. She was housed with a 33-yr-old female Asian elephant and occasionally that female's 6-yr-old male offspring. This female had a relatively unremarkable medical history, with the exception of chronic dental malposition and a small chronic left elbow abscess. At the time of presentation, she was on long-term, low-dose ibuprofen (3,600 mg p.o. s.i.d.) for management of possible discomfort associated with mastication, and a glucosamine and chondroitin supplement (Cosequin® Equine Concentrated Powder, Nutramax Laboratories, Edgewood, Maryland, 21040 USA) intended for maintenance of joint health.

On 14 January 2007, keepers reported that the elephant had a decreased appetite and stool production, mild lethargy, and reluctance to train, particularly for behaviors that involved lying down. A complete blood cell count (CBC) and chemistry panel were unremarkable other than a hematocrit concentration of 30.8% and hemoglobin level of 10.1 g/dl, both at the low end of her historic range (hematocrit concentration, 30–43.7%, average 36%; hemoglobin level, 10.1–14.9 g/dl, average 12.02 g/dl), and an elevated fibrinogen level of 900 mg/dl (range, 200–700 mg/dl; average, 479 mg/dl). Urinalysis, fecal parasite check, fecal cytology, and fecal occult blood were unremarkable. Mild colic of unknown etiology was initially suspected, and clinical signs were rapidly responsive to a 2-day course of treatment with injectable flunixin meglumine (Banamine® 50 mg/ml, Merck Intervet/Schering Plough Animal Health, Summit, New Jersey 07901, USA; 1,000–3,000 mg i.m. s.i.d.). The hematocrit concentration remained relatively stable, at 30.1% on 16 January, and 31.9% on 22 January 2007.

On 29 January 2007, 15 days after initial presentation, the female's appetite and activity had improved, although it was not completely back to normal levels. However, bloodwork showed that the hematocrit concentration had dropped dramatically, to 19.3%, with a hemoglobin concentration of 6.4 g/dl. Repeated samples confirmed the severity of the anemia. There was no evidence of hemolysis and mean corpuscular volume (MCV) (128/fl), mean corpuscular hemoglobin (MCH) (42 pgm/cell), and mean corpuscular hemoglobin concentration (MCHC) (33 g/dl) remained within her normal ranges, but target cells were subjectively increased. Fibrinogen level had returned to within her normal range, at 500 mg/dl. Fecal parasite check and fecal occult blood tests were negative. Urinalysis, fecal cytology, iron panel, mineral panel, estrogen level, and coagulation panel results were within acceptable limits. Based on the diagnostic test results and clinical signs, a recent episode of acute internal hemorrhage was suspected. Empiric treatment with ceftiofur (Naxcel®, Pfizer Animal Health, New York, New York 10017, USA) was administered at 6–8 g i.m. s.i.d. beginning on 29 January 2007, for a total of 23 days.

By 7 February 2007, 24 days after initial presentation, the elephant's appetite and activity had returned to normal baseline levels and s.i.d. to every other day blood samples showed a gradual increase in the hematocrit concentration, to 28.7%, and in the hemoglobin level, to 9.1 mg/dl. At that time, the elephant was given 30 mg detomidine (Dormosedan® 10 mg/ml; Pfizer Animal Health, New York, New York, 10017,

USA) and 30 mg butorphanol i.m. (Torbugesic® 10 mg/ml; Pfizer) for standing sedation in an elephant restraint device to allow for rectal and transabdominal ultrasound evaluation by an experienced elephant ultrasonographer. An additional 10 mg detomidine and 10 mg butorphanol were administered i.m. as a supplement to deepen sedation at approximately 60 min into the procedure. Transabdominal ultrasound was performed on the left side; no evidence of free fluid was identified, and the spleen, part of the caudal liver lobe, and intestinal loops appeared normal. Transrectal examination of the caudal abdomen was performed by using a 3.5 MHz convex transducer to scan the caudal region of the genital tract and by using a 5.0–7.5 MHz transducer attached to a specially designed probe extension to scan the cranial region. The examination revealed a large mass consistent with a blood clot, estimated at more than 18 L, which expanded the vagina and extended into the uterus (Fig. 1A). The uterus was drawn ventrally into the abdominal cavity and could not be examined in its entirety. Visibly enlarged blood vessels were identified on the dorsal surface of the reproductive tract near the cervix (Fig. 1B). Although these vessels were considered likely to be associated with a vascular tumor, no masses consistent with a tumor could be identified, possibly due to the limited visualization of the ventrally displaced uterus. The caudal lobe of the left kidney appeared normal, and no fluid was noted in the caudal pelvic flexure.

The most likely cause for this elephant's episode of colic followed by severe anemia was considered to be hemorrhage into the vagina and uterus. Underlying reproductive tract pathology was strongly suspected. Differentials included leiomyoma, cystic endometrial hyperplasia, uterine artery rupture, neoplasia, or infection, but the etiology could not be definitively determined due to limited visualization of the reproductive tract, which was expanded and weighed down by the suspected blood clot. The decision was made to resolve the reproductive tract pathologies by using a GnRH vaccine (Repro-BLOC).

MATERIALS AND METHODS

The elephant had been conditioned to venipuncture without sedation, as part of the normal management routine. Blood was collected from an ear vein approximately weekly, generally in the morning. The blood sample was maintained at approximately 4°C, allowed to clot at room temperature, then centrifuged (approximately 1,500 *g*) and frozen. Serum was stored at –20°C or colder until analysis.

The Repro-BLOC vaccine was first administered on 27 March 2007 at a dose and dose interval proven effective to sterilize heifers: 3 mg s.c., with a booster vaccination of 3 mg s.c. given approximately 14 wk later, on 3 July 2007.[11] Based on serial evaluation of serum progestagen concentrations and GnRH antibody titers, 3 additional boosters of increasing dosage (7.5 mg on 29 November 2007, 8 mo after initial injection; 12.5 mg on 27 March 2008, 12 mo after the initial injection; 30 mg on 20 November 2008, 20 mo after the initial injection) were given. The total injection volume increased from 4.5 to 22 ml, with increases in dosage; the volume of each dose was divided in two and administered s.c. by hand injection at two sites on the neck.

Management changes during the study interval included no longer asking the elephant to lie down or perform activities that were thought likely to disrupt the blood clot in her reproductive tract and potentiate further hemorrhage. Ibuprofen and Cosequin treatments were discontinued in case they were contributing to any tendency to bleed; no negative clinical effect of this change was observed. Monitoring by keepers included daily assessment of appetite, attitude, and activity level, and for vaccine site reactions, and for any indication of hemorrhage.

CBC and chemistry panels were obtained at least weekly in 2007, at least twice a month in 2008, and at least monthly with twice monthly hematocrit concentration assessments in 2009. Urine was submitted for urinalysis at least twice monthly throughout the years 2007 to 2009, primarily to monitor for hematuria. Follow-up rectal ultrasound examinations under standing sedation as previously described were performed in April of 2007 and April of 2009.

Anti-GnRH antibody titers were determined in sera at a 1:100 dilution by using a ^{125}I-GnRH radioimmunoassay.[33] Titer results were obtained from samples collected approximately weekly from 19 March 2007 (just before the initial vaccination) through 6 February 2008 and then approximately every 2 wk through 6 January 2010. Serum progestagens were analyzed by using a solid-phase ^{125}I-progesterone radioimmunoassay (Coat-a-Count®, Siemens Diagnostic Products Corporation, Costa Mesa, California 92626, USA) validated for elephants.[7] Serum FSH and LH concentrations were quantified by using double antibody ^{125}I radioimmunoassays validated for elephants.[6] Hormone results were analyzed

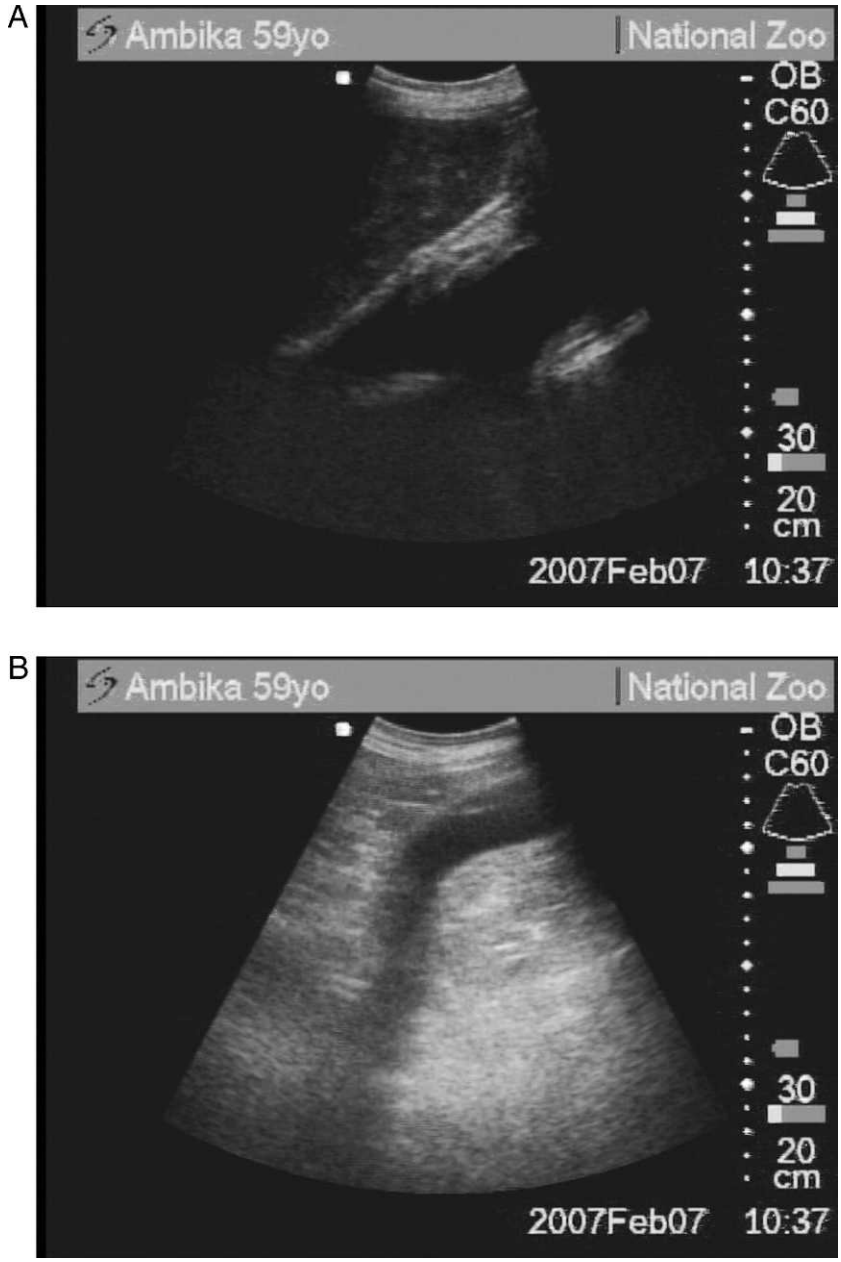

Figure 1. Ultrasound images from the 7 February 2007 examination, showing (**A**) the distended vaginal canal at the top of the image and a suspected blood clot enlarging to the left from the cervix with the urinary bladder below and (**B**) an enlarged blood vessel adjacent to the distended vagina. Images provided by Dr. Dennis Schmitt.

from samples collected approximately weekly from 4 January 2006 to 6 January 2010.

Statistical methods

To determine this elephant's estrous cycle patterns, baseline progestagen concentrations were calculated by using an iterative process previously developed for Asian elephants.[8] All data points with values above the mean plus two times the standard deviation (SD) were removed, and the process was repeated until no values that exceeded the mean plus two times the SD remained. The remaining data points defined the

baseline, and all points above that were considered part of a luteal phase. The highest point in each luteal phase was considered the peak. Estrous cycle duration was calculated as the number of weeks from the first increase in serum progestagens until the next increase. Peaks of LH and FSH levels also were determined by using the same iterative process by excluding values that exceeded the mean plus two times the SD.[8]

Titer and hormone data were subjected to statistical time series analysis and also were modeled with the ASTRA program with SPSS Statistics (ver. 20, 2011, IBM Corp. Armonk, New York 10504, USA) used for simple descriptive statistics, tests of assumptions, and general linear model hypothesis testing and modeling.[50] Autoregressive integrated moving average models were fit to the data for each of the variables. By using these models, the differences in cyclicity over time were examined by trend analysis methods that are related to ordinary least-squares regression.[50] In addition, the relationship over time intervals before and after vaccine introduction was examined. The variables were divided into six intervals based on the timing of vaccine administrations.

RESULTS

Health and ultrasound examinations

The elephant's appetite, attitude, activity, and weight had remained at normal levels with no recurrence of colic throughout the study period. The anemia fully resolved by 14 February 2007, and CBC parameters remained within normal ranges. Chemistry panel values remained unremarkable other than a period of mild intermittent hyperglycemia of undetermined etiology, with a low-level glucosuria in May 2009. Rare trace positive blood results on urine dipstick have been identified without elevations in red blood cells on microscopic urine sediment examination.

Episodes of passage of small volumes of mucohemorrhagic discharge after urination were noted occasionally in 2006 (prevaccination) as well as in 2007 and 2008. Cytologies of this suspected vaginal discharge revealed mild hemorrhage, mild granulocytic, and histiocytic inflammation, and small numbers of gram-positive cocci widely scattered in mucous suggestive of mild vaginitis. Pigment identified within the macrophages was consistent with hemosiderin and suggested breakdown of the ultrasonographically identified blood clot or potentially breakdown of clots from more recent undetected bleeding. This discharge continued intermittently until mid October 2008, approximately 1 mo before administration of the final vaccine booster, and has not been noted in the following 3 yr since this report.

A transient mild localized reaction occurred at both injection sites within 24 hr after the first GnRH vaccination; firm, nonpainful, subcutaneous swellings persisted for approximately 2 mo. A warm, firm, subcutaneous swelling developed as well at both injection sites after the final vaccine administration, which, in contrast to the first vaccination reaction, was sensitive to touch and caused guarded neck movement. The elephant's apparent discomfort resolved with treatment with ibuprofen (6,000 mg p.o. s.i.d.) for 3 days, but the firm subcutaneous swellings have persisted 2 yr later. Other than these local reactions, no negative adverse effects associated with the vaccine had been noted.

A transrectal ultrasound evaluation on 2 April 2007, approximately 11 wk after initial presentation and 6 days after administration of the first GnRH vaccination, revealed an approximately 10-cm-diameter, well-encapsulated, relatively homogenous, soft tissue mass in the cranial vagina. Blood vessels were identified in the capsule but not within the mass itself. Fluid and pseudomembranous tissue surrounded the mass, but there was no evidence of ongoing hemorrhage. Due to the location of the vaginal mass, there was concern that enlargement could compress the urethra and cause obstruction to urine flow and potential renal compromise. The uterus was again difficult to visualize in its entirety but appeared small, irregular, and misshapen, with prominent, visibly enlarged blood vessels, interpreted as being more suggestive of an infectious or neoplastic process than of menopausal changes. Fibrosis and cysts were identified in both kidneys.

A follow-up transrectal ultrasound was performed on 19 April 2009, approximately 5 mo after the last booster was administered and when serum monitoring had indicated cessation of ovarian cyclicity in conjunction with a rise in GnRH antibody titers. A 10-cm diameter vaginal cyst just beyond the opening to the vestibule was observed. Both ovaries appeared small and inactive (Fig. 2A). The uterus was small and indistinct, with a visible decrease in size of the uterine vessels compared with the previous studies (Fig. 2B). The vaginal soft tissue mass identified in April 2007 appeared to have resolved, and no clot or active hemorrhage associated with the reproductive organs was identified. The ultrasound findings supported the hormonal data that indicated cessation of ovarian cyclicity and reproduc-

Figure 2. Ultrasound images from the 19 April 2009 examination, showing (**A**) an inactive ovary and (**B**) the inactive uterus in cross section. Images provided by Dr. Thomas Hildebrandt.

tive quiescence. No progression of the renal changes was identified.

Serum GnRH antibody titer, progestagen, and LH and FSH profiles

GnRH percent binding data in sera diluted at 1:100 is presented in Figure 3A. Time series regression indicated a significant change in binding over time, and a quadratic trend fit to these data showed a monotonically increasing trend ($P = 0.001$). Dividing these time-dependent observations for antibody titers into six time periods starting before the first dosage resulted in significantly different and increasing means ($P < 0.001$), with SDs that increased until time period 4, then decreased (Table 1). The change in GnRH titer remained nonsignificant until after the sec-

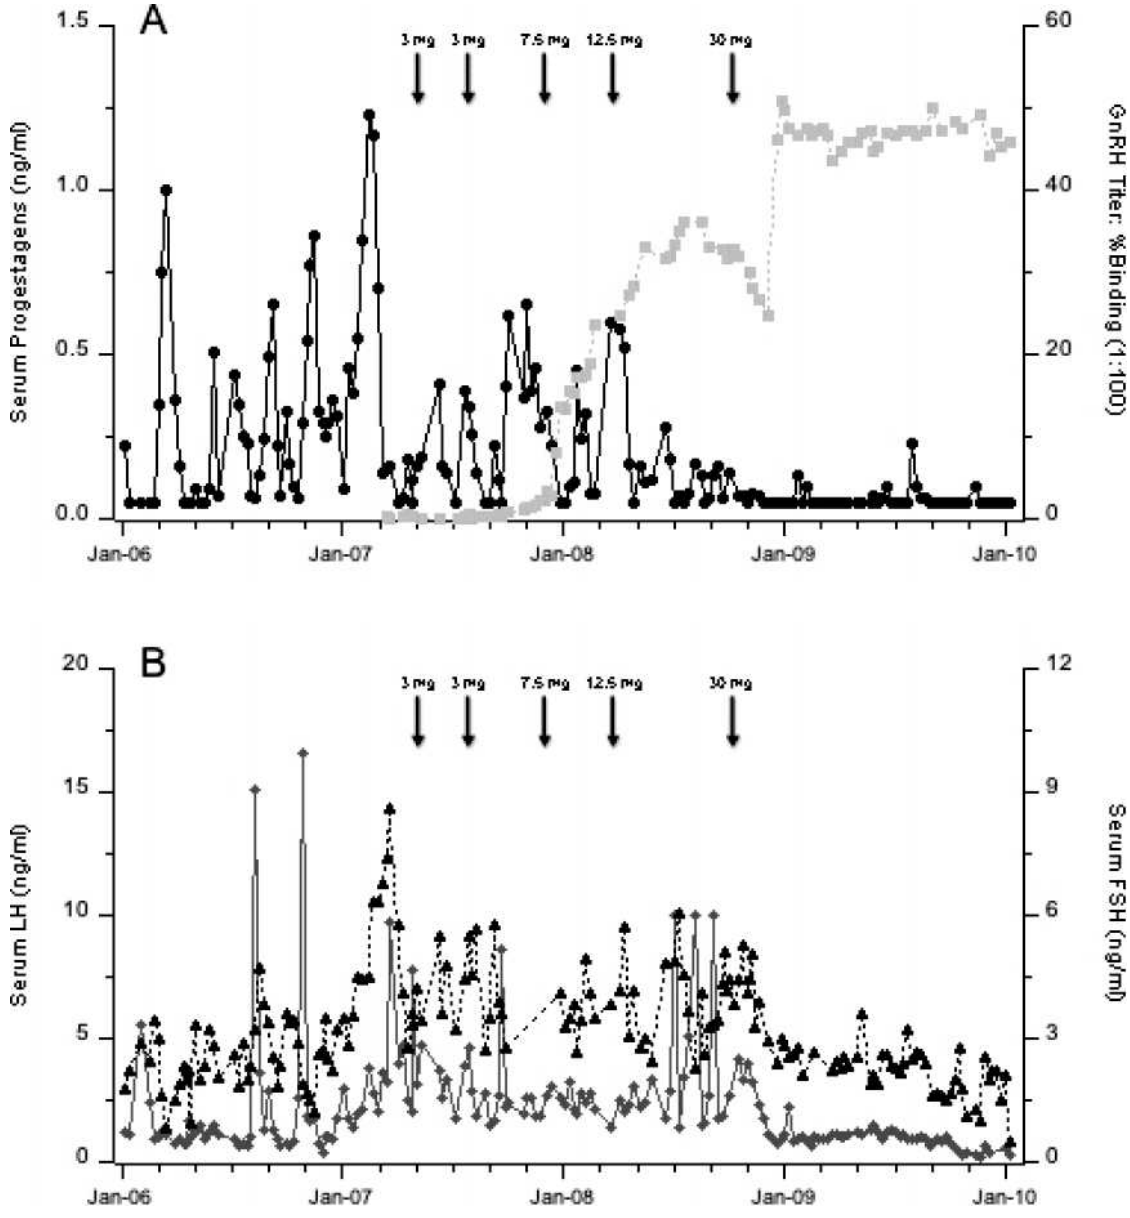

Figure 3. Profiles of (**A**) serum progesterone (●) and gonadotropin-releasing hormone (GnRH) titers (■) indicated by the percentage binding of sera diluted at 1:100; and (**B**) serum luteinizing hormone (LH) (♦) and follicle-stimulating hormone (FSH) (▲) concentrations in an Asian elephant administered a GnRH vaccine. Vaccination dosages were administered at each of five time points indicated by the arrows.

ond 3-mg dose was given on 3 July 2007 in time period 3, after which titers exhibited a continuous and significant increase. The slope of this linear fit was significant as were the two sets of combined observations ($P = 0.001$). The variances, like the means, also were significantly different across these periods ($P = 0.0001$). Although a quadratic trend could be fit, it was apparent that there was a significant change induced after time period 3. In considering all data, there were 2 distinct groups of time periods, which consisted of time periods 1 through 3, and time periods 4 through 6 (Table 1).

The length of the female's estrous cycle before vaccination (time period 1) averaged 14.1 ± 0.5 wk, with a mean peak progestagen concentration of 0.78 ± 0.4 ng/ml (range, 0.45–1.23 ng/ml).

Table 1. GnRH antibody titer, progestagen, LH, and FSH levels, means (SDs) and (ranges), during six time periods, pre- and postvaccination.[a]

Time period	Date range	Vaccine dose (mg)[b]	GnRH antibody Titer (% binding)			Progestagen (ng/ml)			LH (ng/ml)			FSH (ng/ml)		
			n	Mean (SD)	Range	n	Mean (SD)	Range	n	Mean (SD)	Range	n	Mean (SD)	Range

[a] GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; SD, standard deviation.

[b] Vaccine doses were administered on the first day of each of the time periods 2 through 5.

Serum progestagen concentrations decreased after GnRH vaccination, with a definitive cessation in ovarian cyclicity and luteal function after the final 30-mg vaccine dose (Fig. 3A; Table 1). The variances, like the means, were significantly different across time ($P = 0.001$). A linear, not a quadratic trend could be fit to the mean values over the time periods ($P = 0.0001$). However, it was apparent that there was a significant change in progestagen concentrations after time period 3 (Table 1). When considering the prevaccine time period 1 as a baseline, Dunnett's test showed that time periods 3 and 4 were not different from baseline, whereas the subsequent time periods 5 and 6 were lower ($P = 0.013$). The average estrous cycle length through time period 4 was 13.9 ± 0.6 wk, with a mean peak progestagen concentration of 0.45 ± 0.06 ng/ml (range, 0.40–0.65 ng/ml). In time periods 5 and 6, after the 12.5-mg dose, only 4 clear cycles were observed; the average length had decreased to 10.1 ± 0.3 wk, and progestagen peak concentrations had decreased from a high in time period 4 of 0.60 ng/ml to successive declining peak concentrations of 0.28, 0.17, 0.16 and 0.14 ng/ml (Fig. 3A). Thereafter, serum progestagen concentrations remained at or near baseline (<0.07 ng/ml).

After an initial increase compared with the prevaccination baseline (time period 1), mean LH and FSH concentrations decreased, with the greatest effect observed after the final 30-mg booster, more than 1.5 yr after the initial vaccination (Fig. 3B; Table 1). When examined as serial data, only time periods 1 and 6 were statistically different from the remainder ($P < 0.001$). Mean LH, which was more variable, declined to 0.92 ng/ml at time period 6, from a baseline of 2.32 ng/ml, whereas mean FSH declined to 2.23 ng/ml at time period 6, from a baseline of 3.06 ng/ml. The decline in gonadotropin secretion occurred coincident with the suppression of serum progestagen concentrations. This decrease in mean concentrations was associated with a dampening of pulsatile LH and FSH secretion in time period 6, as evidenced by a decrease in the SDs (Table 1). Peak concentrations of LH exceeded 6 ng/ml nine times, and peak concentrations of FSH exceeded 4 ng/ml eight times through time period 5. No significant pulses of LH or FSH were observed in time period 6 after the 30-mg dose was given.

DISCUSSION

This is the first published report, to the authors' knowledge, on the effects of a GnRH

vaccine on health and reproductive function of a female Asian elephant. Altogether, GnRH antibody titer, serum hormone, ultrasonographic, and clinical results strongly suggest that the cessation of ovarian cyclicity and the associated decrease in uterine size and vascularity occurred as a result of GnRH vaccination. The significant increase in GnRH antibody binding was inversely related to a sustained suppression in LH and FSH secretion and in serum progestagens after the final booster was administered. Based on time-series analyses, effects of the vaccine on GnRH and progestagens were evident after the 12.5-mg booster (time period 5), approximately a year after the initial injection. Significant effects on LH and FSH secretion were observed after the final 30-mg booster. The vaccinations were well tolerated, with no adverse effects other than relatively minor localized reactions at the injection sites after two of the five vaccinations. Any appreciable discomfort associated with these subcutaneous swellings resolved quickly. Thus, the results of this current study suggest that GnRH vaccination is a safe and effective method for resolving significant health problems associated with uterine pathologies likely caused by continuous ovarian cyclicity.

Caution in not overinterpreting these results is advised, however, because only one female was studied. A definitive diagnosis of the underlying pathology that led to the strongly suspected hemorrhage into this elephant's reproductive tract and associated severe anemia could not be determined. In addition, it cannot be determined with certainty if this elephant would have hemorrhaged again without therapy. Although analysis of limited laboratory data suggests that female Asian elephants can continue cycling normally into their 60s (Brown, unpubl. data), it is possible that this geriatric female would have stopped cycling naturally without vaccine administration. However, the strong correlation in timing of the rise in GnRH antibody titer with the cessation of ovarian cyclicity, appearance of reproductive quiescence on ultrasound and resolution of intermittent mucohemorrhagic vaginal discharge makes this possibility seem unlikely.

GnRH vaccination has potential for treating reproductive tract disorders, such as endometriosis and ovarian tumors, as well as prostate and breast cancer and other diseases driven by gonadal steroids.[21,34,46,53] In elephants, common pathologies of the reproductive tract, particularly in nulliparous females, include leiomyomata and cystic endometrial hyperplasia. Although these processes are thought to be generally benign, they are suspected to contribute to infertility and could lead to erosion of vessels and associated hemorrhage.[24,28] Cessation of cycling through GnRH vaccination would be expected to decrease the likelihood of negative outcomes with these pathologic conditions, and the likelihood of significant negative adverse effects is considered low.[11,16,18,20,26,39]

Many factors can influence the immune response to GnRH vaccination, including individual genetic and immune status variation, patient age, vaccine dose, species variation in regard to optimal adjuvants, and the conjugant and specific design used in the manufacture of the vaccine.[17,19,20,40,41,48,54] Preliminary evaluation of a GnRH vaccine for control of aggression and musth behavior in bull elephants has shown some degree of variation in the response of individuals, and this phenomenon has been noted in a variety of other species.[2,13,23,30,32,52] More work clearly is needed to optimize the dose and frequency of vaccination when using the Repro-BLOC formulation in elephants, because it took more than a year for the effects to be realized. It is not clear why this elephant required multiple boosters before the desired effect of vaccination occurred. The initial doses administered may have been too low, the dose intervals could have been suboptimal, the adjuvant used may not be as immunostimulatory in elephants as in beef cows, or this individual's immune response could have been compromised due to age or disease status. Other GnRH vaccines are available, some of which are being designed for multiyear contraceptive effects after a single injection and act more rapidly in tested species, within weeks (e.g., GonaCon™, National Wildlife Research Center, USDA-APHIS Wildlife Services, Fort Collins, Colorado 80521, USA), but they have not been evaluated in female elephants.[36,37,41,43] The initial doses of Repro-BLOC used in this study were based on data in cattle in which peak antibody titers were reached 2 wk after administration of a 1.5-mg booster (16 wk after initial injection of 1.5 mg).[11] Based on the progestagen and possibly the FSH results, suppression of ovarian activity in this elephant was not evident until after the 12.5-mg dose, whereas a significant effect on LH was evident only after the final 30-mg dose. However, it cannot be concluded that 12.5 mg is the optimal dosage or that the cumulative effects of multiple doses over time were not significant. But once the response occurred, it has been sustained, and the elephant continues to be reproductively suppressed. Ongoing routine progestagen monitoring that continues to date, con-

tinues to show that concentrations average less than 0.07 ng/ml, 3 yr after the final booster. The reversibility of this vaccine approach in elephants now remains to be determined.

Based on studies in other species, GnRH vaccination also offers exciting possibilities as a new option for potentially reversible contraception in female elephants.[3,18,30,36,41,43] In elephant bulls, GnRH vaccination has shown efficacy in suppressing testosterone production and musth behaviors, presumably by similarly inhibiting pituitary control of gonadal steroidogenic activity.[2,13,14] A carefully managed contraception strategy would be of particular value in areas of high elephant density in close proximity to humans to mitigate human-elephant conflicts and in game parks where protected space and resources are limited. It would be beneficial to compare the efficacy, duration of effect, reversibility, long-term health and genetic effects, and social and behavioral effects of GnRH vaccination in elephants with those of porcine zona pellucida vaccination, which prevents fertilization by blocking sperm binding to the egg and is currently used in female elephants for contraception.[2,12,14,15,38,47] Porcine zona pellucida vaccination would not be efficacious for resolving health problems associated with ovarian steroidogenic activity, however, because contracepted females continue to cycle.

Acknowledgments: The authors thank the staff of the Smithsonian Conservation Biology Institute (SCBI)'s National Zoological Park's Departments of Animal Health, Pathology, and Animal Programs for their contributions to this case. Particular thanks go to curator, Tony Barthel, and biologist, Marie Galloway, for their long-standing dedication to the management and care of our Asian elephants and for overseeing sample collection. The authors also thank Drs. Dennis Schmitt, Thomas Hildebrandt, Frank Goritz, and Robert Hermes for their ultrasound expertise and input into the management of this case. The authors thank Drs. Valeria Conforti and Jerry Reeves for their work in development of the Repro-BLOC vaccine and advice regarding dosing. In addition, we thank SCBI technician, Nicole Parker, for running all of the endocrine analyses. In addition, the authors thank the Smithsonian Institution librarian, Polly Lasker, for her invaluable assistance with obtaining reference materials. The authors are grateful to Amplicon Vaccine for donating the Repro-BLOC vaccine and reagents for antibody testing. Finally, thanks to Ambika for being such a cooperative patient and excellent elephant ambassador.

ABSTRACT: Objectives were to evaluate the administration of an anti-gonadotropin releasing factor (GnRF) analog on suppression of estrus, consistency of feed intake, and growth performance in market gilts and to investigate the impact the physiological changes would have on carcass characteristics and fresh meat quality. Gonadotropin releasing factor stimulates the anterior pituitary to release luteinizing hormone that acts on the ovary to induce follicle development and indirectly initiates ovulation. Improvest (Zoetis, Kalamazoo, MI) contains an incomplete version of naturally occurring GnRF and causes the production of anti-GnRF antibodies that bind to the GnRF receptor and thus render GnRF inactive. This in turn suppresses estrus in female pigs. Gilts were initially separated into 10 blocks based on age and then within each block allotted to a pen (n = 114; 5 pigs/pen) based on BW. Gilts received the first dose at 12 wk of age and the second dose at 16 wk of age, were exposed to a boar daily from 20 to 26 wk of age, and were slaughtered at 26 wk of age (10 wk after second dose). Meat quality was analyzed on the 2 gilts closest to pen average ending live weight in 5 of the 10 blocks. Pen served as the experimental unit for all data analysis. During the 15-wk finishing period, ADG was 0.03 kg greater ($P < 0.01$) and G:F was 0.009 greater ($P = 0.02$) in gilts administered GnRF suppression (treated) compared with untreated gilts (control). The majority of improvements in growth performance were observed from 16 to 20 wk of age (4 wk after second dose), as ADG was 0.07 kg greater ($P < 0.001$) and G:F was 0.021 greater ($P < 0.01$) in treated gilts compared with control gilts. Ovarian weights were reduced ($P < 0.0001$) by 64.15% and gilts exhibiting puberty were reduced by 87.80% ($P < 0.001$) in treated gilts compared with control gilts. Back fat depth was 3.78 mm greater ($P < 0.0001$) and estimated lean was 1.31 percentage units less ($P < 0.0001$) in treated gilts compared with control gilts. With the exception of subjective color, there were no differences ($P \geq 0.12$) in meat quality parameters between treated and control gilts. Subjective color was darker ($P = 0.03$) in treated gilts compared with control gilts. These data suggest market gilts treated with an anti-GnRF analog had suppressed estrus and episodical changes in ADFI, while they had improved feed efficiency, increased ADG, and increased back fat depth when compared with gilts without an anti-GnRF analog treatment.

Key words: estrus suppression, gilt, gonadotropin releasing factor, Improvest

INTRODUCTION

Historically, 3-way crossbred gilts (0.69 kg/d) grew 5.8% slower than contemporary barrows (0.73 kg/d) from weaning until 91 kg BW (Comstock et al., 1944). Today, gilts consume 11.3% less feed, grow 7.3% slower, and yield a 1.53 percentage unit leaner carcass than counterpart barrows (Boler et al., 2014; Puls et al., 2014). Management strategies to increase growth rate and increase feed intake while maintaining feed efficiency in market gilts would be desirable to pork producers in managing pig flow and marketing of barrows and gilts.

Anti-gonadotropin releasing factor (**GnRF**) analog (Improvest; Zoetis, Kalamazoo, MI) is currently used for temporary immunological castration and reduction of boar taint in intact male pigs intended for slaughter.

However, GnRF is a compound both male and female pigs produce naturally; therefore, the opportunity to use an anti-GnRF analog in market gilts exists. In females, GnRF stimulates the anterior pituitary to release luteinizing hormone that acts on the ovary to induce follicle development and indirectly initiates ovulation. Improvest contains an incomplete version of naturally occurring GnRF and causes the production of anti-GnRF antibodies to competitively bind to the receptor, thus suppressing estrus in female pigs. The estrous period accompanying puberty lasts between 4 and 5 d (Eliasson, 1989), and feed intake and growth are typically decreased during this time (Hinson et al., 2012). To date, there has been limited research analyzing the effectiveness of managing market gilts with an anti-GnRF analog to suppress estrus. Even so, gilts managed with an anti-GnRF immunological consumed 5.99% more feed and grew 5.55% faster than control gilts when slaughtered at 125 kg (Latorre et al., 2013). Therefore, the objective of this study was to determine the effects of GnRF suppression for the management of market gilts on growth performance, estrus activity, carcass characteristics, and fresh meat quality.

MATERIALS AND METHODS

Experimental procedures involving animals were approved by the North Carolina State University Institutional Animal Care and Use Committee. No approval was obtained from The Ohio State University Institutional Animal Care and Use Committee for this experiment because only fresh meat was used in that portion of the experiment.

Live-Phase Experimental Design

Five-hundred seventy crossbred gilts (62.1 ± 1.3 d of age; Landrace × Large White × Yorkshire sows mated with 3 crossbred boars composed of Duroc, Hampshire, Pietran, and Spot breeds) were allocated into 10 blocks over a 20-wk period. Blocks were based on farrowing group (age) at the date of allocation. Each block consisted of 3 to 8 replications, based on the number of available gilts, with 5 gilts per pen. Pens contained 4.09 m^2 of useable animal space, so each pig was initially provided 0.82 m^2 of floor space. Each pen had 2 nipple drinkers and a 2-hole feeder to provide ad libitum access to feed throughout the experiment. Two finisher barns were used and each finisher barn had a curtain-sided, underslat ventilation system equipped with thermostatically controlled cooling/stirring fans and misters. At 9 wk of age, gilts were individually weighed, examined, and selected for inclusion of the study (Fig. 1). Within each age block, gilts were allocated by BW and provided a 3-wk acclimation period. At 12 wk of age half of the replicates

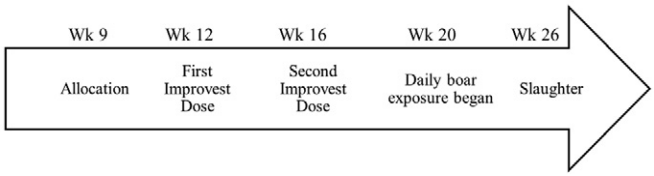

Figure 1. Timeline of study.

in each block were randomly assigned to the GnRF suppression treatment group (treated) and administered 2 mL of an anti-GnRF immunological product (Improvest; each milliliter contains 0.2 mg GnRF analog–diphtheria toxoid conjugate, 150 mg of diethylaminoethyl-dextran hydrochloride, 1 mg chlorocresol, sodium hydroxide as needed to adjust pH, and water for injection; Zoetis, Kalamazoo, MI) while the remaining half were assigned to the untreated group (control). At 16 wk of age, gilts were weighed and treated gilts were administered a second 2-mL dose of the anti-GnRF immunological product (Improvest) and control gilts remained untreated. No placebo injection was administered to control gilts. At 20 wk of age, gilts were weighed and daily boar exposure began. Boar exposure consisted of allowing a mature boar (3 yr old and 340 kg) to move freely in the alley in front of 2 to 3 pens for 10 to 15 min. Daily boar exposure continued until gilts were 26 wk of age. Feed remaining in the feeders was weighed and recorded as feed not consumed on the same day gilts were weighed during wk 9, 12, 16, 20, and 23. Feed remaining in the feeders was weighed on the day after gilts were sent to slaughter. At 26 wk of age, gilts were transported to the processing facility at each of the scheduled slaughter dates and were humanely slaughtered using electrical immobilization and exsanguination. Ovarian weights, ovarian morphology, and HCW (which included weight of the head) were obtained at the slaughter facility.

Carcass Characteristics

Back fat depth and LM area were estimated using real-time ultrasonography at approximately 25 wk of age. Real-time ultrasonography (Aloka 500 V, 3.5 MHz; Corometrics Medical Systems, Inc. Wallingford, CT) was conducted 2 to 5 d before scheduled slaughter date depending on the schedule of the ultrasound technician. These measurements, along with HCW, were used to predict estimated lean weight with the following equation (Burson and Berg, 2001): estimated lean, kg = 5.7769 + (0.401 × HCW, lb) – (18.838 × 10th rib fat depth, in.) + (4.357 × 10th rib loin muscle area, sq. in.) + (1.006 × sex of pig; gilt coefficient = 2). This procedure likely underestimates estimated lean, because HCW of this study included weight of the head. Estimated percent lean was determined by dividing estimated lean by HCW.

Downloaded from www.journalofanimalscience.org at Acquisitions Dept on October 13, 2014

Estrus Activity

Ovarian activity was evaluated using 3 different methods. First, paired ovarian weights were obtained at the slaughter facility. Second, each gilt was given a numerical score based on ovarian morphology according to the following scale: 0 = no visible follicles; 1 = only small follicles present (≤3.0 mm in diam.); 2 = medium follicles present (3.1–5.9 mm in diam.); 3 = large follicles present (≥6.0 mm in diam.); 4 = corpora lutea, corpora hemorrhagica, or corpora albicantia present (1 ovulation cycle); and 5 = corpora lutea or corpora hemorrhagica and corpora albicantia (2 ovulation cycles). Third, the percentage of pens within each treatment that had at least 1 gilt ovulating during the study and the percentage of all gilts within treatments that ovulated were determined.

Meat Quality

Gilts were loaded on trucks on the morning of slaughter and transported approximately 60 km. Gilts were provided a short rest (<2 h) on arriving before slaughter. Meat quality was assessed in 5 of the 10 blocks. The 2 pigs in each pen of a selected block with ending live weights closest to the pen mean weight were selected for meat quality evaluation. A total of 116 loin sections were shipped from the slaughter facility to the meat science laboratory at The Ohio State University. Sections were cut from the posterior section of the 10th rib, vacuum packaged, and shipped under refrigeration. Sections remained vacuum packaged and were stored in a refrigerated cooler (4°C) on arrival. Fresh meat quality was assessed at 7 d postmortem. Initially, sections were faced and allowed at least 15 min to bloom. The piece removed from face was used to determine proximate composition (percentage moisture and fat). The loin sample was trimmed of all subcutaneous fat and homogenized in a food processor. A 10-g sample was oven-dried at 100°C for at least 24 h to determine moisture percentage. The dried sample was washed multiple times in warm petroleum ether to remove fat using the modified procedure from Novakofski et al. (1989). The fresh cut surface was evaluated for subjective color (1 = pale pinkish gray to white, 2 = grayish pink, 3 = reddish pink, 4 = dark reddish pink, 5 = purplish red, and 6 = dark purplish red; NPPC, 1999), marbling (1 through 10 corresponding to intramuscular lipid content; NPPC, 1999), and firmness (1 = soft; cut surface distorts easily; 2 = firm; cut surface tends to hold shape; and 3 = very firm; cut surface were very smooth with no distortion of shape; NPPC, 1999) by trained Ohio State University personnel and recorded in whole numbers. The surface was evaluated for ultimate pH using a handheld Hanna HI 99163 pH meter (Hanna Instruments; Woonsocket, RI.) and was evaluated for objective CIE L*, a*, and b* with a Minolta CR-400 (Konica Minolta; Chiyoda, Tokyo, Japan) using a D65 light source and a 0° observer and an aperture size of 50 mm. The remaining section was then cut into 1 chop cut 1.25 cm thick and 1 chop cut 2.54 cm thick. Water holding capacity was evaluated using the drip-loss method where the 1.25 cm thick chop was suspended from a fish hook in a Whirl-pak bag (Nasco; Fort Atkinson, WI) for approximately 24 h at 4°C. Chops were weighed before and immediately after suspension for 24 h. Results were reported as a percent of weight loss. Chops designated for Warner-Bratzler shear force (2.54 cm thick) testing were vacuum packaged and immediately frozen until further evaluation. Twenty-four hours before analysis, chops were removed from the freezer and placed in a cooler at 4°C to thaw. Chops were trimmed of excess fat and cooked on a clamshell-type grill. Chops were cooked to a final internal temperature of 70°C. Internal temperature was monitored using copper-constantan thermocouples (Type T; Omega Engineering, Stanford, CT) connected to a digital scanning thermometer (model 92000-00; Barnant Co., Barington, IL). Next, chops were allowed to cool to 25°C and four 1.25-cm diam. cores were removed parallel to the orientation of the muscle fibers. Cores were sheared using a Texture Analyzer TA.HD Plus (Texture Technologies Corp., Scarsdale, NY/Stable Microsystems, Godalming, UK) with a blade speed of 3.3 mm/s and a load cell capacity of 50 kg. A single shear force was determined on each of the 4 cores. Shear force was reported as the average of the 4 cores. Cook loss was determined by weighing chops used for shear force immediately before and after cooking. Reported values are percent weight lost during cooking.

Statistical Analysis

Data were analyzed with the MIXED procedure in SAS (SAS Inst. Inc., Cary, NC) as a randomized complete block design with the fixed effect of treatment and the random effect of replication nested within block. Pen served as the experimental unit for all analysis, with the exception of gilts exhibiting puberty, which used pig as the experimental unit. Statistical differences were considered significant at $P \leq 0.05$ and tendencies at $0.05 < P \leq 0.10$ using a 2-tailed test.

RESULTS

Growth Performance

Results for growth performance are presented in Table 1. From 12 to 16 wk of age (time between first and second dose), ADG was not different ($P = 0.52$) between treated and control gilts. Average daily feed intake was 0.09 kg (3.80%) less ($P = 0.04$) in treated gilts. Feed efficiency (G:F) was not different ($P = 0.19$). From 16 to 20 wk of age (0–4 wk after second dose, before boar exposure),

[1]Gilts received a 2-mL subcutaneous injection of Improvest (Zoetis, Kalamazoo, MI) at 12 and 16 wk of age (initial BW at 12 wk of age = 38.23 kg). Gilts were slaughtered at 10 wk after second dose.

[2]Twelve- to sixteen-week period was between first and second Improvest dose (16-wk BW = 61.76 kg).

[3]Sixteen- to twenty-week period was after second injection but before boar exposure (20-wk BW = 85.63 kg).

[4]Twenty- to twenty-three-week period was after initiation of boar exposure but likely before estrous period (23-wk BW = 102.20 kg).

[5]Twenty-three- to twenty-six-week period was after initiation to boar exposure and likely during estrous activity (26-wk BW = 118.51 kg).

[6]Sixteen- to twenty-six-week period was after second injection until slaughter.

ADG was 0.07 kg (8.54%) greater ($P < 0.001$) in treated gilts. Average daily feed intake was not different ($P = 0.28$). Feed efficiency (G:F) was 0.021 (7.12%) greater ($P < 0.01$) in treated gilts. From 20 to 23 wk of age (4–7 wk after second dose and during boar exposure), ADG was 0.05 kg (6.02%) greater ($P = 0.01$) in treated gilts. Average daily feed intake was 0.12 kg (3.87%) greater ($P = 0.01$) in treated gilts. Feed efficiency (G:F) was not different ($P = 0.16$). From 23 to 26 wk of age (7–10 wk after second dose and during boar exposure), ADG was not different ($P = 0.73$). Average daily feed intake was not different ($P = 0.89$). Feed efficiency (G:F) was not different ($P = 0.66$). During the entire finishing period (12 to 26 wk of age), ADG was 0.03 kg (3.66%) greater ($P < 0.01$) in treated gilts. Average daily feed intake was not different ($P = 0.67$). Feed efficiency (G:F) was 0.009 (3.09%) greater ($P = 0.02$) in treated gilts. Overall, treated gilts grew faster and were more feed efficient throughout the finishing period than control gilts (Table 1).

Table 2. Effect of immunological gonadotropin releasing factor suppression on carcass characteristics of market gilts

	Management			
Parameter	Control	Treated[1]	SEM	*P*-value
Pens, *n*	57	57		
Initial live weight,[2] kg	38.43	38.02	0.68	0.18
Final live weight,[3] kg	117.39	119.63	1.18	0.05
HCW (including head weight), kg	96.19	97.62	1.00	0.16
Back fat depth,[4] mm	21.75	25.53	0.05	<0.0001
LM area,[4] cm^2	45.13	45.20	0.64	0.91
Estimated lean,[5] kg	48.46	48.11	0.44	0.46
Estimated lean,[5] %	50.53	49.22	0.21	<0.0001

[1]Gilts received a 2-mL subcutaneous injection of Improvest (Zoetis, Kalamazoo, MI) at 12 and 16 wk of age. Gilts were slaughtered at 10 wk after second dose.

[2]Initial weight was taken at 12 wk of age.

[3]Final weight was taken at 26 wk of age.

[4]Real-time ultrasonography images were used to estimate LM area and back fat depth 2 to 5 d before slaughter.

[5]Estimated lean was calculated using a modified version of procedure 6 of the procedures for estimating pork carcass composition (Burson and Berg, 2001).

Carcass Characteristics

Results for carcass characteristics are presented in Table 2. Tenth rib LM area was not different ($P = 0.91$) between treated and control gilts. Tenth rib back fat depth was 3.78 mm (17.38%) greater ($P < 0.0001$) in treated gilts. Hot carcass weight was not different ($P = 0.16$). Estimated weight of the lean (an equation including LM area, back fat depth, and HCW; Burson and Berg, 2001) was not different ($P = 0.46$). Yet estimated lean percentage was 1.31% units less ($P < 0.0001$) in treated gilts. Overall, these data suggest that when slaughtered at 10 wk after second dose, treated gilts had more fat and a reduction in estimated carcass lean percentage compared with control gilts; however, muscling and estimated lean weight were not different between treated and control gilts (Table 2).

Estrus Activity

Results for estrus activity are presented in Table 3. Ovarian weights were 6.80 g (64.15%) lighter ($P < 0.0001$) in treated gilts compared with control gilts. Ovarian activity scores were 1.80 (75.00%) less ($P < 0.0001$) in treated gilts. Pens with at least 1 pubertal gilt were 28.10% units less ($P < 0.001$) in treated gilts. Gilts exhibiting puberty were reduced ($P < 0.001$) by 18.00% units in treated gilts. Overall, administering the

[1]Gilts received a 2-mL subcutaneous injection of Improvest (Zoetis, Kalamazoo, MI) at 12 and 16 wk of age. Gilts were slaughtered at 10 wk after second dose.

[2]Values assessed using National Pork Producers Council (NPCC, 1999) standards and recorded in whole numbers.

anti-GnRF analog (Improvest) was an effective method for suppressing estrus in market gilts; however, it did not completely eliminate signs of puberty in market gilts. Possible explanations could be that when slaughtered at 10 wk after second dose (the maximum marketing window for male pigs), the GnRF analog immunity was beginning to diminish and dropped below suppressive antibody levels potentially allowing puberty to develop after antibody titers have degraded to a level lower than the level necessary to elicit an immune response.

Meat Quality

Results for meat quality are presented in Table 4. Subjective color evaluation scores were darker ($P = 0.03$) in treated gilts compared with control gilts. At the same time, objective color scores (L*, a*, and b*) were not different ($P \geq 0.50$) between treated and control gilts. All other meat quality traits evaluated (including marbling, firmness, pH, drip loss, cook loss, shear force, percentage moisture, or percentage fat) were not different ($P \geq 0.12$). Overall, meat quality parameters were not different between gilts administered the anti-GnRF analog (Improvest) and control gilts (Table 4).

DISCUSSION

The improved growth performance (Dunshea et al., 2001; Fàbrega et al., 2010) and carcass cutability (Boler et al., 2012) associated with male pigs immunologically castrated with an anti-GnRF analog in comparison to physically castrated barrows has been well documented. Dunshea et al. (2013) reported, via meta-analysis, that ADG was greater (0.16 kg) and back fat depth was less (2.64 mm) in immunologically castrated males when compared with physically castrated barrows. Immunologically castrated barrows had greater ADFI (0.43 kg), which resulted in greater ADG (0.12 kg), and an improved feed conversion ratio when compared with entire males, although back fat depth was also increased (1.53 mm; Dunshea et al., 2013). Therefore, immunologically castrated barrows have advantages in growth rate when compared to physically castrated barrows and entire males and have less back fat depth than physically castrated barrows but have more back fat depth than entire males.

The management of gilts with an anti-GnRF analog has been considerably less well documented. Puberty of gilts occurs before marketing (less than 180 d) but is very dependent on genetics and management factors (including nutrition, exposure to boars, and growing season; Evans and O'Doherty, 2001). These data suggest gilts managed with an anti-GnRF analog had increased growth rates and improved feed efficiency compared with control gilts. Albeit, when slaughtered at 10 wk after second dose, gilts managed with an anti-GnRF analog had greater back fat thickness and reduced estimated lean percentage compared with control gilts. These findings were comparable with other available data. Among the limited available information, Latorre et al. (2013) reported gilts slaughtered at approximately 125 kg BW (67 kg of BW gain after second dose) managed with an anti-GnRF analog had greater ADG (0.99 vs. 0.94 kg) than control gilts but also had greater ADFI (2.83 vs. 2.67 kg) than control gilts; therefore, feed conversion was not different between treated and control gilts. Differences in response between the 2 studies was likely

Downloaded from www.journalofanimalscience.org at Acquisitions Dept on October 13, 2014

due to the present study ending at a fixed time and Latorre et al. (2013) ending at a fixed weight (125 kg). Even so, treated gilts in the current study grew 5% faster and were over 3% more feed efficient than control gilts without affecting feed intake during the finishing phase from the second injection through slaughter. Gómez-Fernández et al. (2013) reported treated gilts (slaughtered 14 wk after second dose, at approximately 170 kg) had greater ADG (0.84 vs. 0.80 kg), ADFI (3.48 vs. 3.21 kg), and reduced feed conversion (Feed:Gain; 4.16 vs 4.04) compared with control gilts. Furthermore, Gómez-Fernández et al. (2013) reported ending live weight and HCW tended to be greater in treated gilts compared with control gilts. Although Gómez-Fernández et al. (2013) did not report 10th rib LM area and back fat thickness, they did report that trimmed shoulder, loin, and trimmed ham were lower yielding in treated gilts compared with control gilts.

Finally, in a study where gilts were slaughtered at 4 wk after the second dose, treated gilts grew 18% faster than control gilts but also consumed 18% more feed (Oliver et al., 2003). Therefore, feed efficiency was not different between treated and control gilts. The management of market gilts with an anti-GnRF analog is a novel concept to increase ADG and ADFI and in turn increase carcass weight with more desirable levels of carcass fat and marbling without exaggerated detrimental impacts on feed efficiency. In this study, treated gilts had slightly greater back fat and reduced estimated lean percentage and numerically increased fat content (0.24%, or approximately a 10% increase) in the LM when gilts were slaughtered 10 wk after the second dose.

Market gilts tend to have leaner carcasses in comparison to physically castrated barrow counterparts (Ekstrom, 1991). From a U.S. pork packer perspective, gilts are consistently leaner and have more carcass muscle resulting in greater carcass cutability (Boler et al., 2014). However, a greater proportion of gilts can have carcasses that are considered excessively lean for the U.S. packing industry standards and have loin muscles with less marbling or fat content than counterpart barrows (Boler et al., 2014). Additionally, lean gilt carcasses can yield bellies that are excessively lean and thinner than bellies considered ideal to process under commercial conditions to optimize belly value (Kyle et al., 2014). Further research is warranted to better understand appropriate age and timing of slaughter after second dose to optimize lean growth, carcass fat deposition, carcass characteristics, and determine carcass cutability.

Abstract. The aim of this study was to evaluate the effect of active immunisation against GnRH on ovarian activity and serum progesterone concentrations in a large group of mares (10 control and 55 experimental) under field conditions as a model for wildlife species such as zebra and African elephants. Within the experimental group, mares were subdivided into three age categories: Category 1 (4 years and younger, $n = 26$), Category 2 (4–10 years old, $n = 18$), and Category 3 ($\geq$11 years old, $n = 11$). Experimental mares were vaccinated intramuscularly with 2 mL (400 μg) of the GnRH vaccine Improvac (Pfizer Animal Health, Sandton, South Africa). Control mares received the same amount of saline solution. The vaccinations were repeated 35 days later. The ovaries and reproductive tracts of each mare were examined by means of rectal palpation and ultrasonography on Days 0, 35 and 70. Blood was collected weekly for determination of serum progesterone concentration until Day 175. On Day 35 after primary vaccination all of the control mares and 14.5% of the experimental mares showed evidence of ovarian activity on the basis of clinical examination and serum progesterone concentration. On Day 70, all control mares and none of the experimental mares showed evidence of cyclic activity. No age-related effect within treatment groups was found. The serum progesterone concentration indicated that all experimental mares remained in anoestrus until Day 175. Five of the control mares fell pregnant between Days 35 and 70. The five non-pregnant control mares continued to cycle until the end of the observation period. Having achieved such promising results in this trial we now plan to test the GnRH vaccine in Burchell's zebra mares and African elephant cows.

Introduction

Contraception as a means of population management of captive wildlife species is well established. Methods that have been used include separation of sexes, surgical techniques and steroid hormone implants. The safety, practicality and reversibility of methods have enjoyed more attention in recent years, particularly where endangered and rare species are involved. Because of developments during the last 15 or so years it has become possible to successfully apply some methods for the management of free-ranging wildlife populations. Typical examples of these are the use of the porcine zona pellucida (pZP) vaccine to control reproduction in wild horses (Kirkpatrick *et al*. 1982, 1990; Kirkpatrick and Turner 2002) and white-tailed deer (Naugle *et al*. 2002; Rutberg *et al*. 2004).

In mares, the control of reproductive activity is a vital management aspect from both a fertility and behavioural perspective. Anecdotally, oestrous behaviour may negatively influence the performance ability of mares engaged in work and competition events (Elhay *et al*. 2007).

In the past, fertility control and the suppression of aggressive and sexual behaviour in horses was successfully managed by administration of progesterone or progestagens, in oral or injectable formulation, to simulate dioestrus. The high costs and the frequent administration associated with the administration of progesterone or progestagens and the short duration of action made their use impractical. A potential negative effect on future reproduction after repeated administration of progesterone or progestagens in prepubertal fillies has also been described (Skelton *et al*. 1991).

The major alternative to pharmacological manipulation for long-term control of reproductive cyclicity and behaviour involves the surgical removal of both ovaries (ovariectomy). Ovariectomy is invasive and also associated with various complications. After this procedure, some mares may still show signs associated with oestrous behaviour (Ginther 1979; Asa *et al*. 1980; Hooper *et al*. 1993). The factors of cost, associated trauma, potential postoperative complications, production setbacks and the irreversible loss of breeding potential make this method difficult to implement (D'Occhio 1993). Ovariectomy is therefore considered undesirable unless circumstances are exceptional.

Recent studies on the use of gonadotropin-releasing hormone (GnRH) vaccination for suppression of fertility, aggressive and sexual behaviour have shown promising results. Vaccination entails the administration of a modified form of the GnRH hormone in order to stimulate the production of anti-GnRH antibodies. These antibodies then bind to the endogenous GnRH and inhibit the natural binding of this molecule to its

receptors on the pituitary gonadotropes. This results in suppression of secretion of both follicle-stimulating hormone and luteinising hormone at the level of the pituitary.

Immunocastration by means of GnRH vaccination as an alternative to surgical castration to control unwanted male characteristics and behaviour has been studied in male animals of different species, including bulls (Jago *et al*. 1997), stallions (Malmgren *et al*. 2001; Stout 2001; Turkstra *et al*. 2005; Burger *et al*. 2006), Chinese pigs (Zeng *et al*. 2001), lambs (Janett *et al*. 2003), rats, dogs and rams (Ferro *et al*. 2004), African elephants (Bertschinger *et al*. 2004; Delsink *et al*. 2004), cats (Levy *et al*. 2004; Robbins *et al*. 2004), puppies (Jung *et al*. 2005) and feral swine (Killian *et al*. 2006).

The use of the commercially available GnRH vaccine (Improvac, Pfizer Laboratories, Sandton, South Africa) in boars eliminates boar taint and enhances growth performance in uncastrated male pigs (Dunshea *et al*. 2001; Chumkam and Ravungsook 2003).

In stallions and colts the semen quality of animals vaccinated with a GnRH vaccine deteriorated but the production of semen was never completely suppressed (Dowsett *et al*. 1996; Malmgren *et al*. 2001; Turkstra *et al*. 2005; Burger *et al*. 2006). The shedding status of stallions infected with equine viral arteritis was also converted to non-shedder status in vaccinated stallions (Burger *et al*. 2006).

The effect of GnRH vaccination in female animals of various species (including deer, wild rats and bison) has also been reported. With the use of an early form of a GnRH vaccine it appeared that GnRH vaccination is not an effective means of contraception in deer (Becker *et al*. 1999). However, a larger and more comprehensive study on immunocontraception of white-tailed deer (Miller *et al*. 2000) showed immunocontraception of deer to be effective. Female white-tailed deer treated with GnRH immunocontraceptive vaccine showed fewer oestrus cycles per female than either females treated with a porcine *zona pellucida* (PZP) vaccine or an untreated control group (Curtis *et al*. 2001). In wild rats, GnRH vaccine was found to be more effective than mouse *zona pellucida* peptide vaccine (Miller *et al*. 1997). Finally, a single dose of GnRH vaccine prevented pregnancy in female bison for ≥1 year (Miller *et al*. 2004).

In mares, the few studies to date report a successful but variable effect on suppression of ovarian activity and corresponding prevention of oestrous behaviour in adult mares. These studies have, in most instances, been limited by relatively small numbers of mares: in 10 mares (≥2.5 years of age) (Garza *et al*. 1986), in six mares (2 years of age) (Tshewang *et al*. 1997), in four mares (age range: 6–14 years) (Dalin *et al*. 2002), in seven mares (Stout *et al*. 2003), in 18 mares (age range: 3–17 years) (Imboden *et al*. 2006). In only one study was a relatively large population of 48 mares (age range: 3–12 years) studied (Elhay *et al*. 2007). In addition, an effect of mare age on treatment response has been reported in some studies (Dalin *et al*. 2002; Stout *et al*. 2003), with significant injection-site reactions observed in older mares (Stout *et al*. 2003).

The aim of the present study was to investigate the effects of active immunisation against GnRH on reproductive cyclicity in a large group of mares of different age categories and to monitor the effect of vaccination and mare age on injection-site reactions. A secondary aim of the study was to use the domestic mare study as a model for contraception of zebra mares and African elephant cows.

Materials and methods

Experimental design

A total of 65 mares, of either barren or maiden reproductive status, of various horse breeds and between 3 and 17 years of age from the Mounted Unit of the South African Police Services were used for this trial. The trial was approved by the Animal Use and Care Committee of the Faculty of Veterinary Science of the University of Pretoria (V068/05). The mares were housed in outdoor paddocks or extensive pastures for the duration of the trial. They were assigned to either a control ($n = 10$) or an experimental ($n = 55$) group. For management purposes, all experimental mares were excluded from breeding attempts whereas certain control mares were later assigned for breeding. Within the experimental group, mares were subdivided into one of three age categories: Category 1 (4 years and younger, $n = 26$), Category 2 (5–10 years old, $n = 18$), and Category 3 (≥11 years old, $n = 11$).

GnRH immunisation

On Day 0, mares from all three age categories of the experimental group were injected with 2 mL Improvac (400 µg RnRF-protein conjugate) (Pfizer Animal Health, Sandton, South Africa) intramuscularly into the left gluteus muscle, whereas all mares from the control group received 2 mL of a sterile saline solution using a 20-gauge, $1\frac{1}{2}''$ needle (Terumo Corporation, Tokyo, Japan). The subsequent booster vaccination (2 mL) was administered into the right gluteus muscle 35 days after the primary vaccination (J. F. Kirkpatrick, pers. comm.).

Transrectal monitoring of the reproductive tract

On Day 0, all mares were examined by means of transrectal palpation and ultrasound of the internal genitalia using a 5-MHz linear array probe (Aloka Echocamera SSD-500, Aloka Mitakashi, Tokyo, Japan) to establish their reproductive status. All clinical findings were recorded on a standardised data-capture form.

Ovarian activity was described using mean ovarian volume. The length, height and width of the left and right ovaries were estimated on transrectal palpation for each mare. These were used to calculate the ovarian volume using the prolate ellipsoid formula (length × height × width × 0.523) (Pavlik *et al*. 2000). The mean ovarian volume for each mare was calculated as the average of the left and right ovarian volume. The diameters of all ultrasonographically visible follicles ≥2 cm and the presence and number of *corporae luteae* (CLs) were also recorded.

The dimensions of the uterine horns and body and cervix were also estimated on transrectal palpation and their palpable tone was scored. The observed uterine oedema patterns were scored and the presence of intraluminal uterine fluid and other ultrasonographically visible abnormalities were recorded. A subjective scoring system was used to grade the degree of observed endometrial oedema to reflect changes in circulating oestrogen and progesterone concentrations that define oestrus status (Hayes *et al*. 1985): 0 (no oedema with a homogeneous echo texture), 1 (the least amount of detectable uterine oedema),

2 (moderate amount of oedema throughout), and 3 (most obvious oedema throughout the whole uterus, typical 'wagon-wheel' appearance). The gynaecological data collection was repeated on Days 35 and 70.

Blood sampling

Blood samples were collected by means of jugular venipuncture commencing on Day 0 (6 December), approximately the midway point of the Southern Hemisphere physiological breeding season, and repeated at weekly intervals until Day 175 (29 May), which is approximately the onset of the non-ovulatory season. The blood samples were collected in plain Vacutainer tubes (BD Vacutainer Systems, Plymouth, UK) and left to allow clotting. Serum was separated by centrifugation (4000*g*, 10 min) on the same day as sample collection. The labelled samples were stored at −20°C until assayed for serum progesterone concentration.

Serum progesterone assay

Assay for serum progesterone concentration were conducted by means of Radioimmunoassay (Coat-a-Count, Diagnostic Products Corp, Los Angeles, CA, USA).

Injection site reactions

Mares were observed daily in their enclosures by the same operator for one week after the vaccinations for injection-site reactions. Reactions at the injection site were scored as follows: 0, no visible reaction; 1, visible swelling; and 2, visible swelling accompanied by lameness.

Statistical analysis

All data were analysed using Systat 12 (Systat Software Inc., San Jose, CA, USA), using an analysis of variance (ANOVA) of treatment and age on clinical variables for general linear models to assess the level of significance. Significance was set at $P < 0.05$

Results

Transrectal monitoring of the reproductive tract

On Day 0, all control and experimental mares showed clinical evidence of cyclic reproductive activity on clinical examination. On Day 35 after the primary vaccination, all control mares and only 8 of 55 (14.5%) experimental mares showed evidence of ovarian activity on clinical examination. On Day 70 after the primary vaccination, all control mares and none (0%) of the 55 experimental mares showed evidence of ovarian activity on clinical examination. There was no difference between the volumes of the left and right ovaries within individual mares and therefore the mean ovarian volume of each animal at each examination was subjected to further statistical analysis. The mean ovarian volumes of both groups of mares on the days of primary (Day 0) and booster (Days 35) vaccinations and on Day 70 of the trial are shown in Fig. 1.

There was a significant treatment effect on ovarian volume between the control and experimental mares; no age effect was seen within the experimental groups. All clinical variables of the reproductive tract observations recorded are summarised in Table 1.

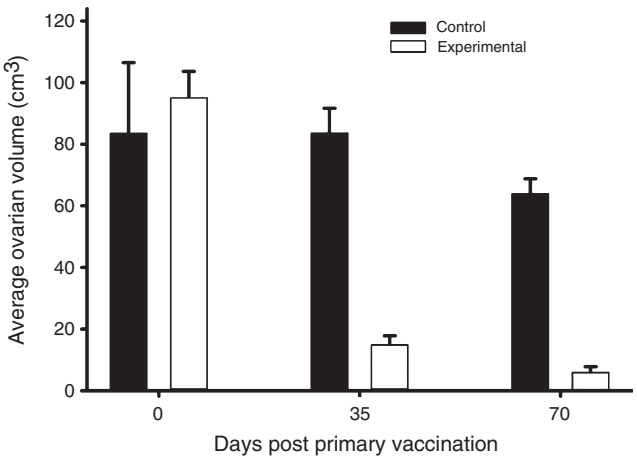

Fig. 1. Mean volume (±s.e.) of the ovaries in control and experimental groups on Day 0 (day of first vaccination), Day 35 (day of second vaccination) and Day 70.

Serum progesterone concentration (SPC)

The serum progesterone concentrations of the control and experimental groups over the 175-day observation period are shown in Fig. 2. Within the experimental group there was no effect of age on SPC ($P = 0.452$) whereas between the two treatment groups there was a significant difference ($P < 0.001$). Five of the control mares were mated and fell pregnant between Days 35 and 70. The remaining five control mares continued to cycle until the end of the observation period (Day 175).

Injection-site reactions

The control mares showed no injection-site reactions to the intramuscular saline injections. Table 2 shows the side effects due to GnRH vaccination in experimental mares. The side effects were transient by nature and by Day 6 were no longer visible. No age-related effect was observed.

Discussion

The effects of GnRH vaccination on a large group of experimental mares on both the reproductive tract (Fig. 1, Table 1) and SPC (Fig. 2) were observed. These effects were shown to be rapid in onset and statistically significant.

Thirty-five days after the primary vaccination, only eight (14.5%) of the experimental mares showed evidence of cyclic ovarian activity. By Day 70 (35 days after the booster vaccination) all experimental mares showed suppressed ovarian activity. For this trial cyclic inactivity was characterised by the absence of any follicle >2 cm in diameter, no visible CL and SPC <1 nmol/L. This effect was significant (and bilateral, as described by Imboden *et al.* 2006), with a marked decrease in the mean ovarian volumes as well as in concurrently observed changes to the dependant variables characterising ovarian structures and the tubular genitalia (cervix and uterus). The ovaries were uniformly small and apparently inactive with follicular atresia, similar to seasonally anoestrus mares (Dalin *et al.* 2002; Elhay *et al.* 2007). The tubular genitalia also showed atrophy typical of seasonal anoestrus. Two GnRH vaccinations (Improvac)

35 days apart apparently resulted in the effective downregulation of ovarian activity in all 55 experimental mares.

The small percentage of mares that still showed evidence of ovarian activity and progesterone secretion after the initial vaccination is probably due to individual variation in cyclic status at the time of initial vaccination. The eight mares (14.5%) that were still cyclic 35 days after the initial vaccination were all in the luteal phase at the time of the vaccination (on the basis of both clinical findings and SPC values of >1 nmol/L). This supports the findings that the stage of oestrous cycle and nature of ovarian structures at first administration of vaccine is of importance in terms of the observed response (Tshewang *et al*. 1997; Dalin *et al*. 2002; Imboden *et al*. 2006).

The SPC was shown to provide a reliable indication of ovarian activity for both group and individual monitoring of the response to GnRH vaccination of a relatively large number of mares. The SPC clearly characterises the effect of GnRH vaccination on the ovarian activity of the mares. Following the primary vaccination, eight mares still showed signs of ovarian activity, whereas after the second vaccination no luteal activity was evident. Baseline SPC persisted until the end of the observation period on Day 175. Once again, there was no age effect within the experimental group, contrary to the findings of Tshewang *et al*. (1997) and Dalin *et al*. (2002). On Days 42, 49 and 56 there were 3, 1 and 1 mares, respectively, with SPC >1 nmol/L. Thereafter, and until the end of the observation period, SPC of all experimental mares remained <1 nmol/L. This is well below the threshold value of 6 nmol/L quoted by Elhay *et al*. (2007). In comparison, all five non-pregnant control mares showed SPC indicative of ovarian cyclicity.

Five of the control mares became pregnant during the course of the observation period. This would explain the large increase in standard error obtained between Days 80 and 110. While the non-pregnant control mares continued to cycle until the end of the observation period (Day 175), none of the experimental mares resumed cyclicity. This probably reflects antibody titres that were still sufficiently high to neutralise endogenous GnRH. As a result, insufficient gonadotropins were available to resume normal ovarian activity. The relatively late stage of the physiological equine breeding season may also have contributed to this observation.

The efficacy achieved with the Improvac GnRH vaccine in our trial was greater than that stated in earlier reports (Garza *et al*. 1986; Tshewang *et al*. 1997; Stout *et al*. 2003). Likely explanations for this are improvements in the antigen and adjuvant used in the final vaccine formulation that evoke a better, more consistent and longer-lasting immune response. The details of the Improvac vaccine are unknown to the authors as they constitute proprietary information with a single exception that the antigen is a RnRF-protein conjugate. Equity (Pfizer Animal Health, West Ryde, NSW, Australia) is manufactured by the same company and consists of a GnRH peptide conjugated to a protein carrier combined with an immunostimulating complex consisting of Saponin Quil A, cholesterol and dipalmitoylphosphatidyl choline as adjuvant (Elhay *et al*. 2007). The results of our trial to date, however, indicate better and more consistent results than those reported with Equity.

No adverse effects were observed in the experimental mares after the initial vaccination, which is consistent with the findings described by Dalin *et al*. (2002), but contrary to the findings of Imboden *et al*. (2006), where injection-site reactions occurred after the initial vaccination. The few animals displaying injection-site reactions during this study were observed only after the booster vaccination. All adverse reactions were found to be transient and mild, and by Day 6 were no longer visible. This is in contrast to the findings of Imboden *et al*. (2006), where the adverse effects to the vaccination with Improvac were found to be quite severe. This can possibly be due to the fact that in the present study all injections were administered intramuscularly into the gluteal muscles (J. F. Kirkpatrick, pers. comm.) and not into the neck, as described by Imboden *et al*. (2006).

This study showed a close relationship between the observed clinical response and SPC within a large group of mares. This finding supports the conclusion that SPC provides an effective method for monitoring the response to GnRH vaccination in horse mares of all ages.

On the basis of the results of our trail in mares, Improvac is a promising prospect for the contraception of zebra, African elephants and perhaps other wildlife species. The vaccine is freely available, cheap, stored at 4°C and no further preparation (e.g. mixing of antigen and adjuvant) is required before injection. Side effects at the chosen site of injection were minimal. Although of a slightly viscous nature, the vaccine has been successfully administered remotely via darting in African elephant bulls with both Dan Inject (Børkop, Denmark) and Pneu-Dart (Williamsport, PA, USA) darts (H. Bertschinger, pers. comm.). Reliable reversibility of anoestrus induced by Improvac has yet to be investigated. Imboden *et al*. (2006) were unable to establish this because the mares were no longer accessible after the initial phase of the trial. Elhay *et al*. (2007) established a 100% return to folliculogenesis 8–28 weeks after the second vaccine with Equity. The mares in the present study will continue to be monitored during the 2007–08 breeding season and the data regarding reversibility of Improvac contraception will

become available in the near future. A likely advantage of a GnRH vaccine used for contraception of wildlife species such as African elephant and zebra is induced anoestrus. The females of species like African elephants and zebra, once they have reached reproduction age, spend most of their lives in a state of anoestrus. African elephants have an average intercalving interval of four years. Of this, 22 months is accounted for by pregnancy and approximately two years by lactation anoestrus (Brown *et al*. 2004). This means that cows usually conceive during the first oestrus once cycling resumes. Thus, an elephant cow probably comes into oestrus approximately only once every four years. The use of pZP immunocontraception in feral horses (Kirkpatrick *et al*. 1990) and African elephants (Delsink *et al*. 2006) causes infertility by interfering with fertilisation and the immunised females continue to exhibit oestrous cycles. The authors of the present study hypothesise that pZP is more likely to result in behavioural and social disturbance because individuals in herds are continually attracting males as a result of coming into heat. Comparative studies are needed to test this hypothesis.

Acknowledgements

We express our gratitude to the veterinary and other personnel of the South African Police Services and the Section of Reproduction, University of Pretoria, for their valued contributions during the course of this trial.

Immunization of sheep against GnRH early in life: effects on reproductive function and hormones in rams

B. W. Brown*, P. E. Mattner, P. A. Carroll, E. J. Holland, D. R. Paull, R. M. Hoskinson and R. D. G. Rigby

CSIRO, Division of Animal Production, PO Box 239, Blacktown, NSW 2148, Australia

Groups of Merino ram lambs were immunized against GnRH either soon after birth (prepubertal) or around puberty (peripubertal) with a prototype commercial preparation and studied over the following 2 years to determine the long-term effects of such immunization on reproductive development, function and hormone concentrations. The treatment was equally effective in suppressing reproductive function and hormones when given at either time. Growth rates of immunized and controls rams were similar throughout the study. Prepubertal immunization delayed testicular growth until the rams were at least 27 weeks of age and some rams had subnormally sized testes even at 115 weeks of age. After peripubertal immunization, the mass of the testes declined and remained regressed until the rams were from 51 to 90 weeks old. There was a significant correlation between total testicular mass at 115 weeks of age and duration (weeks) of suppression of testicular growth (prepubertal, $r = -0.7375$; peripubertal, $r = -0.7132$, $P < 0.001$). Prepubertal immunization markedly delayed separation of the penis from the prepuce. The immunized rams did not display sexual activity until their total testicular mass reached at least 70 g. In control and immunized rams with testicular mass > 100 g, the semen did not differ in the percentage of spermatozoa that were unstained (live), of normal morphology, or showed progressive movement. Compared with the increase in plasma LH and FSH concentrations with age in control rams, the concentrations of these hormones in the immunized animals were lower and remained relatively constant from 46 to 90 weeks of age. Plasma FSH concentration was particularly suppressed in immunized rams and was significantly ($P < 0.05$) lower than the control values at 61 and 90 weeks of age. LH release after injection of 1 μg GnRH at 90 weeks of age was either absent or markedly suppressed in immunized rams compared with that for controls.

Introduction

It is well known that repeated immunization of adult male and female domestic animals against the hypothalamic decapeptide gonadotrophin releasing hormone (GnRH) can prevent the production of gonadotrophins and result in the cessation of reproductive function (Jeffcoate *et al.*, 1978, 1982; Robertson *et al.*, 1979, 1982; Schanbacher, 1982). As a result, considerable attention has been paid to the production of practical methods to induce infertility or control of sexual activity in domestic animals through long-term immunity to GnRH.

Although it has been shown that the suppressive effects of anti-GnRH immunization of adult sheep and cattle (Keeling and Crighton, 1984) on reproductive function is reversible with time, the long-term effects of such immunization when applied to animals early in life has not been thoroughly investigated. Gonadotrophins play a vital role in normal development of the gonads and their cellular components (Courot, 1967), and endogenous GnRH is essential for the maintenance of normal concentrations of pituitary GnRH receptors (Fraser *et al.*, 1982; Popkin and Fraser, 1985). A prolonged reduction in the number of pituitary GnRH receptors following immunization against GnRH (Popkin and Fraser, 1985), together with a concomitant decrease in endogenous LH and FSH concentration during early life, might have some permanent effect on the maturation of the CNS centres controlling reproductive function.

Accordingly, the present study was initiated to examine the duration and severity of effect of an anti-GnRH immunization treatment on subsequent growth, sexual behaviour and reproductive physiology in rams immunized early in life. In addition, the plasma concentrations of the reproductive hormones and the release of LH and testosterone following injection of 1 μg GnRH were compared with those in control rams.

Materials and Methods

Animals and immunization schedule

Fifty Merino ram lambs born in August were used in this study at Armidale, NSW, until they were approximately 115 weeks of age. They were weaned at 12 weeks of age and maintained at pasture thereafter. Twenty of the lambs each received 1 mg of antigen (see below) in a 2 ml dose (primary dose) at 3–4 weeks of age (prepubertal immunized group) and a boost with the same type and amount of dose at 13–14 weeks of age. Twenty other rams received their primary and booster dose when they were 20–21 weeks and 30–31 weeks of age, respectively (peripubertal immunized group). The remaining ten non-immunized rams served as controls. The primary and booster doses were each injected s.c. at four sites in the neck region. Thirty of these ram lambs (ten from each of the three groups) were used to examine the effects of such immunization on reproductive endocrinology.

Immunogen

Details of the prototype commercial immunization preparation, which was developed in collaboration with Arthur Webster Pty Ltd, Castle Hill, NSW and Peptide Technology Ltd., Dee Why, NSW, are given by Hoskinson *et al.* (1990). Briefly, the immunogen was prepared by conjugation of a carboxyl-containing GnRH analogue to ovalbumin using the diimide reaction. This conjugate was emulsified using a mixture of a solution of 5% DEAE–dextran (pH 7.5) in a 50% water-in-mineral oil emulsion.

Anti-GnRH antibody titre

At frequent intervals (initially 2 weeks, then 4–6 weeks) after booster immunization, 5 ml of blood was taken from the jugular vein in all GnRH-immunized rams to monitor anti-GnRH antibody titre. Antibody titre was determined for all plasma samples from any one sheep in the same radioligand binding assay, which was similar to that reported for steroids (Abraham, 1974) but using GnRH (specific activity: 100 Ci mmol^{-1}). Titre is defined as a dilution of antiserum that bound 50% of the available radioligand.

Body and testicular growth

From about 14 weeks of age, the animals were weighed at frequent intervals (every 4–6 weeks) to assess rate of body growth. Coinciding with these times, estimates of total testicular mass (of the two testes) were also obtained using a palpation method described by Oldham *et al.* (1978), which has been calibrated against actual weights of testes. The period of delayed testicular growth was defined as the time during which no sustainable increase in testicular mass occurred above that at the time of the booster immunization.

Assessment of sexual activity and semen characteristics

Sexual activity of each control and GnRH-immunized ram was evaluated from the total number of services they performed when individually joined with oestrous ewes in pens for 20 min on each of two consecutive days (Mattner *et al.*, 1971). At the end of the study, a semen sample was collected from each ram (where possible) using the electroejaculation procedure (Blackshaw, 1954) to evaluate seminal characteristics. The percentages of unstained (live) and morphologically normal spermatozoa were determined from nigrosin–eosin stained smears of semen (Hancock, 1952). The percentage of spermatozoa exhibiting progressive movement was assessed as described by Mattner and Voglmayr (1962) using prewarmed slides and direct microscopy.

Blood sampling and GnRH challenge

Jugular blood samples (5 ml) were obtained by venepuncture from ten control, ten prepubertal immunized and ten peripubertal immunized rams at intervals of 30 min for 6 h when they were 46, 61 and 90 weeks of age, to measure mean concentrations of the reproductive hormones. The samples were held on ice until centrifugation (at 5°C and 3000 ***g*** for 20 min) within 30 min of collection, and the plasma stored at − 10°C until assay. At 90 weeks of age, 1 μg GnRH (ICI, Melbourne) in 2 ml of 0.9% saline was injected into a jugular vein in each of three control rams and seven GnRH-immunized rams (which were selected from either immunized group to provide a range in testicular mass), to assess the LH and testosterone response to a GnRH challenge. Blood samples (5 ml) were obtained by jugular venepuncture before the GnRH injection and afterwards, at 10 min intervals for 1 h and then at 20 min intervals for a further 2 h.

Hormone assays

All hormones were measured by radioimmunoassay. The sensitivity of the assays for LH (Radford *et al.*, 1987a) and FSH (Radford *et al.*, 1987b) were 0.19 and 0.06 ng ml^{-1}, respectively. The intra-assay and interassay coefficients of variation (at 50% displacement of tracer) were all < 10%.

Testosterone concentrations were measured in duplicate. The samples and standards (20 μl) were extracted for 5 min with 2 ml of toluene:hexane (2:1, v:v), the solvent phase was evaporated to dryness under N_2 and the single antibody technique of Garnier *et al.* (1978) was then used. An antiserum raised in a sheep against testosterone-3-carboxymethyloxime–BSA (M. S. F. Wong and R. I. Cox, CSIRO, Division of Animal Production, Blacktown, NSW) was used at a dilution of 1:60 000. Crossreactivity with dihydrotestosterone, 4-androstene-3β,17β-diol and androstenedione was 31%, 30% and 1.3%, respectively. All oestrogen and progesterone compounds had < 1% crossreactivity. Mean nonspecific binding was 2.8%; the sensitivity of the assay was 0.1 ng ml^{-1}; and for pooled ovine plasma samples with mean concentrations of 0.6, 3.5 and 7.3 ng ml^{-1} the intra-assay and interassay coefficients of variation were < 8% and < 10%, respectively.

Statistical analyses

Data were analysed using standard procedures for repeated measures analysis of variance, one-way analysis of variance,

Table 1. Mean (± SEM) body mass (kg) and mean total testicular mass (g) for control and GnRH-immunized rams at different stages in life

Animals	Age (weeks) 46	61	90	115
Control rams				
Body mass	26.2 ± 1.1	39.8 ± 1.1	51.8 ± 1.3	50.4 ± 1.9
Testis mass	101 ± 12[a]	242 ± 24[a]	214 ± 10[a*]	338 ± 12[a]
Prepubertal immunized rams				
Body mass	25.4 ± 0.8	43.6 ± 1.5	48.7 ± 1.8	50.6 ± 1.8
Testis mass	43 ± 10[b]	112 ± 16[b]	147 ± 20[b]	202 ± 22[b]
Peripubertal immunized rams				
Body mass	28.3 ± 0.8	44.1 ± 1.5	48.3 ± 1.5	49.5 ± 1.4
Testis mass	23 ± 3[b]	79 ± 12[b]	116 ± 20[b]	170 ± 19[b]

Values in any column with different superscripts differ significantly from each other ($P < 0.05$).
*Value probably suppressed owing to effect of season (June) in adult rams (see text).

Student's *t* test and regression analysis (Minitab, Release 7.2, Minitab Inc., Pennsylvania). After GnRH injection, a positive response (rise in LH and testosterone) was said to occur when (i) the concentration of the hormone increased by at least 50% above the preceding baseline value, (ii) there were at least two points between the peak value and the succeeding baseline, and (iii) the rate of decline in concentration after the peak was no greater than that allowed by the half-life of the hormone (Khalid *et al.*, 1987).

Results

During the course of the study, one prepubertal and two peripubertal immunized rams died from causes unrelated to the immunization treatment.

Anti-GnRH antibody titre

In all treated animals, the peak anti-GnRH antibody titre response occurred 2 weeks after the booster dose, after which the titre declined at various rates. There were very great differences in antibody titre response between animals (range of 1:2000 to 1:50 000) and the magnitude of the peak titre values after the boost could not be related to severity or duration of the effect on testicular development. Furthermore, the magnitude of the peak titre value after the boost was not related to the subsequent rate of decline in antibody titre.

The rate of decline in antibody titre tended to be slower in the rams that had testicular masses < 100 g at the end of the study than in those that ultimately developed testes > 100 g. Thus, at 20, 30 and 60 weeks after booster immunization, the prepubertal immunized rams with small testes had mean circulating antibody titres that were 27, 15 and 8%, respectively, of the peak value after the boost, while in all other prepubertal immunized rams, the corresponding values were 9, 4 and 2%, respectively. Similarly, with the peripubertal immunized rams, there was a tendency for those animals with small testes to have a slightly higher mean antibody titre (as a percentage of the peak value after the boost) from 30 weeks after the booster dose, than for other animals in this immune group. By the end of the study, antibody titres were detectable in only three of the 37 GnRH-immunized rams, with the values ranging from 3 to 16% of the peak titre after the boost (1:500 to 1:1000).

Body and testicular growth

Throughout the study, the rate of body growth for the two groups of GnRH-immunized rams did not differ significantly from each other or from that for the control rams (Table 1).

For all treatment groups, mean testicular mass increased significantly with increasing age, but the rate of testicular growth differed between the groups. While the group mean values for testicular mass for the prepubertal and the peripubertal immunized rams did not differ materially from each other from 46 to 115 weeks of age, they were significantly ($P < 0.05$) lower than the corresponding values for the control rams (Table 1).

To understand the trends in testicular development with respect to severity and duration of effect of the treatment, the immunized animals were grouped according to their total testicular mass at 115 weeks of age as follows: those with normally sized testes and in the testicular mass range of the control rams, > 200 g (range for control animals was 220–360 g); those with small testes (juvenile-like), ⩽ 100 g; and those with medium-sized testes that were substantially smaller than those of control animals, > 100 ⩽ 200 g. In the prepubertal ($n = 11$) and in the peripubertal ($n = 6$) immunized rams that ultimately developed testes in the normal range, the treatment delayed testicular growth from 27 to 46 weeks and from 21 to 44 weeks, respectively. For the immunized animals with small testes at 115 weeks, testicular development was delayed from 51 to 99 weeks for the prepubertal immunized group ($n = 4$) and from 64 to 90 weeks in the peripubertal immunized animals ($n = 5$), but some of the rams in both of these groups exhibited little testicular growth even at 115 weeks of age. At 115 weeks of age, there was a significant correlation between the mean testicular mass and the duration

Table 2. Mean (± SEM) service score* for control and GnRH-immunized rams and the percentage of rams serving at various stages in life

Animals	Age (weeks) 61	90	115
Control rams			
Service score	3.0 ± 0.7[a]	3.4 ± 0.5[a†]	6.4 ± 0.6[a]
Rams serving (%)	90	100	100
Prepubertal immunized rams			
Service score	1.3 ± 0.4[b]	3.0 ± 0.6	4.0 ± 0.6[b]
Rams serving (%)	50	72	83
Peripubertal immunized rams			
Service score	0.9 ± 0.4[b]	1.7 ± 0.5[b]	4.1 ± 0.6[b]
Rams serving (%)	25	50	89

*Service score for individual rams is the total number of services performed in two pen tests of 20 min each conducted 24 h apart. Values in any column with different superscripts differ significantly from each other ($P < 0.05$).
†Value probably suppressed owing to effect of season (June) in adult rams (see text).

(weeks) of suppression of testicular growth (prepubertal, $r = -0.7375$; peripubertal, $r = -0.7132$, $P < 0.001$).

Assessment of sexual activity and semen characteristics

The GnRH-immunized rams showed no interest in mounting oestrous ewes until they had attained a testicular mass of at least 70 g. Rams with testes of 70–100 g only occasionally served oestrous ewes. For all treatment groups, the mean service score increased significantly ($P < 0.05$) with increasing age (Table 2). The group mean service score for the prepubertal or the peripubertal immunized rams did not differ significantly from each other at any of the age periods studied, but the values for the two immunized groups at 61 and at 115 weeks of age and for the peripubertal immunized rams at 90 weeks of age were significantly lower ($P < 0.05$) than the corresponding values for the control rams (Table 2). The lack of a difference between control and prepubertal immunized animals at 90 weeks of age was possibly due in part to the suppression of libido that occurs in normal adult rams at this time of year (June) in the nonbreeding season (Mattner, 1977). When only the rams that actually served in pen tests were considered, the mean service scores for the immunized and control rams did not differ significantly.

Semen characteristics

At 46 weeks of age, separation of the penis from the prepuce had occurred in 90% and 37% of animals in the control and prepubertal immunized groups, respectively.

In three GnRH-immunized rams with testes < 100 g at 115 weeks of age, separation of the penis from the prepuce had still not occurred and no semen sample could be obtained. In three other rams in this testis size range in which the penis was free, the ejaculates consisted of seminal fluid devoid of or almost devoid of spermatozoa.

Ejaculates were obtained from all control rams and from all GnRH-immunized rams with testes > 100 g. There was little difference between the control or the immunized animals with respect to the percentage of spermatozoa that were unstained (live), morphologically normal, or showed progressive movement (Table 3).

Although the mean value for the percentage of motile spermatozoa in the ejaculates of the immunized rams with medium-sized testes was low, it was not statistically different from that in ejaculates from control or from the immunized rams with normally sized testes.

Plasma concentrations of testosterone, LH and FSH

Analysis of the data revealed a significant ($P < 0.001$) effect of age on testosterone concentrations, with the mean values increasing markedly in all groups from 46 weeks to 61 weeks of age (Table 4). The decline in mean concentration of this hormone for the control and the prepubertal immunized rams at 90 weeks of age is probably due to a suppressive effect of the nonbreeding season (Mattner, 1977). The mean circulating concentration of testosterone for the peripubertal immunized group of rams at both 46 and 61 weeks of age was significantly lower ($P < 0.02$) than that for the control rams (Table 4). However, in immunized rams (of either group) and control rams with testes of comparable size, mean plasma testosterone concentrations were of a similar order.

The mean plasma concentrations for LH and FSH increased with age in control animals, but the values were relatively constant from 46 to 90 weeks of age in both groups of immunized rams. As a result, the group mean LH values for the two immunized groups at 61 weeks of age and their group mean FSH values at both 61 and 90 weeks of age were significantly lower ($P < 0.002$) than the corresponding values for the control rams (Table 4).

Responsiveness to GnRH injection

The endocrine responses obtained in control and immunized rams to an i.v. injection of 1 μg GnRH are shown (Table 5). In

Table 3. Semen characteristics of ejaculates obtained from control ($n = 10$) and GnRH-immunized rams with medium-sized ($n = 17$) or normally sized ($n = 11$) testes at 115 weeks of age (values are means ± SEM)

Animals	Semen characteristics		
	Live (%)	Normal (%)	Motile (%)
Control rams	73.9 ± 2.5	85.1 ± 3.2	79.5 ± 2.6
GnRH-immunized rams (normal-size testes)	79.6 ± 2.5	74.7 ± 4.2	80.6 ± 5.2
GnRH-immunized rams (medium-size testes)	79.0 ± 4.5	73.8 ± 5.3	68.5 ± 11.5

Data for prepubertal and peripubertal immunized rams are pooled since there were no significant differences between the two immunized groups.

Table 4. Mean (± SEM) concentrations (ng ml^{-1}) of testosterone, LH and FSH for control ($n = 10$) and GnRH-immunized ($n = 20$) rams at different stages in life, and in relation to mean anti-GnRH antibody titre (the percentage of rams with measurable antibody titre is given in parentheses)

Hormone	Age (weeks)	Controls	Prepubertal	Peripubertal
Testosterone	46	0.9 ± 0.2	0.7 ± 0.1	0.3 ± 0.1*
	61	3.2 ± 0.6	2.0 ± 0.5	1.3 ± 0.3*
	90	2.1 ± 0.7†	0.9 ± 0.2	1.5 ± 0.5

GnRH-immunized rams were treated either soon after birth (prepubertal) or around puberty (peripubertal).
Within rows asterisk denotes a significant difference ($P < 0.05$) from control value.
†Mean possibly lower because of seasonal effects observed in adult rams.

each of the control rams, there was a marked increase in plasma LH concentration within 10 min of the injection of GnRH, followed approximately 20 min later by a rise in plasma testosterone concentration. A similar response did not occur in any of the GnRH-immunized rams with testicular mass < 100 g. GnRH injection into the immunized rams with testicular mass ≥ 100 g resulted in peak plasma LH concentrations that were considerably less than those in the controls, and peak plasma testosterone concentrations that were of a similar order to those in control animals (Table 5). Two of the rams with testes < 100 g had measurable antibody titres that were very low (6 and 8% of the peak antibody titre value after the boost). All other rams injected with GnRH had no measurable antibody titres.

Discussion

Immunization of adult animals against GnRH appears to produce only temporary suppression of gonadal function and sexual behaviour, as reproductive function usually resumes fairly rapidly after decline of antibody titre without any apparent detrimental effects occurring (Robertson *et al.*, 1982; Keeling and Crighton, 1984). In contrast, the present study shows that similar immunization of rams very early in life can produce profound and extremely long-lasting effects on their reproductive capacity, with some of the animals having juvenile-like reproductive organs and a complete lack of libido two years later.

Since many of the immunized rams lacked normal gonadal development long after anti-GnRH antibodies had dissipated, it appears that such immunization early in life may have induced some permanent damage to mechanisms that control reproductive function. Indeed, the results of the present investigation on a selection of these GnRH-immunized animals revealed that their mean plasma gonadotrophin concentration was significantly lower than that of the non-immunized controls. The lower hormone concentrations in the immunized rams at 61 weeks of age is not surprising, since at that time, 14

Table 5. Peak plasma LH and testosterone concentrations (ng ml^{-1}) in control and GnRH-immunized rams injected with 1 μg GnRH at 90 weeks of age

Sheep	Response to injection	Peak LH[a]	Peak testosterone[a]	Testis mass (g)
Control rams	Positive[b]	15.4	7.8	250
	Positive	36.9	9.2	220
	Positive	23.3	7.8	250
GnRH-immunized rams	No response	0.3	0.5	40
	No response	0.4	0.8	50
	No response	0.3	2.1	70
	Positive	2.2	10.7	100
	Positive	8.4	3.0	130
	Positive	1.0	4.8	160
	Positive	1.4	6.8	160

[a]Peak values refer to the maximum concentration of the hormone subsequent to GnRH injection.
[b]Positive response: a rise in concentration of the hormones following injection of GnRH, in accordance with the defined criteria.

of the 20 immunized animals still had some anti-GnRH antibodies present that could be expected to bind at least some of the circulating GnRH (titre range: 2–33% of the peak titre value after the boost). However, at 90 weeks of age, the lower plasma FSH concentrations persisted in both immunized groups of rams, despite the lack of measurable anti-GnRH antibody titres in 12 of the 20 immunized animals and very low titre values for the remainder. Accordingly, these findings indicate that the immunization may have induced some degree of impairment to hypothalamic function, resulting in long-term suppression of GnRH and of gonadotrophin release in the majority of the immunized rams.

The absence of an LH response in the immunized rams with small testes ($\leqslant 100$ g), or the markedly reduced LH release (relative to that for controls) in those with testes $\geqslant 100$ g following injection of GnRH at 90 weeks of age, suggests that the immunization also induced some degree of impairment to pituitary function, resulting in a reduced capacity of the gland either to respond to GnRH stimulation or to produce and release LH and FSH. However, as the concentration of pituitary GnRH receptors appears to be under positive autoregulatory control of GnRH (Clayton and Catt, 1981; Popkin and Fraser, 1985), it is possible that the diminished LH response in the immunized animals to GnRH injection may merely reflect a state of downregulation of pituitary GnRH receptors due to little or no unbound GnRH in the hypophyseal portal circulation.

The significantly lower mean circulating concentrations of testosterone in the peripubertal immunized rams at 46 and at 61 weeks of age would appear to result from many rams in this immunized group having testes of extremely small size rather than to an inability of the testes to produce this hormone (at 46 weeks of age all peripubertal immunized rams and three control rams had testes $\leqslant 70$ g; at 61 weeks of age six peripubertal immunized rams but no control rams had testes $\leqslant 70$ g). Unlike the LH responses in the immunized animals following GnRH injection, the peak plasma testosterone concentrations in those immunized rams with testes $\geqslant 100$ g were of a similar order as those in the controls. Consequently, it appears that the testes of the immunized rams may have become more sensitive to LH stimulation; this feature could account for the ultimate increase in testis mass in the majority of the immunized rams, despite the significantly reduced circulating concentrations of the gonadotrophins. These findings suggest that while the immunization suppressed testicular development, it had no long-term detrimental effect on testicular or Leydig cell function *per se* and that the normal development of the testes was merely delayed owing to insufficient gonadotrophic stimulation. Once testicular development commenced, immunized and control rams with testes of similar size (irrespective of age) had similar mean plasma testosterone concentrations. It seems likely, therefore, that the size of the testes was the main limiting factor to the production of this hormone in the immunized animals.

In both groups of GnRH-immunized rams, the lower mean libido score occurred as a result of the presence of sexually immature animals and other rams that did not serve, despite them having well-developed testes. Some of the immunized rams with estimated testicular mass between 70 and 100 g at 115 weeks of age served oestrous ewes, suggesting that while mechanisms facilitating testicular development may be permanently impaired, maturation of the neural centres that regulate sexual behaviour may not be seriously affected by the absence of gonadotrophin or androgens over a period during early life. Once these centres had been activated, the GnRH-immunized rams soon developed service capacity similar to that of untreated controls.

It is well known that expression of sexual behaviour normally precedes the full development and maturation of the testes. Even though, overall, sperm production was considerably reduced in GnRH-immunized rams owing to reduced testicular size, the quality of semen in those rams that developed a testicular mass > 100 g appeared to be normal. Thus, it is likely that the rams of this class that became sexually active could impregnate at least a proportion of the ewes served by them.

As the anti-GnRH vaccine, whether administered soon after birth or at about the time of onset of puberty, is effective in suppressing gonadal development and sexual activity for considerable periods, commercial producers have wide scope

for the time of immunization. However, the present data show that the suppressive effects on reproductive function may not be reversible in all treated animals. With appropriate booster immunization schedules, the procedure appears to have potential for use in other animal industries, such as companion animals, as an alternative method to conventional spaying when permanent infertility is required.

The authors are grateful to R. J. Welch, B. E. Harrison and S. Cuthbert for valuable technical assistance and to P. Baker of the CSIRO Biometrics Unit for advice on the statistical analysis.

Abstract

Context. Federally protected wild horses on public lands are undergoing population growth that overwhelms the historical management strategy of removal and adoption. Porcine zona pellucida (PZP) has been used as an injectable immunocontraceptive vaccine to induce reversible infertility in free-roaming horses. PZP vaccination during February and March, which is the optimal time for administering current vaccines, is not possible for the herd on Jarita Mesa Wild Horse Territory (JM WHT), New Mexico, due to severe weather, terrain and subject wariness.

Aims. The first goal was to assess bait trapping and remote darting as a minimally disruptive alternative to helicopter gathers for treatment. The second goal was to quantify the efficacy over 2 years following spring treatment with a single injection of PZP-22 (a combination of PZP-adjuvant emulsion and controlled-release pellets) by remote dart delivery.

Methods. Bait trapping and dart delivery of PZP-22 was carried out on JM WHT from 4 April to 16 June 2012. The herd was observed in the summers of 2011, 2013 and 2014 to determine the foaling status of the study mares. Outcome (foal or no foal) as a function of treatment was analysed using Fisher's exact test.

Key results. There were 157 individuals, including 66 females >1 year old, documented in 2011. In 2012, 26 females (including three yearlings) identified by colour and markings were bait trapped and darted with PZP-22. The proportion of treated females foaling was lower than that of untreated females in 2013 and 2014, but the difference was only significant in 2013. Of the treated mares observed in 2013, the two that foaled were the last two treated in 2012. Untreated mares >4 years old were significantly more likely to foal than younger mares.

Conclusions. Bait trapping at JM WHT permitted successful delivery of PZP-22 in a previously inaccessible herd. Dart administration of PZP-22 in April–June induced at least 1 year of measurable infertility.

Implications. This is the first demonstration of the efficacy of an initial treatment of PZP-22 delivered by dart instead of hand injection. Considerations for PZP-22 treatment include seasonal timing of treatments and age of treated mares. Treatments need to take place early enough to allow antibody titers to build to contraceptive levels before the breeding season.

Introduction

Management of wild horses on public lands in the US, as required under the 1971 *Wild Free Roaming Horse and Burro Act* (P.L. 92–195, as amended) has proven challenging. Wild horse herds grow at a rate of 15–20% annually through natural reproduction (Garrott 2018). Growing wild horse populations increase pressure on forage that under the Act they share with wildlife and, where permitted, livestock. Since 1975, the US Bureau of Land Management (BLM) and US Forest Service (USFS) have attempted to control wild horse populations by gathering and removing horses from the range and placing them with adopters, privately funded sanctuaries, contract ranches or

Journal compilation © CSIRO 2019

government-managed long-term holding facilities (Norris 2018). This strategy has not proven sustainable, and the policy of removals may be exacerbating population growth by artificially stimulating reproduction (Kirkpatrick and Turner 1991*a*; Garrott and Oli 2013; National Research Council 2013).

Immunocontraceptives are one possible solution to the control of wild horse populations on public lands. An ideal immunocontraceptive for free-roaming horses is specific, safe for the animal and environment, effective and both cost-effective and practical to administer on a large scale (Kirkpatrick *et al.* 2011; Hobbs and Hinds 2018). First documented to induce infertility in wild and domestic mares by Liu *et al.* (1989), the porcine zona pellucida (PZP) vaccine, tested in a variety of formulations, has been shown to meet many of those requirements (Kirkpatrick *et al.* 1990; Kirkpatrick and Turner 1991*b*; Turner and Kirkpatrick 2002).

Efficacy and cost of administration are key to effective limitation of population size and growth by means of a contraceptive agent. The practicality of delivering PZP to free-roaming mares by hand or dart has been proven in a select group of small, well studied herds (Kirkpatrick *et al.* 1990; Kirkpatrick and Turner 1991*b*; Ransom *et al.* 2011). However, wild horse herds on public lands in the western United States are often challenging to access for vaccine administration because of the rough terrain they inhabit and some horses' avoidance of humans (Turner and Rutberg 2013). In its initial form, consisting of an emulsion of PZP antigen and Freund's Complete Adjuvant, the vaccine required a booster 1 month after the initial injection to reliably decrease fertility for 1 year (Kirkpatrick *et al.* 1990; Turner *et al.* 1997). Extending the period of infertility induced by treatment would eliminate the need for labour-intensive annual boosters and decrease the risk of wary free-roaming horses learning to evade capture and treatment (Naugle and Grams 2013). The goal of extending the longevity of PZP effectiveness has followed two routes. First, PZP has been incorporated into liposomes and delivered with various adjuvants under the trade name SpayVac (IVT, Halifax, NS, Canada). Although SpayVac has shown promise in trials on captive horses (Killian *et al.* 2008; Bechert *et al.* 2013; Roelle *et al.* 2017), it has not yet been field tested on free-roaming wild horses. The second approach has been to add controlled-release components to the PZP emulsion to mimic the effects of boosters. Initial field trials of PZP emulsions combined with PZP embedded in lactide–glycolide polymer microspheres produced 1 year of effectiveness with a single shot, but the microspheres were difficult to handle under field conditions (Turner *et al.* 2001, 2002). Subsequently, a vaccine formulation consisting of the PZP-adjuvant emulsion combined with PZP and QA-21 adjuvant embedded in controlled-release lactide–glycolide polymer pellets ('PZP-22'), delivered by jabstick, induced 2–3 years of substantially reduced fertility with a single injection in January at Clan Alpine HMA, Nevada (Turner *et al.* 2002, 2007). This reduction was followed by a return to a control level of fertility in 4 years (Turner *et al.* 2007). However, attempts to replicate this multi-year effect in mares at three western sites did not meet with the same success (Ransom *et al.* 2011; Rutberg *et al.* 2017). Hypotheses for the observed reduction in effectiveness of PZP-22 primers are currently being tested (Rutberg *et al.* 2017).

Rutberg *et al.* (2017) showed that PZP-22 boosters could be delivered effectively by dart, but remote delivery of PZP-22 priming doses has not been studied. The ability to deliver initial treatments of PZP-22 by dart rifle would permit treatment with less equipment, labour and handling of wild horses.

The aim of the present study was to assess the reduction in fertility of treated mares over 2 years following administration of PZP-22 via dart on unrestrained horses in a corral. Treatments were carried out at Jarita Mesa Wild Horse Territory (JM WHT), Carson National Forest, New Mexico. Access to wild horses for management purposes on JM WHT is challenging. Gathering horses by helicopter is ineffective due to heavily forested terrain and large variations in elevation. JM WHT is generally inaccessible by vehicle in the winter months due to snow cover. Additionally, its resident wild horses avoid direct approaches by people. Thus, access to wild horses on JM WHT requires the development of capture methods other than helicopter gather.

Materials and methods

Study area

The Jarita Mesa Wild Horse Territory (JM WHT) in Carson National Forest, New Mexico, is a 22 200-ha range managed by the U.S. Forest Service (2006; USFS Environmental Assessment). Elevations range from 2300 to 3200 m. Pinon pines (*Pinus* spp.), juniper (*Juniperus* spp.) and sagebrush (*Artemesia tridentata*) dominate the vegetation at lower elevations, and Ponderosa pine (*P. ponderosa*) forest dominates at higher elevations. The JM WHT is home to native mule deer (*Odocoileus hemionus*) and elk (*Cervus elaphus*). As in most western landscapes, JM WHT has a long history of human use, including grazing by domestic livestock; in 2011, the US Forest Service permitted private livestock owners to graze 502 cow–calf pairs and 16 bulls. Appropriate Management Level (AML) for wild horses on JM WHT is 20–70 horses.

Field observations and individual identification

Wild horses were surveyed by vehicle and on foot from 26 May to 17 December 2011, 14 June to 7 August 2013 and 6 June to 7 August 2014. High horse-traffic areas were identified by the presence of tracks and faeces. Two Bushnell (Overland Park, KS, USA) wildlife cameras with 24-h motion activated sensors were placed at heavily used water holes and high traffic areas to document movement of the wild horse groups. When observed directly, wild horses were photographed with a Rebel EOS T3i camera (Canon, Tokyo, Japan) and telephoto (120–400 mm) lens (Sigma, St Louis, MO, USA) and further observed with a Prostaff (20–60 × 82 mm) spotting scope (Nikon, Tokyo, Japan). Horses were photographed for positive identification based on colour, unique face and leg markings, scars and sex. Band composition was recorded, including associations among mares, immatures and stallions. Foals were associated with the dam using affiliative behaviours such as nursing or, occasionally, repeated proximity while grazing or traveling. A few mares were associated with foals by ruling out all other mares present in the group as the possible dam, because they closely associated with other foals present. Foals were aged at first observation to approximately the nearest 2 weeks based on size, tail length and

behaviour. Disturbance of the horses' natural activities by the observer was avoided whenever possible.

The Wild Horse Identification Management System (WHIMS; Wildwise Ecological Solutions, http://wildwisesolutions.com/Whims.aspx) is application-based software used to visually catalogue all the horses identified in a study herd. Each horse is assigned a unique ID number. Information associated with each entry includes sex, age, colour, markings, current and past band associations, dam and photos from each year observed (U.S. Geological Survey 2013). New entries were generated when sufficient photographic evidence was collected during the 2013 and 2014 surveys to prove the animal was not previously identified. New entries were made for all foals of the year.

Capture methods

Groups observed during 2011 field observations were chosen for the PZP-22 treatment regime based on ease of identification, access and regular sightings. As part of a management action that also included capture and removal from the range, eight sites were identified for bait placement based on locations where horses had been observed in the past, road access, horse trails and water sources. Only two sites were set up at a time. Wild horse bands were attracted to gather sites using a proprietary bait formula provided by Mt Taylor Mustangs (Santa Fe, NM), which was hired by USFS under independent contract to treat the JM WHT horses. Timing of bait set-up depended on seasonal horse movements, road condition, snow cover and presence or absence of livestock, which may also be drawn to bait. When a band had acclimated to the bait at a gather site, a 10–13-m diameter catch corral made of portable metal pipe panels was set up at the bait site and the gate left open for several days (typically 3–7), so that horses could come and go freely from the catch corral. Cameras were used to monitor band activity with observers out of the horses' sight. After acclimatisation, when most horses in a group were in the corral, the gate was shut and secured by remote control, with the operator in a nearby blind. All mares trapped in April through mid-June were vaccinated; all mares trapped after mid-June were removed.

Porcine zona pellucida treatment

Females were injected with PZP-22 between 4 April and 16 June 2012 in catch corrals during daylight hours; horses corralled after sunset were held until daylight for darting. All females ≥1 year old that were not removed were treated. The PZP-22 consisted of 100 μg PZP (Science and Conservation Center, Billings, MT, USA) dissolved in 0.5 mL phosphate-buffered saline and emulsified in 0.5 mL modified Freund's Complete Adjuvant (mFCA, Calbiochem, LaJolla, CA, USA) plus three heat-extruded lactide–glycolide polymer pellets containing a total of 450 μg PZP and 625 μg QA-21 (Antigenics, Lexington, MA, USA) (Turner *et al.* 2007). The vaccine was loaded into a 1.0-mL Pneu-Dart (Williamsburg, PA, USA) dart designed with a rod within the 13-gauge, 1.5-inch needle to simultaneously inject the emulsion and the pellets. Darts were delivered into the gluteal musculature via Pneu-Dart X-Caliber rifle at a range of 10–15 m. The corral was videotaped during darting to confirm identification of treated horses and successful dart discharge. Once all mares in a captured group had been treated, the gate was opened and the group was released.

Statistical analysis

For purposes of statistical testing, foaling by PZP-treated and untreated mares was determined using only positively identified females 2 years and older (determined by size and, where known, individual histories) with a definitive foaling status. Mares that were positively identified but had an unclear foaling status were excluded from calculations relating to the outcome variable of foal or no foal.

Fisher's Exact tests (FET) were used to compare outcome (foal or no foal) among treatment groups and years. Because previous studies have not shown a difference in fertility between placebo-treated females and untreated females (Turner *et al.* 1997), the fertility of PZP-22-treated females was compared within a given year with that of individually identified females not captured for treatment. The proportion of females foaling in 2011 (before PZP treatment) also served as a comparison to the post-treatment proportions in 2013 and 2014. Alpha was set at $P = 0.05$ for all tests.

Results

Between 4 April and 16 June 2012, 26 females (three yearlings and 23 mares ≥2 years of age) were darted with PZP-22 in catch corrals and released back to the range. In addition, 78 wild horses were captured and removed; 60 of these (including 15 adult females, and three 2-year old females) had been previously identified in 2011. Horses did not avoid bait areas after corral panels were put in place. Reactions to injection were moderate and non-violent. We saw no abnormalities at or near the injection site on any of the treated mares at any time during the study, and no mares sustained injuries during capture or darting.

Among known mares observed from June to August 2013 (Year 1), the proportion foaling was 79% lower in PZP-treated mares (2/17; 12%) than in untreated mares (15/27; 56%) (FET, $P = 0.0046$). Among known mares observed from June to August 2014 (Year 2), the proportion foaling was 36% lower in PZP-treated mares (6/17; 35%) than untreated mares (14/26; 54%); this difference was not statistically significant (FET, $P = 0.349$). The pooled proportion of all treated and control mares in the sample foaling did not differ among the 3 years of the study (2×3 FET, $P = 0.736$).

Except for the decline associated with removals during trapping activity in 2012, the sample of individually recognised animals continued to grow throughout the study (Fig. 1). Part of that growth was due to identification of new adult animals not observed on the study site in previous years, and part due to birth and recruitment of new foals. The number of females ≥2 years old included in the individually recognised sample was 69 in 2011, 60 (post-removal) in 2012, 78 in 2013 and 86 in 2014. Thus the number of females treated with PZP-22 in 2012 represented only a small proportion of the sample of individually recognised mares on JM WHT (43.3% in 2012, 33.3% in 2013 and 30.2% in 2014).

With respect to the sample of all identified mares, 27 (40.3%) of 66 mares observed had a foal present in 2011 (pretreatment), 16 (37.2%) of 43 mares observed had a foal present in 2013, and

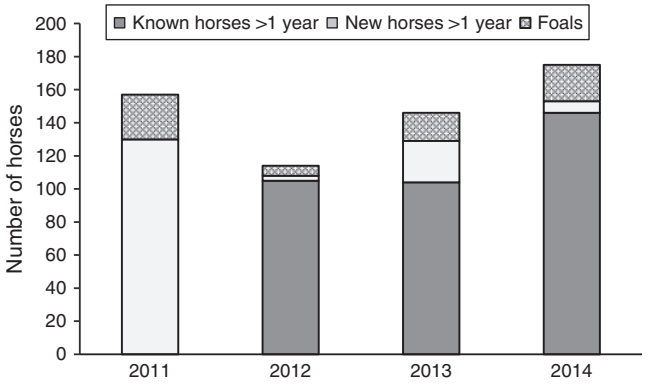

Fig. 1. Total sample of wild horses individually identified on the Jarita Mesa Wild Horse Territory, NM, USA in 2011–14. Numbers of known horses declined in 2011–12 because of removals conducted in 2012, then increased with the addition of newly identified individuals and new foals of the year. Clear, new horses >1 year old; solid grey, horses >1 year old documented in previous years; stippled, foals of the year.

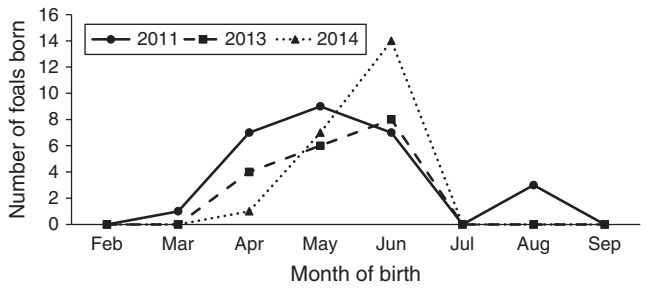

Fig. 2. Dates of foaling for individually identified mares on Jarita Mesa Wild Horse Territory, NM, USA in 2011–14. Dates estimated to within 2 weeks based on foal size, tail length and behaviour at first observation.

20 (46.5%) of 43 mares observed had a foal present in 2014. Untreated mares 4 years old or more had significantly higher foaling rates than mares less than 4 years of age in both 2013 (15/26, 58% for mares ≥4 years of age *v.* 0/5 for females <4 years of age, FET, $P = 0.0098$) and 2014 (13/20; 65% for mares ≥4 years of age *v.* 1/6, 17%, for mares <4 years of age, FET, $P = 0.0192$).

Of 79 foaling dates estimated from 2011 to 2014, 94.5% occurred in April–June (Fig. 2). Estimates of birth dates for the eight known births to treated mares in 2013 and 2014 fell within that window.

Discussion

Single injections of PZP-22 by dart delivery to mares accessed using bait trapping in late spring 2012 reduced foaling rates in the treated mares in the JM WHT for at least 1 year. Although fertility rates for treated mares were lower than those of untreated mares in 2014 (the second year after treatment), this reduction in fertility was not statistically significant. The efficacy data reported here is more similar to those shown in recent work (Ransom *et al.* 2011; Rutberg *et al.* 2017) than those shown in initial tests in the Clan Alpine, Nevada, study (Turner *et al.* 2007). This diminished initial efficacy of PZP-22 could be due to a variety of factors, including variation in the composition and manufacturing of vaccine or the other components of PZP-22, including the adjuvant and polymer used to make the controlled-release pellets (Ransom *et al.* 2011; Rutberg *et al.* 2017).

Timing of delivery also may play some role. Previous field testing of hand-injected PZP-22 at Cedar Mountains Herd Management Area (HMA), UT, USA, and Sand Wash Basin HMA, CO, USA, suggests a relationship between timing of delivery and effectiveness. Hand-injected PZP-22 primers in these studies showed highest effectiveness when delivered in February, moderate effectiveness when delivered in December and lowest effectiveness when delivered in October–November (Rutberg *et al.* 2017). Depending on the timing of the breeding season at a given site, however, there is likely to be a drop-off for the efficacy of late-spring delivery. At JM WHT, where most foaling occurs between April and June, one would expect diminishing first-year efficacy in late May through June, because more treated mares will already be pregnant (given a roughly 11-month gestation period for horses and a 2–3-week time lag in elevation of antibody titres to contraceptive levels; Liu *et al.* 1989, 2005). Anecdotally, the two PZP-22-treated mares observed to have produced offspring in 2013 were treated on 1 and 2 June 2012, which were the latest treatment dates for females observed in 2013 (one gave birth in April and one in June; unfortunately, three mares treated as late as or later than those two in 2012 were not located in 2013). It is also not known whether delivering a PZP-emulsion primer (ZonaStat-H) alone this late in the season would produce a comparable reduction in fertility, i.e. whether the pellet components of PZP-22 enhance the effectiveness of the priming vaccine.

Because this was a pilot study of the efficacy of PZP-22 remote delivery, we did not examine nor expect population-level effects. Fewer than 50% of individually recognised sample mares were treated in 2012, and in a challenging site like JM WHT we are confident that the sample significantly undercounted the population. Either way, treating a larger proportion of the fertile mares in a herd will be necessary to create a substantial and biologically important reduction in overall population fertility.

Another factor affecting the proportion of females foaling in the total sample might have been the preferential removal of younger horses in 2011 and 2012. Mares ≥4 years old were observed to be more fertile; therefore, preferential removal of younger mares could also have driven the sample foaling rates higher post-treatment and post-removal. Similar effects of age on foaling rate have been documented in other wild horse herds on public lands (Ransom *et al.* 2011; Rutberg *et al.* 2017) and, depending on vaccine costs and ease of access to the horses, female age might be a consideration in deciding which mares to treat.

Conclusions and implications

It was shown here for the first time that initial treatments of PZP-22 are effective for at least 1 year when delivered by dart, as long as vaccination occurs early enough for antibodies to reach contraceptive levels before the onset of the local breeding season. We also showed that corral trapping with bait can be

used to access very wary wild horses in remote and challenging terrain, allowing administration of contraception or removal of surplus wild horses, or both.

It has already been shown that PZP boosters (either PZP-22 or simple PZP emulsion formulations) administered by dart to mares primed with PZP-22 provide at least three additional years of contraception (Rutberg *et al.* 2017). The present study implies that two dart-delivered treatments of PZP – an initial PZP-22 primer followed by a PZP booster delivered 2–3 years later – should produce 4–5 years of contraception. This protocol significantly reduces the level of effort relative to the annual darting required by simple PZP emulsions and should extend the range of management applications of dart-delivered PZP. Additional field-testing of PZP-based SpayVac and the gonadotropin-releasing-hormone-based vaccine GonaCon (National Wildlife Research Center, Fort Collins, CO, USA) could also provide foundations for long-term wild horse contraception and management applications (Baker *et al.* 2018; Bechert and Fraker 2018). Ultimately, the use of fertility control for populations to treat and prevent overabundance could decrease the financial burden of humanely protecting wild horses and ease tension among diverse stakeholders seeking to use resources on multiple-use public lands (Bartholow 2007; NRC 2013; Garrott 2018).

Neutering affects mRNA expression levels for the LH- and GnRH-receptors in the canine urinary bladder

V.A. Coit, F.J. Dowell, N.P. Evans *

Division of Cell Sciences, Institute of Comparative Medicine, University of Glasgow Veterinary School, Bearsden Road, Glasgow G61 1QH, UK

Received 9 November 2007; received in revised form 17 June 2008; accepted 18 June 2008

Abstract

Neutering a bitch increases the incidence of acquired urinary incontinence (AUI) 20-fold. Mechanistically this effect is thought to be related to altered steroid/reproductive hormone concentrations and a recent study showed that gonadotrophin releasing hormone (GnRH) analogue treatment improved continence in bitches with AUI. The aim of this study was to examine mRNA expression levels for luteinizing hormone (LH)- and GnRH-receptors in the canine bladder and the correlation between these and *in vitro* contractility of the bladder using age matched entire and neutered, male and female canines and canines with AUI.

Biopsies from the dome of the bladder were dissected post mortem with informed owner consent. mRNA expression for LH- and GnRH-receptor was quantified by rtPCR (relative to β-actin). Contractility was assessed (cumulative concentration response curve for carbachol) in strips of bladder muscle using standard protocols.

Analysis of variance (Tukey post-test) demonstrated thet neutering was associated with significantly increased levels of expression of LH- and GnRH-receptor mRNA in both sexes ($P < 0.01$). mRNA expression for both receptors was significantly higher in female versus male canines. Neither effect was affected by animals' age and/or weight. A significant inverse correlation (Spearman's test) was found between bladder contractility and mRNA expression for both receptors. This effect was most pronounced in canines with AUI which demonstrated the highest mRNA expression levels yet had the lowest contractility of all animals studied. This suggests that increased LH- and GnRH-receptor mRNA expression is associated with changes in bladder function that increase an animal's predisposition to develop AUI.

1. Introduction

Acquired urinary incontinence (AUI) is a debilitating and so far incurable condition that causes significant welfare problems. Two diverse populations have been identified that are particularly susceptible to AUI, post-menopausal women and spayed female canines. Information relating to the exact pathophysiology of the condition in these two groups is not understood well enough to allow determination of commonality of cause; however, both groups are subject to a reduction in gonadal steroids and associated endocrine changes.

Urinary incontinence (UI) is defined as the involuntary leakage of urine [1] and, in the bitch, is an increasingly recognised clinical problem with severe welfare implications that can lead to the ultimate

doi:10.1016/j.theriogenology.2008.06.093

euthanasia of the animal. Interestingly, AUI is reported to affect up to 20% of neutered bitches [2] but is seen in less than 1% of intact bitches [3] and is rarely reported in male canines regardless of gonadal status. A direct relationship between neutering and AUI has been reported [4] which is proposed to occur as a consequence of hormonal, vascular or neurological changes [5], rather than mechanical damage of the lower urinary tract, sustained during surgery [6]. Incontinence in the neutered bitch is frequently associated with a decrease in maximal urethral closure pressure [7,8], however, as this is not a defining characteristic of AUI, multiple causative factors are likely to be involved, not all of which will be a consequence of gonadectomy. It has thus been hypothesized that factors in addition to those that decrease urethral closure pressure, lead to a bitch's developing urinary incontinence after neutering. Previous *in vitro* studies have shown that neutering a canine of either gender leads to a decrease in maximal contractile response of the detrusor muscle to both muscarinic and electrical field stimulation as well as a decreased sensitivity to muscarinic stimulation [9]. These decreases in contractile function *in vitro* are similar to those reported in post-menopausal women who suffer from UI due to impaired contractility of the bladder [10].

Given the commonality of endocrine change in the two populations identified as being susceptible to AUI, it is now a widely held hypothesis that the condition may be due to, or be exacerbated by, hormone-mediated effects. This view is supported by the fact that a pharmacological treatment for AUI in the bitch, is steroid replacement [11]. In both spayed bitches and post-menopausal women there is a deficiency of endogenous gonadal steroid hormones which decreases or removes the normal negative feedback to the hypothalamo-pituitary axis, and results in greatly increased production and secretion of gonadotrophin releasing hormone (GnRH) from the hypothalamus, and increased secretion of the pituitary gonadotrophins (luteinizing hormone (LH) and follicle stimulating hormone (FSH)) [12–18]. This increase in plasma concentrations of LH and FSH post-neutering has been demonstrated to have a direct relationship with the development of urinary incontinence in the bitch [19]. A recent paper has described the clinical use of GnRH analogues to decrease LH and FSH concentrations in neutered female canines suffering from AUI. The results of this study also indicated that GnRH analogue treatment resulted in clinical continence, or a decrease in incontinence, during the treatment period [12,13]. This result would suggest that the increase in the concentrations of either GnRH and/or the pituitary gonadotrophins could be a causative factor for AUI in the bitch. Whilst GnRH and the gonadotrophins are classically thought of as hormones of the hypothalamo-pituitary-gonadal axis, the presence of their receptors in tissues such as skin [20], reproductive tract, prostate and mammary gland [21,22] as well as the urinary bladder [23–25] would suggest more widespread actions. In particular the presence of receptors within the urinary tract would indicate that altered concentrations of gonadotrophins could induce local effects within the bladder which could affect function. As specific tissue action and function rely upon the presence of specific receptors in the tissue it is possible that changes in either absolute receptor numbers or receptor–ligand concentration could influence the action of a tissue. In this regard a study in women has reported a decrease in LH-receptor numbers in the bladder of post- compared to pre-menopausal women [25], and a number of recent studies in the canine have reported either a decrease [24,26] or no effect on LH-receptor mRNA concentrations after neutering [17]. However, there are no published reports of mRNA levels for LH-, FSH- or GnRH-receptors in the bladder of bitches known to be suffering from AUI or the correlation between detrusor contractility, a factor known to be involved in UI [10,27], and receptor mRNA expression levels within the urinary bladder.

The aim of this study was to determine the effects of gonadal status and gender on the expression levels of GnRH-, LH- and FSH-receptor mRNA in the canine urinary bladder and to investigate whether these levels are altered in individuals suffering from AUI. A further aim was to see if there is a correlation between the expression of the mRNAs for these receptors and maximal contractility of the bladder, using age matched groups of entire and neutered, male and female canines.

2. Materials and methods

2.1. Animals and tissues

The study was approved by The University of Glasgow Veterinary School's ethical review committee. A total of 78 canines were included in the study, with a mean age of 6.0 years (range 1–16 years) and a mean weight of 22.7 kg (range 8–50 kg). The majority of canines were cross bred, with no pedigree breeds appearing more than once.

In all cases tissue was collected from canines euthanized (intravenous overdose of pentobarbatone),

with full informed owner consent, for reasons other than scientific investigation. The majority of animals were destroyed for severe behavioural problems, the remainder for a number of different complaints, none of which involved the urinary system. In all cases a detailed history of each animal was taken and, within 2 h of death, a gross post mortem study was performed. None of the animals used in the study were receiving medical treatment in the 7 days prior to euthanasia and there was no evidence of previous medical therapy in at least the month prior to this. Biopsies were collected in the area of the bladder dome and samples either stored at 4 °C in Krebs solution for tissue bath studies or immediately frozen and stored at −80 °C until required for mRNA studies. Any animal with a history or signs of gross pathological urinary, neurological or reproductive tract disease (e.g. tumours, cystitis, pyometra) were excluded from the study (except for those suffering from AUI—see below). The remaining animals were split into five groups depending on sex and gonadal status: entire males (ME), entire females (FE), neutered males (MN), neutered females (FN) and neutered females known to be suffering from AUI (FN AUI). All of the entire bitches were considered to be in anoestrous, as the ovaries showed no signs of follicular activity or of an active corpus luteum and all of the neutered animals were at least 6 months post-gonadectomy (determined by history and clinical examination). A diagnosis of AUI was made on the basis of history and clinical signs at time of euthanasia, coupled with full gross post mortem results that ruled out other causes of UI in the bitch such as ectopic ureters, kidney disease, uroliths, cystitis and gross abnormalities of the urinary system.

Ovarian tissue as well as skin biopsies, from the shoulder and groin regions were collected from a subset of animals included in the study, as a control for FSH-receptor mRNA expression [28]. Ovarian and skin samples were handled and stored as described above.

2.2. mRNA extraction and quantitative reverse transcription PCR

Biopsies where placed in 1 ml ice cold TRIzol reagent (Invitrogen, Paisley, UK), homogenised and RNA extracted according to the manufacturers protocol. After extraction, RNA was suspended in 40 μl RNase-free water and the concentration of RNA determined using a NanoDrop ND-1000 spectrophotometer. The purity of RNA (A_{260}/A_{280}) was greater than 1.9 in all samples. 1 μg of each RNA sample was reverse transcribed into cDNA using random hexamers (Promega, Southampton UK), Moloney-Murine Leukaemia virus (M-MLV) reverse transcriptase (Invitrogen, UK) and Rnasin (Promega, UK), as described previously [28]; final reaction volume of 24 μl. Quantitative real time taqman PCR (qPCR) was performed on cDNA for GnRH-, LH- and FSH-receptor with β-actin as the housekeeping gene using the Amplitaq Gold kit (Applied Biosystems, Warrington, UK) and a Strategene MX 3000P thermal cycler. The primers and probes for the three receptor mRNAs were as described by Welle et al. [20], sourced from Eurogentech (Southampton, UK). Prior to use in the current experiment the concentration of primers and florescent FAM-labelled probes against LH-, GnRH- and FSH-receptor mRNAs [20] were optimised relative to the housekeeping gene β-actin, to ensure that amplification of each of the genes of interest matched that of the housekeeping gene. All probes used were at a final concentration of 530 nM, with forward (f) and reverse (r) primers at: LH- and FSH-receptor mRNAs 1000 nM (f), 800 nM (r), GnRH-receptor mRNA 660 nM (f), 800 nM (r), β-actin mRNA 800 nM (f and r). All samples were run in duplicate, PCR conditions used were an initial step of 95 °C for 10 min followed by 45 cycles of 95 °C for 30 s and 60 °C for 1 min. Non-template controls were included for each primer pair to check for significant levels of any contaminants and in all cases were negative.

2.3. Tissue preparation for tissue bath studies

Tissue was used within 48 h of collection. Following removal of the lining urothelium strips of smooth muscle (2 mm × 10 mm) were dissected from the dome of the bladder. The strips were mounted under 4 g resting tension (the optimum tension demonstrated in preliminary previous length-tension studies) on a fixed hook in a 15 ml organ bath bathed at 37 °C in Krebs solution (NaCl 118 mM, KCl 4.8 mM, $CaCl_2$ 2.5 mM, $MgSO_4$ 1.2 mM, KH_2PO_4 1.2 mM, $NaHCO_3$ 24 mM and glucose 11 mM) gassed with 95% O_2/5% CO_2. Tension was measured with a BIOPAC TSD125C isometric force transducer and displayed using the AcqKnowledge 3.8.1. Biopac data acquisition system (Linton Instruments). Tissues were allowed to equilibrate for 60 min before experiments were begun, during which time the resting tension was re-adjusted to 4 g if required [9]. For all studies, a minimum of 2 muscle strips per animal were included.

2.4. Assessment of carbachol-induced contraction

To determine the response to the non-specific muscarinic agonist carbachol, cumulative concentration

Table 1
Age and weight of animals, by group.

	ME ($n = 27$)	MN ($n = 17$)	FE ($n = 18$)	FN ($n = 13$)	FN AUI ($n = 3$)
Age (years)	5.6 ± 0.7	5.8 ± 0.9	6.1 ± 1.0	6.5 ± 1.0	4.3 ± 2.0
Weight (kg)	23.7 ± 1.8	27.4 ± 3.2	21.9 ± 2.2	21.1 ± 3.1	17. ± 5.0

Mean ± S.E.M. values for age and weight in groups of entire and neutered, male and female canines, and neutered bitches identified as suffering from AUI (ME, MN, FE, FN and FN AUI, respectively). n = number of animals.

response curves to carbachol (1 nm–30 μM) were generated in strips of bladder smooth muscle. Maximal tension was recorded and data calculated as grams tension produced per milligram of wet tissue.

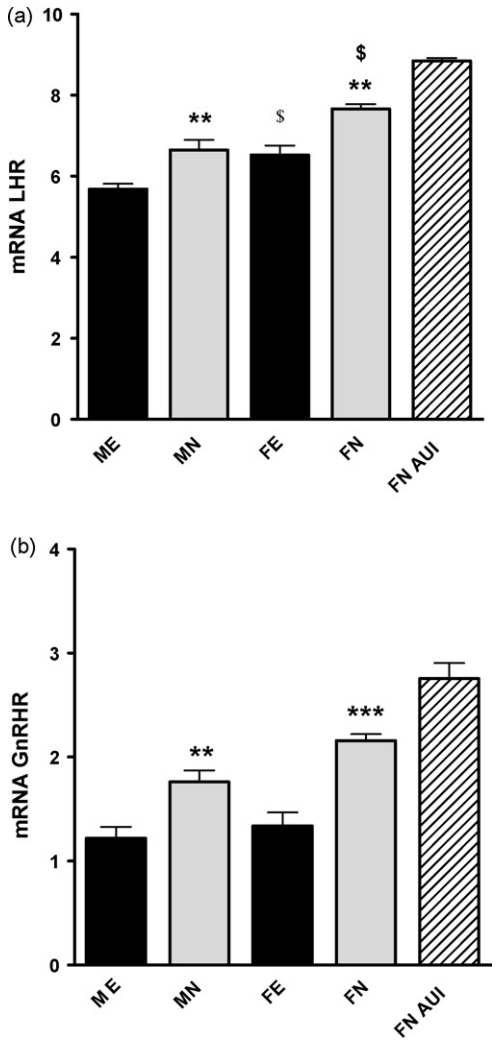

Fig. 1. Mean (±S.E.M.) mRNA expression for: (a) LH-receptor and (b) GnRH-receptor, in entire and neutered male and female canines and neutered female canines identified as suffering from AUI. mRNA values are logarithmically transformed. $^{***}P < 0.001$, $^{**}P < 0.01$ compared entire of same gender. $^{\$}P < 0.05$ compared to male animals of same gonadal status.

2.5. Statistical analysis

Results for both mRNA expression levels and contraction to carbachol were analysed against both age and weight using multivariant analysis with $P < 0.05$ considered significant.

Results are given as mRNA expression levels relative to β-actin using the comparative C_T method (User Bulletin no. 2, PE Biosystems, UK). Data was ln-transformed prior to statistical analysis to equalise the variance between groups and data compared by two-way ANOVA for effects of gender and gonadal status. Post hoc comparisons were conducted using Tukey's test with a significance threshold of $P < 0.05$.

To examine relationships between the levels of mRNA expression of the hormone receptors studied and the ability of the detrusor to contract when stimulated with carbachol, mRNA expression levels of each hormone receptor were plotted against maximal contraction (as grams of tension produced per milligram of wet tissue) and tested for a correlation using Spearman's test with a significance threshold for P (two tailed) <0.05.

3. Results

The mean age and weight of the 78 canines included in this study, 27 entire males (ME), 17 neutered males (MN), 18 entire females (FE), 13 neutered females (FN), and 3 neutered females known to suffering from AUI (FN AUI) are presented in Table 1. There was no statistical difference between the mean ages and weights for the five groups.

The mean levels of mRNA expression for LH- and GnRH-receptor are shown in Fig. 1a and 1b, respectively. Two-way ANOVA indicated significant effects of gonadal status on the expression of the mRNAs for both LH- and GnRH-receptor, whilst there was an additional effect of gender on the expression of LH-receptor mRNA. There was no interaction between the effects of gonadal status and gender. Neutering was associated with significantly ($P < 0.01$) higher levels of mRNA expression for both LH- and GnRH-receptor in

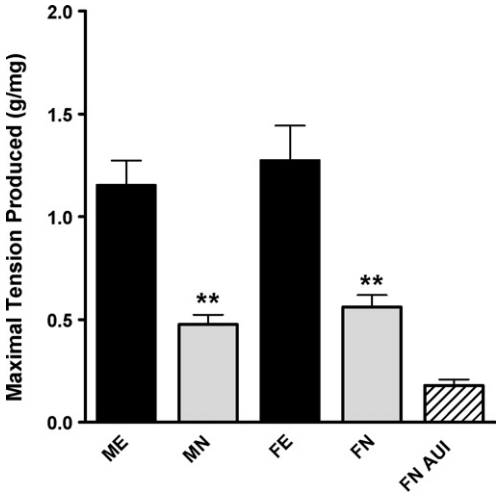

Fig. 2. Mean (±S.E.M.) maximal tension values (g/mg wet tissue) in response to carbachol in entire and neutered male and female canines and neutered female canines identified as suffering from AUI. $^{**}P < 0.01$ compared entire of same gender.

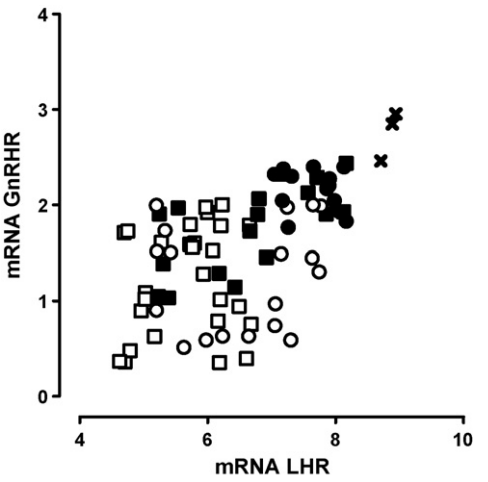

Fig. 3. Correlation between mRNA expression levels of LH- and GnRH-receptor ($P < 0.001$, $r = 607$). (□) Male entire, (■) male neuter, (○) female entire, (●) female neuter, and (×) AUI female neuter.

both genders. Furthermore, female animals showed significantly ($P < 0.05$) greater levels of mRNA expression of LH-receptor, regardless of gonadal status, than their male counterparts (Fig. 1a).

The mRNA expression levels for both LH- and GnRH-receptor for the females identified as AUI were the highest of all the animals in the study and fell above the 95% CI for the continent FN group, although this increase was not considered statistically significant using ANOVA analysis.

Real time rt-PCR was performed for the quantification of FSH-receptor mRNA expression within samples of urinary bladder. In all cases, expression was found to be below the limits of detection of the assay system. To ensure validity of the primers and probes used, they were tested against samples of canine ovary and skin as described in Welle et al. [20]. mRNA for the FSH-receptor was found at very low levels ($3.22E^{-15}$, $n = 2$) in samples of canine skin but was not found in canine ovary.

Carbachol-induced dose dependant contraction of the isolated strips of detrusor muscle from all animals. As in our previous study [9], maximal response was significantly decreased ($P < 0.01$) in neutered compared to entire canines of either gender (Fig. 2). Sensitivity of strips to carbachol, as measured by log EC_{50} values, was also decreased ($P < 0.01$) in neutered compared to entire animals (Table 2). Two-way ANOVA revealed that there was no effect of gender and no interaction between gender and gonadal status. The group of animals identified as suffering from AUI had the lowest maximal contraction of all animals studied, although this was not considered significant using ANOVA.

Statistical analysis revealed a significant positive correlation ($P < 0.001$, $r = 0.607$) between LH- and GnRH-receptor mRNA expression (Fig. 3) and significant negative correlations between the maximal tension produced by detrusor muscle strips and both LH-receptor ($P < 0.001$, $r = -0.671$) and GnRH-

Table 2
Maximum and log EC_{50} values for Carbachol.

	ME ($n = 11$)	MN ($n = 10$)	FE ($n = 10$)	FN ($n = 8$)	FN AUI ($n = 3$)
E_{max}	1.15 ± 0.12	0.49 ± 0.05*	1.27 ± 0.17	0.56 ± 0.06*	0.18 ± 0.03
log EC_{50}	−6.98 ± 0.05	−6.39 ± 0.02*	−7.09 ± 0.06	−6.51 ± 0.07*	−6.26 ± 0.10

Maximum (E_{max}) and log EC_{50} values for carbachol in isolated strips of detrusor muscle from entire and neutered, male and female dogs and neutered females identified as suffering from AUI (ME, MN, FE, FN and FN AUI, respectively). Data are expressed as g/mg of wet tissue with results given as mean ± S.E.M. where n: number of animals.

* $P < 0.01$, indicates different from entire of same gender.

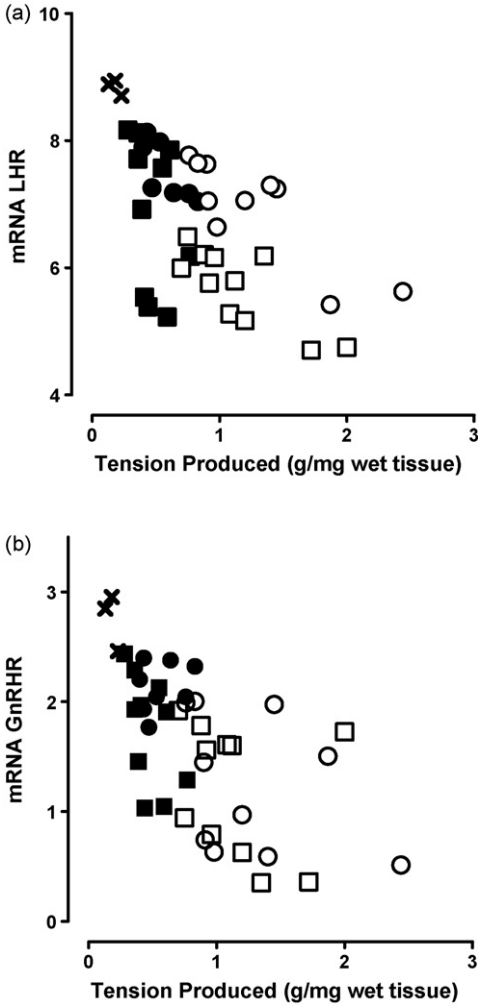

Fig. 4. Correlation between maximal tensions produced by detrusor muscle strips *in vitro* and mRNA expression levels for: (a) LH-receptor ($P < 0.001$, $r = -0.671$) and (b) GnRH-receptor ($P < 0.001$, $r = -0.612$). (□) Male entire, (■) male neuter, (○) female entire, (●) female neuter, and (×) AUI female neuter.

receptor ($P < 0.001$, $r = -0.612$) mRNA expression (Fig. 4a and b, respectively).

Multivariant analysis of the levels of expression of mRNA for both GnRH- or LH-receptor, and the maximum tension produced by detrusor muscle strips indicated no significant effect of age or weight of the animal on the results.

4. Discussion

This is the largest study of the expression levels of the mRNAs for LH- and GnRH-receptors in the canine urinary bladder, and the only study to correlate levels of receptor mRNA expression to bladder contractility (*in vitro*). In addition, although numbers are low, this is the only study to report bladder LH/GnRH-receptor mRNA expression in neutered bitches known to be suffering from AUI.

Bladder contractility is thought to play a significant role in the development of clinical signs of UI [29]. We have previously shown that the maximal contractile response of isolated strips of detrusor muscle to muscarinic and neurogenic stimulation was significantly decreased in neutered compared to entire canines of either gender [9]. We have also demonstrated that sensitivity of the detrusor to muscarinic stimulation is decreased in neutered compared to entire animals of either gender. These results are similar to those reported for studies conducted with tissues collected from women who suffer from UI due to impaired contractility of the bladder [10], a condition known to cause decreased speed and magnitude of detrusor contractions during the emptying phase of micturition. This leads to residual urine retention, a shortened storage phase and predisposes the patient to cystitis [30]. That decreased contractility and sensitivity of the detrusor to muscarinic stimulation in neutered canines may be involved in AUI is supported by the results of this study, looking at animals known to be suffering from AUI, as these had the lowest contractility of all the animals studied. Although impaired bladder contractility has been implicated in UI, the exact mechanisms responsible for its development have not been reported and we hypothesise that the muscarinic receptor effector pathway is involved, its function being altered due to effects in reproductive hormones and the expression of their receptors in the bladder post-neutering/menopause.

It was first suggested that gonadotrophins could influence bladder function in a study which showed that post-menopausal women, who are most likely to suffer from UI, had lower numbers of LH mRNA transcripts and receptors in their bladders than their premenopausal counterparts [25]. As post-menopausal women have a similar hormonal profile to neutered canines, and as both post-menopausal and post-neutering UI are thought to be hormonally related, it follows that a similar aetiology and pathophysiology may link both conditions. Our results clearly show that neutering a canine, regardless of gender, significantly increases levels of mRNA expression for both LH- and GnRH-receptors, and that in general, female animals, regardless of gonadal status, have higher levels of mRNA expression for these receptors than their male counterparts. Although our results, for female canines, are in contrast with those of Tao et al. [25] it should be noted

that in addition to the species difference our study include age matched groups of healthy entire and neutered animals as well as those neutered female canine suffering from AUI, whereas the study by Tao et al. compared women of two distinct age groups, with a number of patients in both groups suffering from UI and genital prolapse, therefore an additional explanation for the difference in the two studies could be an effect of age and mechanical stress on the lower urinary tract. Interestingly, the results of the FN animals in this study known to be suffering from AUI suggest that incontinent neutered bitches may have higher levels of LH-receptor mRNA than their continent counterparts. These findings support the hypothesis that altered gonadotrophins have a role in the pathophysiological mechanism of post-neutering UI as suggested by the efficacy of GnRH analogues in the treatment of canine AUI [13].

In addition to being different from the study reported in humans our results also contradicts with two recent canine studies that reported either no change [24] or a decrease [26] in mRNA expression for these receptors, respectively, in neutered canines. The differences between the three canine studies may again reflect differences in the study populations and conditions. In both of the studies by Reichler et al. [24] and Ponglowhapan et al. [26] a substantially smaller number of animals were used. In addition, the study by Reichler et al. included entire bitches in varying stages of oestrus, thus making comparisons between the groups and studies more complex. Whereas the study by Ponglowhapen et al. looked at relatively acute effects of neutering (24–40 weeks), and thus it is possible as plasma concentrations of FSH and LH continue to increase until week 42 post-neutering [16] and some structural changes may take even longer [31], that there will be significant effects of time post-neutering on the observed mRNA changes.

A further difference between this study and those of Tao et al. and Ponglowhapan et al. is methodological, in that the current study used real time PCR with fresh frozen tissue to quantify mRNA expression levels, whilst the former two studies used in situ hybridisation with formalin fixed, paraffin-embedded tissue. It is known that degradation of target nucleic acids [32,33] and artificial mutations [34] can occur during formalin fixation and paraffin-embedding procedures, which again could have influenced the results, relative to those seen from fresh frozen tissue [35].

The changes in expression of mRNA for LH- and GnRH-receptors observed in our study could support a role for altered expression of GnRH/LH-receptors in the development of AUI in the neutered bitch. Although it is worthy of note that increases in LH- and GnRH-receptor mRNA expression also occurred in the bladders of neutered male canines, which do not typically become incontinent, the magnitude of increase was smaller and the final levels of expression were only marginally above that of entire female canines which also rarely become incontinent. The sex difference in the propensity to develop AUI may also reflect an interaction between post-neutering effects on smooth muscle function and anatomical differences in the urethra of a male canine as has been previously hypothesized [36]. It may be the case however that there is a threshold level of LH- and GnRH-receptor expression, above which UI is more likely to develop. This possibility is supported by the fact that the three animals known to be suffering from AUI had the highest LH- and GnRH-receptor mRNA expression levels observed in this study.

The exact role of the LH-receptor in the urinary bladder has not yet been described. It is known that the plasma concentrations of LH increase in both post-menopausal women and in neutered dogs [16,37], although it is still released in a pulsatile manner. It is also known that this subset of the population is most prone to developing UI. In this study we have shown that neutering causes an increase in mRNA expression levels for the LH-receptor in the canine urinary bladder, and that these expression levels are highest in bitches known to be suffering from AUI. We have also shown that maximal bladder contractility is decreased in neutered animals and is lowest in bitches suffering from AUI and that there is a direct inverse correlation between bladder contractility and mRNA expression levels for LH. It therefore follows that the increase in mRNA for the LH-receptor may be implicated in the decrease in contractility of the detrusor muscle in the canine, either directly or via interactions with another mechanism, possibly involving the muscarinic receptor effector pathway, the primary pathway involved in bladder contraction [38].

The exact role of the GnRH-receptor within the urinary bladder has not been characterised in any species. However, based on a recent study that reported increases in bladder threshold volume following administration of GnRH analogues to neutered continent bitches it has been hypothesized that it may have a role in determining bladder function [12]. This could occur if GnRH-receptor expression modulated the bladders sensitivity to muscarinic stimulation to affect the bladder threshold volume. This hypothesis is supported by the data contained within our study,

where a decrease in *in vitro* detrusor muscle sensitivity to muscarinic stimulation was seen in neutered canines when GnRH-receptor mRNA expression levels were found to be high. Thus, the increase in GnRH-receptor expression could be associated with a decreased sensitivity of the detrusor which would allow further relaxation of the bladder and increased capacity.

Although our study did not identify mRNA for FSH-receptor in the canine bladder two other studies [20,23] have reported its expression within this tissue. The reason for these reported differences studying FSH-receptor mRNA expression, could be methodological, as Ponglowhapan et al. [23] used in situ hybridization whilst our study used real time PCR techniques. Alternatively it could be related to differences in the FSH mRNA sequences used, as our results were similar to those described by Welle et al. [20], who used the same primers and probes and reported expression in canine skin, and inconsistent expression within the canine bladder [20] whilst Ponglowhapan et al. used a different molecular sequence as the basis for their probe. As FSH is known to express multiple isoforms [39] it is a possibility that the primers and probes used in this study and that of Welle et al. [20] were designed against part of the mRNA sequence of an FSH-receptor isoform that is expressed in skin but not in the bladder. As part of the validation of the probe in the current study, in addition to testing the primer and probes against bladder and skin, ovarian tissue was also included as the ovary is a key target organ for the actions of FSH [40]. The ovary, however, was also found to be devoid of significant quantities of the FSH-receptor mRNA expression that could be identified using these primers and probes. Thus, at this point, we are unable to make any definitive conclusions with regard to the effects of neutering on FSH-receptor mRNA expression within the bladder wall.

In conclusion we have shown that neutering a canine, regardless of gender, is associated with an increase in the levels of mRNA for LH- and GnRH-receptors in the canine urinary bladder, and that female animals, regardless of gonadal status have higher LH-/GnRH-receptor mRNA expression levels than males. A further novel observation shown by this study is the positive correlation between increased mRNA expression for LH- and GnRH-receptors and the negative correlation between expression of these receptors and contractility of the detrusor to muscarinic stimulation *in vitro*. It is hypothesized that the changes in mRNA expression for both GnRH- and LH-receptor may have a role to play in the development of post-neutering AUI and this hypothesis is supported by data from a limited number of neutered female canines identified as suffering from AUI which had the highest levels of LH- and GnRH-receptor mRNA expression and the lowest contractility to muscarinic stimulation of all the animals studied.

Genetics, biotechnology and population management of over-abundant mammalian wildlife in Australasia

Abstract. Wildlife management involves regulation of population numbers of wild vertebrate species. In some cases there are too many animals and in others there are too few. Genetic issues arise in both instances. The historical and genetic evidence for the number of mammals that were in the founder populations of successful colonizing species in Australia and New Zealand is reviewed here. Small numbers have often given rise to large populations, despite the concomitant loss of genetic variability. Restriction of the number of over-abundant and pest species by either physical or chemical methods frequently constitutes very strong artificial selection, which leads to rapid genetic change; an example of major importance in the two countries is sodium monofluoroacetate (compound 1080). Pathogenic agents, surgical sterilization, hormonal contraceptives and translocation have all been used with varying degrees of success. The strengths and weaknesses of these techniques are assessed. A method that has received much attention is immunocontraception. We argue that this attempt to use the animals' own immune system to modulate reproduction is incompatible with the basic biological function of protection against infectious disease. Immune function genes are highly variable in vertebrates, and so often genetic change in the population subjected to immunocontraception is likely to be even more rapid than is the case with lethal agents. Selection for failure to respond to the immunocontraceptive will occur, and will change immune function in general. Poor scientific description of ecosystem complexity makes it difficult to predict the consequences of immunocontraception on wildlife populations.

Extra keywords: deslorelin, fertility control, immunocontraception, myxomatosis, sodium monofluoroacetate.

Introduction

The term Australasia was originally used to describe Australia and New Zealand. In recent years it has also been used to include neighbouring areas of Asia. For our purposes this is serendipitous because Wallace's line in the Indonesian archipelago defines the border of the biologically unique region of Australia, New Guinea, New Zealand and the islands of the south-west Pacific. This is sometimes called Wallacia (van Oosterzee 1997). Wallacia's long isolation after the fragmentation of Gondwana has produced endemic flora and fauna on which Australians and New Zealanders place high conservation value. These endemic species are now strongly challenged by the arrival of Northern Hemisphere species, especially in the last two centuries. In scientific terms, Australia and New Zealand constitute a kind of inadvertent laboratory for the study of factors influencing the success of colonizing species. One such factor is the size of the founder population. We review some of the historical evidence on this question from the two countries, which indicates that the most over-abundant introduced pest species can result from very small founder populations. A major aspect of wildlife management in Australia and New Zealand is aimed at reducing the number of introduced species that are most damaging to indigenous species. Management techniques include shooting, poisoning, the introduction of pathogens, translocation, and, most recently, attempts at using biotechnological products. In this review, we will explore the underlying genetic issues and comment on the extent to which successful management is limited by them. Our focus is a mixture of scientific and wider social issues, an approach that is so richly exemplified in the scientific career of Roger Short.

Genetics and small populations

Small population size results in a loss of genetic variability, equivalent to $(2Ne)^{-1}$ per generation, where Ne is the effective population size. Ne is a measure of the number of independent genes in a population and is usually smaller, often much smaller, than the number of actual individuals. It is determined by the number of individuals that reproduce (Crow 1986; Li and Graur 1991). There are a number of species that have colonized New Zealand and Australia from small foundation numbers (Table 1). Australian brushtail possums in New Zealand and English rabbits and foxes in Australia have become major pests. Rapid population expansion after introduction would have prevented excessive loss of heterozygosity. In principle, the accuracy of the

historical records can be checked with genetic techniques, but this has rarely been done. Le Page *et al.* (2000) carried out a microsatellite genetic marker study of the New Zealand Bennett's wallaby population, which was recorded as being founded on three animals. The study showed that the founder number was unlikely to have been as small as three. Nonetheless, the bottleneck was severe, with probably three to five pairs of wallabies for one to three generations.

Small population size leads to a degree of linkage disequilibrium, which is proportional to Ne. Linkage disequilibrium is the non-random association of genes at different loci, usually closely linked. It can now be detected and measured using microsatellite markers. A methodology for calculating Ne in the founder population using linkage disequilibrium has been described by Hill (1981) and applied to a fish population (Bartley *et al.* 1992) and cetaceans (Waples 1991). The Hill approach could be extended to colonizing species for which there is no historical record of founder population. Although a large undertaking, this would allow a comprehensive assessment of the extent to which colonizing species are founded on small numbers. It would also allow, as in the case of the New Zealand Bennett's wallaby, the historical record to be checked. The results might have relevance to the question of the influence of population size on the fate of species endangered by small population size.

New Zealand possums are of both Tasmanian and mainland origin, which are usually thought of as subspecies. Thus, part of their success could be the result of heterosis though hybridization between subspecies. Subspecies crosses can negate loss of variation owing to small population size. The red deer and wapiti (North American Elk) hybridize in nature in New Zealand and so similar remarks apply to this species. Red deer were, however, well established before this occurred.

Table 1. Populations founded on small numbers in Australia and New Zealand

Country	Species	Number
New Zealand	Bennett's wallaby	3
	Brushtail possum	200–300
	Hares	6
	Hedgehog	Some tens
	Chamois	8
	Tahr	30
	Red deer	250
	Wapiti	18
	Sika deer	6
	Sambar deer	2
	Rusa deer	8
	Fallow deer	50–60
	White-tailed deer	19
Australia	Kangaroo Island koalas	18
	Rabbit	13
	Water buffalo	80
	Banteng cattle	20

All New Zealand information is from a volume edited by King (1990). The other references are: rabbits (Palmer-Austin 1993); koalas (Martin and Handasyde 1999); water buffalo and banteng cattle from a volume edited by Strahan (1975).

Genetics, biotechnology and over-abundant populations

For the species of most concern in Australia and New Zealand, a number of management techniques are currently used (Table 2). All of these techniques involve large sections of the population, at least locally. There is therefore the potential for genetic selection to take place. The kind of selection and physiological systems that are likely to be affected are very heterogenous (Table 3).

Sodium monofluoroacetate (*1080*)

Various poisons are being used to control wild animals around the world. By far the most widely used and effective poison in Australia and New Zealand is sodium monofluoroacetate (1080) (Eason *et al.* 1994; Seawright and Eason 1994). This has the effect of inhibiting the enzyme aconitase in the mitochondrion, which governs the step, citrate to isocitrate, in the tricarboxylic acid cycle for the aerobic production of energy. It is one of the most poisonous substances known on a weight-for-weight basis: 5 mg will kill a fox, for example, but death is by no means painless. 1080 is cheap, can be used in small quantities and degrades rapidly in the environment.

In various parts of western, central and northern Australia, native plants of the genera *Gastrolobium* and *Acacia* accumulate sodium monofluoroacetate in their flowers and seeds. This is presumably a defence against over-browsing in what are frequently very arid environments (Twigg and King 1991). Many Western Australian vertebrates have been shown to have high 1080 tolerance, and Western Australian animals often have a much higher tolerance than their eastern conspecifics (Table 4). This unusual situation now forms the basis of a highly successful fox control programme in Western Australia, where 1080-containing baits have been used to reduce fox densities to the point where they no longer threaten small terrestrial marsupials (Bailey 1996; Morris *et al.* 1998). It is also used greatly in eastern Australia for foxes and in New Zealand for possum control even though native species are not immune.

There are two serious reservations concerning the use of 1080. First, it is widely viewed as inhumane. Second, as the Western Australian resistant strains of widely occurring species demonstrate, selection for resistance is inevitable. This may have occurred slowly in Western Australia, and may even have been the result of the inhibition of reproduction rather than lethality, if only small amounts were consumed at any one time (Twigg and King 1991). Both reservations might be ameliorated by adding an anaesthetic

to the baits being used (Marks *et al.* 2000). This would cause death to occur much more humanely. If an anaesthetic that also up-regulates energy production could be found, death may occur more quickly. Less 1080 may be necessary and since resistance must develop to two agents, the anaesthetic and 1080, the rate of selection for resistance may slow.

Resistance to 1080 can evolve within the lifetime of a species (Table 4). May and Dobson (1986) draw attention to the finding that under very strong selection pressure, of the kind imposed by biocontrol agents such as insecticides, rodenticides and herbicides, noticeable resistance appears in 5–100 generations. They explain this by deriving a formula for the rate of appearance of resistance based on a two allele monogenic model. This formula shows that the rate is logarithmically dependent on its main determinants. These are the initial frequency of the allele, the threshold at which resistance appears and the selection strength. The last is determined by dosage levels and the degree of dominance of the resistance gene. The conclusion is that despite there being likely orders of magnitude in the range of these values, the time scale of appearance of resistance is compressed. A general account of the ecological and evolutionary aspects of insecticide resistance is given by McKenzie (1996); the data described therein demonstrate the rapidity with which resistant phenotypes can appear when selection is intense.

Myxomatosis and calicivirus

These viral pathogens have been particularly effective in reducing the large rabbit populations of Australia. Myxomatosis was deliberately introduced into Australia in 1950 (Fenner 1983), and it has been possible to study the co-evolution of host resistance and pathogen virulence (Fenner 1972; Kerr and Best 1998). By 1983, natural selection had resulted in a balance between the two (Fenner 1983). Resistance in rabbits followed with the emergence of less virulent strains, which allowed survival of moderately resistant rabbits (Kerr and Best 1998). Resistance is likely to be owing to an enhanced innate immune response, probably the cellular immune response (Kerr *et al.* 1999). Calicivirus was accidentally introduced into the wild in South Australia in 1995. However, there has been too little time to study the

Table 2. Mammalian wildlife species currently subject to management practices in Australia and New Zealand

Common name	Country	Current control
European rabbit	New Zealand, Australia	Myxomatosis Calicivirus Shooting 1080
Brushtail possum	New Zealand, urban Australia	1080 (NZ) Other poisons (NZ) Shooting (NZ) Trapping (NZ) Translocation (Aus)[a]
Feral cat	New Zealand, Australia	1080 Shooting Fencing
Wild deer (various species)	New Zealand, Australia	Shooting Translocation to farms
Mustelids (stoats, ferrets, weasels)	New Zealand	Trapping 1080 Warfarin and derivatives
Wild ungulates (e.g. pigs, goats, horses)	New Zealand, Australia	Shooting 1080
Kangaroos and wallabies (various species)	New Zealand, Australia	Shooting Surgical sterilization (Aus) 1080
Rodents (rats, mice)	New Zealand, Australia	Warfarin and derivatives 1080
Red fox	Australia	1080 Shooting Fencing
Koala	Australia	Translocation Surgical sterilization

[a]Illegal, but probably widespread. 1080, sodium fluoroacetate; calicivirus, rabbit haemorrhagic disease (RHD) virus.

Table 3. Possible evolutionary consequences of management techniques

Technique	Consequence
Shooting	Altered behaviour
1080	Bait shyness (neophobia)
	Alteration to fatty acid metabolism, entry to mitochondrion, detoxification mechanisms, substrate specificity
Steroid or peptide hormones	Alteration to receptor structure
Warfarin and derivatives	Altered clotting mechanism
	Bait shyness
Pathogens (e.g. myxomatosis, calcivirus)	Many possibilities
	Increased immunocompetence for specific antigens (MHC linked)
	Increased immunocompetence in general (not MHC linked)
Immunocontraception	Reduced immunocompetence
Surgical sterilization	Loss of variability if bottlenecks created

host–pathogen interaction in this case. Young rabbits are protected by maternally derived immunity (Cooke *et al.* 2000). The epidemiology of the disease appears to be influenced by the presence of a so far unidentified pre-existing non-virulent rabbit calicivirus closely related to the virulent form (Nagesha *et al.* 1995).

Surgical sterilization

Surgical sterilization has become a popular form of fertility control in situations where total removal of the species is not the goal. This is particularly the case in areas of Australia where marsupial populations have grown too large and require active management, for example recent wide-scale control operations on Kangaroo Island involving surgical sterilization (via tubal ligation) of female koalas (Ellis 1998).

This method has the advantage that it is permanent and the exact specifications of the treated portion of the population can be planned and put into practice (Menkhorst *et al.* 1998). Surgical sterilization may be more publicly acceptable in particular situations than other options such as culling, and is generally more readily available than other fertility control methods currently undergoing the research and development process. The permanence of this form of treatment may also be a disadvantage in some circumstances, for example when the genetic diversity of a population is low. Other disadvantages are the invasive nature and high cost of these procedures.

Table 4. Resistance to 1080 in eastern versus Western Australian vertebrates (Twigg and King 1991)

Species	LD50 (mg kg^{-1})	
	Western race	Eastern race
Tiliqua rugosa	500, >800	214
Varanus rosenbergi	200–300	40
Antechinus flavipes	12.5	3.5
Isoodon obesulus	20	7
Trichosurus vulpecula	125	0.75
Macropus eugenii	5, 20	3
Rattus fuscipes	20, 80	1.1

Hormonal contraceptives

Hormonal contraceptives can be divided into steroidal and non-steroidal contraceptives. Synthetic progestins are the most widely used form of steroidal contraceptives, particularly in zoo environments, because of their efficiency and relatively low cost (Dutton and Allchurch 1998). Synthetic progestins have several modes of action. They reduce the amount of the pituitary gonadotrophins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), thereby inhibiting follicular maturation, development and ovulation. They also prevent the migration of spermatozoa through the cervical canal by reducing the volume of cervical mucus and increasing its viscosity, and they inhibit implantation by interfering with the development of the endometrium (Segal *et al.* 1991; Nave *et al.* 2000).

Synthetic progestins are usually given in the form of silastic implants (Dutton and Allchurch 1998). Minor surgery under local anaesthetic is often required to administer the contraceptive, for example in tammar wallabies (Nave *et al.* 2000), although there have been published reports of remote delivery using 'biobullet' technology for example in white-tailed deer (DeNicola *et al.* 1997). Contraceptive success can be close to 100% in some species, such as tammar wallabies (Nave *et al.* 2000), koalas (Menkhorst *et al.* 1998) and white-tailed deer (DeNicola *et al.* 1997), once the appropriate dose has been determined (DeNicola *et al.* 1997). The duration of effect for tammar wallabies was found to be at least 36 months (Nave *et al.* 2000).

Commentaries on the use of synthetic progestins as a contraceptive for wildlife often urge caution based on the reports of adverse effects in some species, including

pathology of the reproductive tract (Dutton and Allchurch 1998; Tuyttens and Macdonald 1998). Most of these reports are limited to case reports of animals displaying clinical signs in zoo environments (reviewed by Dutton and Allchurch 1998; Tuyttens and Macdonald 1998). The rate of occurrence of these adverse effects in different species is not clear from the literature and should be reviewed. Recommendations on the use of this form of contraception should be based on sound scientific data from individual species, as it is not clear whether all species are prone to the same negative effects.

Gao and Short (1993*a*, 1993*b*, 1994*a*, 1994*b*) have examined the possibility that steroids (oestrogen, androgen, gestagen, antigestagen) in bait form could be used to control rodent populations. This approach deserves further analysis and trialing, particularly with regard to cost and feasibility for large-scale use in agricultural environments.

Non-steroidal contraceptive agents include analogues of gonadotrophin-releasing hormone (GnRH). Gonadotrophin-releasing hormone is a peptide that is produced and secreted by the hypothalamus. When GnRH agonists are administered continuously, they result in a down-regulation of pituitary GnRH receptors and a subsequent decline in the production of LH and FSH. The end-point of these changes is a decline in the concentration of gonadal steroids, failure of ovulation in females and inhibition of spermatogenesis in males (Fraser 1993).

Gonadotrophin-releasing hormone agonists have been shown to inhibit reproduction in both sexes of many species. They are most effective in the form of a controlled-release implant, administered via subcutaneous injection. Recent advances in slow-release technology (Peptech Pty Ltd, North Ryde, Australia; details in US patent no. 6,211,152) mean that contraception may be effective for one to two years in many species. Gonadotrophin-releasing hormone agonists can be administered by a simple subcutaneous injection once an animal has been captured, and so far there have been no significant negative side-effects documented. As GnRH agonists work by reducing the production of steroids, there are potential changes in behaviour, in particular sexual behaviour, which may affect social dominance hierarchies. This may not be desirable in wild populations of some species in which dominance may confer better access to resources within the environment, such as food, nesting sites and home range size (Tuyttens and Macdonald 1998). The manner and degree to which any behavioural changes will affect the welfare of individuals within a population will be dependent on the social structure of the species in question.

Slow-release implants containing the GnRH agonist, Deslorelin (Peptech Pty Ltd, North Ryde, Australia), are currently being trialed in a range of marsupial species, including tammar wallabies, grey kangaroos and koalas. Preliminary results to date suggest that this is a promising contraceptive for female kangaroos and wallabies (C. A. Herbert and D. W. Cooper, unpublished results).

Hormonal contraceptives, both steroidal and non-steroidal, have the potential to be a relatively inexpensive fertility control option as the costs of research and development are often borne by human or domestic species research. This will make the development phase much less expensive than for other wildlife-specific agents. However, these savings may be offset by the cost of physically catching and treating individual animals if remote delivery is not possible. The reversible nature of this form of fertility control may be viewed as either an advantage or a disadvantage depending on the level of population control that is required. Peptides may be more expensive than steroid derivatives and may have a shorter duration of action. However, they do not have the same potential for negative side-effects as steroidal agents. The incidence of negative side-effects may affect the public perception of steroidal contraceptives and their usefulness for wildlife, particularly with respect to highly valued species such as the koala.

Variation in responses to hormones of all kinds is potentially under genetic control (Spearow *et al.* 1999; Westberg *et al.* 2001). Failure of contraception could result in selection for such genes in the population. All trials of hormonal contraceptives have so far been on a small scale (DeNicola *et al.* 1997; Dutton and Allchurch 1998; Nave *et al.* 2000). These need to be expanded, with particular attention being paid to the heritability of any non-response.

Translocation

Translocation has been used as a management tool for a number of species in Australia and New Zealand. One of the most notable cases was the translocation of koalas from offshore islands in south-eastern Australia to areas of suitable habitat that remained unoccupied following the major population decline in the early 20th century. This programme was extremely successful at restoring koalas to areas of their former range in Victoria, so successful, in fact, that there is now a shortage of suitable release sites (Menkhorst *et al.* 1998; Martin and Handasyde 1999). Translocation of wild deer to deer farms has been used in both Australia and New Zealand, but this strategy is very dependent on the economic viability of the deer industry.

There are a number of animal welfare issues related to translocation of wildlife. There is stress related to the capture and transport of animals, the potential post-translocation mortality, the probable need to sterilize animals so they will not affect the gene pool at their new location, and the environmental impacts of introducing new animals (Edwards and Oogjes 1998). The possible spread of disease is another issue. Furthermore, this is an expensive solution to the problem, which is short-sighted and does not deal with long-term management.

Immunocontraception

This method involves immunizing an animal, usually the female, against some components of the reproductive system (Bradley 1994; Tyndale-Biscoe 1995; Grant and Malin 1997). These can be of sperm, egg or hormonal origin and, as a result, fertilization or mating does not take place. To have long-term usefulness, this method, as for any other control method, should have near 100% effectiveness in the first few generations. Evidence is accumulating that this is not the case (Table 5). In each case, females were immunized and non-responders, in the sense that reproduction has occurred, were present at high levels, probably sufficiently high to prevent effective population decrease (Barlow 1997). Even with a moderate level of heritability, rapid selection for these non-responders would occur if immunocontraception were continued in succeeding generations. One of the largest studies carried out is with white-tailed deer (Miller *et al.* 2000*a*, 2000*b*). Porcine zona pellucida induced a high level of infertility, but recombinant antigens did not produce any. All of the antigens used have been injected in adjuvant, which greatly enhances the level of the immune response. None of the studies where variation in response to immunocontraceptives has occurred have attempted to examine the heritability of response/non- response. This should be done in any future research programme.

Apart from non-responders and the necessity for adjuvant to obtain an effective response, there are other barriers to effective immunocontraception. Multiple immunizations are needed. The cost of the antigen is likely to be higher than for poisons. The mode of delivery is also of concern. If an organism is used as a vector, species specificity becomes difficult to assure. Baits are expensive to deliver, especially if multiple immunizations are needed.

The most difficult problem to assess is the effect of the likely selection for an altered immune response. In some cases there may be increased immunocompetence, but a reduction is more likely. Will such a reduction lead to an increased susceptibility to pathogens that affect the target species itself, as suggested by Nettles (1997)? Or will it lead to the species being a carrier for pathogens of other species in the same ecosystem? One of the two main reasons for wanting to reduce possum density in New Zealand is because of the presence of bovine tuberculosis among them. At least eight genes affect responses to tuberculosis in humans (McNicholl *et al.* 2000). Are responses to tuberculosis and immunocontraceptives related? Any attempt to implement immunocontraception in New Zealand must address this question. Similar remarks apply to koalas in Australia. These are over-populated in some areas, where they are already badly affected by *Chlamydia* (Martin and Handasyde 1999). The general question of the relationship between disease susceptibility and vaccine responses is illustrated by HIV-1. The course of the disease is affected by HLA genotype. Heterozygotes are at an advantage and the haplotype B*35-Cw*04 is at a disadvantage (Carrington *et al.* 1999). The HLA system also affects responses to vaccination against hepatitis B (Kruskall *et al.* 1992; McDermott *et al.* 1999). Attempts to enhance the capacity of a mouse virus to act as a successful vector for an immunocontraceptive by incorporating a cytokine gene (IL-4) have lead unexpectedly to the creation of a lethal virus (Jackson *et al.* 2001). This has caused widespread concern (Finkel 2001), and it raises the question as to whether we have enough fundamental understanding to manipulate the immune system to allow immunocontraception to be used without 'side-effects'. Other reservations have been expressed by Tuyttens and Macdonald (1998). In both

Table 5. Relative fertility of immunocontracepted females in seven mammalian species

Species	Immunogen	Number (Control, Exptl)	Relative fertility[a] (%)	Reference
Baboon	$LDHC_4$ + promiscuous epitope	14, 13	38	O'Hern *et al.* (1997)

Horse	Porcine ZP	83,73	23	Turner *et al.* (1997)

[a]Relative fertility = (No. offspring per immunized female) / (same parameter for control females); [b]recombinant zona pellucida antigens; [c]same animals in controls; [d]not significantly different from 100%; [e]contracepted animals only; no explicit controls. ZP, zona pellucida; LDH, lactate dehydrogenase; ZPB, rabbit zona pellucida B.

Australia and New Zealand, legislation on biosafety and the use of biotechnology is being put into effect. Whether immunocontraception of wildlife would be allowed under this legislation requires detailed examination. The fact that wildlife disease can often be spread as a result of human activity will influence this examination (Daszak *et al.* 2000).

Management of over-abundant wildlife presents a series of difficult problems. There is no one solution. In both Australia and New Zealand, the established techniques of poisoning by 1080 and, in Australia, the use of pathogens are likely to continue to be used for a long period wherever large-scale control is needed. Newer, more 'high-tech' approaches, such as the use of hormone analogues, may have use for high value animals that can be caught relatively easily. We doubt whether immunocontraception will be efficacious; if it is used on a large scale, we are concerned that this could have undesirable ecological consequences.

Acknowledgments

Roger Short's influence on this work is one of scientific method and philosophy. In the last quarter century or so, scientific influence has increasingly been wielded by specialists. His career has gone against this long-term trend. Many of his greatest contributions have been holistic and integrative. This is true of his published work and of the groups he has influenced. We argue that his kind of approach will be the basis of a mature wildlife management science.

The Australian Research Council, the Vice-Chancellor's Fund at Macquarie University and the New Zealand Ministry of Agriculture and Fisheries, support our work on population management.

REVIEW

Immunocontraception of mammalian wildlife: ecological and immunogenetic issues

Desmond W Cooper and Elisabeth Larsen

Abstract

Immunocontraception involves stimulating immune responses against gametes or reproductive hormones thus preventing conception. The method is being developed for the humane control of pest and overabundant populations of mammalian wildlife. This paper examines three fundamental issues associated with its use: (1) the difficulties of obtaining responses to self-antigens, (2) the likely evolution of genetically based non-response to immunocontraceptive agents, and (3) the possible changes in the array of pathogens possessed by the target species after generations of immunocontraception. Our review of the literature demonstrates that the barriers to an effective immunocontraceptive are at present very basic. Should they be overcome, the effects of immunocontraception on the immunogenetic constitution of wildlife populations through the selection for non-responders must be examined. We suggest that the attempt to use the animal's own immune system to modulate reproduction may be incompatible with the basic biological function of protection against infectious disease. Research programs on mammalian immunocontraception should involve measurement of the heritability of non-response and an assessment of the likely change in the response of the contracepted population to possible pathogens.

Reproduction (2006) **132** 821–828

Introduction

The regulation of human and animal population numbers constitutes a difficult and largely unsolved contemporary problem. In the developed world, steroid contraceptives for humans are both widely used and efficacious. Elsewhere they are too costly. The development of less expensive methods is considered necessary (Aitken *et al.* 1993). One such method is immunocontraception, i.e. the vaccination against sperm, eggs, or reproductive hormones to prevent either fertilization or the production of gametes. Attempts to design human immunocontraception have a long history (Joshi 1973, Stevens 1975, Basten 1988, Gupta & Talwar 1994). The targets include sperm antigens, oocyte antigens, especially zona pellucida proteins (PZP), gonadotropin riboflavin carrier protein, gonadotropins and gonadotropin releasing hormones (Delves *et al.* 2002). The most advanced method involves immunization against human chorionic gonadotropin, in reality a method of very early pregnancy termination (Baird 2000). It now seems likely that problems associated with autoimmune disease and variability of response will prevent any widespread use of immunocontraception in humans in the foreseeable future (Rao 2001, Aitken 2002). Women's health advocates have objected to all forms of immunocontraception because of perceived health risks and the potential for political abuse of the vaccine (Richter 1994). Human male immunocontraceptives have received much less attention and do not appear to be feasible in the near future (Delves *et al.* 2002).

Immunocontraceptives for wild animals have a different objective than those for humans. Their main aim is to check population growth rather than to contracept particular individuals. If some animals are irreversibly sterilized so much the better whereas such an effect in human medicine would be ethically most undesirable. Immunocontraceptives for animals are ostensibly humane and could potentially be used on the large scale required for wildlife population regulation. Research progress to date has been reviewed in Tyndale-Biscoe (1991, 1994), Barber & Fayrer-Hosken (2000), Barlow (2000), and Cooper & Herbert (2001). Three fundamental questions remain to be addressed: (1) Can sufficiently strong immune responses be provoked against the antigens (immunogens) of gametes or reproductive hormones to cause contraception in a proportion of animals large enough for effective

population management? (2) How rapidly will variation in these responses lead to the evolution of failure to respond to the immunocontraceptive agent? (3) What will be the ecological consequences of the likely changes to the immunogenetic constitution of the population as a result of selection for non-responders? In particular, will the endemic pathogens of the species change? There is considerable information which allows us to answer at least in part the first two questions. The third is of fundamental importance but even a preliminary answer is not possible at present.

Target species

Population control of native and exotic mammals is generally justified by environmental degradation, competition with and predation on native wildlife, conflicts with humans over food production, potential spread of pathogenic infectious diseases and the possibility of population crashes of over-abundant fauna or of wildlife populations near urban areas. Although still in its infancy, immunocontraception is regarded as being more humane than the traditional methods of wildlife population control, such as shooting, trapping, poisoning, or pathogenic agents and its use has strong support from influential animal welfare agencies worldwide (Oogjes 1997, Grandy & Rutberg 2002). Table 1 lists mammalian species for which immunocontraception is being investigated and for which the method could be applied. In all these species, there are at present no completely efficacious, cost-effective, or socially acceptable methods for population regulation available.

Immune responses to self-antigens

Responses to self-antigens are unusual and mainly weak. This constitutes a major barrier to the development of an immunocontraceptive. Table 2 summarizes data on attempts to induce immunocontraception using a variety of antigens in 14 mammalian species. The data in Table 2 show that in most cases a significant proportion of the population is not contracepted by administration of the immunocontraceptive antigen. The reason for this could be either genetic or environmental. In either case it indicates that a fraction of the population will continue to breed despite the administration of the contraceptive. In most cases, there is likely to be at least in part genetic causes underlying lack of response. If so, the genes for lack of response will be selected for and in a comparatively small number of generations most of the population will be non-responsive. This implies that the immunocontraceptive can be useful for only a short period of time.

All studies summarized in Table 2 involve the use of some kind of adjuvant, i.e. a substance or array of substances designed to enhance the immune response. There are no reports of successful immunocontraception without some form of adjuvant. Moreover, most immunizations were boosted at least once (see Table 2). The need for multiple injections and the dependence upon adjuvant to achieve the necessary level of response renders the whole approach impractical at present. The most commonly used adjuvant, Freund's Adjuvant, also induces a range of undesirable side effects and its use is being challenged on animal welfare grounds (Leenaars *et al.* 1994, 1998). There is at present no feasible or acceptable method of promoting responses to self-antigens sufficient to cause immunocontraception.

Jackson *et al.* (2001) attempted to overcome the problem of lack of immune response to self-antigens in the absence of adjuvant by inserting the cytokine interleukin-4 into mousepox virus with the intention of increasing the humoral response. The virus was then inserted into the mice with the unwelcome outcome that the mice all died very quickly. This work caused alarm because of the possibility that this technology could lead to a method for simple conversion of relatively innocuous viruses into lethal ones, which could be used in biological warfare (Finkel 2001).

Another possible problem with virus-vectored immunocontraception is the potential for the horizontal transfer of the immunocontraceptive gene into viruses affecting other species (Becker 2000). While it may be possible to create genetically modified organisms without adverse effects on the target animals, the effects they might have on related species they come in contact with make any use of this approach questionable.

Variation in response and genetic change

Variation in response to biocontrol agents is a widespread phenomenon. This variation has frequently led to evolution of a degree of resistance so that the agent is no longer useful. The evolution of resistance to insecticides has been reviewed by McKenzie (1996). He draws a distinction between biocontrol agents with responses within the phenotypic range and those with responses outside the phenotypic range of the target species. An agent which initially kills all members of the target species is acting outside the normal phenotypical range, while one which kills only a fraction of the population is acting within the normal phenotypical range. He points out that when resistance appears in the former case it is frequently monogenic, while in the latter case a number of different genetic regions are involved, i.e. it is probably multifactorial. The basic genetic parameter to be estimated in either case is heritability, i.e. the extent to which genetic variation is controlled by genetic as opposed to environmental factors. The relative fertility of the immunocontracepted animals in Table 2 is >10% in 27 out of the 32 data sets. A proportion of non-responders is characteristic of most species. Only three species (Tammar wallaby, Fallow deer and Norway rat) out of 14 had no non-responders (Table 2). Following McKenzie's (1996)

Pinnipeds	Worldwide	Possible contribution to the depletion of fish stocks	Contraception suggested as humane alternative to culling	Butterworth *et al.* (1988), Brown *et al.* (1996), Mohn & Bowen (1996)
Feral cat	Worldwide; major introduced pest species in Australia	Predation on native wildlife (Australia); public and wildlife health concerns	Control over continental area (Australia) Alternative to poison baits (1080)	Newsome (1991), Bomford *et al.* (1996), Mahlow & Slater (1996)
Feral dog	Worldwide	Public and livestock safety and health concerns; predation on native wildlife (Australia)	Control methods with public acceptance	Fleming *et al.* (2001), Sabeta *et al.* (2003)
Feral pig	Worldwide; major introduced pest species in Australia	Habitat degradation; damage to economic resources; public, livestock and wildlife health concerns	Control methods with public acceptance	Choquenot *et al.* (1996)
Badger	UK	Public, livestock and wildlife health concerns; reservoir for bovine tuberculosis	Control methods with public acceptance	Krebs *et al.* (1998), Donnelly *et al.* (2003)
Grey squirrel	UK; introduced species	Habitat degradation; threat to the native Red squirrel	Control methods with public acceptance	Moore *et al.* (1997)
r-selected species				
European rabbit	Worldwide; major vertebrate pest species in Australia	Habitat degradation; major cost to agriculture; public, livestock and wildlife health concerns	Broad-scale control over large areas	Lawson (1995), Williams *et al.* (1995)
Rodents	Worldwide	Major damage to economic resources, incl. crops, pastures, stored grain, livestock, buildings and infrastructure; public, livestock and wildlife health concerns	Broad-scale control over large areas. Species-specific alternatives to rodenticides	Caughley *et al.* (1998), Chambers *et al.* (1999), Seamark (2001)

argument, this implies that non-response is likely to be multi-factorial in genetic terms. There are no data which will allow estimates of the heritability of non-response to immunocontraception in any of the species in Table 2. We are unable to predict the rate at which this characteristic will increase in any one of these populations under the selective influence of immunocontraception. However, some idea of the likely change per generation given the initial frequency of non-responders can be found using Falconer's (1965) model for threshold characters (Table 3).

Table 2 Relative fertility of immunocontracepted females in 14 mammalian species.

Species	Immunogen	Adjuvant	No. of immunizations	Reproductive performance (control, treated)	Statistical significance[a]	Reduction in relative fertility (%)[b]	Reference
Baboon	LDH-C_4+ promiscuous epitope	CGP11637 emulsified w. Squalene:Arlacel -A (4:1)	3	Offspring/females 10/13, 4/14	$P<0.02$	62	O'Hern *et al.* (1997)

Investigations have been conducted on approximately 70 species. This table includes only true experiments, i.e. studies with an immunized group compared with a control group.
[a]The *P* values are those given in the references cited. [b]Relative fertility is defined as the mean no. of offspring for females in the vaccinated group divided by the same figure for the control group (i.e. unimmunized females).

Reproduction is a good example of a threshold character; it is an all-or-none attribute which can be affected by a variety of underlying genetic and environmental factors. If heritabilities are high, rapid selection occurs. This is shown by the high percentage of non-responders that occur within one generation (Table 3).

A limited place for immunocontraception in wildlife management could be in species with long generation times. Genetic changes in them, if they occur, will take decades. Claims have been made for the potential efficacy of immunocontraception for African elephants (Fayrer-Hosken *et al.* 2000, Delsink *et al.* 2002), although this view has been challenged on demographic grounds (Pimm & van Aarde 2001). Long-term studies on immunocontraception in wild horses report 78–94.2% contraceptive efficacy (Kirkpatrick *et al.* 1995, Turner *et al.* 1997, 2002, Turner & Kirkpatrick 2002).

Zoo animals are convenient for immunocontraception studies of wild species, because of their long-term accessibility, although the small numbers usually available make controls hard to find. This is illustrated by an investigation involving 27 females from 10 felid species. Immunization with PZP and Freund's Complete Adjuvant gave several kinds of adverse reaction but no convincing evidence of an effect upon fertility (Harrenstien *et al.* 2004).

Table 3 Predicted proportion of non-responder daughters after one generation of selection by immunocontraception of mothers given various heritabilities (after Falconer 1965).

	Heritability (%)			
Non-responder mothers (%)	100	80	60	50
5	15	11	10	8
10	23	19	16	15

The prediction has been arrived at by entering the table in Falconer (1965) which relates heritability for a threshold trait to incidences in parent and offspring. The response to selection (predicted percentage of non-responders) obtained has been halved because selection is being carried out on one sex.

Delves & Roitt (2005) review attempts to immunocontracept mammals and conclude that GnRH is the most promising target, because of its evolutionary conserved sequence.

Immunogenetic issues

Infectious diseases are assumed to be one of the main classes of selective forces which act upon genes controlling immune responses (Klein *et al.* 1993). Immunocontraceptive agents also have the potential to influence the genetic constitution of a population with respect to the ability to mount immune responses. The two are similar in that pathogens which cause plagues and immunocontraceptive agents are both capable of exerting very strong selective pressure with the potential for rapid genetic change. However, they differ in two important respects. First, most pathogens are cellular and antigenically more complex than most immunocontraceptive agents, which consist of one or a few proteins and in some cases associated carbohydrate. Second, they have opposite directions of selection; resistance to a pathogen involves a positive response, whereas resistance to an immunocontraceptive involves non-response. The consequences of this kind of selection imposed by an immunocontraceptive agent require study. It seems likely that it will alter the immunogenetic constitution of the target species. The existence of genes governing response to pathogens is well documented in humans for malaria (Hill 2001), tuberculosis (Blackwell 1998, Bellamy 2003), and HIV (McNicholl & Cuenco 1999, Carrington & O'Brien 2003). Relevant examples are found in New Zealand Red Deer in which susceptibility to tuberculosis has high heritability (Mackintosh *et al.* 2000) and in the NRAMP1 association with the human response to leishmaniasis (Bucheton *et al.* 2003). The complexities of the co-evolution of pathogens and hosts and its biomedical significance are beginning to be unraveled (Woolhouse *et al.* 2002). Both experimental (Lively & Dybdahl 2000) and theoretical analyses (e.g. Nowak

Case 2:10-cv-01852-MCE-DAD Document 11-8 Filed 07/22/10 Page 15 of 24

& May 1994) point to the inherent difficulties of prediction of the course of these interactions. Prediction and detection of the ecopathological consequences of the use of immunocontraception of wild animals will also be made difficult by the spread of emerging infectious diseases as a result of human activity (Daszak *et al.* 2000).

The effect of immunocontraception upon genetic diversity could be significant. There is the possibility that restriction of breeding to a small group of animals which are closely related will result in localized inbreeding. This will be especially likely if their capacity to resist the immunocontraceptive is the result of shared uncommon genotype. Acevedo-Whitehouse *et al.* (2003) have shown that in California sea lions, inbreeding is associated with a wide range of diseases. They suggest that inbred individuals could act disproportionally as reservoirs of infectious agents.

Selection based upon immune responses could be on one of two parts of the genome: the MHC (major histocompatability complex) region which governs responses to specific immunogens, or other genes, e.g. *NRAMP* which govern the functioning of the immune system in general (Bellamy 1999). The tightly linked *MHC* genes and the resultant linkage disequilibrium mean that selection on one gene will result in changes in gene frequencies at other loci. This could either raise or lower susceptibility to other pathogens. Understanding of the non-MHC genetic component of variability of the immune response is much less advanced than for the MHC component. This understanding is needed to attempt any predictions concerning immunocontraception-based selection.

Experimental approaches to this question have until now been very difficult. The existence of genetic maps of some wild animals (e.g. Tammar wallaby (Zenger *et al.* 2002)) may now allow a genomic approach, in which whole genome DNA typing may allow the identification of changes in gene frequency which accompany the application of immunocontraception or a pathogen, through comparing treated and control populations. A concomitant survey of pathogens in the two groups may identify susceptibility regions, whose existence could be further tested in lab-based investigation. The genome would thus be assayed for these genes, and test the extent to which the same genes are involved in responses to different pathogens and to immunocontraception.

A good model system to address these questions is wildlife tuberculosis which is of economic significance in several countries, e.g. Britain (Delahay *et al.* 2002), New Zealand (Buddle *et al.* 2002), and the United States (Palmer *et al.* 2002). Considerable information on the genetic control of response to mycobacterial antigens is available (North & Medina 1998, Kramnik *et al.* 2000, Bellamy 2003). The possibility of obtaining results relevant to human mycobacterial susceptibility may also encourage use of this system.

We conclude that attempting to use the immunological system to modulate reproduction could be incompatible with the basic biological function of resisting pathogens. We have not discussed some of the practical issues. For example, all fertility control methods have the problem of delivery of the control agent. Highly valued animals must be treated without harming them. When this is the case, fertility control methods with fewer concomitant problems, such as surgical sterilization or the use of steroids or gonadotropin-based hormones, would be competitive with immunocontraception (Cooper & Herbert 2001).

THE ECOLOGY OF STRESS

The ecology of stress: effects of the social environment

Summary

1. Many aspects of the social environment affect hypothalamic-pituitary-adrenal (HPA) axis function and increase circulating glucocorticoid concentrations. In this review, we examine the relationships between the social environment and the function of the HPA axis in vertebrates.

2. First, we explore the effects of the social environment on glucocorticoid secretion in territorial (primarily non-social) species, with an emphasis on the effects of variation in population density, as modified by environmental factors such as predation risk and food availability. In general, high population density or frequent territorial intrusions are associated with increased glucocorticoid secretion in a wide range of taxa, including mammals, birds, fish and reptiles, although there is considerable variability across species.

3. Second, we consider the effects of social interactions and dominance rank on glucocorticoid secretion in social species, mostly in birds and mammals. We review studies that have detected an association between social status and glucocorticoid levels – sometimes with higher glucocorticoid levels in low-ranking individuals, and sometimes with higher glucocorticoid levels in dominant individuals. The relationship between dominance and glucocorticoid levels varies among species, populations and years, in a manner that depends on the stability of the social hierarchy, environmental conditions, the type of breeding system, and the manner in which high rank is obtained and maintained.

4. Finally, we discuss the concept of allostasis and consider interactions between social effects and other environmental factors, noting that there is relatively little research on these interactions to date. For both non-social and social species, we identify priorities of future research. These priorities include more complete descriptions of HPA function that move beyond measurements of basal glucocorticoid concentrations (which will generally require field experiments), to studies that examine organizational effects of social stressors, that directly test the relationship between HPA function and fitness, and that examine how glucocorticoid responses affect population dynamics.

5. Although several lines of evidence suggest that glucocorticoid responses can affect the fitness of individuals and therefore can alter the dynamics of populations, the effect of glucocorticoid responses on population dynamics remains essentially unstudied.

Key-words: allostasis, dominance, glucocorticoid, hypothalamic-pituitary-adrenal axis, sociality, social behaviour, stress, territoriality

Introduction

Animals are faced with a constant flood of information from their external environment. Although much of this information can be ignored, some of it can be used in an adaptive fashion. In vertebrates, one of the primary mechanisms by which external environmental information elicits such an adaptive response is through initiating a physiological cascade of internal changes mediated in part through the hypothalamic-pituitary-adrenal (HPA) axis.

The HPA axis is the neuroendocrine pathway by which stress hormones (glucocorticoids) are released from the adrenal cortex. The structure and function of the HPA axis are reviewed elsewhere (e.g. Sapolsky, Romero & Munck 2000; Sapolsky 2002). The HPA axis integrates environmental information and the downstream release of glucocorticoids can potentiate an adaptive behavioural response (Monclús *et al.* 2005; Schulkin, Morgan & Rosen 2005) or alteration in life-history strategy (Wingfield *et al.* 1998; Boonstra 2005).

The social environment is one of the primary sources of information that can induce a physiological stress response. In both social and non-social animals, the frequency and type of interaction with conspecifics as well as status in social species can affect HPA axis activity. In this review, we examine the relationships between the social environment and the function of the HPA axis in vertebrates. First, we explore the effects of the social environment on glucocorticoid secretion in territorial species, with an emphasis on the effects of variation in population density, as modified by environmental factors such as predation risk and food availability. Second, we consider the effects of social interactions and dominance rank on glucocorticoid secretion in social species. Many studies have detected an association between social status and glucocorticoid levels – sometimes with higher glucocorticoids in low-ranking individuals, and sometimes with higher glucocorticoids in dominant individuals. Many studies also consider the particular traits associated with dominance or subordination that might be causally related to variation in glucocorticoid secretion. Other studies suggest that the general social environment (e.g. the stability or instability of social relationships and the type of dominance hierarchy) can affect the association between glucocorticoids and rank. Finally, we discuss the concept of allostasis and consider interactions between social effects and other environmental factors, noting that there is relatively little research on these interactions to date. Thus, this review reveals relationships between glucocorticoid secretion, environmental variables such as predation risk, population variables such as density or the rate of territorial intrusion and social variables such as dominance rank, and behavioural variables such as the rate of aggression. Clearly the HPA response is a physiological mechanism that might mediate a wide range of fitness effects. The review also reveals considerable variability among species in the response of glucocorticoid levels to these factors and suggests new hypotheses that might explain this variation.

Effect of the social environment on the stress axis in territorial vertebrates

NON-SOCIAL SPECIES: TERRITORIALITY

The patchy distribution of limited but defendable resources such as food, mates or preferable habitats can favour the evolution of territoriality. Territoriality is the exclusive use of an area (i.e. 'ecological' territoriality) or the active defence of an area from conspecifics using various visual, acoustic, or chemical signals that indicate ownership (i.e. 'behavioural' territoriality; Brown & Orians 1970). Signals advertising ownership may deter intrusions by conspecifics of the same gender or both genders and can also attract opposite-sex conspecifics, which can allow for the monopolization of mates and other limited resources.

Many vertebrate species exhibit either temporary or extended periods of territoriality. Although territoriality implies exclusiveness from conspecifics of the same or opposite gender, the true degree of non-sociality (i.e. avoidance of conspecifics) exhibited by territorial vertebrate species is variable. For example, males of many avian species breeding in temperate climates establish breeding territories but aggregate in large flocks at times outside of the breeding season (Nice 1941). The breeding territories of male songbirds are often defended from male but not female conspecifics, which results in male birds spending a significant portion of each year exclusive of other males. Similarly, females of some small mammal species (e.g. *Microtus*, *Clethrionomys,* and *Peromyscus* spp.) defend nesting territories during the breeding season, but will live in groups of related or unrelated individuals during the non-breeding season (Ostfeld 1990; Wolff 1993). At the other end of the continuum of non-sociality are species that defend year-round territories from both intra- and inter-sexual intruders. For example, both female and male North American red squirrels (*Tamiasciurus hudsonicus*) defend exclusive food-based territories year-round (Smith 1968). Female red squirrels are spontaneous ovulators, and they only appear to allow male intruders on their territories when they are in behavioural oestrous, which is approximately 1 day per year (Smith 1968; Lane *et al.* 2008). Thus, the degree of non-sociality in territorial vertebrate species can range from highly non-social (red squirrels) to tolerance of both sexes for most of the year except during the breeding season (temperate breeding avian species and some small mammal species). There is similar variation in the degree of non-sociality in species that actively defend mates (mate-defence polygyny) rather than actively defending a territory (resource-defence polgyny or monogamy). In mate-defence polygyny (e.g. impala, *Aepyceros melampus*), males typically attack other males during the mating season, but aggregate in large herds with little aggression outside of the mating season (Jarman 1974). Because social interactions can strongly affect the activity of the HPA axis, variation in the degree of non-sociality may interact with stress physiology. Here, we focus on the effects of the social environment on the activity of the HPA axis in vertebrate species that exhibit some degree of non-sociality due to territoriality (Fig. 1).

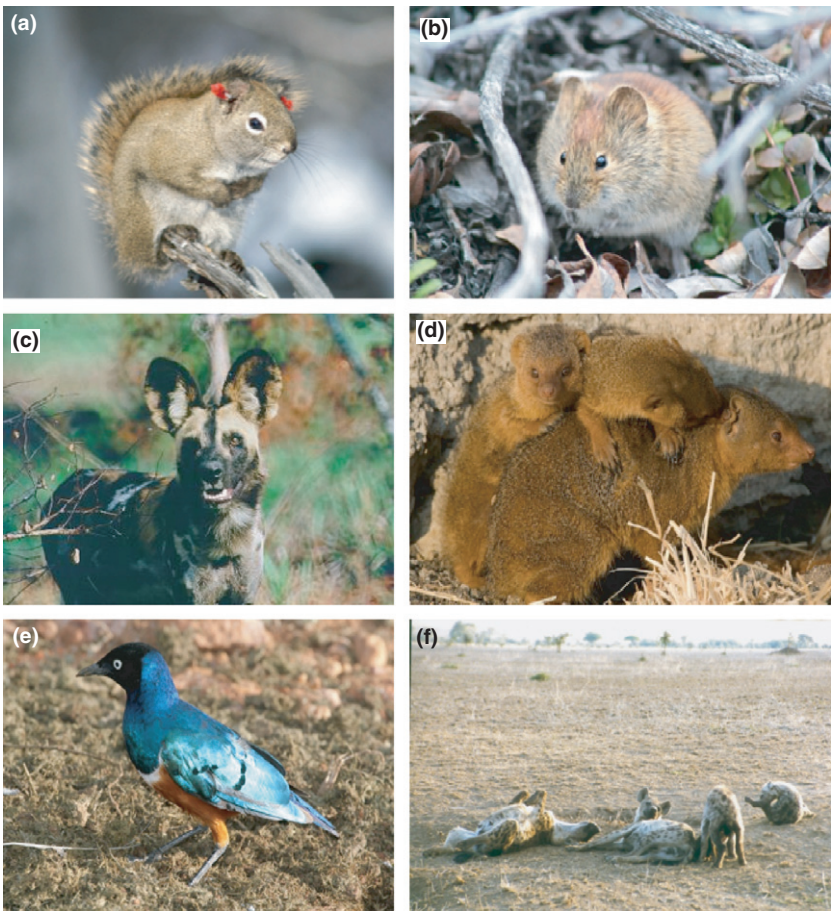

Fig. 1. (a, b) Population density and glucocorticoid levels are usually positively associated in non-social species, although the degree to which territorial vertebrate species are non-social is highly variable. For example, both male and female North American red squirrels (a) defend year-round food-based territories. In other small mammal species such as the northern red-backed voles (b), females only defend nesting territories during the breeding season (photos by R.W. Taylor). In many social species, behavioural dominance is strongly correlated with reproductive success but dominance is also associated with heightened glucocorticoid levels. For example, within groups of African wild dogs (c) and dwarf mongooses (d), only the behaviourally dominant individual of each gender is assured of breeding (photos by S. Creel). However, dominant wild dogs and dwarf mongoose also engage in more aggressive interactions and their glucocorticoid levels are higher than those of subordinates, which may impose fitness costs. In many social species, the relationship between social status and glucocorticoid levels can be complicated by both environmental variation and the method by which social status is acquired and maintained. (e) For example, in cooperatively breeding superb starlings, annual differences in rainfall and resource availability not only influence glucocorticoid levels, but they may do so differently in dominants and subordinates (photo by D. R. Rubenstein). (f) Unlike most other carnivores, social rank in spotted hyenas is inherited from the mother, which complicates the positive relationship between social status and age/size that is seen in many other species (photo by W. Goymann).

FACTORS AFFECTING ACTIVITY OF THE HPA AXIS IN TERRITORIAL SPECIES

In territorial vertebrates, population or breeding density is one of the best documented factors that influence the activity of the HPA axis. Christian (1950) first used Selye's description of stress (or general adaptation syndrome; Selye 1936) to describe how the adrenocortical response to population density might cause the density-dependent population cycles exhibited by some small mammal species. Christian (1950) hypothesized that increases in population density in small mammal species such as voles led to increased antagonistic social interactions, which caused an increase in adrenocortical activity. Christian further predicted that the consequences of this heightened adrenocortical activity were a decrease or suppression of reproduction and an increase in mortality due to decreased resistance to disease or other limiting factors (Christian 1950; Christian & Davis 1964). As a result, population growth ceased or declined during peak population densities due to heightened mortality and decreased fecundity. Christian and colleagues (Christian 1950, 1956, 1961, 1964, 1971; Christian & Davis 1964, 1966) provided extensive empirical documentation in territorial mammalian species of the relationship between adrenal gland mass (a proxy of adrenocortical activity: Bronson & Eleftheriou 1964) and population density and/or the frequency of antagonistic interactions.

Christian's pioneering studies were instrumental in connecting how environmental factors influence the HPA axis

activity of individuals, which in turn affected population dynamics. Groundbreaking studies in a variety of mammalian taxa (primarily rodents) found significant positive relationships between population density and adrenal mass (reviewed by Christian 1971; To & Tamarin 1977) or *in vitro* adrenal secretion of glucocorticoids (Andrews 1968). However, Christian's research has been criticized because it was largely performed on captive animals often in a laboratory setting (Krebs & Myers 1974; Lee & McDonald 1985). Nonetheless, more recent studies in other mammalian species have documented a similar positive relationship between population density and plasma glucocorticoids (Boonstra & Boag 1992; m 1998) or faecal glucocorticoid metabolite concentrations (Novikov & Moshkin 1998; Harper & Austad 2004; Bian *et al*. 2011) in free-living individuals. For example, Boonstra & Boag (1992) found that populations of meadow voles (*Microtus pennsylvanicus*) at the highest densities had the highest free plasma corticosterone concentrations and lowest corticosterone-binding globulin concentrations. Support for this positive relationship between population density and stress axis activity in territorial mammalian species is not universal (e.g. To & Tamarin 1977; Harper & Austad 2004; Kuznetsov *et al*. 2004; Charbonnel *et al*. 2008), and we have little information about the relationship between population density and stress axis activity in some mammalian orders that include many solitary species (e.g. carnivores, of which more than 80% of species are solitary: Gittleman 1984).

The relationship between population density and the activity of the stress axis is best known from studies of mammals. This is not surprising given the initial focus of Christian and colleagues (see above). Although less well-studied than mammals, birds often show similar relationships between density and HPA function. With regard to stress physiology, most of the well-studied avian species breed in temperate regions exhibit territoriality only during the breeding season, and only defend territories from same-gender conspecifics. Although there are fewer studies of birds than mammals, a positive relationship between population density and plasma (Silverin 1998a) or yolk glucocorticoids (Love *et al*. 2008) has been reported for several species, while others have detected no relationship (Beletsky, Orians & Wingfield 1990, 1992). However, further support for the predicted positive relationship between density and stress axis activity in avian species may come from simulated territorial intrusion (STI) experiments. In these experiments, a territorial male is presented with an unfamiliar caged male (or a stuffed male) within his territory, paired with an audio playback of the species' song. Several studies in temperate-breeding birds have found that STIs cause a pronounced increase in plasma glucocorticoids (e.g. Silverin1993, 1998b; Van Duyse *et al*. 2004; Canoine & Gwinner 2005; Landys *et al*. 2007), whereas others have not found such a relationship (e.g. Harding & Follett 1979; Wingfield 1985; Pärn *et al*. 2008; Scriba & Goymann 2010). Because antagonistic interactions and other territorial intrusions are predicted to increase as population density rises (e.g. Bretagnolle, Mougeot & Thibault 2008), we therefore would predict that population density is also positively correlated with stress axis activity in species that responded to STIs with elevated glucocorticoid production. To date, very few studies in avian species that exhibit year-round territoriality have directly tested the relationship between glucocorticoids and population density. However, some studies have found that STIs cause a significant increase in plasma glucocorticoids in bird species exhibiting year-round territoriality (e.g. Gill, Costa & Hau 2008; Landys *et al*. 2010), providing indirect evidence for a positive relationship between population density and stress axis activity.

Other taxa, including amphibians, reptiles and fish, also offer insights into the relationship between population density and HPA function. Amphibians and reptiles often defend resource-based territories and are non-social as adults. Many species only interact with conspecifics during the larval stage or during breeding as adults. Some studies in amphibians and reptiles also support the positive relationship between population or breeding density and stress axis activity. For example, increased population density during mating in anurans (Leary, Garcia & Knapp 2008) or nesting density in turtles (Jessop, Limpus & Whittier 1999) is associated with increased plasma glucocorticoids. High population density either were associated with increased or decreased plasma glucocorticoids in female side-blotched lizards (*Uta stansburiana*) depending upon the female reproductive tactic (Comendant *et al*. 2003). In contrast, experimentally increased densities in breeding salamanders did not elicit elevated plasma glucocorticoids (Cooperman, Reed & Romero 2004). It is important to note, however, that increased glucocorticoid concentrations during breeding aggregations might be driven by changes associated with reproduction that are not related to density (e.g. glucocorticoid concentrations rise during gestation in many mammals; Creel, Winnie & Christianson 2009; Dantzer *et al*. 2010; or glucocorticoid concentrations rise during intense mate competition in marsupials; Bradley, McDonald & Lee 1980; Bradley 1987). Evidence for positive effects of population density on stress axis activity in amphibians and reptiles also comes from laboratory studies. For example, heightened competition over burrows in captive spotted salamanders (*Ambystoma maculatum*; Cooperman, Reed & Romero 2004) or increased housing density in American alligators (*Alligator mississippiensis*; Elsey *et al*. 1990) was associated with increased plasma glucocorticoids (see also Hayes 1997; Glennemeier & Denver 2002). In some lizard species, forced antagonistic interactions with conspecifics in laboratory experiments can elevate plasma glucocorticoids (Klukowski & Nelson 1998; Schuett & Grober 2000; Yang & Wilczynski 2003), which suggests that stress axis activity would be elevated under high density conditions due to a heightened

frequency of antagonistic interactions. In many ways, such studies of forced interaction are similar to early studies of 'social stress' in captive animals that we discuss in the second part of this review.

Finally, it is well established that crowding increases stress axis activity in captive or hatchery reared fish (Barton & Iwama 1991), but we are aware of no studies examining the relationship between population or breeding densities and stress axis activity in free-ranging territorial fish. This is not surprising given the logistical difficulties of such a study. However, future studies in fish species in which males provide paternal care and actively defend brooding sites from conspecifics such as bluegill (*Leopomis macrochirus*; Neff & Knapp 2009) and smallmouth bass (*Micropterus dolomieu*; Hanson *et al*. 2009; Dey *et al*. 2010) should investigate how breeding or nesting density affects stress axis activity.

REMAINING QUESTIONS IN TERRITORIAL SPECIES

In the above section, we have detailed how population or breeding density increases HPA activity in vertebrate taxa and in some cases how forced antagonistic interactions between conspecifics can elevate stress axis activity. However, the positive relationship between population density or the frequency of antagonistic interactions and HPA axis activity is not universal across different taxa. Departures from the general pattern of increased density leading to increased HPA activity could be due to the confounding effects of reproductive condition, seasonality or recent extreme weather events on HPA axis activity or responsiveness (Kenagy & Place 2000; Romero 2002; Romero *et al*. 2008) or to the effects of trapping/handling stress on glucocorticoid levels (Kenagy & Place 2000; Sheriff *et al*. 2011a). As such, future studies examining relationships between population density and HPA axis activity should sample their study animals carefully to avoid these potentially confounding effects.

A central remaining question is to identify if the relationship between population density and HPA axis activity that has been found in many species is due to an increase in antagonistic interactions between conspecifics at high density, decreased per capita food abundance, or even increased attraction of predators. For example, food-abundance often co-varies with population density such that increased overall food abundance is associated with increased reproductive output and/or population density, but perhaps constant or decreased per capita food availability. As a result, determining the actual mechanism that induces heightened HPA axis activity under high population density conditions will require experimental manipulations of the potential causal variables, or careful sampling designs with multiple populations.

Few studies have experimentally manipulated population density, food-abundance or predator densities in free-living non-social territorial animals. In a recent study using a non-social species, the North American red squirrel, population density was positively correlated with faecal cortisol metabolite concentrations (B. Dantzer, unpublished data). Experimental increases in both actual (using long-term food supplementation) and perceived population density (using audio playbacks of territorial vocalizations to simulate high density conditions) also caused a significant increase in faecal corticosteroid metabolites (Dantzer *et al*. unpublished data). This suggests that, at least in this species, the actual variable causing changes in glucocorticoids (and also density-dependent behavioural responses; Dantzer *et al*. in press) is the perception of social competition and not food abundance or predator densities.

In addition to population density, predation risk may affect HPA axis activity in territorial species. For example, predator density affects plasma free glucocorticoid concentrations in snowshoe hares (*Lepus americanus*) (Boonstra *et al*. 1998; Sheriff, Krebs & Boonstra 2011b) and total plasma glucocorticoid concentrations in African stonechats (Scheuerlein, Van't Hof & Gwinner 2001). In elk, (*Cervus elaphus;* Creel, Winnie & Christianson 2009), predator density did not detectably affect faecal corticosteroid metabolites concentrations, although progesterone concentrations and calf production did decline in response to predation risk (Creel *et al*. 2007). To date, too few studies have examined the relationship between HPA activity and predation risk to infer general relationships with confidence. However, recently Zanette *et al*. (2011) simulated a strong increase in the perceived risk of predation using predator vocalization playbacks and observed behavioural changes in territorial female song sparrows, associated with a nearly 40% reduction in clutch size at fledgling. The impact of predation pressure in natural situations may be more subtle than in this experiment, because it simulated a situation with severe predation pressure by broadcasting predator vocalizations steadily for 130 days on a 4 day on/off basis (Zanette *et al*. 2011). This reduction in clutch size may be through a stress-mediated pathway because previous studies have found that glucocorticoids were elevated in response to increased predator abundance (Clinchy *et al*. 2004, 2011). This study experimentally confirms observational studies that have shown strong effects of predation risk on individual reproduction in wild populations, although these are not necessarily stress-mediated (Creel *et al*. 2007). We suggest that future studies examining relationships between population density and the activity of the stress axis should also consider how food abundance and predation risk co-vary with population density and HPA activity (see also McColl 1998).

As with studies of social species (see below), broader assessments of HPA function and tests for fitness effects in non-social species remain important. Although the initial focus of Christian and colleagues was to examine how population density or environmental variation influences the population dynamics of non-social animals through HPA axis activity, no studies that we are aware of have actually explored how HPA axis activity of individuals affects population dynamics as the focus of most field

studies to date has been on *individuals*. While it is reasonable to assume that effects on individual fitness often have consequences for population dynamics, it will be productive to return to the ideas of Christian and explore how the glucocorticoid responses of individuals to environmental variation can influence population or even community dynamics (Hawlena & Schmitz 2010). This will require careful experimentation of population densities and even HPA axis activity with tractable study species to examine if the glucocorticoid responses of individuals to environmental variation affect population density.

Effect of the social environment on the stress axis in group-living vertebrates

SOCIAL SPECIES: SOCIAL STATUS AND DOMINANCE RANK

Animals living in social groups often form dominance hierarchies. An individual's position within the dominance hierarchy can have strong effects on fitness, because social dominance often confers priority of access to mates, food and other resources (Fig. 1). In many cooperatively breeding birds and mammals, the probability of breeding is almost one for the socially dominant individual of each gender and almost zero for social subordinates. Given these clear benefits of social dominance, many early studies of aggression, rank and physiological stress responses were based on the hypothesis that low social status is stressful. Early research on captive rodents and primates supported this hypothesis (Bronson & Eleftheriou 1964; Louch & Higginbotham 1967; Manogue, Leshner & Candland 1975). In paired contests between laboratory rats, mice and monkeys, aggression increased glucocorticoid secretion in both winners and losers, but the effect was significantly stronger among losers. Thus, as field studies began to examine stress responses in the wild in the 1980s, a plausible hypothesis was that the 'stress of subordination' might underlie the reproductive suppression of social subordinates in many cooperatively breeding species.

However, social hierarchies and agonistic behaviour evolve to avoid the costs of overt aggression. This general explanation for the evolution of agonistic behaviour is predicated on the assumption that contests among group members can carry costs (Rubenstein & Shen 2009). The costs of engaging in agonistic or aggressive interactions (and more generally the costs of a given social position) are often not equal for both of the individuals involved, and this observation raises an interesting range of possibilities. If winning a direct contest provokes a weaker stress response than losing, but dominant individuals engage in more contests, then the total effect may be that dominants have higher mean circulating glucocorticoid levels than subordinates. In addition to direct contests, it is plausible that the maintenance of high rank requires more monitoring or 'policing' of the behaviour of others than is required for animals with low rank, simply due to differences in the number of group mates who are subordinate to individuals of different rank. Observations of wild groups commonly show that dominant animals do engage in higher rates of aggressive and agonistic behaviour in many species (e.g. most social carnivores: Creel *et al*. 1997; Sands & Creel 2004), so it is plausible to hypothesize that social stress is greater for dominants than for subordinates, but the fitness costs are offset by the other benefits of high rank.

Given that one might plausibly hypothesize either positive or negative correlations between social status and glucocorticoid secretion, empirical data from wild populations are necessary to advance the science. Robert Sapolsky, one of the pioneers of social stress research in free-living animals, found that subordinate male olive baboons (*Papio anubis*) are more likely to be physiologically stressed than dominants and show chronically elevated levels of glucocorticoids (Sapolsky 1982, 1983). As a consequence of chronically elevated glucocorticoids, subordinate baboons are more likely to develop stress-related pathologies than dominants (Sapolsky, Alberts & Altmann 1997; Sapolsky & Spencer 1997). In follow-up studies, Sapolsky and coworkers discovered that this rank-related pattern in glucocorticoid physiology may be modified by styles of dominance (Ray & Sapolsky 1992), or may be suspended by environmental impacts, such as during a severe drought during which all members of the social group devoted most of their time to foraging, leaving little opportunity for social harassment (Sapolsky 1986). Most notably, Sapolsky (1992a) suggested that the relationship of glucocorticoid concentrations to rank depended on the stability or instability of baboon hierarchies. In stable hierarchies, the glucocorticoid levels of subordinates were higher than the glucocorticoid levels of high-ranking baboons, but this pattern was reversed during periods of social instability. Sapolsky's early results from free-ranging baboons supported the prevailing view from laboratory studies (e.g. Manogue, Leshner & Candland 1975) that subordinates are generally more likely to suffer from social stress than dominants. More importantly, these studies highlighted the role that social stability has on glucocorticoid levels in some species.

With the availability of non-invasive methods to measure hormone metabolites from urine or faeces, studies on the relationship between social rank and glucocorticoid levels of free-living animals have become more common over the past two decades. Some of these studies challenged the traditional view of the relationship between glucocorticoids and social rank in free-living animals that subordinates tend to have higher levels than dominants, arguing instead that dominants experience more psychosocial stress and often express higher levels of glucocorticoids than subordinates (Creel 2001). For example, glucocorticoid levels were higher in dominants than in subordinates in free-living African wild dogs (*Lycaon pictus*) and dwarf mongoose (*Helogale parvula*) (Creel, Creel & Monfort 1996; Creel *et al*. 1997). Both species are cooperative breeders and live in groups with '*despotic hierarchies*'

(Sapolsky 2005). Similarly, in cooperatively breeding African cichlid fish (*Neolamprologus pulcher*) dominants had higher glucocorticoid levels than subordinates (Mileva, Gilmour & Balshine 2010). The same pattern has been reported for several wild populations of cooperatively breeding primates (reviewed in Creel 2001) and gray wolves (*Canis lupus*; Sands & Creel 2004). In cooperatively breeding birds, dominants and subordinates often show similar glucocorticoid levels (e.g. Schoech, Mumme & Moore 1991; Wingfield, Hegner & Lewis 1991; Mays, Vleck & Dawson 1991; Malueg, Walters & Moore 2009). Together, these studies demonstrate that social rank has important effects on glucocorticoids in social species, but that the patterns differ among taxa and may vary with the stability and type of dominance hierarchy. Even in closely related pairs of species, pronounced differences have been observed. For example, dominant dwarf mongooses largely monopolize reproduction (Creel & Waser 1991; Creel *et al.* 1992), although dominant individuals have higher mean glucocorticoid levels than subordinates. When subordinate females do breed, their offspring are often killed, but social interactions with the breeding subordinate do not detectably change. In contrast, glucocorticoid levels are higher in subordinate females of alpine marmots (*Marmota marmota*), which are frequently attacked by dominant females (Hackländer, Möstl & Arnold 2003) and slender meerkats (*Suricata surricata*), who are subject to violent eviction from their group if they become pregnant (Young *et al.* 2006). Sapolsky (2005) reviewed the conditions under which social stress is stronger for dominants or stronger for subordinates and suggested several social conditions or individual traits that promote differences in social status related glucocorticoid patterns (resource inequity, maintenance of dominance, breeding style, stability of social ranks, subordinate coping strategies, subordinate avoiding mechanisms of dominants, subordinates' use of alternative strategies, stress of dominating mating, atmosphere of culture and personality). While much has been learned, further work is needed to fully disentangle the relationships between glucocorticoid secretion, social status and the behavioural causes and consequences of rank in social vertebrates (Creel 2001; Goymann & Wingfield 2004; Sapolsky 2005; Rubenstein & Shen 2009).

Social status and social interactions can be described in many ways. Some studies treat social status as a dichotomy, pooling subordinates into one category and comparing them to the top-ranked (alpha) individual in each group. Other methods produce a rank-order, treating social status as an ordinal variable. Still other methods consider quantitative variation, treating rank as a continuous variable. Most studies to date have tested for a categorical difference in the glucocorticoid levels of alphas and subordinates, or for a linear relationship between glucocorticoid levels and rank. Empirical research is just beginning to evaluate the possibility that glucocorticoid secretion may relate to social rank in a more complex manner. A recent, long-term study of savannah baboons (*Papio cynocephalus*) illustrates this point well. Although the highest-ranking (alpha) males had elevated glucocorticoid levels, high-ranking males other than alphas tended to have lower glucocorticoid levels than low-ranking males (Gesquiere *et al.* 2011). Studies of other species have also reported that the glucocorticoid levels of alphas are elevated, with no detectable relationship between rank and glucocorticoids among non-alphas (e.g. in Yellowstone wolves; Sands & Creel 2004). Still other studies have found that the endocrine profiles of alphas and betas (second-ranked) animals are similar, with little relationship among lower ranks (for example in African wild dogs; Creel *et al.* 1997). Interestingly, the patterns that Gesquiere *et al.* (2011) observed for baboons were not affected by the stability or instability of the hierarchy, in contrast to the results of Sapolsky (1992a) for the same species.

LIVING IN SOCIAL GROUPS MAY REDUCE STRESS

An important, but often neglected, aspect in the discussion of the effect of the social environment on stress physiology is that the social environment may not only produce stress, but in fact it may reduce overall stress levels. For example, social support may buffer glucocorticoid levels in baboons (Alberts, Sapolsky & Altmann 1992; Ray & Sapolsky 1992; Virgin & Sapolsky 1997) and in greylag geese (*Anser anser*), the size of the family unit led to a decrease in the stress response during competitive feeding situations with other flock members (Scheiber *et al.* 2005; Scheiber, Kotrschal & Weiss 2009; see also a review on social buffering of the HPA-axis by Hennessy, Kaiser & Sachser 2009).

HOW SOCIAL STATUS IS ACQUIRED AND MAINTAINED MAY AFFECT THE RELATIONSHIP BETWEEN SOCIAL STATUS AND GLUCOCORTICOIDS

It is often assumed that success in aggressive interactions and the achievement of high dominance status are always a function of morphological and physiological characteristics. However, it has now become clear that social rank means different things in different species or even populations of the same species. Rank as a descriptor of social status does not specify the process by which social roles are obtained or maintained. Thus, behavioural strategies related to the acquisition and maintenance of rank, rather than the rank *per se*, are likely to determine the degree of social stress (and glucocorticoid levels) associated with a particular social status (von Holst 1998; Creel 2001; Goymann *et al.* 2001, 2003; Abbott *et al.* 2003; Goymann & Wingfield 2004; Sapolsky 2005).

In groups where dominance rank is inherited or dominance is achieved via queuing conventions social status is unlikely to have a major effect on glucocorticoid levels,

as long as there are no acute challenges (Goymann & Wingfield 2004; Sapolsky 2005). A similar scenario may occur in many 'high skew' cooperatively breeding species where a single dominant pair breeds and the other group members assist rearing the offspring (Vehrencamp 1984; Keller & Reeve 2004). In some species (e.g. many cooperatively breeding birds), adult subordinates are mainly offspring from prior years (e.g. Brown 1978). In other species, group structures are more complex and subordinates encompass a wide range of ages and degrees of genetic relatedness, including immigrants from other groups (e.g. in African wild dogs; Creel & Creel 2002). In cooperatively breeding species with high skew in reproductive success, reproductive suppression is experienced by most group members at some stage of their lives, and many individuals remain socially subordinate for their entire lives. Neuroendocrine mechanisms that operate mainly within the hypothalamic-pituitary-gondal axis are the prime mediators of reproductive suppression and glucocorticoid levels play only a minor role (e.g. Faulkes & Abbott 1997; Saltzman, Digby & Abbott 2009). Hence, similar to species with rank-inheritance or queuing conventions, rank-related patterns of glucocorticoid levels are unlikely to be the cause of reproductive suppression, and as long as there are no acute challenges, the correlation between rank and glucocorticoids could be positive, negative or neutral (Creel, Creel & Monfort 1996; Goymann & Wingfield 2004; Sapolsky 2005).

In contrast to stable social societies where rank is inherited or reproductive suppression is common, when there is conflict about reproduction in cooperative species, rank-related patterns of glucocorticoids may arise. For example, dominant pregnant female meerkats (*Suricata suricata*) aggressively target older and more distantly related subordinate females that represent a threat to their own reproduction. These subordinates show an impaired function of the hypothalamic pituitary gonadal axis, which may be caused by chronic elevation of glucocorticoid levels (Young *et al.* 2006). A similar situation occurs in many plural breeding species (where there are normally multiple breeding individuals within the group). Here, reproductive options exist for more than one breeding pair in a group and social dominance is acquired and maintained with low level or overt aggression, and subordinates are frequently threatened by dominants. Here, a social status related pattern of acute and chronic elevation of glucocorticoid levels is commonly observed in subordinates (Abbott *et al.* 2003; Goymann & Wingfield 2004; Sapolsky 2005). Such patterns are more likely to occur in societies with strong group cohesion as opposed to fission-fusion groups (Goymann & Wingfield 2004; Sapolsky 2005). In summary, current research suggests that it may not be the dominant or subordinate position itself, but rather the process by which social status is acquired and maintained that determines the physiological and psychosocial effects associated with a given social status (Sapolsky 1992b; Abbott *et al.* 2003; Goymann & Wingfield 2004).

INTERACTIONS BETWEEN SOCIAL AND ENVIRONMENTAL FACTORS

Social living is strongly influenced by ecological and environmental factors. In particular, resource distribution in time and/or space drives dispersal decisions, movement patterns and patterns of association in many taxa (Jarman 1974; Emlen & Oring 1977; Rubenstein & Lovette 2007; Jetz & Rubenstein 2010). These same ecological and environments factors also affect glucocorticoid levels in social species. In cooperatively breeding superb starlings (*Lamprotornis superbus*) (Fig. 1), annual differences in rainfall and resource availability not only influence glucocorticoid levels, but they may do so differently in dominant and subordinate individuals (Rubenstein 2007). However, these rank-related differences in glucocorticoid patterns may be more related to environmentally driven differences in levels of social conflict than to environmental factors directly (Rubenstein & Shen 2009). Similarly, in ring-tailed lemurs (*Lemur catta*), where social stressors and rank influenced glucocorticoid levels in captivity (Starling *et al.* 2010), socially-mediated glucocorticoid levels were also differentially impacted by food availability and environmental stress in the wild (Pride 2005). Although glucocorticoid levels are strongly influenced by social rank in savannah baboons (Gesquiere *et al.* 2011), environmental stressors also had strong effects on the patterns (Gesquiere *et al.* 2008). Thus, while social factors like rank and dominance interactions shape glucocorticoid levels in many species of birds and mammals, environmental factors like resource availability often interact with social factors to shape hormone profiles. One of the future goals in comparative studies of stress physiology in social species should be to disentangle the effects of social and environmental factors on hormone levels and social roles. So far, few studies have experimentally altered social (population density) or environmental factors (predator densities or food-abundance) in social species and investigated the consequences on demography, reproductive success and glucocorticoid secretion For example, food supplementation increased reproductive success in Florida scrub jays (*Aphelocoma coerulescens*). Breeding females supplemented with food started to reproduce earlier, laid larger clutches, and the survival of their offspring was increased (Schoech *et al.* 2008). Glucocorticoids possibly play a role in the mediation of this enhanced reproductive success, as jays supplemented with a high fat and high protein diet had lower glucocorticoid levels than controls and jays supplemented with a diet high in fats but low in proteins (Schoech, Bowman & Reynolds 2004; Schoech 2009). As a consequence, food supplementation may increase local population densities of this threatened species perhaps by lowering glucocorticoid levels and enhancing reproduction.

ALLOSTASIS, SOCIAL STATUS AND GLUCOCORTICOIDS

Separating the effects of social and ecological factors on glucocorticoid levels in free-living social animals may be difficult. The theoretical framework of allostasis has been proposed to help simultaneously study the effect of social and ecological factors on glucocorticoid levels in group-living species (Goymann & Wingfield 2004; Rubenstein & Shen 2009). Allostasis is a controversial theory that emerged from the biomedical literature (McEwen & Wingfield 2003) and has been applied more broadly to other biological disciplines, including studies of vertebrate social behaviour (Goymann & Wingfield 2004; Rubenstein 2007; Rubenstein & Shen 2009; Saltzman, Digby & Abbott 2009). Allostasis, which means achieving internal stability through bodily change of state, supports homeostasis by adjusting set-points to unpredictable stressors away from homeostatic baselines (Sterling & Eyer 1988). McEwen & Wingfield (2003) have used this allostasis framework to describe the physiological costs of coping with social and environmental challenges, and how physiological mediators such as glucocorticoids regulate responses (McEwen & Wingfield 2003). The allostasis framework has been extended by Romero, Dickens & Cyr (2009) in the reactive scope model to build from the allostasis model and address some of its criticisms. Together these models provide a starting place for exploring how predictable and unpredictable social and environmental stressors influence physiology and behaviour in social species.

Models of allostasis treat social interactions as a type of unpredictable social stressor (McEwen & Wingfield 2003; Goymann & Wingfield 2004; Romero, Dickens & Cyr 2009; Rubenstein & Shen 2009). Laboratory experiments have shown that unpredictable or uncontrollable stressors (such as electric shocks) provoke stronger glucocorticoid responses than the same stimuli when they are predictable or controllable (e.g. Weiss 1970). Although it is obvious that intense, short-term stressors like storms are unpredictable challenges that organisms cannot anticipate, many types of social interactions may also be relatively unpredictable. Animals that live in groups will experience affiliative social interactions daily (e.g. foraging, grooming, sleeping), and although these interactions may increase seasonally, they are still generally predictable events because animals can largely anticipate their occurrence. However, for social animals living within a dominance hierarchy that defines reproductive roles, changes in social status are often triggered by violent, escalated aggression. These escalated fights might be less predictable (although they are more likely under certain circumstances, such as the annual breeding period: Creel & Creel 2002; Young *et al.* 2006). In response to such interactions, an individual will rapidly shift its level of glucocorticoids to a new optimum in order to cope with the stressor. Thus, an acute social conflict might be analogous to a somewhat unpredictable environmental challenge (McEwen & Wingfield 2003; Goymann & Wingfield 2004; Romero, Dickens & Cyr 2009).

Allostasis models also specifically address the idea we described above that the physiological and psychosocial effects associated with a given social status are the result of the process by which social status is acquired and maintained rather than the resulting dominance rank *per se*. The process of rank acquisition is reflected in the level of allostatic load, or the cumulative physiological burden exacted on the body, as individuals adjust behaviour to aggressive social interactions (Goymann & Wingfield 2004). Allostatic load can be reflected in glucocorticoid levels (McEwen & Wingfield 2003; Goymann & Wingfield 2004; Rubenstein & Shen 2009). A comparative study by Goymann & Wingfield (2004) demonstrated that across a large sample of social bird and mammal species, the relative levels of glucocorticoids in dominants and subordinates are related to allostatic load and the way that rank is achieved and maintained in different societies. This work was extended theoretically and empirically by Rubenstein & Shen (2009) to predict the environmental conditions under which dominants or subordinates are expected to have higher allostatic load. This work also demonstrated that group structure (i.e. the ratio of breeders to non-breeders in a group) could also influence allostatic load and relative glucocorticoid levels. Together, these studies suggest that the allostatic load framework may help explain not only the different rank-related patterns seen in glucocorticoid patterns in vertebrates, but also the environmentally driven intra-specific variation in levels seen across years in long-term studies of individual species. The allostasis framework may also prove fruitful in studying the effects of factors on stress physiology in social species, such as the role of ontogeny and maternal effects during development.

SOCIAL ENVIRONMENT DURING ONTOGENY: PRENATAL AND POSTNATAL DEVELOPMENT

The effect that the social environment may have during the ontogeny of animals has received little attention in studies of free-living social species. The hormonal stress-axis of the mother and the offspring during early life may play a role in shaping the expression of phenotypic traits. Phenotypic plasticity, or the ability of an individual organism to alter its phenotype in response to changes in environmental conditions (Stearns 1989; Garland & Kelly 2006), is relatively understudied at both the functional and mechanistic levels in social species. In social species, individuals may adapt their phenotype to the social conditions encountered during ontogeny. A variety of laboratory studies have demonstrated that stressors acting on the mother during pregnancy or lactation (or during oogenesis in birds) may result in long-lasting effects on the offspring (reviewed in de Kloet *et al.* 2005; Catalani *et al.* 2011; Henriksen, Rettenbacher & Groothuis 2011). Whereas the mammalian literature generally takes a biomedical

perspective with the prevailing view that environmental stressors lead to pathologies, or deviations from the norm, the avian literature typically takes a more evolutionary perspective (Groothuis *et al.* 2005), with the prevailing view that environmental influences during early ontogeny (e.g. maternal effects) may help offspring to adapt to the current environment (Henriksen, Rettenbacher & Groothuis 2011). In captive animals, such as guinea pigs (Kemme, Kaiser & Sachser 2007, 2008), manipulations of the stability of social groups had no effect on HPA activity. Interestingly, however, male guinea pigs whose mothers lived in an unstable social environment during pregnancy and lactation had higher levels of testosterone later in life compared to males whose mothers lived in a stable social environment during this period. A study in spotted hyenas (Fig. 1) found that androgen metabolite levels are higher in dominant female spotted hyenas during pregnancy, which may affect offspring aggression (Dloniak, French & Holekamp 2006). However, the observed effect on aggressive behaviour was small, and potential effects on the HPA axis of the offspring were not investigated. A study of adoption in free-living spotted hyenas found that the influence of the social status of the surrogate mother on offspring behaviour was much stronger than the effects of the prenatal hormonal environment (East *et al.* 2009). In birds, development occurs in both the egg and during the nest stage (when direct hormonal effects from the mother are unlikely to occur). In cooperatively breeding Florida scrub-jays, parental provisioning rates directly influence baseline glucocorticoid levels in nestling (Rensel, Boughten & Schoech 2010b). The stress response in this species varies in different developmental stages (Rensel, Wilcoxen & Schoech 2010a) and is quite repeatable across different developmental periods (Rensel & Schoech 2011). Therefore, early life and developmental experiences in the nest may influence stress-physiology throughout adulthood.

Developmental effects on stress physiology in social species may not just be limited to circulating hormone levels. In studies of laboratory rats, variation in maternal care altered the expression of genes that regulate behavioural and hormonal stress responses, forming the basis of consistent individual differences in stress reactivity (Meaney *et al.* 1996; Meaney 2001). Similar programming may occur during adolescence. In guinea pigs, housing conditions from early adolescence through adulthood had profound effects on behaviour and hormone physiology of males: males that spent the adolescence period in mixed gender colonies showed a reduction in stress responsiveness compared to males that were housed with a single female during adolescence (Kaiser *et al.* 2007; Lürzel, Kaiser & Sachser 2010). It is unclear if these laboratory studies can be generalized to free-living animals, but it is possible that this kind of programming of the offspring stress responsiveness may be adaptive. For example, the social status of the mother, the stability of the social hierarchy she lives in, or the amount of alloparental care provided by helpers could influence offspring provisioning and/or care. This variation in offspring care may then transduce a social status related signal to the offspring, which could in turn, programme the offspring's reactivity to environmental stressors. Rank-related differences in maternal care that may potentially lead to such programming are known from wild populations (Pusey, Williams & Goodall 1987), and in wild baboons, persistent effects of female rank on offspring HPA activity have been demonstrated (Onyango *et al.* 2008). In summary, laboratory studies suggest that the social environment during embryonic development, in the nursing or nestling phase, and during adolescence may programme the hormonal stress response. Because it is currently unclear whether such programming may affect fitness or what consequences this programming may have on population demography, studies of free-living animals are needed to answer these questions.

Future directions

LINKING HPA FUNCTION AND FITNESS IN THE WILD

For both social and non-social species, much of our interest in relationships between social or environmental conditions and glucocorticoid concentrations is motivated by a desire to understand the physiological mechanisms by which the environment affects fitness. However, it is difficult to establish causal relationships between glucocorticoid levels and social behaviour or environmental conditions. Likewise, understanding the relationship between glucocorticoids and fitness is not straight-forward. Prolonged elevated baseline levels of glucocorticoids are commonly viewed to be detrimental, costly and decrease fitness (Sapolsky, Romero & Munck 2000). However, there is little consistent evidence for a negative association between elevated baseline glucocorticoids and fitness (Bonier *et al.* 2009a). Part of the variation among species in the glucocorticoid/fitness relationship could be attributed to a variety of demographic, social (e.g. social rank, age, group size) or environmental factors (e.g. resource availability). Additionally, seasonal patterns of glucocorticoid release could also obscure the relationship. For example, many of the studies of HPA-fitness relationships reviewed by Bonier *et al.* (2009a,b) were conducted in the breeding season. Although many species show elevated baseline levels of glucocorticoids during breeding (Romero 2002), this does not necessarily indicate that these breeders are chronically stressed. Rather, elevated levels of glucocorticoids during breeding may play a role in the regulation of enhanced metabolic needs during reproduction. During breeding, elevated baseline levels of glucocorticoids may actually be predictive for high reproductive success in some species (Bonier *et al.* 2009b; Ouyang *et al.* 2011). Just as the accumulation of studies across a range of species and conditions altered our understanding of relationship between HPA function and rank, we suggest that studying the relationship between HPA function and fitness across a range

of species and conditions will yield new insights. Studies along ecological or social gradients (e.g. variation in population density or variation in group size) will be of particular value.

HYPOTHALAMIC-PITUITARY-ADRENAL FUNCTION AT MULTIPLE LEVELS

In addition to looking at glucocorticoids in different life history stages, it may also be important to look at other components of the HPA-axis. Studies that incorporate a range of methods [baseline glucocorticoid measurements, glucocorticoid responses to acute stressors, adrenocorticotropic hormone (ACTH) challenge and dexamethasone suppression] will be of particular value. For example, baseline and maximal stress-induced glucocorticoid levels bind to different types of receptors (Romero 2004) and may have fundamentally different effects on behaviour. In cooperatively breeding, superb starlings, baseline, maximal levels and stress responses tended to show similar patterns in individuals of different social rank (Rubenstein 2007), but the same may not be true in all species. What may be most relevant to understanding the relationship between glucocorticoids and fitness in social species is the response to stress and the feedback regulation of glucocorticoid release (reviewed in Romero 2004), which has been demonstrated for baboons (Sapolsky & Altmann 1991; reviewed in Sapolsky, Romero & Munck 2000; Sapolsky 2002). Although dominant baboons typically expressed lower baseline glucocorticoid levels than subordinates, when faced with a stressor, glucocorticoid levels not only increase much faster in dominants than in subordinates, but dominants also terminated the release of glucocorticoids more quickly after cessation of the stressful event (Sapolsky & Altmann 1991; Sapolsky 1993). These differences between dominants and subordinates were neurally driven and could not have been elucidated simply with studies of circulating hormones levels. When injected with corticotropin-releasing factor (CRF), the hypothalamic peptide that induces release of ACTH from the anterior pituitary, dominants responded with a larger increase in ACTH than subordinates, which then led to a much faster increase in glucocorticoid production. Shutting down the adrenocortical stress response via negative feedback was more efficient in dominants. Sapolsky demonstrated this by administering dexamethasone, a synthetic glucocorticoid that artificially stimulates negative feedback of the HPA axis (Sapolsky & Altmann 1991; Sapolsky 1993). To our knowledge, these data are the only ones relating negative feedback regulation of the HPA-axis with fitness and social status in a free-living vertebrate. Data from marine iguanas (*Amblyrhynchus cristatus*) suggest that individuals with an effective negative feedback regulation were more likely to survive a severe environmental stressor than individuals with a less effective negative feedback regulation (Romero & Wikelski 2010). Thus, for baboons and marine iguanas, the effectiveness of negative feedback regulation of the HPA-axis can be a predictor of fitness. These studies demonstrate that field studies can examine not only circulating glucocorticoid levels, but also feedback mechanisms. Broad inferences will not be possible until more studies have been performed, because HPA sensitivity can vary with age, and despite their generally inhibitory effects on CRF, glucocorticoids can have locally positive feedbacks on CRF release (e.g. in the central amygdala, which is involved in social behaviour: Schulkin, Morgan & Rosen 2005).

Conclusion

In summary, the increase in the number of studies of glucocorticoids in free-living vertebrates in the past two decades has greatly influenced our understanding of stress physiology. However, many exciting avenues for future research exist. More complete descriptions of HPA function and a better understanding of the complex relationships between glucocorticoids and fitness will be fundamental. Determining these relationships will require long-term studies of organisms with known ages in different life history stages and demographic, social and environmental contexts, as well as comparisons among populations or experimental manipulations of the putative causal variables that affect HPA axis activity. Maternal and organizational effects on neuroendocrine and epigenetic components of stress physiology in free-living animals are also areas ripe for exploration. To achieve these and other goals, we must move beyond simply assaying plasma glucocorticoid or faecal glucocorticoid metabolite levels. Studies should simultaneously examine natural and experimentally induced stress responses and the associated negative feedbacks. Moreover, studies of glucocorticoid receptors and binding globulins are mostly lacking in field studies and would help to fully understand the complexities of stress physiology. Much of what we know about stress comes originally from the biomedical literature. For several decades, extending concepts from biomedical research to studies in the wild has been a productive way to learn how individuals respond to unpredictable social and environmental challenges, and how these responses influence fitness or population demography. While much has been learned, well-identified avenues for future research remain.

Comparative effects of GnRH and porcine zona pellucida (PZP) immunocontraceptive vaccines for controlling reproduction in white-tailed deer (*Odocoileus virginianus*)

P. D. Curtis[1], R. L. Pooler[2], M. E. Richmond[2], L. A. Miller[3], G. F. Mattfeld[4] and F. W. Quimby[5]

[1]Department of Natural Resources, Cornell University, Ithaca, NY 14853, USA; [2]New York Co-operative Fish and Wildlife Research Unit, USGS-BRD, Cornell University, Ithaca, NY 14853, USA; [3]National Wildlife Research Center, USDA, 4101 LaPorte Avenue, Fort Collins, CO 80524, USA; [4]New York State Department of Environmental Conservation, Albany, NY 12233, USA; and [5]College of Veterinary Medicine, Cornell University, Ithaca, NY 14853, USA

Fawning rates and mating behaviour were compared between white-tailed deer (*Odocoileus virginianus*) treated with GnRH and porcine zona pellucida (PZP) immunocontraceptive vaccines from 1997 to 2000. Female deer from a herd of 102 deer at Seneca Army Depot, near Romulus, New York, were treated with prime and booster injections of PZP ($n = 22$) or GnRH vaccine ($n = 32$), or remained untreated as controls ($n = 34$). During the summers after booster treatment, observed fawning rates for adult female deer were similar for both PZP-treated (0.10–0.11 fawns per female) and GnRH-treated (0.13–0.22 fawns per female) female deer, and were significantly lower ($t = -8.93$ and $t = -9.73$; $P \leqslant 0.0005$, respectively) than those observed for control female deer (1.22–1.38 fawns per female). During the second (0.36 fawns per female) and third summers (0.61 fawns per female) after the last booster injection, GnRH-treated female deer still produced significantly fewer fawns than did the controls (1.38 and 1.31 fawns per female, respectively). In one breeding season after treatment, five of 18 (28%) females vaccinated with PZP produced fawns, similar to the rate for GnRH-treated females (29%). In addition, females treated with GnRH had fewer oestrous cycles per female (0.06, $P \leqslant 0.05$) than did either control (0.22 cycles per female) or PZP-treated deer (0.36 cycles per female). Initial PZP treatment followed by a booster dose 5–7 months later reduced fawn production and prolonged the breeding season as females repeatedly returned to oestrus, similar to results reported in other studies.

Introduction

White-tailed deer (*Odocoileus virginianus*) densities have reached unprecedented levels in some suburban communities (Curtis and Richmond, 1992) and deer populations in North

America are still increasing. Safety concerns and ethical issues have rendered deer population regulation via managed recreational hunting impractical in many residential areas, and have increased interest in the use of non-lethal methods, such as immunocontraceptive vaccines for controlling birth rates in deer (Warren *et al.*, 1995; Miller, 1996; Curtis *et al.*, 1997; Cowan *et al.*, in press).

Fertility control as a tool in wildlife management has been the subject of research for many years (Harder and Peterle, 1974; Kennelly and Converse, 1997) with variable results (Bomford, 1990; Turner *et al.*, 1997; Warren *et al.*, 1997). Porcine zona pellucida (PZP) has been the most commonly used immunocontraceptive antigen for fertility control in female mammals (Sacco, 1987) and has been administered experimentally to > 70 species of wild mammals, including several captive ungulates (Kirkpatrick *et al.*, 1997; Miller *et al.*, 2000a). The continuing expansion of humans into deer habitat and vice versa has resulted in much recent research with PZP vaccines being focused on widespread and growing concerns with deer in suburban settings (Turner *et al.*, 1992, 1996; McShea *et al.*, 1997; Underwood and Verret, 1998).

A second immunocontraceptive antigen, GnRH, has been shown to have potential for fertility control in domestic animals (Jeffcoate *et al.*, 1978, 1982; Adams and Adams, 1992; Brown *et al.*, 1994; Meloen *et al.*, 1994), companion animals (Ladd *et al.*, 1994), and a variety of wildlife species including Norway rats (*Rattus norvegicus*, Miller *et al.*, 1997), African elephants (*Loxodonta africana*, Brown *et al.*, 1993), rainbow trout (*Oncorhynchus mykiss*, Riley and Secombes, 1993) and the marmoset monkey (*Callithrix jacchus*, Hodges and Hearn, 1977). GnRH has been evaluated for efficacy in captive white-tailed deer (Killian, 1998; Miller *et al.*, 2000b); however, little research has been conducted with GnRH vaccines in free-ranging white-tailed deer.

The issue of remotely delivering an immunocontraceptive antigen and following that event with timely delivery of booster doses to the same free-ranging animal is an obvious challenge (Rudolph *et al.*, 2000). PZP booster injections were delivered by dart rifle during early autumn 1997 before the breeding season, 5–7 months after the initial injection. We hypothesized that a similar reduction in fawning rates would be observed for PZP-treated deer and GnRH-treated females that received both prime and booster doses a few weeks apart in autumn 1996.

The aims of the present study were to compare the efficacy of PZP and GnRH vaccines for reducing fawn production in the same herd of white-tailed deer. Fawning rates and breeding behaviour of PZP- and GnRH-treated female deer were compared between treatments and also with untreated control deer. A direct comparison of these vaccines under similar herd and field conditions provides an optimal setting for determining whether either or both of these immunocontraceptive antigens have potential for further development as a tool for wildlife fertility control.

Materials and Methods

The study was conducted in the quarantine area (QA) of the 4000 ha Seneca Army Depot (SAD) located near Romulus, New York. The 263 ha QA is enclosed by three 2.4 m parallel, security fences and consists of 5% paved roads, railroads and buildings, 17% woodland and 78% open grasslands. Natural forage was abundant, and was further supplemented with apples, apple mash, corn, alfalfa hay and salt to ensure that deer were in good condition during the breeding season and winter months. These food items were strategically placed to serve also as bait sites that were used for darting of deer and behavioural observations.

Experimental animals included 61 adult (≥ 2.5 years) and 27 yearling (1.5 years) female deer, and eight adult and five yearling males. Deer were captured with rocket nets (Hawkins *et al.*, 1968), dart guns (Pneu Dart, Inc., Williamsport, PA) and Clover traps (Clover, 1954) from

Table 1. Immunocontraceptive treatment schedule for female white-tailed deer vaccinated with porcine zona pellucida (PZP) or GnRH antigens at Seneca Army Depot, Romulus, New York from 1996 to 1998

Experimental group	Sample size	Prime dose	First booster	Second booster
PZP	22	6 March – 1 May, 1997[a]	26 August – 28 October, 1997	3 September – 30 October, 1998
GnRH	32	31 August – 9 October, 1996	20 September – 9 November, 1996	10 September – 17 October, 1997

[a]The prime dose of PZP vaccine was injected by hand into female deer at the time of capture and marking. All other vaccinations were delivered remotely by dart-syringe and rifle.

surrounding SAD property during winter and early spring in 1996 and 1997. Deer captured in rocket nets or Clover traps were restrained under the net and immobilized with 2.2 mg xylazine hydrochloride kg^{-1} (Rompun; Miles Laboratories, Shawnee Mission, KS) administered i.m. The antagonist yohimbine hydrochloride (Yobine; Lloyd Laboratories, Shenandoah, IA) was administered i.v. at 0.11 mg kg^{-1} upon release of the deer (Mech *et al.*, 1985). For immobilization with a dart rifle, disposable 2 cc darts with 1.9 cm needles and gelatin collars were used. These syringe darts injected either pure xylazine hydrochloride, or a mixture of xylazine hydrochloride tiletamine hydrochloride and zolazepam hydrochloride (Telazol; Fort Dodge Labs, Fort Dodge, IA) at 2.2 mg kg^{-1}. No antagonist was administered at release when the Telazol mixture was used for deer immobilization. Each deer was fitted with a numbered collar for individual identification before release into the research enclosure.

For the field study, female deer were assigned to GnRH (1996–2000), PZP (1997–2000) or control (1996–2000) groups (Table 1). All vaccine treatments were administered in the hip region either by injection by hand at capture (PZP) or by remote delivery later with self-injecting 1 cc darts (Pneu Dart Inc., Williamsport, PA). In this investigation, a prime dose of PZP vaccine was administered during winter 1997 when deer were food-stressed and more easily lured to bait sites, thereby increasing darting efficiency. Deer were darted from canvas shelters at baited sites (< 35 m) near dawn and dusk, or from a vehicle at night with the aid of a spotlight at distances of 14–45 m along roadsides. All treatments followed positive identification of individual deer.

GnRH experiments

The immunocontraceptive vaccines used in the present study were prepared by L. A. Miller (US Department of Agriculture-National Wildlife Research Center, Fort Collins, CO). The 10 amino acid GnRH was made immunogenic by coupling it to the carrier keyhole limpet haemocyanin (KLH, Miller *et al.*, 2000b). A glycine was added at the C-terminus of GnRH as a spacer, and a cysteine was added to provide a coupling agent to maleimide on KLH. Maleimide-activated KLH was purchased from Pierce Chemical Co. (Rockford, IL) and the C-terminal Cys-GnRH was coupled to the activated KLH following the manufacturer's instructions. Both KLH-maleimide and the peptide were lyophilized and rehydrated in a 1:1 (w:w) ratio for coupling. The 1 cc prime dose of GnRH vaccine contained 65 µg KLH–GnRH in saline mixed with Freund's complete adjuvant (FCA) at a 1:1 ratio (Miller, 1997). The 1 cc booster dose contained 65 µg KLH–GnRH mixed with Freund's incomplete adjuvant (FIA) in a 1:1 ratio. The prime dose (GnRH + FCA) was remotely injected into 32 female deer and the first booster shot (GnRH + FIA) was administered 3–4 weeks later, before the breeding season

during September and October 1996. A second booster dose (GnRH + FIA) was delivered by remote injection during September 1997. No GnRH booster treatment was provided in September 1998 or 1999; however, fawning rates were again monitored in the summer of 1999 and 2000 to determine any residual effects of the GnRH vaccine in female deer at 1 and 2 years after treatment.

PZP experiments

Female deer ($n = 22$) were immunized with purified PZP, which was prepared by and purchased from B. S. Dunbar (Baylor College of Medicine, Houston, TX; Skinner *et al.*, 1994). The 1 cc prime dose of PZP vaccine consisted of 0.5 cc saline containing 65 μg PZP mixed with 0.5 cc FCA. Similarly, a 1 cc booster dose contained 65 μg PZP in 0.5 cc saline mixed with 0.5 cc FIA at a 1:1 ratio. The prime dose (PZP + FCA) injection was administered by hand at the time of capture during late winter 1997 (February–April), as deer were readily caught at bait sites during the winter. The effectiveness of a prolonged period between administration of the prime and the initial booster dose was determined by administering the initial booster (PZP + FIA) by remote injection 5–7 months later in September 1997. A second booster treatment (PZP + FIA) was delivered by dart-rifle in September and October 1998. These deer were monitored for mating and subsequent fawning activities from autumn 1997 to summer 2000.

Fawn observations

Fawn searches were conducted in the 263 ha enclosure each day from May to September 1997–2000. Maternity was determined on the basis of repeated observations of fawns following females and by females displaying maternal behaviour toward fawns. A minimum of three doe–fawn interactions was used to determine parentage. Parturition dates were initially based on fawn motor skills and size at first observation relative to fawns of known age (McShea *et al.*, 1997). In September, October and December of each year, fawns were captured and removed from the research enclosure. These fawns were classified by age on the basis of incisor development (Severinghaus, 1949). Adjustments to initial estimated parturition dates were made on the basis of incisor development.

From 1996 to 1998, observations of deer breeding activity were conducted each day at dawn and dusk from mid-October until all males had shed their antlers (early March 1997 and late March 1998). A female was considered to be in oestrus when she was observed being tended (Hirth, 1977) or mounted by a male. The breeding season was divided into five, 1 month periods beginning with the date on which a male was first observed tending a female. If the oestrous cycle overlapped two periods, the doe was placed only in the earlier period.

For analysis of parturition and dates of observed oestrus, the Wilcoxon rank sum test (Z) or Kruskal–Wallis test (chi-squared) for multiple groups were used. All percentages were subjected to angular (arcsine) transformation (Steele and Torrie, 1960) before ANOVA.

Results

Fawn production

Only four of 32 (13%) and four of 30 (13%) GnRH-treated female deer produced fawns in 1997 and 1998, respectively (Table 2). None of nine GnRH-treated yearlings, and only four of 23 (17%) GnRH-treated adults, produced fawns in 1997. The apparent value of providing a booster treatment is shown by comparing fawn production in boosted, sexually mature adults with those deer that did not receive the booster. During the fawning seasons of 1997 and 1998

[a]PZP-treated female deer that received their last booster injection in autumn 1998, so that fawning rates for summer 2000 occur > 20 months after treatment.

[b]GnRH-treated female deer that received their last booster injection in autumn 1997, so that fawning rates in summer 1999 occur > 20 months after treatment, and those in summer 2000 occur > 32 months after the last booster injection.

after booster treatments during the previous autumn, only eight of 62 females (13%) treated with GnRH produced fawns and only one of the eight females produced twins. During summer 1999, after one breeding season without a booster, eight of 28 (29%) adult females previously treated with GnRH produced fawns and of these, two does produced twins, which is the common litter size for adult females in good health (Verme, 1969). In the second breeding season after treatment, 16 of 28 females (57%) bore fawns. During these same four reproductive seasons, 110 fawns were produced by control does (n = 38 in 1997; 33 in 1998; 22 in 1999; and 17 in 2000; Table 2).

For females treated with PZP, three of 22 (14%) and two of 20 (10%) produced offspring during 1998 and 1999, respectively. One of three (33%) PZP yearlings and two of 19 (11%) PZP adults produced fawns in the summer of 1998. During the reproductive seasons immediately after booster treatments the previous autumn, none of the PZP-treated females that produced fawns had twins. One breeding season after treatment, five of 18 females (28%) bore young, which was similar to the rate for GnRH-treated females (29%).

During summers immediately after autumn booster treatments, fawn production for both GnRH- and PZP-treated females was significantly lower than that of control females ($t = -8.93$; $P < 0.0005$ and $t = -9.73$; $P < 0.0005$). In addition, in the second reproductive season after booster injections, GnRH- and PZP-treated females still produced significantly fewer ($P < 0.0005$) fawns than did the controls.

There was no difference in parturition dates between 1997, 1998 and 1999 (chi-squared = 1.58; 2 df; $P > 0.1$; Table 3) among control females, as most fawns were born before 1 July. Fawning dates for the GnRH- and PZP-treated females were later in 1998 than for the 1997 GnRH group (chi-squared = 8.34; 2 df; $P \leq 0.03$) and later than the control groups in 1997 and 1998 (chi-squared = 3.87; 1 df; $P \leq 0.05$). There was no difference in parturition dates between any of the three groups in 1999 (chi-squared = 0.00; 2 df; $P > 0.995$).

	1998	4	0	0	0	0

[a]GnRH-treated female deer that received their last booster treatments during autumn 1997.

Mating activity

There was no difference in observed timing of oestrus for the control females between 1997 and 1998, or for the PZP-treated females between 1997 and 1998 ($Z = 1.49$, $P = 0.136$ and $Z = 0.406$, $P = 0.682$, respectively; Table 4). However, females treated with GnRH for a second year cycled later than females in their first year of treatment with GnRH ($Z = 1.93$; $P = 0.05$). Observed oestrous cyclicity for PZP-treated females was significantly later than that for control females ($Z = 2.62$; $P = 0.009$) and marginally later than that for GnRH-treated females ($Z = 1.78$; $P = 0.075$). In 1997, females treated with PZP showed significantly more mating activity (0.36 oestrous cycles per doe) than those treated with GnRH (0.06 oestrous cycles per doe) and control females (0.22 oestrous cycles per doe).

Discussion

The results from this study demonstrate successful inhibition of fertility in semi-free ranging white-tailed deer with a remotely delivered GnRH vaccine. The observed fawning rates (0.13–0.22 fawns per female) in the present study were similar to those reported by Miller *et al.* (2000b) for hand-injected, captive deer in Pennsylvania (0.21 fawns per female) with an 88% reduction in fawn births as compared with control females.

PZP treatments with 5–7 months between prime and booster injections markedly reduced fawn production, and reduced the incidence of twin births for those females that produced fawns. PZP treatment also prolonged the breeding season due to an increased number of oestrous cycles in each doe; this finding is similar to results reported in studies with 2–4 weeks between prime and booster injections (Turner *et al.*, 1992, 1996; McShea *et al.*, 1997; Killian, 1998). Miller *et al.* (2000a) also noted that the best immune response to PZP vaccination often occurs in the second year after original antigen exposure and that infertility may be retained for 1–4 years in some females without additional booster treatments.

GnRH and PZP vaccines reduced fawn production in white-tailed deer to a comparable degree. However, the GnRH treatment was apparently more effective for yearling females, and more adult females responded to PZP treatment. Three of the four GnRH-treated adult females that did not respond to vaccine injection and produced fawns in 1997 also produced fawns in 1998, and all four females again produced fawns in 1999. Apparently, either a small proportion of the adult female population did not respond to the GnRH vaccine (Bomford, 1990; Becker and Katz, 1997) or the first, second or both remotely delivered injection failed to deliver a complete dose.

Suppression of reproductive hormones with GnRH may be more effective in yearlings (deer classified as 1.5 years old), which generally ovulate less frequently than do adults (Hesselton and Jackson, 1974), and do not reach full reproductive potential until adulthood (deer classified as 2.5 years or older; Verme and Ullrey, 1984). None of the nine females immunized with GnRH as yearlings produced fawns during their first or second year as adults. Adams and Adams (1992) and Brown *et al.* (1994) reported that immunization of domestic stock against GnRH very early in life (prepubertal) may be more efficacious and longer lasting than immunization later in life. Warren and White (1995) suggested that treating prepubertal fawns may increase the efficiency of a contraceptive management programme.

Contraceptives delivered orally will probably be necessary for practical wildlife management in the future (Warren *et al.*, 1995; Miller, 1996; Curtis *et al.*, 1997; Linhart *et al.*, 1997; Miller *et al.*, 2000a), and, thus, may be administered to deer of all ages via bait consumption. Therefore, it is important for future investigators to examine the potential impacts of immunization on all age classes (fawns, yearlings, adults) of white-tailed deer. However, the risk of unintentional treatment of non-target wildlife species is much greater with oral delivery than for injection or implants (Guynn, 1997). Species specificity could be achieved either by genetically engineering the antigen, or by designing a bait station to exclude non-target animals. Much work is still required to develop safe and effective delivery systems for contraceptive drugs or vaccines (Cowan *et al.*, in press).

Parturition dates for PZP-treated females were not substantially delayed, as all three births occurred before early July. The few deer that did not develop a sufficient antibody response to inhibit reproduction must have conceived on their first or second oestrous cycle. Jackson and Hesselton (1973) reported that 95% of females (including fertile fawns) in New York gave birth before 19 July, which is similar to the results obtained for the control females.

Variation in the response to GnRH among adult females or incomplete injections may also explain the delayed breeding in 1997 and resulting delayed parturition in 1998 shown by

GnRH-treated females. Only two oestrous cycles were observed for GnRH-treated females in 1997; however, the first was not observed until December. Cyclicity in deer in all other experimental groups was first observed in November. If GnRH injections administered in autumn 1996 were incomplete in the four non-responding females and insufficient to block reproduction (all four females fawned in early June), then administration of the third injection to these females in autumn 1997 may have acted as a single-injection treatment. If this was the case, only a short-lived antibody response would be produced and, thus, there would be only a delay in the onset of oestrus and subsequent fawning. Miller *et al.* (2000b) noted variations in antibody titre and immune response for captive female deer treated with GnRH vaccines. These observations were consistent with past immunocontraceptive studies and are thought to be due to genetic differences among individual animals. Feral horses treated with GnRH showed delayed foaling (Goodloe, 1991), and captive red deer stags showed a delayed rut (Atja *et al.*, 1992; Freudenberger *et al.*, 1993). McShea *et al.* (1997) also noted delayed fawning for PZP-treated females that received only a single injection.

Females treated with GnRH for a second year and PZP-treated females breeding late in the season showed reduced rates of twin births. This finding may have resulted from decreased sperm production often experienced by males during late winter (Mirarchi *et al.*, 1977; Knox *et al.*, 1988), which may be associated in part with loss of body weight (Gittleman and Thompson, 1988). GnRH can also function as a contragestation agent depending on timing of the vaccine delivery and immune response of the individual deer (Miller *et al.*, 2000b). Therefore, GnRH could have inhibited implantation or even the maintenance of pregnancy in some female deer resulting in fetus resorption and, thus, smaller litter sizes.

GnRH-treated females that did not receive a booster treatment in autumn 1998 showed an earlier onset of oestrus than did GnRH-treated females that received a booster injection immediately before the breeding season. Similarly, 14 of 20 (70%) of the oestrous cycles observed for second year PZP-treated females occurred before the end of December compared with only four of eight (50%) for the first year PZP-treated does. This finding may be attributable to non-parous and non-lactating does entering the breeding season in better body condition and, therefore, showing an earlier onset of breeding activity (Verme and Ullrey, 1984; McShea *et al.*, 1997).

Only eight of 28 (29%) GnRH-treated female deer bore fawns in 1999, indicating that GnRH continued to inhibit reproduction in 71% of females 1 year after treatment. If the four non-responsive GnRH-treated females that consistently produced fawns during the study are excluded, then only four of 24 (17%) of females produced young in the second fawning season after booster treatment. Miller *et al.* (2000b) noted that infertility was directly related to anti-GnRH serum antibody titres above 64 000 with infertility lasting 2 or more years without booster treatment. However, studies in domestic stock revealed that short-term anti-GnRH immunization was reversible (Keeling and Crighton, 1984), and thus unlikely to be accompanied by a prolonged period of reduced fertility after treatment.

Turner *et al.* (1996) reported that PZP-mediated infertility for white-tailed deer was reversible within 2 years for 75% of treated females. In contrast, Miller *et al.* (2000a) observed that PZP produced variable infertility for up to 4 years. Overall, birth rates were reduced by 76% during the 6 year study, and there was an 89% reduction in fawn production during the first 2 years of active immunization. For this captive herd in Pennsylvania, immune responses among deer were variable, especially in the first year of treatment (Miller *et al.*, 2000a).

The obvious impact of a residual effect and the ultimate reversibility of contraception are of considerable importance to population modelling efforts (Barlow, 2000; Hobbs *et al.*, 2000). A predictable natality rate is a cornerstone for accuracy in building and understanding wildlife population models (Courchamp and Cornell, 2000; Hobbs *et al.*, 2000; Cowan *et al.*, in

press). Although Nettles (1997), Kirkpatrick *et al.* (1997) and other workers have alluded to this issue, additional studies of the long-term effects of both PZP and GnRH vaccines, as well as other candidate agents, are needed. In addition, recent modelling of virus vectors and bait delivery for immunocontraceptive agents highlighted the importance of delivery systems to the overall success for field application of fertility control programmes (Courchamp and Cornell, 2000; Cowan *et al.*, in press).

In summary, both PZP and GnRH vaccines were effective for inhibiting reproduction in white-tailed deer when administered as described here. In addition, the GnRH vaccine was responsible for a reduced fawning rate for female deer 1 and 2 years after treatment. Hobbs *et al.* (2000) showed that fertility control with long-lived or irreversible agents may be more efficient than culling for regulation of ungulate populations. However, longer term studies and pathological examination of deer treated with immunocontraceptive vaccines may be required to reveal potential detrimental health effects resulting from interference with the reproductive system of white-tailed deer (Seal, 1991; Muller *et al.*, 1997).

Our experience and data, plus recent reports, indicate that implementation of an immunocontraceptive programme using current protocols, even in a semi-free ranging but enclosed deer herd, would be expensive and perhaps impractical due to high equipment and labour costs (Rudolph *et al.*, 2000; Pooler *et al.*, in press). The need for a single dose, oral contraceptive agent for free-ranging animals has been highlighted in a number of studies (Warren *et al.*, 1995; Miller, 1996; Bradley *et al.*, 1997; Curtis *et al.*, 1997; Linhart *et al.*, 1997). Further research to develop such a single-dose, fertility control agent that can be delivered orally and at lower cost is warranted.

This research was conducted in the Department of Natural Resources at Cornell University in conjunction with the New York State Department of Environmental Conservation, SUNY-College of Environmental Science and Forestry in Syracuse, and the USDA National Wildlife Research Center in Fort Collins, CO. The authors thank the Seneca Army Depot for use of their fenced lands and especially M. Stofka for assistance with military regulations and background information. The authors also thank the volunteers who helped with deer trapping and G. Parsons, G. Mattfeld, J. O'Pezio, J. Hauber, B. Penrod and D. Odell from the DEC for use of their equipment and technical advice. K. Fagerstone provided helpful comments on the early drafts of this manuscript.

Abstract: Before immunocontraceptives can be considered safe to use on wildlife species, potential health risks should be assessed. Gonadotropin-releasing hormone (GnRH) immunocontraceptive has successfully reduced fertility of white-tailed deer (*Odocoileus virginianus*); however, associated deer physiology has rarely been examined. We conducted gross necropsy examinations, histology, and blood chemistry comparisons on euthanized deer previously vaccinated with immunogenic GnRH (n = 18 females and n = 4 males), or left as untreated controls (n = 7 females and n = 6 males). Granulomas were found at injection sites of most deer, even 3 years post-treatment. There were no significant differences in ovary ($F_{2,22}$ = 0.31, P = 0.73), or pituitary weights ($F_{2,22}$ = 0.30, P = 0.75) between treatment groups. Ovaries from control females had significantly more secondary follicles ($F_{2,21}$ = 20.56, $P \leq$ 0.001), but not Graafian follicles ($F_{2,22}$ = 2.22, P = 0.13). Immunized males had significantly lower mean testes weights, a number of morphologic abnormalities, and varying degrees of aspermatogenesis with fewer mature spermatozoa. We do not recommend treating male deer with anti-GnRH immunocontraceptive vaccines.

Key words: deer–vehicle collision, GnRH, gonadotropin-releasing hormone, human–wildlife conflict, immuno-contraception, *Odocoileus virginianus*, reproduction, white-tailed deer

POPULATION DENSITIES of white-tailed deer (*Odocoileus virginianus*) in many suburban communities are reaching unprecedented levels (Curtis and Richmond 1992, DeNicola et al. 2008) and continue to escalate throughout North America. In suburban settings, where deer densities are often highest, safety concerns and ethical issues have rendered population regulation via recreational hunting impractical (DeNicola and Williams 2008). Higher deer densities have caused increases in deer–vehicle collisions (DVCs; Hussain et al. 2007, Mastro et al. 2008), and there is no easy way to reduce the frequency of these collisions (Mastro et al. 2008, Ng et al. 2008). In response, efforts to control growth of suburban deer herds with nonlethal methods, such as immunocontraception, have intensified (Warren et al. 1995, Curtis et al. 1997, Cowan et al. 2003, Miller et al. 2008, Rutberg and Naugle 2008). However, recent modeling efforts have shown that it will be very difficult to attain sufficient numbers of treated deer to have measurable reductions in open populations experiencing emigration and immigration (Merrill et al. 2006). Furthermore, community residents' attitudes towards fertility control as a deer management option are not fixed, and after stakeholders received additional information concerning the effectiveness or humaneness of contraception, their perceived acceptance of this technique often declined (Lauber and Knuth 2004). Consequently, it is imperative that communities and wildlife management agencies study all aspects of immunocontraception so that informed decisions can be made about applying these technologies for suburban wildlife management.

Fertility control as a tool in wildlife management has been investigated for many years (Harder and Peterle 1974, Kennelly and Converse 1997) with variable results (Bomford 1990, Turner et al. 1997, Warren et al. 1997).

However, success with effective fertility control of individual deer has been achieved by vaccinating them with the immunocontraceptive antigens gonadotropin-releasing hormone (GnRH; Killian 1998, Miller et al. 2000*a*, Curtis et al. 2002, Killian et al. 2006) or porcine zona pellucida (PZP; Kirkpatrick et al. 1997, McShea et al. 1997, Miller et al. 2000*b*, Rutberg et al. 2004). While many researchers have documented successful fertility suppression, few investigators have considered the effects of immunocontraceptive vaccine treatment on deer physiology or histopathology (McShea et al. 1997, Killian et al. 2006). Kirkpatrick and Rutberg (2001) even stated that, "the absence of significant health side effects" is an important characteristic of any contraceptive vaccine. Hence, in this study, we conducted detailed necropsies on anti-GnRH-immunized deer to document potential pathological impacts.

Materials and methods

In accordance with an amendment approved by the Cornell University Institutional Animal Care and Use Committee (Protocol Number 96-10-99), postmortem examinations were conducted on a sample of euthanized, free-ranging, white-tailed deer (n = 18 females and 4 males) that had been injected with an anti-GnRH vaccine or left as untreated controls (n = 7 females and 6 males) during 1996–2000. The deer were included in a fertility control study contained within a 263-ha fenced, natural area at Seneca Army Depot near Romulus, New York (Curtis et al. 2002).

The immunocontraceptive vaccines used for the study were prepared by L. A. Miller (USDA/APHIS/Wildlife Services' National Wild-life Research Center). A 10-amino acid GnRH complex was made immunogenic by coupling it to the carrier keyhole limpet hemocyanin (KLH; Miller et al. 2000*a*). A glycine residue was added at the C-terminus of GnRH as a spacer, and cysteine residue was added to provide a coupling agent to maleimide on KLH. Maleimide-activated KLH was purchased from Pierce Chemical Company (Rockford, Ill.) and the C-terminal Cys-GnRH was coupled to the activated KLH following the manufacturer's instructions. Both KLH-maleimide and the peptide were lyophilized and rehydrated in a 1:1 (weight:weight) ratio for coupling. Each 1-ml dose of anti-GnRH vaccine contained 0.5 mg of KLH-GnRH in 0.5 ml of phosphate-buffered saline (PBS) solution emulsified with 0.5 ml of Complete Freund's Adjuvant (CFA) or Incomplete Freund's Adjuvant (IFA).

Treated deer had received a primary vaccination (KLH-GnRH + CFA) in the hip region with remotely delivered, self-injecting, 1-ml darts (Pneu Dart Inc., Williamsport, Pa.). We administered the first booster shot (KLH-GnRH + IFA) 3 to 4 weeks later during September and October 1996 prior to the breeding season. A second booster dose (KLH-GnRH + IFA) was delivered by remote injection during September 1997. No other booster treatments were given until 7 female deer were revaccinated in 2000 (KLH-GnRH + IFA) to compare the effects of recent vaccination to deer previously treated 3 years earlier. No males were revaccinated during 2000.

With a permit from the New York State Department of Environmental Conservation (NYSDEC), we administered euthanasia of deer for necropsy in October 2000 using a single, lethal shot from a high-powered rifle fired either out of a blind or from a vehicle (Beaver et al. 2001). We collected blood samples via heart puncture immediately at the time of death, and we stored them in vials on ice for transport. Deer (n = 35) were quickly transported (usually within 1–2 hours after collection) to the Cornell University College of Veterinary Medicine (CUCVM), Necropsy Lab, and placed in a cooler at 4.4°C. Most necropsies were conducted the day the deer were collected.

Blood chemistry analysis was performed by the CUCVM, Animal Health Diagnostic Center, on all of the collected deer. Anti-GnRH titer (1/titer x 1000) levels were determined via an enzyme-linked immunosorbent assay (ELISA), while progesterone and testosterone were determined by radioimmunoassay (RIA; Miller et al. 2000*a*). These values were then compared to the deer's histology and to its ovarian, testes, and pituitary weights.

Gross examinations included an accurate assessment of deer's age by tooth wear (Severinghaus 1949), evaluation of bone marrow fat (Cheatum 1949), examination of injection sites, and documentation of any abnormalities.

Figure 1. Buck treated with GnRH immunocontraceptive vaccine, Romulus, New York, USA. Note malformed antlers covered in velvet during the rut.

Ovaries, testes, pituitary gland, internal iliac lymph node, popliteal lymph node, and thyroid glands were stripped of fat and connective tissue then weighed immediately (to the nearest mg). Morphologic analysis was performed on tissues fixed in formalin, embedded in paraffin, sectioned to 7 microns, and stained with hemotoxylin and eosin, Masson's Trichrome, or acid-fast stains. Each ovary, testis, and pituitary gland was halved before fixation in formalin, and each half was embedded in paraffin. Multiple sections (but not step sections) were made of each surface to be examined with the previously mentioned stains, and if a suspected lesion was observed grossly, a section was also made through the lesion.

The total number of secondary and Graafian follicles were enumerated from 2 cross-sectional slices from each ovary from each deer. Any normal-appearing follicle with a corona radiata (a single layer of columnar cells anchoring the oocyte) or total follicular size >0.5 cm was classified as a Graafian follicle. Follicles with greater than 10% of their granulose cells (small cells that form the wall of an ovarian follicle) exhibiting cell death (apoptosis) were classified as atretic ovarian follicles (degenerated prior to maturity). Apoptosis was characterized as granulose cells with dark, small consolidated (hyperchromatic) nuclei.

A single layer of cuboidal epithelium (surface) lined several large fluid filled follicles. Because none of these follicles exceeded 1 cm in diameter, they were classified as atretic Graafian follicles; however, they could have been small follicular cysts. Also, some larger Graafian follicles with diminished numbers of granulosa cells may have also been early follicular cysts. However, we found no advanced cyst to confirm this.

Results

Gross necropsy observations

Blood chemistry. There was no significant difference in any of 28 standard blood chemistry measures between control and anti-GnRH-treated female (Table 1) or male deer (Table 2). Although there was some variation for selected blood parameters, these values fell within normal ranges, and patterns were unremarkable.

Body condition. On the basis of body weight, external visibility of individual rib bones, and subcutaneous fat observed during gross necropsy, most animals were judged in good to excellent condition and had a bone marrow fat score of >85%. Two exceptions were: (1) female no. 66, an anti-GnRH revaccinate in year 2000, had poor body condition and was grossly underweight. She also had very poor teeth and had raised twins that summer. (2) Control female no. 323 had good body condition; however, her bone marrow fat score was <50%.

Injection sites. Injection sites for the year 2000 revaccinates were compared to those for deer vaccinated in 1997 to evaluate current and former dart site lesions induced by Freund's adjuvant. While abscesses were more evident and larger in recent revaccinates, granulomas could be found at the injection site of nearly all vaccinated deer.

Lung abscess. A 4x4-cm-circumscribed lung abscess, greenish in color, was noted during the necropsy of deer no. 25 (anti-GnRH-vaccinated female, year 2000). Tissue sections demonstrated this to be a giant cell granuloma containing acid fast bacilli similar to those found at the injection site.

Parasites. Three deer (nos. 13, 19, and 378) had liver cysts, most likely associated with the tapeworm *Echinococcus granulosus*, and 1 deer had an encysted parasite in skeletal muscle consistent with sarcosporidiosis (*Sarcocystis* spp.; no. 20). Each of these animals was in good to excellent body condition.

Table 1. Means, standard errors, and *t*-test statistics for blood parameters of female white-tailed deer in control and anti-GnRH-treated groups at Seneca Army Depot, Romulus, New York, 2000.

Blood parameter	Control group ($\bar{x}$ ± SE)	GnRH group ($\bar{x}$ ± SE)	*t*-test results

Multifocal lymphocytic infiltrates. Focal infiltrates and nongiant cell granulomas were seen in kidney, skeletal muscle, and liver. These lesions were consistent with immunological action against migrating parasites in tissues.

Female deer

Neither combined ovarian weights ($F_{2,22} = 0.31$, $P = 0.73$) nor pituitary weight ($F_{2,22} = 0.30$, $P = 0.75$) differed significantly between treatment groups and showed no correlation with antibody titer (Table 3). Mean anti-GnRH antibody titers were greater in the year 2000 vaccinates than for control females (Table 3; $t_1 = 2.31$, $P = 0.03$). The average titer for female deer treated in 1997, including 2 of 8 deer that had no detectable titer, was not significantly different from control females ($t_1 = 0.13$, $P = 0.90$).

The average total number of secondary follicles was less in both 1997 and year 2000 vaccinates than for control females ($F_{2,22} = 17.8$, $P \leq 0.001$). The mean number of Graafian follicles ($F_{2,22} = 2.22$, $P = 0.13$), and average total follicle count did not differ between treatment groups ($F_{2,22} = 1.60$, $P = 0.23$).

Male deer

When collected in October 2000, most of the male deer were in breeding condition with hardened antlers and swollen necks. Blood analysis confirmed appreciable levels of testosterone in the bucks sampled. Average testosterone levels of the control males (312 ng [nanograms]/100 ml) were considerably higher

Table 2. Means, standard errors, and *t*-test statistics for blood parameters of male white-tailed deer in control and anti-GnRH-treated groups, Seneca Army Depot, Romulus, New York, USA, 2000.

Blood parameter	Control group ($\bar{x}$ ± SE)	GnRH group ($\bar{x}$ ± SE)	*t*-test results

[a]aspartate aminotransferase; [b]sorbitol dehydrogenase; [c]gamma-glutamyltransferase; [d]total iron binding capacity

than the vaccinated males (100 ng/100 ml) even 3 years post-treatment.

The mean combined testicular weight for anti-GnRH-treated male deer ($\bar{x}$ = 70.3) was significantly lower ($t_1 = 3.56$, $P = 0.007$) than for the control group ($\bar{x}$ = 130.5). Similarly, the average testes:pituitary index for anti-GnRH-treated ($\bar{x}$ = 69.2) male deer was less ($t_1 = 2.52$, $P = 0.04$) than for the control group ($\bar{x}$ = 130.0). However, there was no difference in pituitary weights ($t_1 = 0.30$, $P = 0.77$) for anti-GnRH-treated males ($\bar{x}$ = 1.0) and control ($\bar{x}$ = 1.0) bucks.

Morphologic alterations were observed in the testes of anti-GnRH-treated males (Table 4). The pathologies included diffuse lymphocytic infiltrate with associated seminiferous tubule degeneration, segmental tubular aspermatogenesis (where large contiguous areas of the testes were seen with only sertoli-

Table 3. Mean left and right ovary weights (milligrams), pituitary gland weights, anti-GnRH antibody titers, and follicle counts for control does vaccinated during 1977 or 2000 with anti-GnRH at Seneca Army Depot, Romulus, New York, 2000.

	Control does	Anti-GnRH does				
		1997	2000	*F*	*df*	*P*
	n = 7	*n* = 11	*n* = 7

cell-lined tubules); subepithelial concretions in the collecting tubules, decreased cross-sectional diameter of seminiferous tubules, decreased cytoplasmic volume of Leydig cells, interstitial fibrosis, and total aspermatogenesis. Histology of testes from control males revealed none of these abnormalities. Among the treated males, one had only segmental aspermatogenesis with none of the associated pathologies. The remaining 3 males all had ≥2 of the abnormalities noted above.

Male no. 31, had malformed (atypical) antlers still covered in velvet (Figure 1), exhibited total aspermatogenesis with small fibrotic testes, and vacant epididymi. This same male had no detectable anti-GnRH antibody titer, but also lacked any measurable blood testosterone level. The 3 other anti-GnRH vaccinated males did have some epididymal spermatozoa.

Discussion

Observations for both male and female deer

Lesions. A variety of infectious, parasitic, and noninflammatory lesions were observed in our study animals. Most noteworthy was the formation of granulomas at the injection site with all the characteristics of tuberculosis. These granulomas were characterized by the presence of a necrotic core surrounded by mixed inflammatory cells and fibrous connective tissue. All granulomas had Langerhans giant cells typical of a tuberculosis condition. Likewise, giant cell inflammation was seen in the regional (popliteal) and deep (intral iliac) lymph nodes draining these sites. Acid fast bacilli were documented in these giant cells.

These injection site lesions and reactions, including the production of multi-nucleated giant cells associated with the presence of *Mycobacteria* in the adjuvant in other species vaccinated with CFA have been previously described (Stills and Bailey 1991, Kleinman et al. 1993, Munson et al. 2005, Stills 2005). In other studies, remote lesions comparable in composition to the Freund's injection sites had also been documented in lungs and other organs (Rigdon and Schadewald 1972, Broderson 1989, Kleinman et al. 1993, Malaga et al. 2004).

When evaluating the safety of immunocontraceptive vaccines, potential complications associated with treatment should be considered. Killian et al. (2006) reported that pulmonary disease was the most common cause of death in their captive deer herd and that males treated with anti-GnRH vaccine had significantly higher mortality than did control deer. Microbes associated with pneumonia were endemic in their captive herd and anti-GnRH-treated bucks appeared less resistant to infection.

Table 4. Presence (+) or absence (-) of different features in the testes of control (n = 6) and anti-GnRH-treated bucks at Seneca Army Depot, Romulus, New York, 2000.

	Deer identification number	Estimated age at start of trial	Diffuse lymphocytic infiltrate genesis (sertoli cells only)	Segmental tubular aspermatogenesis	Subepithelial concretions	Total aspermatogenesis seminiferous tubules	Decreased cross-sectional diameter	Decreased cytoplasm in Leydig cells	Interstitial fibrosis
Controls		3 ½	-	-	-	-	-	-	-
GnRH	22	2 ½	-	+	-	-	-	-	-
	31	3 ½	+	+	+	+	+	+	+
	37	3 ½	-	-	+	-	+	-	-
	4	3 ½	+	-	+	-	+	-	+

Likewise, Miller et al. (2000*b*) reported that 3 female deer died of complications resulting from pneumonia during a study of porcine zona pellucida (PZP) immunocontraceptive with Freund's adjuvant. It was unclear if there was an association between the pneumonia cases and treatment with Freund's adjuvant. Bearing in mind the warning by Billiau and Matthys (2001) that too few studies consider the biological effects of using CFA when evaluating experimental vaccines, we feel that future researchers should examine the possibility that injections with CFA could predispose deer to pneumonia.

Hypothalamic-pituitary response. Normally GnRH released from the hypothalamus circulates into the anterior pituitary gland where it activates production of follicle stimulating hormone (FSH) and luteinizing hormone (LH) by gonadotrophs. Antibodies to GnRH interacted with neurons secreting GnRH from the hypothalamus at terminals within the median eminence. These GnRH release points are accessible because they are not within the blood-brain barrier that otherwise protects the hypothalamus from circulating antibodies. One study demonstrated degeneration of the neuron cell bodies (perikarya) and a sharp decrease of the GnRH immunochemical reactivity in the terminals within the median eminence of hyperimmunized hogs (*sus scrofa*; Molenaar et al. 1993). With hymotoxylin and eosin stain on fixed pituitary gland tissue, gonadotrophs appear as large cells with secretory granules of moderate and variable size. Cells with little or no cytoplasmic staining (chromophobes) are likely degranulated chromophilic cells. Thus, we classified large granule-bearing cells as gonadotrophs in this study, and found large variation in their numbers among females in each treatment group. A more precise staining method would involve immunoperoxidase staining with anti-LH/FSH. This would allow simultaneous quantification of cell numbers and the relative intensity of intracytoplasmic LH/FSH stores.

Female deer

Titers in 5 of the 7 deer revaccinated in 2000, and 6 of the 8 deer last vaccinated in 1997 were well below the level of 64,000 to 128,000 identified in deer with successful contraception, or the 16,000 to 32,000 level for contragestation (Miller et al. 2000*a*). Because the revaccinates in 2000 were retreated <4 weeks prior to collection, it is possible that the immune response was incomplete and that a peak anti-GnRH titer would be greater. Lower anti-GnRH titer in females vaccinated in 1997 than those vaccinated in the 2000 treatment group validates the assumption that, if not boosted, the anti-GnRH vaccine treatment is reversible for most deer. There were no identifiable health concerns associated with anti-GnRH treatment for female deer.

Male deer

Little has been reported about the effects of anti-GnRH vaccination on the reproductive physiology of male deer. Miller et al. (2000*a*) injected 4 male deer with the anti-GnRH vaccine, and testes size observed for treated bucks was <50% testes size in control bucks. Killian et al. (2006) also observed similar physical differences in testicular size and qualified those observations reporting histological changes in the testes "which resembled the testes of males during the non-breeding season." They further noted that the Leydig cells, which produce testosterone, appeared inactive in anti-GnRH treated males. Similar testicular pathologies have also been documented in research conducted on hogs (Molenaar et al. 1993, Meloen et al. 1994).

It is clear from testes weights and histology that sperm production was reduced, even 3 years after the last anti-GnRH vaccination. The significantly lower average weight of testes in this study correlated with a number of persistent morphologic abnormalities and decreased (qualitative assessment) spermatozoa in epididymi. Observing these effects 3 years after vaccination suggested that anti-GnRH vaccination early in the adult lives of deer may be sustained over several years. Similarly, in a study on 3- to 4-year-old sheep vaccinated with anti-GnRH antigen as neonates, Clarke et al. (1998) reported that in these study animals males had small gonads and females had no large follicles or corpora lutea, and titers had dropped to undetectable levels.

Immunized bucks had reduced cross-sectional diameter of seminiferious tubules and varying degrees of aspermatogenesis, including

buck no. 31 with total aspermatogenesis that was vaccinated at 3.5 years of age. This latter animal had no detectable anti-GnRH titer, suggesting a possible permanent alteration in the hypothalamic-pituitary-testes axis. The other 3 anti-GnRH treated bucks had normal outward physical traits and detectible mature spermatozoa, although the latter were fewer than normal. While it was not possible to assess their actual fertility from this study, this evidence suggests that anti-GnRH contraception is reversible; however, some portion of treated males may become permanently sterilized.

Variations in the residual immune response and the extent of physiological, morphological, or pathological differences among the treated deer are thought to be due to genetic differences among individual animals (Miller et al. 2000*a*). In fact, substantial research has been conducted using anti-GnRH vaccines to chemically castrate hogs as an alternative to surgical castration typically used to control boar taint, with considerable variations in efficacy documented (Molenaar et al. 1993, 1994; Oonk et al. 1995, 1998).

Management implications

Many factors affect the success and potential pathology associated with an immunocontraceptive vaccine, including formulation of the immunogen, concentration of the immunogen, adjuvant used, and species treated. Therefore, before judgments can be made concerning the effectiveness and health risks associated with a given vaccine for a particular species, adequate evaluation must be conducted.

Curtis et al. (2002) demonstrated that vaccinating free-ranging female white-tailed deer with anti-GnRH immunocontraceptive vaccines can be effective at reducing fawn production. We further evaluated anti-GnRH vaccinated deer and identified no detrimental, morphologic effects that could jeopardize the normal health of vaccinated females. Vaccinating female deer with anti-GnRH vaccines eliminates the potential problems associated with repeated estrous cycl-ing commonly observed in deer treated with PZP immunocontraceptive vaccines (McShea et al. 1997, Miller et al. 2000*b*, Kirkpatrick and Rutberg 2001). Baker et al. (2004) studying leuprolide, a GnRH agonist, which would cause similar effects as the anti-GnRH immunocontraceptive vaccine used in this study, also reported no significant adverse health impacts to female deer resulting from the reduced systemic GnRH. Furthermore, if GnRH could be administered to newborn female fawns, as Clarke et al. (1998) were able to do with neonatal lambs, considerable long-term efficacy could be achieved.

Morphologically, anti-GnRH-treated males essentially became neutered and exhibited behavioral and physiological traits consistent with castrated males (Pooler 2001, Killian et al. 2006). Antlers on treated males did not harden or shed velvet and became atrophied (Killian 1998, Miller et al. 2000*a*, Curtis et al. 2002, Killian et al. 2006). Such antlers are spindly, atypical, and possibly pose a health risk to deer from frost bite when they freeze and break off during winter. Treated male deer also could develop adverse health effects including increased risk for pneumonia. Killian et al. (2006) recommended that anti-GnRH vaccines should not be used on male deer due to these concerns. Our results were consistent with these previous studies, and we also do not recommend treating male deer with anti-GnRH vaccines.

Acknowledgments

This project was successful because of the dedication and hard work provided by our friend and colleague R. Pooler. We are all saddened by his untimely passing and are richer for time he spent with us. This project was supported by the USGS Biological Resources Division, New York Cooperative Fish and Wildlife Research Unit, the New York State Department of Environmental Conservation, and the USDA National Wildlife Research Center. We appreciate helpful review comments from M. Smith, College of Veterinary Medicine, at Cornell University.

PAUL D. CURTIS (right in photo above) received a Ph.D. degree from North Carolina State University (1990), an M.S. degree from Colorado State University (1981), and a B.S. degree from West Virginia University (1978). He is currently an associate professor and extension wildlife specialist at Cornell University, where he has coordinated the wildlife damage management program during the past 17 years. His research interests include wildlife damage management in urban and agricultural landscapes, wildlife fertility control, and resolving community-based wildlife issues. He is a certified wildlife biologist, and was a former chair of The Wildlife Society's wildlife damage management working group.

MILO E. RICHMOND (left in photo above) received his M.S. (1964) and Ph.D. (1967) degrees from the University of Missouri. He joined the Department of Natural Resources at Cornell University in 1968 as an assistant professor. He was an assistant unit leader of the New York Cooperative Fish and Wildlife Research Unit, and he became its unit leader in 1977. His research interests involve all of the major vertebrate taxa. He has directed graduate students in the areas of wildlife ecology, organismal biology, reproductive studies, and animal behavior. His current research interests include analysis of biodiversity in the Hudson River Corridor, population dynamics of colonial waterbirds and cormorants, and immunocontraception of white-tailed deer.

LOWELL A. MILLER received his Ph.D. degree in physiology-immunology at Colorado State University, Fort Collins, Colorado. He has been the project leader of pest animal induced infertility research at the National Wildlife Research Center (NWRC) in Fort Collins since 1992. The current project is called Reproductive Control Methods, which is researching ways to induce infertility in overabundant species of wildlife. The project is researching infertility agents that include immunocontraceptive vaccines, as well as compounds that reduce fertility by interfering with reproductive hormones in a variety of species. Also, the project is testing several compounds that reduce egg laying or hatchability in several pest avian species, such as cowbirds, monk parakeets, and Canada geese. The project has developed a single injection GnRH contraceptive vaccine that has successfully contracepted several mammalian species, including deer, elk, bison, feral cats, feral horses, and feral hogs.

FRED W. QUIMBY is associate vice president and senior director of the Laboratory Animal Research Center at Rockefeller University. Previously, he was a professor of pathology at Cornell University. He received his V.M.D. degree from the University of Pennsylvania in 1970 and his Ph.D. degree in pathology at the same institution in 1974. He completed a post-doctoral fellowship in hematology at the New England Medical Center in 1976 and was appointed instructor, and later assistant professor (1977), of pathology and surgery at Tufts Medical School. In 1993, he was promoted to full professor of pathology at Cornell Medical College and the New York State College of Veterinary Medicine. He is a former member of the Graduate School Faculties of Veterinary Medicine (Pathobiology), Immunology, and Environmental Toxicology. He also is former director of the Division of Laboratory Animal Services (NYSCVM) and the Cornell University Center for Research Animal Resources.

Abstract

The aim of the present study was to investigate the effect of active immunization against GnRH in mature Standardbred mares (three experimental and one control mare) on antibody titres, ovarian function, hormonal levels and oestrous behaviour. The mares were individually teased with a stallion once each day. During the first part of the experiment (period I: late April until November), blood was sampled every third day during the first 3 months, thereafter once per week. In the second part of the experiment (period II: December until August), sampling was carried out every second week. Progesterone, oestradiol-17β and LH were analysed. Rectal gynaecological examination was made with the same intervals as the blood samplings and included palpation of the genital organs and ultrasonography. The experimental mares were immunized against GnRH with a GnRH–BSA conjugate. Equimune® (Vetrepharm, Bracetown, Business Park, Clonee, Co. Meath, Republic of Ireland) was used as adjuvant. The mares were immunized on four occasions (20–30 day intervals) and GnRH antibody titre was determined. All immunized mares produced antibodies against GnRH but the maximum titres as well as the duration of a greater than 10% binding capacity varied between the mares (1 : 1600 to 1 : 50 000; 5 to 12 months, respectively). After the first injection, all mares showed one oestrus and ovulated at the regular time. In two of the mares, the immunization resulted in ovarian atrophy. Their hormone levels of progesterone, oestradiol-17β and progesterone decreased to basal levels and the cyclical hormone pattern was interrupted from approximately 30 days onwards. They continued to show oestrous signs but with irregular durations and intervals. The third mare showed ovarian suppression only for short periods and not in both ovaries at the same

time; the hormone levels were basal for only about 20 days (days 50–70) and the mare ovulated on day 75 after start of immunization. The other mares ovulated after 13.5 and 15 months, respectively. It is concluded that the effect of immunization against GnRH in mature mares was individual concerning antibody titre response and the suppression of ovarian activity and hormone levels. Mares with totally inactive ovaries continued to show oestrous signs but with irregular intervals and durations.

ABSTRACT

Antibodies against GnRF elicited by vaccination with Improvac are expected to have the same effects on the gonads of female pigs as those observed in males and thus suppress estrus. The objective of this study was to evaluate whether a 3- or a 4-dose regimen of Improvac was effective in inducing and maintaining suppression of estrus in intact Iberian female pigs through 14 months of age. Sixty 18-week-old gilts were randomly assigned to one of the following three treatment groups: control (PBS injected), V3 (3-dose Improvac regimen), and V4 (4-dose Improvac regimen). Animals were tested for the presence of standing estrus in the presence of a boar three times per week until study completion at 60 weeks of age. Blood samples were regularly collected to determine the serum levels of anti-GnRF antibodies and progesterone. The weight and size of the uterus and the weight and activity of the ovaries were assessed at the time of euthanasia. For both treatment groups V3 and V4, a large reduction in the incidence of standing estrus was observed when compared to the control group ($P < 0.0001$). No significant differences between the V3 and V4 groups were observed. Both V3 and V4 groups had higher serum anti-GnRF antibody levels than the control group from 28 days after the first vaccination until the end of the study. In addition, both V3 and V4 groups had lower levels of progesterone than the control group from Day 112 until the end of the study ($P < 0.0001$ in all cases). Mean ovary weights at study end in treatment groups V3 and V4 were significantly lower ($P < 0.0001$) than those for the control group and not significantly different between the V3 and V4 groups. An onset of immunity of 2 weeks after the second vaccination and a long-lasting immunity of at least 20 weeks after the third vaccination were observed. In summary, both the 3-and 4-dose Improvac regimens were efficacious in reducing the incidence of standing estrus, serum progesterone levels, and the development of the uterus and ovaries.

1. Introduction

The Iberian pig is a native breed of the Iberian Peninsula, which originates from *Sus scrofa mediterraneous* and is reared in La Dehesa, an extensive system. This is a Mediterranean ecosystem based on an oak forest (*Quercus*

rotundifolia and *Quercus suber*) with herbaceous species, mainly grasses and legumes where animals can graze [1]. The Iberian pig is characterized by its fat-production ability [2] and high rusticity. This enables the animals to cope better with climatic hazards. The Iberian pig has been raised for centuries to produce dry-cured meat. The whole reproductive cycle of the animals is planned to provide an adequate physiological status capable of taking advantage of La Dehesa during the late fattening phase which starts when pigs are around 10 months of age and 90- to 120-kg live weight. However, the age range during this stage varies widely, from 10 months to 2 years [2]. In fact, the requirements to be classified as an Iberian pig product prescribes a minimum slaughter age of 14 months and a minimum carcass weight of 115 kg per animal (180 kg per animal in purebred Iberian pigs) [3].

There is limited information available on the precise time of onset of estrus in Iberian gilts. It has been stated that the Iberian female pig begins puberty at an average age of 207 days (7 months) [1] or 180 days [4]. It is clear that males and females are reared for several months after becoming fertile. As a result, for different reasons, males are traditionally castrated and females are spayed. The negative effect on growth due to estrous behavior in Iberian females [5,6] or in other breeds slaughtered late [7] has been used to justify the need for spaying, but this has not scientifically examined. However, the main reason to justify the spaying of Iberian pigs is the presence of wild boars in the La Dehesa. Wild boars cohabitating with intact females can produce a high percentage of pregnancies which is undesirable from health, welfare, and economic perspectives. As a result, spaying was traditionally seen as the best solution. However, Council Directive 2008/120/EC restricts this practice resulting in the need for other alternatives as it is not always possible to avoid cohabitation with the wild boars.

Improvac, a vaccine inducing the production of antibodies against GnRF, was developed for the control of boar taint in intact male pigs and subsequently licensed in Europe and elsewhere. In males, vaccination reduces production of LH and FSH by the pituitary gland, reducing the production of sex hormones by the testes [8,9]. The immunization regimen comprises two subcutaneous injections in the neck, at least 4 weeks apart. The first vaccination only primes the pig's immune system; the second one (usually administered 4–5 weeks before slaughter) stimulates high levels of anti-GnRF antibodies that neutralize the pig's endogenous GnRF which inhibits testicular function [10]. This regimen ensures freedom from boar taint at slaughter and allows pigs to spend most of their fattening period as functional males before puberty. In commercial systems where the vaccine is currently used, pigs are usually given their second dose before 24 weeks of age which has been found to be highly effective [11]. However, in older animals such as those from Iberian ham production systems, delaying the second dose until 4 to 5 weeks before slaughter is likely to result in a considerable period during which animals express marked sexual behavior. This is because the animals would be immunized well after reaching sexual maturity. Claus et al. [12] found that the vaccine was efficacious for at least 10 weeks after the second vaccination, and Zamaratskaia et al. [13] confirmed an even longer time. Both cases, however, showed that the 2-dose vaccination regimen is effective for only a limited time and that if administered early would be unlikely to last until slaughter age in a significant proportion of Iberian Pigs. In consequence, Allison et al. [11] propose using a three-dose vaccination regimen for male pigs slaughtered at 14 months of age.

In female pigs, antibodies against GnRF are expected to reduce LH and FSH production and thus to have similar effects in the gonads of females as those in males, resulting in suppression of estrus. First evidence for this was provided by the administration of a GnRF-tandem dimer peptide [14] to males at 10 to 13 weeks and 8 weeks later which resulted in a decrease of serum LH levels and in a suppression of reproductive functions. However, not all the animals responded to immunization with this experimental formulation. Furthermore, immunization against GnRF has been investigated under experimental conditions in Chinese female pigs as a practical alternative to surgical castration [7].

On the basis of these data, the present study was conducted with the objective of testing whether either a 3- or a 4-dose regimen of Improvac is effective in maintaining suppression of estrus and estrus-related behavior in Iberian female pigs until 60 weeks of age in comparison to non-treated animals. In addition, concentrations of progesterone and antibodies against GnRF in blood samples were measured throughout the study, and reproductive organs were assessed at the end of the study.

2. Materials and methods

2.1. Animals

Sixty intact Iberian × Duroc crossed female pigs were transported at the age of 16 weeks from Extremadura in the south of Spain to the Institut de Recerca i Tecnologia Agroalimentàries (IRTA) facilities in Monells, Catalonia, Spain. On arrival, pigs were individually weighed, identified with a double ear tag (one tag in each ear), and randomly allotted into four groups of 15 animals each. Five animals from each pen were randomly assigned to the control, the 3-dose (V3), or the 4-dose (V4) vaccination regimen with Improvac. Floor space was 1.7 m^2 per pig with *ad libitum* access to food and water during the whole study.

At the end of the study, 290 days after arrival, pigs were euthanized in the experimental abattoir of IRTA in four batches of 15 animals each (one per pen) with a difference of 7 days from the first to the fourth slaughter day. Animals were individually weighed before being stunned with a carbon dioxide (90%) stunning system.

This study was approved by both the Institutional Animal Care and Use Committee of IRTA and Zoetis Ethical Review Committee according to Directive 2010/63/EU on the protection of animals used for scientific purposes. Animals were kept in line with regulations applicable in Spain regarding housing and animal welfare.

2.2. Application of treatment

The control group received 2 mL of a PBS solution subcutaneously. The V3 and V4 groups received 2-mL Improvac

subcutaneously. The treatment schedule is listed in Table 1. The first injection was at 18 weeks of age, Day 0 of the study. The second injection was performed 28 days later, at 22 weeks of age. Subsequent vaccinations occurred at 12-week intervals as applicable. Pigs in group V3 received a total of three vaccinations, and those in group V4 received a total of four vaccinations. In all cases, injections were performed in the neck using disposable needles of 19-mm length and a 16-ga diameter.

2.3. Estrus detection

Gilts in estrus were assessed for presence of estrus using the back-pressure test. The test was performed three times per week in the presence of a teaser boar from the start of the study until Day 290. The boar was led past the gilts' pens and allowed to have head-to-head contact from the corridor during the test. Estrus detection was assessed by rubbing the flank and pressing the back of the gilt in the presence of the boar. Gilts were deemed to be in estrus when they remained in standing response, immobile with arched back, and cocked ears. The following scoring system was used: 0 = no estrus; 1 = doubtful estrus; 2 = clear (standing) estrus. Staff performing estrus detection were blinded to treatment groups. Two different boars were alternately used. They were housed in separate facilities without visual or olfactory contact with the females except during estrus testing.

2.4. Serum analysis

A plain blood sample was taken before the first injection on Day 0 from all pigs. Blood samples were collected before vaccine administration on the day of the second, third, and fourth vaccination. In addition, blood samples were collected from all pigs 2 and 5 weeks after the second, third, and fourth vaccinations, 10 weeks after the fourth injection, and just before study end. Blood samples were allowed to clot for 24 hours at 4 °C and then centrifuged at 3500 rpm for 10 minutes to obtain the serum. The serum samples were divided into two aliquots: one was used for progesterone determination and the other for GnRF antibody testing. All aliquots were coded to ensure appropriate blinding during analysis. Aliquots were stored at −20 °C until they were analyzed.

The amount of progesterone in porcine serum was quantified by the progesterone Enzyme Immunoassay (EIA) Kit from Enzo Life Sciences (Farmingdale, NY, USA; catalog number, ADI-900-011 Progesterone EIA). This test is a competitive immunoassay which uses an antibody to bind in a competitive manner with progesterone. After a simultaneous incubation, the excess reagents were washed away and the substrate was added. After a short incubation time, the enzyme reaction was stopped and the yellow color generated was read on a microplate reader. The intensity of the bound yellow color was inversely proportional to the concentration of progesterone in either standards or samples. The measured optical density for the samples was used to calculate the concentration of progesterone in the samples. The detailed method, validation data from the supplier of the kit, and publications can be found in http://www.enzolifesciences.com/ADI-900-011/progesterone-elisa-kit. The laboratory in charge of testing Zoetis samples took care to check the intra-assay coefficient of variation (CV; duplicates on the same plate) and to check the interassay CV between titers of samples tested "fresh" and titers of the same samples stored frozen. The CVs were respectively below 10% and 12%.

The amount of antibody against GnRF in porcine serum was measured by a noncompetitive ELISA, which uses GnRF peptide as the capture phase. Dilutions of sera from pigs were added to plates coated with GnRF peptide. After several washes, the plates were incubated with horseradish peroxidase–labeled antiswine immunoglobulin. Finally, 3,3′,5,5′-tetramethylbenzidine substrate was added. After a short incubation time, the enzyme reaction was stopped and the color generated was measured spectrophotometrically. The amount of color produced was directly proportional to the amount of antibody present in the sample. The limit of quantification is 18.56 U/mL. The laboratory took care to check the interassay CVs which were below 10% (8.4%). They also checked the intra-assay CVs which were below 10% (5.9%) in the linear phase of the standard curve.

Table 1
Treatments applied in the study.

Treatment	Dosage	Study day	Age of pigs (wk)	Route of administration	Pigs per treatment group
Control	2 mL	0	18	Subcutaneous	20
	2 mL	28	22	Subcutaneous	20
	2 mL	112	34	Subcutaneous	20
	2 mL	196	46	Subcutaneous	19
V3	2 mL	0	18	Subcutaneous	20
	2 mL	28	22	Subcutaneous	20
	2 mL	112	34	Subcutaneous	19
V4	2 mL	0	18	Subcutaneous	20
	2 mL	28	22	Subcutaneous	20
	2 mL	112	34	Subcutaneous	20
	2 mL	196	46	Subcutaneous	20

2.5. Reproductive organs

At study end, the uterus and ovaries were removed and weighed, and the length of the uterine horns was recorded after straightening them. Each ovary was scored in relationship to the presence and size of the developing follicles and CL: 0 = no follicles; 1 = immature follicles: 3 to 4 mm of diameter; 2 = mature follicles: 8 to 11 mm of diameter; and 3 = mature follicles and luteal tissue [15]. The person responsible for assessing these variables was blinded to treatment groups.

2.6. Statistical analysis

Statistical analysis was carried out with Statistical Analysis System (SAS Release 9.2, SAS Institute, Cary, NC, USA). All treatment differences were assessed at the two-sided 5% significance level. The experimental unit for analysis was the individual animal.

Standing response (estrus score = 2) in each time period between the vaccinations and throughout the study was analyzed using the Cochran–Armitage test adjusted for block. All possible pairwise comparisons were made if the overall effect of treatment was significant. At each time point, the proportions of pigs with titers of antibodies against GnRF and progesterone levels below the level of quantification in each treatment group were calculated. The log-transformed GnRF antibody titers and progesterone levels were analyzed using a linear mixed model for repeated measures, with treatment, time, and their interaction as fixed effects and block, block-by-treatment interaction (pen term), animal within block and treatment, and residual as random effects. All possible pairwise treatment comparisons were made at each time point if the treatment and/or treatment by time point effect(s) was significant. For animals with anti-GnRF antibody titers below the level of quantification, these were defined as half the level of quantification and included in this analysis. The weight of uteri and ovaries and uterine horn length were analyzed using a general linear mixed model with treatment as a fixed effect and random effects of block, block-by-treatment interaction, and residual. If the treatment effect was significant, then all possible pairwise treatment comparisons were made.

3. Results

3.1. Estrus detection

During the study, 17 of 20 animals in the control group showed standing estrus (score 2) on at least one occasion. In treatment group V3, three of 20 animals showed standing estrus (score 2) on a single occasion. One animal did so on Day 29 (1 day after the second vaccination), another one on Day 36 (8 days after the second vaccination), and the third one on Day 244 (132 days after the third vaccination). In treatment group V4, not a single animal had an estrus score greater than one at any time point. Both groups V3 and V4 showed a significantly lower incidence of standing estrus compared to cover the entire study period ($P < 0.0001$). The difference between the V3 and V4 groups was not significant ($P = 0.3236$).

When analyzed by time period (with periods related to the injection day), there were no differences between the V3 and V4 groups in the percentages of sows showing no estrus for any period. Both Improvac groups showed significantly less estrus ($P < 0.0001$) than the control group (Fig. 1).

3.2. Serum analysis

The level of anti-GnRF antibodies in serum was not significantly different between the treatment groups on Day 0. Thereafter, both treatments V3 and V4 had higher anti-GnRF antibody levels at all time points ($P < 0.0001$), including Day 28 before the second vaccination (Fig. 2), when concentrations were low but detectable. Differences between the V3 and V4 groups were not significant until Day 210 of the study; beyond that point, antibody levels in treatment V4 were significantly higher ($P < 0.0001$) than those in treatment V3.

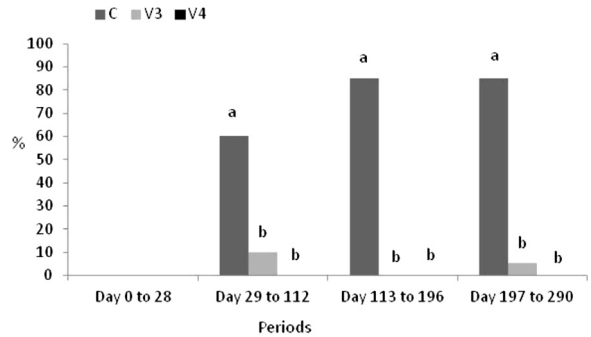

Fig. 1. Percentage of sows that showed standing estrus (score = 2) when tested three times weekly during the different periods of the study in the control group (C) and groups vaccinated with a 3-dose regimen (V3) or a 4-dose regimen (V4). Different letters annotate significant differences between the treatments at $P < 0.001$ in each study period.

The level of progesterone in serum remained low in treatments V3 and V4 throughout the study. In the control group, it started to rise from Day 42 (approximately 24 weeks of age) onward as gilts approached sexual maturity. There were no significant differences in progesterone levels between any of the three treatment groups until Day 63. From Day 112 onward, the progesterone levels were significantly ($P < 0.0001$) lower in both treatments V3 and V4 compared to the control group (Fig. 3). There were no significant differences in progesterone levels in the serum between V3 and V4 at any time point.

3.3. Reproductive organs

On average, ovary weights in treatment groups V3 and V4 were significantly lower ($P < 0.0001$) than those in the control (Table 2). No significant difference was observed when comparing weights of treatment groups V3 and V4 ($P = 0.3250$). In the control group, follicles were present in all ovaries. In group V3, one animal had mature follicles on both ovaries (Table 3). In group V4, no follicles were observed on any of the scored ovaries.

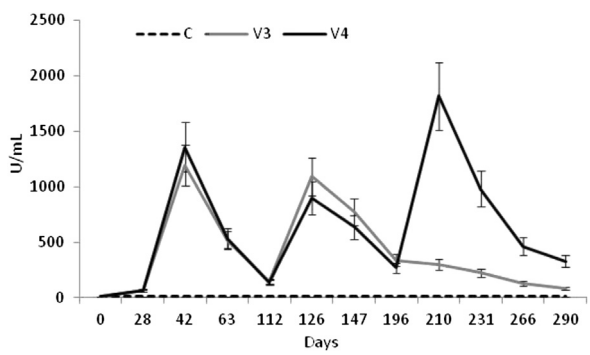

Fig. 2. Anti-GnRF antibodies (U/mL) detected in serum samples taken from control gilts (C) and gilts vaccinated with a 3-dose regimen (V3) or a 4-dose regimen (V4).

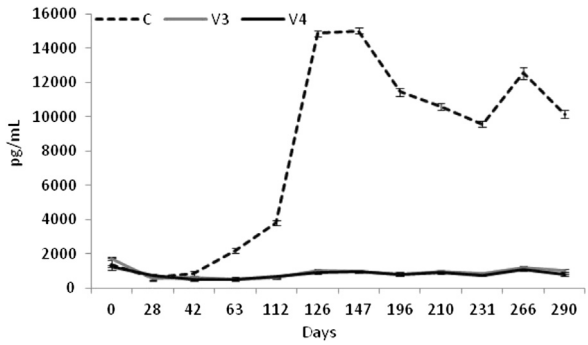

Fig. 3. Progesterone (pg/mL) detected in serum samples taken from control sows (C) and sows vaccinated with a 3-dose regimen (V3) or a 4-dose regimen (V4).

Comparisons between the treatment groups showed a significant reduction in uterus weight and horn length (Table 2) for treatment groups V3 and V4 versus control ($P < 0.0001$ for both measures and for both pairwise comparisons). Weight and length of the uterus were not significantly different between treatment groups V3 and V4 ($P = 0.3498$ and 0.9737, respectively).

4. Discussion

Although progesterone levels were not significantly different between vaccinated and control animals until Day 112, estrus was effectively inhibited starting around 10 days after the second injection. Dunshea et al. [16] also described, in male pigs, clear effects of Improvac within 2 weeks after administration of the second dose. It therefore appears that the time needed for the efficacy of the vaccine to appear is similar in both sexes.

There were no significant differences in standing estrus behavior between the treatment groups V3 and V4 in the last phase of the study, from Day 197 to Day 290 (178 days after the third injection). This suggests that a 3-dose regimen is sufficient for animals up to 14 months of age to suppress estrus and its related behavior. The continuous reduction seen in anti-GnRF antibodies of group V3 from Day 126 does suggest that efficacy will eventually wane and that a 4-dose regimen might prove more efficacious in ensuring consistent estrus suppression if the growing period is further prolonged. The duration of immunity against GnRF has been studied in males by Claus et al. [12] and Zamaratskaia et al. [13]. Their research suggested a duration of immunity for Improvac of at least 10 weeks after a second injection and a duration of 16 and 22 weeks, respectively. In the study presented in this paper, the duration of immunity shown in the females was up to 20 weeks after the third injection in 93% of V3-treated animals and at least 13 weeks after a fourth injection in 100% of V4-treated animals. This duration of immunity is as least as long as that observed in male pigs.

Table 2
Ovary weight, uterus weight, and horns length after study end for control sows (C) and sows vaccinated with a 3-dose regimen (V3) or a 4-dose regimen (V4).

Measure	C	V3	V4
Ovaries weight, g	20.8 ± 2.13^{a}	1.5 ± 0.36^{b}	1.2 ± 0.12^{b}
Uterus weight, g	821.0 ± 93.86^{a}	46.9 ± 12.83^{b}	34.48 ± 3.73^{b}
Horn length, mm	2844 ± 273.3^{a}	797 ± 216.5^{b}	787 ± 211.2^{b}

[a,b]Different letters annotate significant differences between the treatments at $P < 0.001$ in each study period.

Table 3
Presence and size of follicles in the ovaries of sows of control group (C) and groups vaccinated with a 3-dose regimen (V3) or a 4-dose regimen (V4) after study end.

Treatment	Follicle size score				Total (n)
	0	1	2	3	
C, n (%)	0 (0)	15 (39)	12 (32)	11 (29)	38

V4, n (%)	40 (100)	0 (0)	0 (0)	0 (0)	40

Benito et al. [1] stated that puberty in Iberian female pigs begins at an average age of 207 days. On the other hand, Gonzalez-Añover et al. [4] concluded that Iberian females can reach puberty before 180 days of age. In our study, the Iberian females showed first estrus behavior at around 160 days of age. This is in accordance with studies in other commercial breeds, such as those of Patterson et al. [17], in which first estrus was detected from Day 154 to Day 167 in a high percentage of the animals if boar contact commenced on Day 140. According to Kummer [18], with good boar contact, 73% of gilts can be cyclic within 40 days of daily boar exposure. These numbers are consistent with our results in which contact with a boar three times per week started at an age of 126 days and around 30 days later, the first gilts began to show estrus behavior. This could be one of the main reasons why the time of sexual maturation observed in the present study was earlier compared to previously reported times [1]. Obviously, in commercial conditions, contact with the boar normally starts later. van Wettere et al. [19] suggested that the optimal timing and synchrony of puberty attainment occur when boar contact commences at 160 days of age. So under commercial conditions, the first signs of estrus would be expected a little later. Another possible explanation for the early maturation observed in this study is the fact that animals were a cross between Iberian and Duroc. However, there is no clear information about the real impact of this specific cross on the sexual maturation of these animals. For instance, Gonzalez-Añover et al. [4] described that the onset of puberty was earlier in Iberian gilts compared to a Large White × Landrace commercial cross which differed from the traditional assumptions.

In the control group, three animals did not show a standing estrus at any time during the study. Inspection of the serum progesterone levels, weight of ovaries and uteri, and follicle size score after the end of the study (Day 290) showed that these animals developed a reproductive cycle, despite the fact that no standing estrus was observed during any of the testing days. Hemsworth et al. [20] described an ability to detect estrus by the back-pressure test in the presence of a boar in 81% of gilts when the boar was continuously housed in a pen adjacent to the females and only separated by a wire-mesh wall. A similar

result was obtained in the present study. However, in our case, the boar was housed in a separate building without continuous visual or olfactory contact with the females, so results closer to 100% would have been expected in these conditions [20]. The effect of hierarchy or fear should be considered as possible reasons to explain the lack of clear standing estrus detection in these animals. In fact, Pedersen et al. [21] concluded that both heat detection and mating may be impaired in subordinate sows when they were pair housed. This effect could even be higher in animals housed in groups of 15 individuals as in this study.

4.1. Conclusions

The use of Improvac in Iberian female pigs will reduce the risk of unwanted mating by wild or domestic boars, being a suitable alternative to spaying in sows.

AN ECONOMIC MODEL DEMONSTRATING THE LONG-TERM COST BENEFITS OF INCORPORATING FERTILITY CONTROL INTO WILD HORSE (*EQUUS CABALLUS*) MANAGEMENT PROGRAMS ON PUBLIC LANDS IN THE UNITED STATES

Charles W. de Seve, Ph.D., and Stephanie L. Boyles Griffin, M.S.

Abstract: In recent years, the Bureau of Land Management's (BLM) Wild Horse and Burro Management program costs have increased dramatically due to a rise in the number of animals removed from public lands coupled with significantly decreased adoption rates. To assist with development and implementation of effective, cost-containing management programs, a robust economic model to project the costs and optimize outcomes of various management scenarios was created. For example, preliminary demonstration model runs show that by gradually replacing "removal-only" programs with contraception-and-removal programs on one hypothetical Herd Management Area (HMA), the BLM could save about US$8 million over 12 years while maintaining an area target population of 874 horses. Because the BLM estimates that more than 38,000 wild horses roam on 179 HMAs in the United States, the use of this economic model could result in a cost-savings of tens of millions of dollars if applied broadly across all HMAs.

Key words: Bureau of Land Management, economic model, *Equus caballus*, fertility control, porcine zona pellucida, wild horses.

BRIEF COMMUNICATION

The Wild Free-Roaming Horses and Burros Act of 1971 (Public Law 92–195)[13], as amended, directs the Bureau of Land Management (BLM) to manage wild horse herds by setting appropriate management levels (AMLs). AMLs are estimates of the optimum number of wild horses which results in a "thriving natural ecologic balance and avoids deterioration of the range" for each Herd Management Area (HMA). As of February 2012, the BLM estimates that approximately 37,300 wild horses and burros (31,500 horses and 5,800 burros) exist on 179 HMAs that comprise 31.6 million acres of public lands, of which 26.9 million are under BLM management.[10]

Herds can grow at an average rate of 20% annually.[2,3,4] When herd populations exceed established AMLs, the BLM conducts roundups to remove excess animals from HMAs, and roundups occur every 3–5 yr to ensure BLM complies with the requirements of the amended act. Removed animals are transported to long-term government holding pastures in the Midwest where they are cared for in perpetuity or, to a lesser extent each year, adopted by private individuals.

From 1971 to 2012, the BLM has removed over 300,000 wild horses and burros from the range and adopted out more than 230,000 animals.[10,12] However, in recent years the number of animals removed from the range and placed in long-term holding has far exceeded the number adopted or sold; adoption demand has fallen in response to the U.S. economic recession and other factors. According to the BLM's data reports for 2000 through 2012, over 121,000 animals were removed from the range while only 62,000 were adopted or sold. In Fiscal Year (FY) 2012, 66% fewer animals (i.e., 2,598) were adopted compared to FY 2002 when the BLM adopted out 7,746 animals.[10]

The remaining 46,500 animals have been placed in government holding facilities and, as a result, off-the-range wild horse and burro management costs have increased dramatically.[10] In FY 2012 alone, the cost of holding and caring for these animals exceeded $43 million—59% of the $72.4 million in total annual expenditures for the entire wild horse and burro management program.[10]

BLM is committed to caring for these animals, but the costs associated with their care will continue to increase because mortality rates in captivity are low, the average life span of wild horse and burros in captivity is approximately 30 yr, and every year the agency continues to remove more animals from the range and place them in additional holding facilities. This situation will

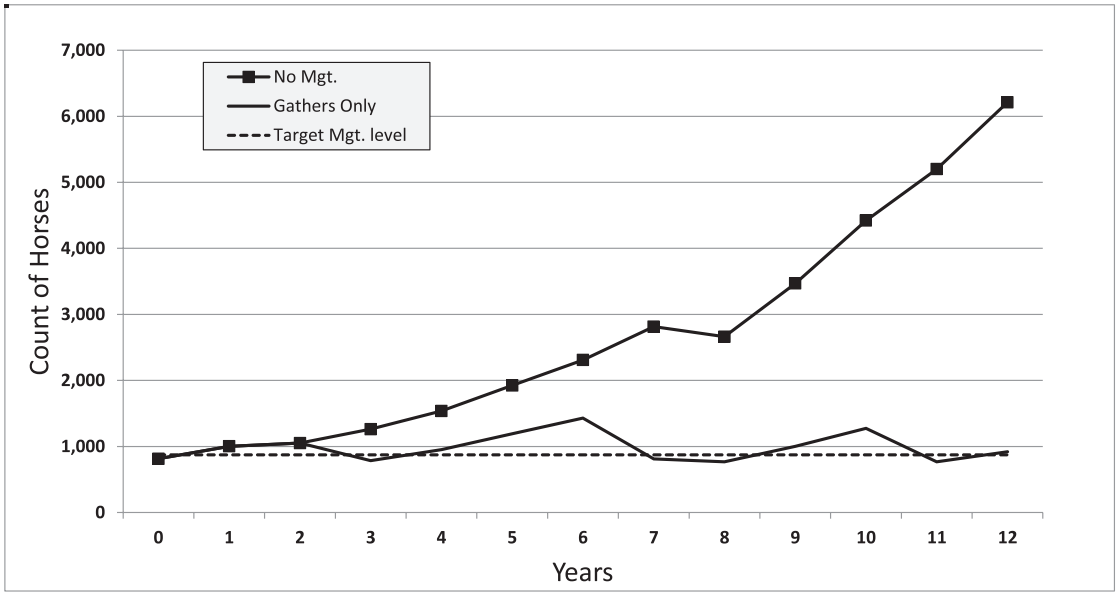
From American Economics Group, Inc., 6512 Lakeview Drive, Falls Church, Virginia 22041, USA (de Seve); and from The Humane Society of the United States, 700 Professional Drive, Gaithersburg, Maryland 20879, USA (Boyles Griffin). Correspondence should be directed to Ms. Boyles Griffin (sboyles@humanesociety.org).

result in exponentially increasing holding costs that will continue to rise as holding facilities become scarce and operators increase their prices, a trend now evident. Unless the agency develops and implements long-term management strategies to reduce the number of removals by reducing population growth rates on-the-range, the current removal-only approach seems doomed by inevitable budget constraints off-the-range.

Fertility control is a viable alternative to the current wild horse management regime. In early 2012, the Environmental Protection Agency (EPA) registered the first contraceptive vaccine for wild horses commonly known as porcine zona pellucida (PZP) and registered under the brand name ZonaStat-H.[11] Fertility control techniques and immunocontraception vaccines have been shown to be safe, humane, reversible,[8] and capable of stabilizing and reducing wild horse populations over time, either when used alone or when combined with other wild horse population growth suppression methods.[5,6,9] A United States Geological Survey (USGS) economic study[1] also demonstrated that reducing wild horse population growth rates through the combined use of fertility control drugs and sex ratio adjustments may reduce the need and frequency of removals which, in turn, could lead to long-term reductions in off-the-range management costs. This study estimated that fertility control on-the-range could reduce total wild horse and burro management costs by 14%, saving $6.1 million per year. The question is how to implement a humane and efficient cost-saving management plan.

Currently the BLM uses WinEquus, a stochastic wild horse population model, to evaluate possible management actions and select preferred alternatives, but the model does not calculate any costs associated with various management options.[7] The model cannot optimize management options, compare the combined removal and holding costs of alternative management plans, loop through multiple ranges to help build an efficient overall strategy, or simulate multi-year planning.

To assist the BLM in developing and implementing a long-term plan to maintain healthy wild horse and burro herd populations, a robust economic model to project the costs and outcomes of various management regimes was created which can be used by the agency to plan effective, cost-beneficial programs. The management system is designed to simulate range populations and alternative BLM management interventions and costs in either a single HMA or over multiple HMAs. It employs not only simulation methods but also optimization. Thus, it can help make sound management decisions under uncertainty, including allocating resources and reducing costs. The modeling incorporates stochastic simulations, conventional optimization, and stochastic optimization. There are four sub-models in the overall model framework: The Dynamic Population Simulation Model, The Economic Costing Model, The Management Intervention and Optimization Model, and The Population and Range Database System.



Recognizing the sparse data currently available for wild horse populations, the database system incorporates techniques for simulating missing data. It also guides the user to track range management results and enter additional data as the years pass, helping to initiate sound data collection procedures on the range and from contractors hired to conduct gathers. As with range data, missing cost items can be approximated or simulated using appropriate BLM assumptions.

BLM could use the model to decide on the optimum number and locations of round-ups, age–sex gather targets, fertility control elements, and remove:release ratios in order to allocate a fixed total budget, thus selecting the "best" limited set of gathers, or allocate to minimize cost in a single year or over multiple years to reach annual or overall population targets. The model might also optimize to control costs by suggesting adjustments to consider to HMA target populations or AMLs.

To demonstrate, using a hypothetical HMA with a target population of 874 animals, initial model runs over a 12-yr period demonstrate that the "no management" alternative, meaning no round-ups, removals, or contraception (or any combination thereof), is incapable of maintaining the target population and would lead to an exponential population growth rate that is not desirable or sustainable, as the population would rise from under 874 to over 6,000 in 12 yr (Fig. 1a, b). A model run of a typical "removal-only" management regime, where animals are removed from the HMA at years 3, 7, and 11, shows that such a scenario is capable of maintaining a population at or near the target population level (Fig. 1a.) but at a cost of over $13 million over 12 yr (Table 1).

A lower cost approach uses a contraception-and-removal management program where during a gather some animals are removed, selected by age and sex, but a high proportion of the mare population is treated with fertility control drugs and released. Population projections for years 3,

a.

b.

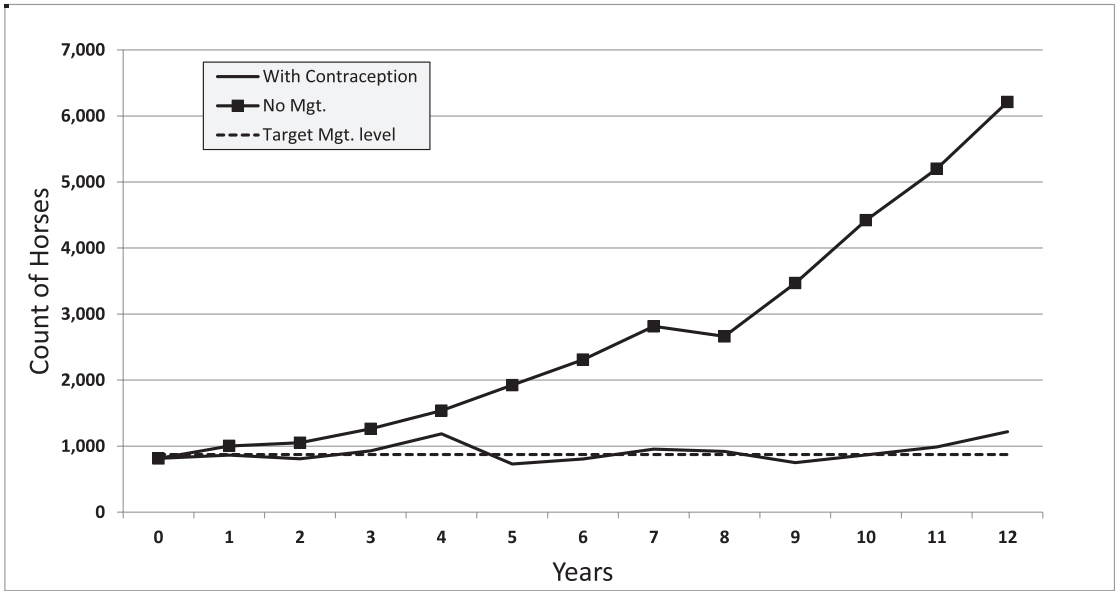


Figure 1. Example economic model output for a hypothetical Herd Management Area (HMA) with a target management population of 874 animals. The model simulates the difference in population growth rates over a 12-yr period when no management is conducted on the HMA versus (**a**) removal-only and (**b**) contraception-and-removals at years 3, 7, and 11.

7, and 11 show that such a management scheme will both maintain the target population level (Fig. 1b.) and reduce management costs by approximately $8 million over 12 yr—or $5.9 million present value compared to the "removal only" scenario (Table 1). Note that even a suboptimal effectiveness of PZP can achieve substantial population control and cost savings.

The model is flexible and, while these demonstration runs are based on realistic working assumptions provided by experts in the field, virtually all inputs can be adjusted to see the

Table I. Example of economic model output results of 12-yr contraception-and-removals versus removals-only scenarios.

	Contraception and removals	Removals only	Change (%)
Total horses to holding over 12 yr	798	1,790	−55.4
Average range pop. over 12 yr	910	982	−7.3
AML[a]	874	874	
Average difference from AML (%)	4.1	12.4	
Total gather and treatment costs	$2,435,523	$2,634,579	−7.6
Total holding costs	$5,560,426	$10,694,712	−48.0
Total cost (sum of years)	$7,995,949	$13,329,290	−40.0
Total cost (present value)	$5,852,135	$9,314,090	−37.2

[a] AML = appropriate management levels.

impact of other conditions, to test the limits of the model, the risks of other outcomes, or to use other assumptions. The examples here describe the population in an individual HMA while the gold-standard model would be a simultaneous collection of model runs for multiple, or all, HMAs in order to calculate the full population impact and the total cost to the agency's budget.

BLM estimates that there are approximately 38,000 wild horses and burros roaming on 179 HMAs located on public rangelands in 10 Western states. If about $8 million could be saved by implementing the proposed management scheme at one HMA over 12 yr, it stands to reason that such an approach could result in a cost-savings of tens of millions of dollars, if applied across all HMAs, recognizing the size differences among ranges.

Given current budget constraints imposed on federal and state wildlife and land management agencies, the hybrid population and economic model describe here could be used to develop and support the implementation of cost-effective and long-term wildlife and land management programs. It is clear to us that BLM and other agencies should invest more resources into both modeling and population growth suppression methods.

Journal of Neuroendocrinology

Gonadotrophin-releasing hormone (GnRH) is a hypothalamic hormone transported by the hypophyseal portal bloodstream to the pituitary gland, where it binds to GnRH receptors. However, GnRH receptors are expressed in multiple extrapituitary tissues, although their physiological relevance is not fully understood. GnRH agonists are employed extensively in steroid deprivation therapy, especially to suppress testosterone in prostate cancer. Because GnRH agonist treatment is associated with increased coronary heart disease and myocardial infarction, we investigated the impact of GnRH on cardiomyocyte contractile function. Cardiomyocytes were isolated from mouse hearts and mechanical and intracellular Ca^{2+} properties were evaluated, including peak shortening amplitude (PS), time-to-PS (TPS), time-to-90% relengthening (TR_{90}), maximal velocity of shortening/relengthening (± dLdt), electrically-stimulated rise in Fura-2 fluorescence intensity (ΔFFI) and Ca^{2+} decay. GnRH (1 ng/ml) increased PS, ± dL/dt, resting FFI and ΔFFI, and prolonged TPS, TR_{90} and Ca^{2+} decay time, whereas 1 pg/ml GnRH affected all these cardiomyocyte variables, except TPS, resting FFI and ΔFFI. A concentration of 1 fg/ml GnRH and the GnRH cleavage product, GnRH-[1–5] (300 pg/ml), had no effect on any cardiomyocyte parameter. The 1 pg/ml GnRH-elicited responses were attenuated by the GnRH receptor antagonist cetrorelix (10 μM), the protein kinase A (PKA) inhibitor H89 (1 μM) but not the protein kinase C inhibitor chelerythrine chloride (1 μM). These data revealed that GnRH is capable of regulating cardiac contractile function via a GnRH receptor/PKA-dependent mechanism. If present in the human heart, dysfunction of such a system may play an important role in cardiac pathology observed in men treated with GnRH agonists for prostate cancer.

Key words: GnRH, cardiomyocyte shortening, intracellular Ca^{2+}, PKA, PKC.

[1]These authors contributed equally to this work.

Prostate cancer is the most common noncutaneous cancer in the USA and is second only to lung cancer in carcinoma-associated mortality. Because most prostate cancers are androgen-dependent, it is essential to suppress circulating testosterone. Continuous exposure to GnRH causes the pituitary gland to desensitise to the stimulatory signal, resulting in reduced gonadotrophin release and, consequently, testosterone secretion. Gonadotrophin-releasing hormone (GnRH) agonists are thus used therapeutically to chemically castrate men. This treatment is accompanied by various side effects (hot flashes, weight gain and decreased libido), and has recently been associated with an overtly increased cardiovascular risk, although this effect was ascribed to the loss of circulating testosterone (1–3). However, an ensemble of epidemiological studies has provided convincing evidence of a significant increase in the prevalence of coronary heart disease, myocardial infarction and sudden cardiac death in patients receiving GnRH agonist treatment compared to untreated and castrated men (4–8), resulting in an Food and Drug Administration warning (20 October 2010). In addition, oral anti-androgen monotherapy is not associated with negative cardiac outcomes (9), favouring the hypothesis that the GnRH agonists *per se*, rather than the loss of androgenic effects, are directly responsible for the negative health outcome.

Similar to many other hypothalamic peptides, the attributed function of GnRH focuses on gonadotrophin release from the pituitary (10). However, the peptide hormone and its receptor are synthesised in several sites outside of the hypothalamus and pituitary gland, including other regions of the brain (11–13), the reproductive

system (12,14,15), bladder (16–20), spleen (21), pancreas (22) and heart (23,24). Nonetheless, the physiological significance of GnRH within these extrapituitary sites remains unclear. Accordingly, the present study was designed to examine the impact of GnRH exposure on murine cardiomyocyte contractile function and intracellular Ca^{2+} homeostasis. This model is particularly suitable for this purpose because neither GnRH II nor the GnRH type II receptor is synthesised in mice (25).

Materials and methods

Isolation of adult murine cardiomyocytes

The experimental procedure used in the present study was approved by the University of Wyoming Animal Use and Care Committee (Laramie, WY, USA). Adult male FVB mice (approximately 22 g) were anaesthetised with ketamine/xylazine (5 : 3, 1.32 mg/kg i.p.). Hearts were rapidly removed and perfused (at 37 °C) through the aorta with Krebs–Henseleit bicarbonate (KHB) buffer (in mM: 118 NaCl, 4.7 KCl, 1.2 $MgSO_4$, 1.2 KH_2PO_4, 25 $NaHCO_3$, 10 HEPES, 11.1 glucose, pH 7.4). The hearts were then perfused via the aorta for 15 min with KHB containing Liberase Blendzyme 4 (Hoffmann-La Roche, Indianapolis, IN, USA). After perfusion, left ventricles were removed and minced. Dispersed cardiomyocytes were filtered through a nylon mesh (300 μm). Extracellular Ca^{2+} was added slowly and incrementally to 1.25 mM over 30 min. A total of 12 mice were used for this study.

Cell shortening/relengthening

Mechanical properties of cardiomyocytes were assessed using an IonOptix™ soft-edge system (IonOptix, Milton, MA, USA). Myocytes were placed in a chamber mounted on the stage of an Olympus IX-70 microscope (Olympus, Tokyo, Japan) and superfused (approximately 2 ml/min at 25 °C) with a KHB buffer containing 1 mM $CaCl_2$. Mammalian GnRH (GnRH 1; American Peptide Co, Sunnyvale, CA, USA; 1 ng/ml, 1 pg/ml, 1 fg/ml or no GnRH in KHB buffer) was applied for 10 min before the myocytes were field stimulated at 0.5 Hz (80 V) for the duration of 3 ms. Cell shortening and relengthening were assessed, including peak shortening (PS), time-to-PS (TPS), time-to-90% relengthening (TR_{90}) and maximal velocities of shortening/relengthening (± dL/dt).

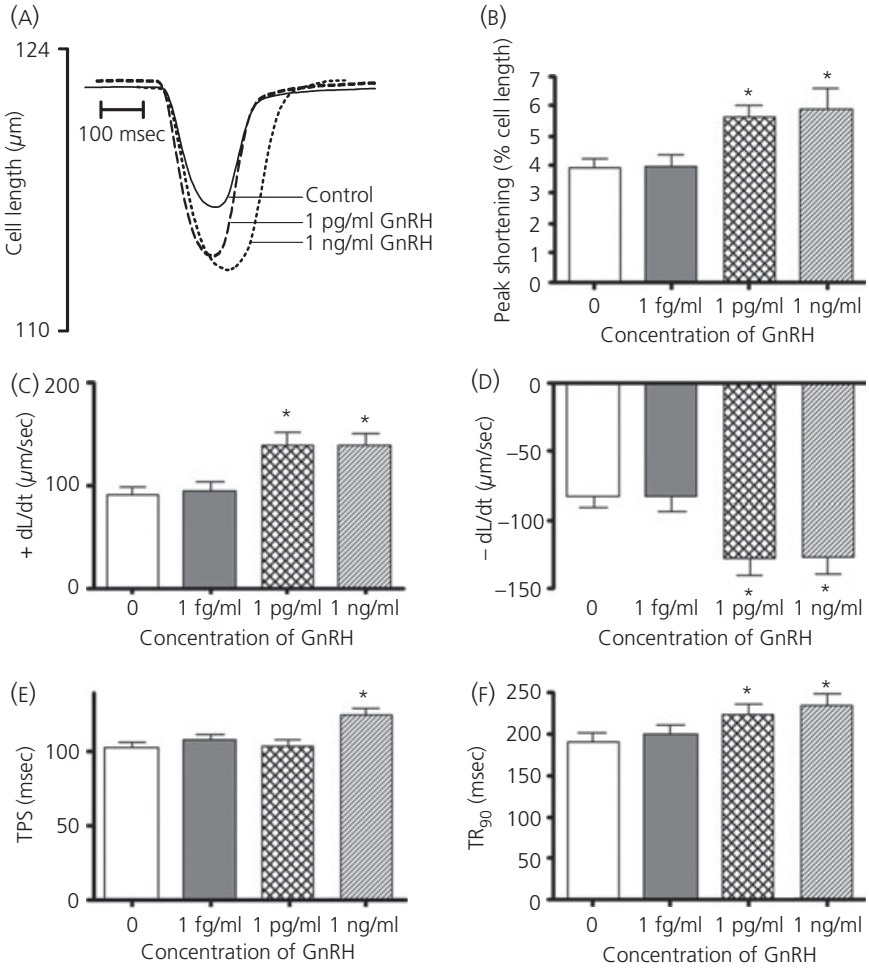

Fig. 1. Effect of acute exposure to gonadotrophin-releasing hormone (GnRH) (1 fg/ml–1 ng/ml) on cardiomyocyte contractile function. (A) Representative traces of cell shortening in the absence or presence of GnRH (1 pg/ml and 1 ng/ml in Krebs–Henseleit bicarbonate); (B) peak shortening normalised to resting cell length; (C) maximal velocity of shortening (+ dL/dt); (D) maximal velocity of relengthening (–dL/dt); (E) time-to-PS (TPS); and (F) time-to-90% relengthening (TR_{90}). Mean ± SEM, n = 74–76 cells per group, *P < 0.05 versus control (0 GnRH).

Effect of cetrorelix, protein kinase inhibitors and GnRH-[1–5]

Both protein kinase A (PKA) and protein kinase C (PKC) have been shown to participate in GnRH-regulated reproductive function (26–29). To determine whether these two kinases and the GnRH receptor *per se* are involved in the GnRH-induced cardiac contractile response, the effect of acute GnRH exposure on cardiomyocyte shortening was re-examined in the presence of the GnRH receptor antagonist cetrorelix (10 μM; Anaspec, San Jose, CA, USA), the PKA inhibitor H89 (1 μM; Calbiochem, San Diego, CA, USA) or the PKC inhibitor chelerythrine chloride (1 μM; Calbiochem). These pharmacological agents were all applied for 20 min alone and then in the presence or absence of GnRH (1 pg/ml) for 10 min before the 0.5-Hz stimulation.

GnRH can be enzymatically cleaved into GnRH-[1–5], which is a pentapeptide with biological activity independent of the GnRH receptor (30). To investigate whether the observed effects could be mediated by this pentapeptide, GnRH-[1–5] was synthesised (Michael Flora, Biomedical Instrumentation Center, Uniformed Services University of the Health Sciences, Bethesda, MD, USA) and applied (300 pg/ml) to cardiomyocytes for 10 min before the 0.5-Hz stimulation.

Intracellular Ca^{2+} transients

A cohort of myocytes was loaded with Fura-2/AM (0.5 μM; 10 min) and fluorescence intensity was recorded with a dual-excitation fluorescence photomultiplier system (IonOptix). Myocytes were placed onto an Olympus IX-70 inverted microscope and imaged through a Fluor × 40 oil objective. GnRH (1 ng/ml, 1 pg/ml, 1 fg/ml or no GnRH in KHB buffer) was applied for 10 min before electrical stimulation. Cells were exposed to light emitted by a 75-W lamp and passed through either a 360 or 380 nm filter, at the same time as being stimulated to contract at 0.5 Hz. Fluorescence emissions were detected in the range 480–520 nm and qualitative change in Fura-2 fluorescence intensity (FFI) was inferred from the FFI ratio at the two wavelengths (360/380 nm). Fluorescence decay time was calculated as an indicator of $[Ca^{2+}]_i$ clearing (11).

Statistical analysis

Data are presented as the mean ± SEM. Statistical significance ($P < 0.05$) for each variable was independently estimated by analysis of variance (ANOVA) followed by a Tukey's post-hoc analysis to correct for the probability of making a type I error.

Results

Effect of GnRH exposure on cardiomyocyte contractile and intracellular Ca^{2+} response

Acute exposure (10 min) of cardiomyocytes to GnRH had no effect on resting cell length (data not shown). Although GnRH at 1 fg/ml had no effect on cardiomyocyte contractile function, GnRH at the levels of 1 pg/ml and 1 ng/ml significantly increased PS and ± dL/dt, as well as prolonged TPS and TR_{90} in murine cardiomyocytes (Fig. 1). The GnRH-induced cellular response was maximal within 10 min of exposure and was maintained for up to 60 min.

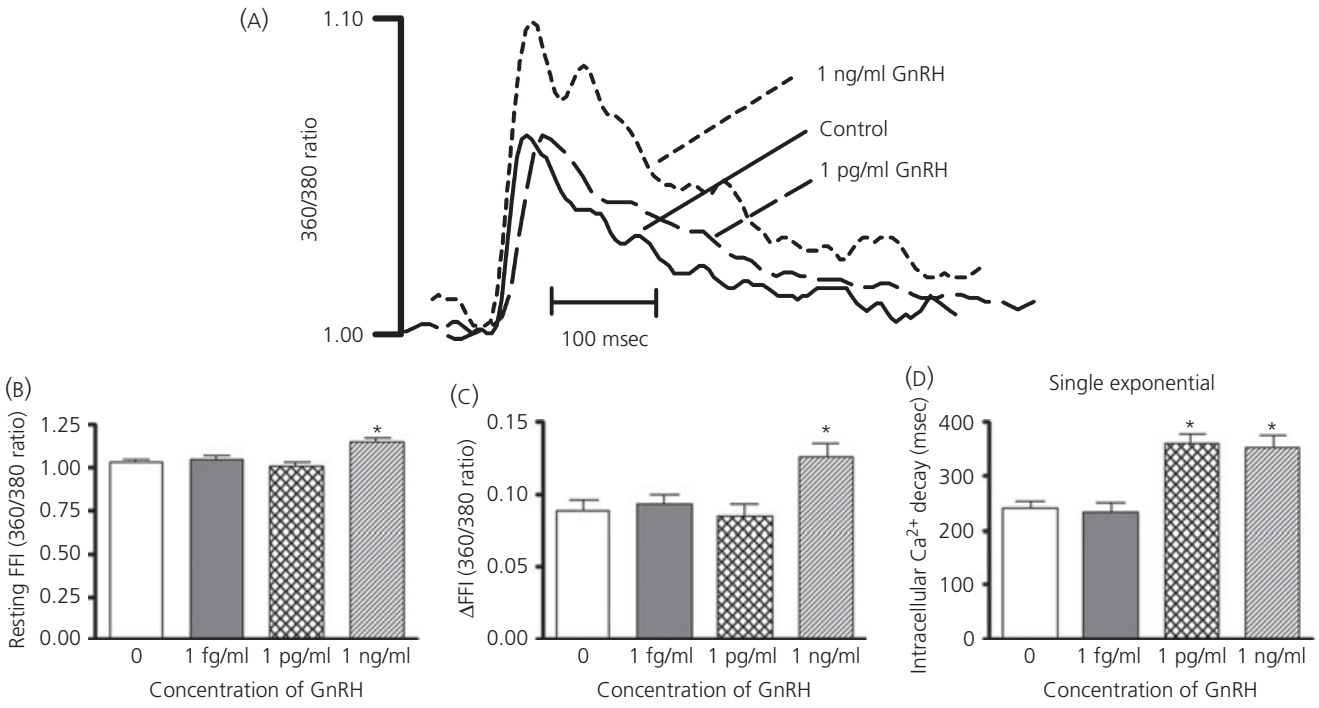

Fig. 2. Effect of acute exposure to gonadotrophin-releasing hormone (GnRH) (1 fg/ml–1 ng/ml) on intracellular Ca^{2+} homeostasis. (A) Representative traces depicting the changes in intracellular Ca^{2+} in response to a 0.5 Hz stimulus in the presence of different concentrations of GnRH; (B) resting Fura-2 fluorescence intensity (FFI); (C) electrically-stimulated rise in FFI (ΔFFI) and (D) single exponential decay of intracellular Ca^{2+}. Mean ± SEM, n = 60 cells per group, *$P < 0.05$ versus control (0 GnRH).

These responses were reversible upon a 20 min washout (data not shown). To explore the possible mechanism of action behind GnRH-induced mechanical response, intracellular Ca^{2+} homeostasis was monitored using the fluorescent dye Fura-2/AM. The results shown in Fig. 2 revealed that higher doses of GnRH elevated resting intracellular Ca^{2+} and electrically-stimulated rise in intracellular Ca^{2+} as well as prolonged intracellular Ca^{2+} decay.

Effect of cetrorelix, protein kinase inhibitors and GnRH-[1–5]

In the absence of GnRH, cetrorelix, H89 and chelerythrine chloride had no overt effect on cell shortening over 30 min (Fig. 3). The GnRH-induced cardiomyocyte mechanical responses were abolished or significantly attenuated by cetrorelix and H89 but not chelerythrine,

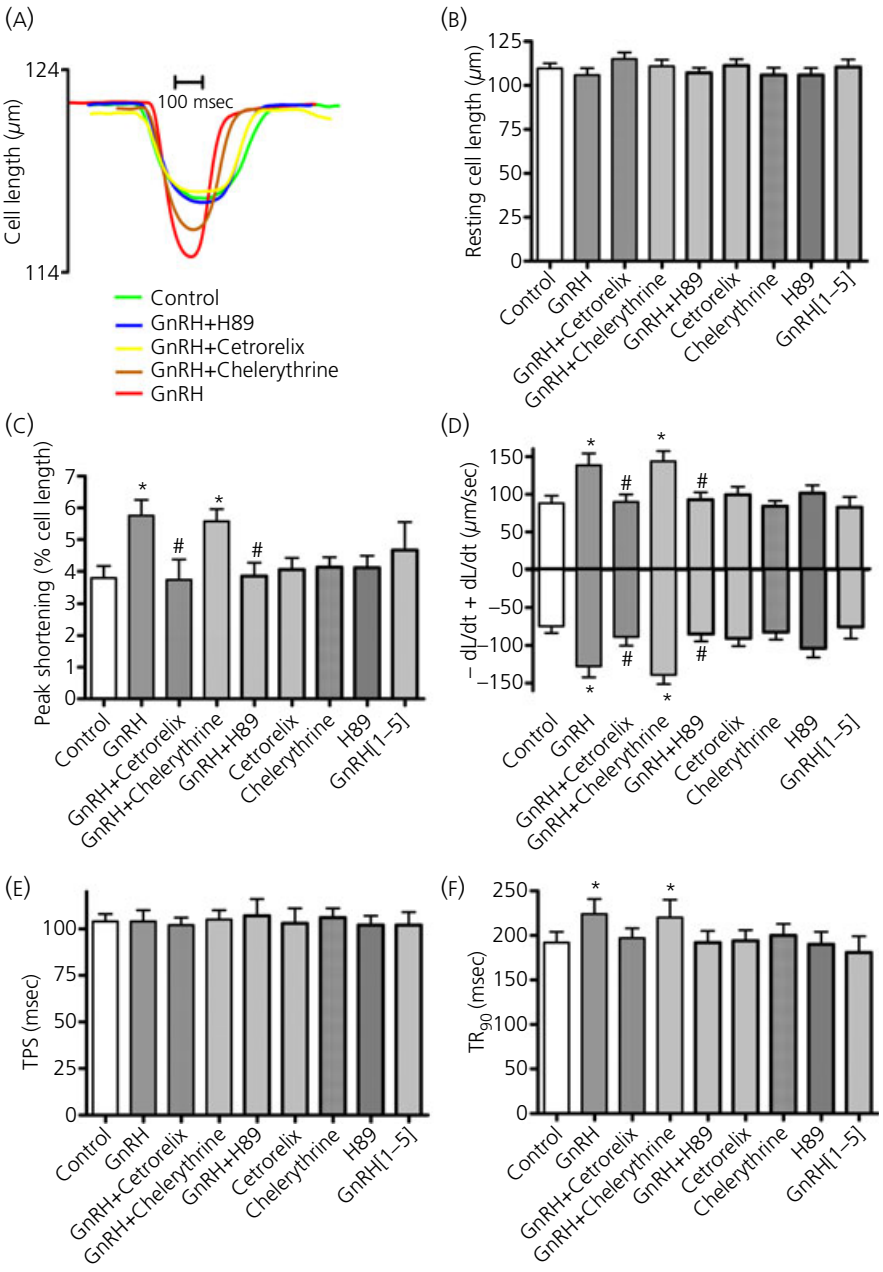

Fig. 3. Effect of the gonadotrophin-releasing hormone (GnRH) receptor antagonist cetrorelix (10 μM), the protein kinase C inhibitor chelerythrine chloride (1 μM) and the protein kinase A inhibitor H89 (1 μM) on acute GnRH (1 pg/ml) exposure-induced cardiomyocyte contractile response. Effect of the truncated form of GnRH (300 pg/ml GnRH-[1–5]) was also exhibited. All pharmacological inhibitors were applied 10 min before GnRH addition. (A) Representative traces depicting GnRH-elicited cell shortening response in the absence or presence of pharmacological inhibitors; (B) resting cell length; (C) peak shortening normalised to resting cell length; (D) maximal velocity of shortening/relengthening (± dL/dt); (E) time-to-PS (TPS); and (F) time-to-90% relengthening (TR_{90}). Mean ± SEM, n = 37–47 cells per group, *P < 0.05 versus control; #P < 0.05 versus GnRH group.

suggesting an involvement of GnRH receptor and PKA (but unlikely PKC) in the GnRH-elicited cardiomyocyte contractile responses. GnRH-[1–5] had no effect on cardiomyocytes (Fig. 3). Similar to the cardiomyocyte mechanical responses, the GnRH-elicited increase in electrically-stimulated intracellular Ca^{2+} (ΔFFI) and prolongation in intracellular Ca^{2+} decay were abolished by H89, but not chelerythrine, thus providing further support for the involvement of PKA (but unlikely PKC) in the GnRH-elicited intracellular Ca^{2+} response in cardiomyocytes (Fig. 4).

Discussion

The present study suggests that that GnRH has positive cardiomyocyte contractile effects in the mouse. This effect appears specific to the intact GnRH molecule because the enzymatically cleaved GnRH product, GnRH-[1–5], a pentapeptide with biological activity independent of the GnRH receptor (30), failed to affect cardiomyocyte mechanical responses, whereas the GnRH type I receptor antagonist, cetrorelix, blocked the GnRH-mediated mechanical response. These observations favour a GnRH receptor-mediated mechanism for the GnRH-modulated cardiac contractile response. The GnRH treatments used in the present study correspond well with the circulating concentrations of a GnRH agonist (leuprorelin) produced by GnRH agonist therapies. Specifically, leuprorelin concentrations of 430–190 pg/ml were evident after a 3-month depot Lupron implant and 930 pg/ml after a 12-month implant (31). Similarly, a different 4-month leuprorelin-releasing implant produced mean serum levels between 1 ng/ml and 100 pg/ml, from day 3 to day 112, with individuals ranging from 50 pg/ml to 5 ng/ml (32). However, it remains to be determined whether GnRH has a physiologically important cardiac role in mammals or whether such effects have become vestigial and only become evident in the face of excess exposure to GnRH or its agonists.

The GnRH-elicited cardiomyocyte contractile response in mice is reminiscent of that seen in isolated bullfrog aortas (33) and guinea pig papillary muscles (34). In rats, GnRH was reported to increase heart rate and blood pressure (35), whereas GnRH antagonists trigger hypotension and bradycardia (36). However, these haemodynamic responses were attributed to indirect effects of GnRH in the cardiovascular system (35,36). In male rats treated for 2 months with the GnRH agonist, goserelin, the mean and maximal aortic velocities (37), as well as the end systolic pressure (38), were significantly decreased, with the effects being attributed to the loss of steroids. Most recently, Wojniusz *et al.* (39) reported that chronic

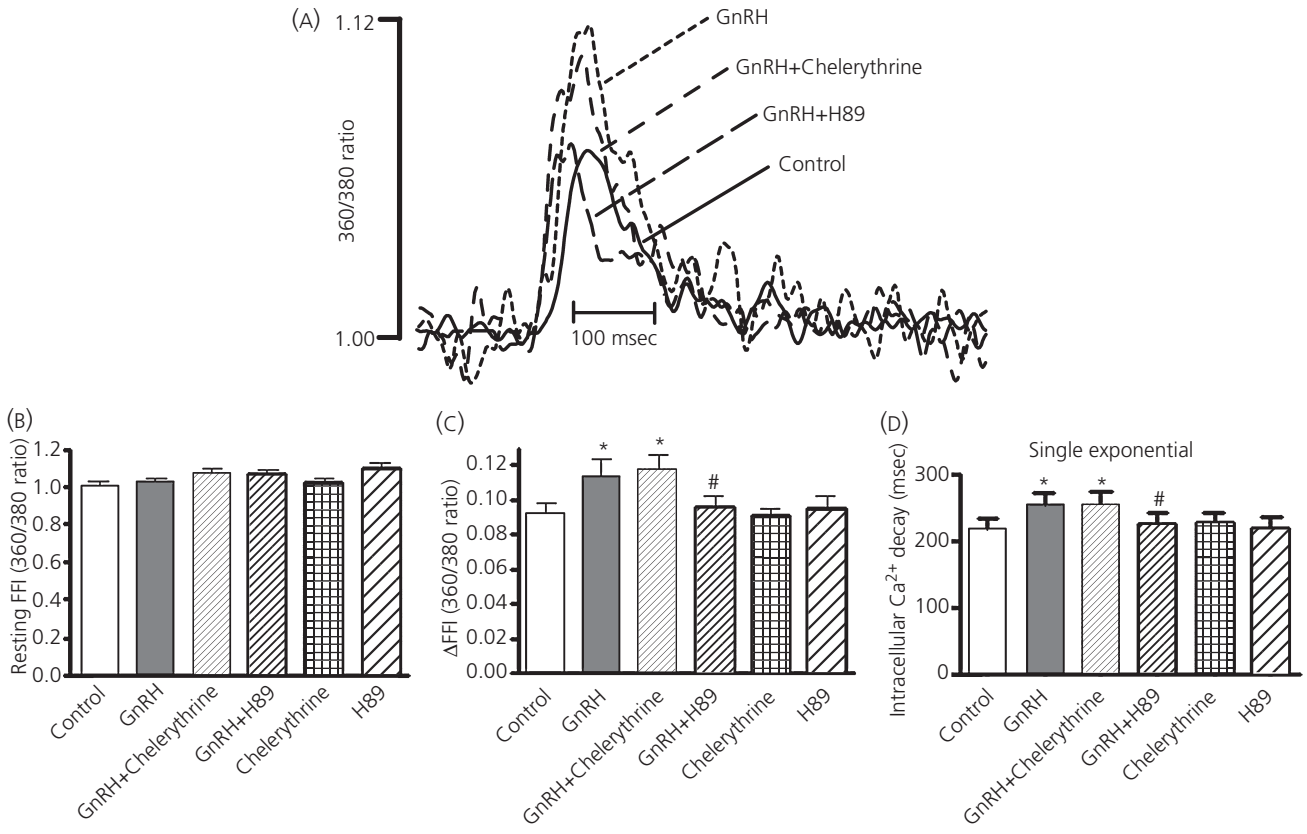

Fig. 4. Effect of the protein kinase C inhibitor chelerythrine chloride (1 μM) and the protein kinase A inhibitor H89 (1 μM) on acute gonadotrophin-releasing hormone (GnRH) (1 pg/ml) exposure-induced cardiomyocyte intracellular Ca^{2+} homeostasis. All pharmacological inhibitors were applied 10 min before GnRH addition, which was added 10 min before the 0.5-Hz stimulation. (A) Representative traces depicting GnRH-elicited intracellular Ca^{2+} transient response in the absence or presence of pharmacological inhibitors; (B) resting Fura-2 fluorescence intensity (FFI); (C) electrically-stimulated rise in FFI (ΔFFI); and (D) single exponential decay of intracellular Ca^{2+}. Mean $\pm$ SEM, n = 57–58 cells per group, *P < 0.05 versus control; #P < 0.05 versus GnRH group.

(10 months) exposure to goserelin increased heart rate variability in male sheep, although it was not determined whether this effect was direct or dependent on testosterone.

Evidence concerning the hemodynamic and cardiac effects of GnRH in humans is sparse. Reports vary from little effect of acutely administered GnRH on heart rate and blood pressure (40), to a notable increase in heart rate (41). In the setting of chronically administered GnRH agonists, it was suggested that the electrocardiographic QT interval may be prolonged in men (42) and, in women, peak flow velocity and cardiac index (stroke volume × heart rate) were significantly reduced after 1 month of treatment (43). Both systolic and diastolic blood pressure were decreased following 3 months of Lupron in women and, notably, this was not prevented with oestrogen replacement (44). As indicated earlier, a plethora of evidence suggests that GnRH treatment may be associated with an increased risk of cardiac dysfunction (1–3,45–47). Such phenomenon of compromised heart function accompanying GnRH therapy is usually attributed to the accompanying androgen deprivation (1–3). However, Keating *et al.* (4,9) provide compelling support for the hypothesis that GnRH *per se* may be a major contributor to the cardiac pathology.

The present study suggests that the PKA pathway (but not the PKC pathway) is involved in the GnRH-mediated increased contractility. In the pituitary gland, the inositol trisphosphate-PKC pathway is known to be the major intracellular pathway activated by GnRH to induce secretion from gonadotrophs (26), although there is accumulating evidence that GnRH also activates PKA within gonadotrophs to affect nonsecretory responses (27–29). It is noteworthy that a previous study suggested the involvement of PKA in a GnRH-associated cardiac response (48). PKA has multiple targets for phosphorylation in cardiomyocytes, including phospholamban (49), the L-type Ca^{2+} channel on the sarcolemma (50) and components of the contractile apparatus (51). PKA also phosphorylates the ryanodine receptor/Ca^{2+} release channel in cardiomyocytes, which in turn regulates the channel opening probability and leads to increased sensitivity to Ca^{2+}-induced activation (52). In the present study, higher doses of GnRH elevated resting intracellular Ca^{2+} and, together with the electrically (0.5 Hz)-stimulated rise in intracellular Ca^{2+}, as well as the prolonged intracellular Ca^{2+} decay, this may be a reflection of increased sarcoplasmic reticulum Ca^{2+} release and, consequently, cardiac contractility.

GnRH receptors have been reported in the heart of the sea hare, *Aplysia californica* (53) (P.S. Tsai, personal communication), and octopus, *Octopus vulgaris* (54,55), where GnRH is shown to exert powerful cardiac effects (56,57), and is well documented in piscine cardiac tissue (58–62). GnRH analogue binding has been reported in rodent hearts (13,63–68) and GnRH receptor mRNA has been noted in the rat (69) and dog (Navratil AM, Roberson MS, personal communication). GnRH receptor mRNA (23,70) and immunoreactive receptor (24,71) have also been demonstrated in human hearts. Taken together, there is compelling evidence for an evolutionarily conserved role for GnRH in the heart.

In summary, our data favour that GnRH promotes cardiomyocyte contractile function through a GnRH receptor/PKA-mediated pathway. The accumulating evidence of multiple extrapituitary GnRH targets allows the consideration of a broader evolutionary hypothesis suggesting that GnRH may not have evolved solely with a reproductive function (53). Moreover, as proposed three decades ago (72), the hypophyseal portal system may not only have evolved solely as a means to deliver hypothalamic peptides to the pituitary gland, but also as a way to restrict their delivery precisely to that target.

15 **Contents**

16 We investigated the effect of immunization against gonadotropin releasing hormone
17 (GnRH) using a commercial canine GnRH vaccine on estrus suppression and unwanted estrous
18 behavior in mares. In experiment 1, mares were immunized (n=6) twice with vaccine (5mL)
19 given intramuscularly 4 weeks apart or received a control diluent (n=5). Transrectal
20 ultrasonographic examination of the reproductive tracts were performed three days a week for 40
21 weeks after initial vaccination. Blood samples were collected weekly for GnRH antibody titer
22 and progesterone concentration determination. In experiment 2, privately-owned mares (n=12)
23 were immunized twice with vaccine (1mL) given intramuscularly 4 weeks apart. Blood samples
24 were collected prior to each vaccination as well as 12 and 20 weeks after initial treatment, and
25 transrectal ultrasonographic examinations of the reproductive tracts were performed 12 weeks
26 after the first vaccination. Vaccinated mares in experiment 1 responded with a GnRH antibody
27 titer, progesterone concentrations significantly lower than controls, and cessation of ovarian
28 activity. Vaccinated mares in experiment 2 also responded with a GnRH antibody titer,
29 progesterone concentrations that remained basal for the duration of the study, and cessation of
30 ovarian activity. Owners of vaccinated mares in experiment 2 reported that the number of
31 unwanted estrous behaviors present before vaccination significantly decreased following
32 vaccination. In conclusion, GnRH immunization using a canine GnRH vaccine is an effective
33 method for suppressing estrus and unwanted estrous behavior.

Introduction

Unwanted behavioral changes in mares during estrus affect handling and performance. Reproductive estrous behaviors exhibited by the mare in the presence of a stallion include raising the tail, clitoral eversion, and urinating (Ginther, 1992). However, mares also exhibit non-reproductive estrous behaviors that limit their performance potential, which include hyperexcitability, oversensitivity, abdominal discomfort, and aggression (McDonnell, 1992). Non-surgical estrous behavior suppression is most commonly achieved via daily treatment with an oral progestin, altrenogest (Regu-Mate®, Intervet Inc., Millsboro, DE) (Pryor and Tibary, 2005). However, daily oral administration is costly and can be impractical for horse owners (Burger et al., 2008). In addition, altrenogest is readily absorbed through human skin, which is a potential human safety concern (Hazan, 2011). Also, since altrenogest does not inhibit follicular activity, some mares continue to display unwanted estrous behavior (Pryor and Tibary, 2005).

Gonadotropin releasing hormone (GnRH) controls ovarian activity by regulating the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH). Therefore, preventing GnRH from stimulating the release of LH and FSH may be a viable approach for the suppression of estrus. Immunization against GnRH to subsequently cease ovarian activity has been investigated in the mare. Two commercial GnRH vaccines, Improvac® (Pfizer Animal Health Australia) and Equity® (Pfizer Animal Health Australia) have demonstrated suppression of reproductive cyclicity (Botha et al., 2008; Elhay et al., 2007; Imboden et al., 2006). Improvac®, labeled for the prevention of boar taint in swine, was shown to suppress ovarian activity in the mare for at least 23 weeks (Botha et al., 2008; Imboden et al., 2006). However, one study reported a high percentage of adverse vaccine reactions (Imboden et al., 2006), while

ACCEPTED MANUSCRIPT

the other study reported a small number of transient side effects (Botha et al., 2008). Equity®, labeled for the control of estrus in mares, showed no adverse reactions, a significant decrease in estrous behavior, and ovarian activity suppression for at least three months (Elhay et al., 2007). However, neither of these products are commercially available in the United States, so there remains a need for a safe and cost-effective method for long-term estrus suppression in mares.

In 2004, a commercial GnRH vaccine was launched in the United States (Canine Gonadotropin Releasing Factor Immunotherapeutic®; Pfizer Animal Health USA). This vaccine was labeled for the treatment of benign prostatic hyperplasia in intact male dogs (Pfizer Animal Health, 2004). The vaccine decreases serum testosterone concentrations and testicular volume in intact male dogs (Donovan et al., 2012) and has been used for pregnancy termination in bitches as well (Chew and Purswell, 2010). Recently, this vaccine has also been shown to be effective in male llamas and alpacas, decreasing serum testosterone concentrations, testicular volume and intermale aggressive behavior (Donovan et al., 2013).

The objectives of the current study were to determine (a) the effect of this canine GnRH vaccine on equine ovarian cyclicity and (b) the effect of the canine GnRH vaccine on equine non-reproductive estrous behavior. It was hypothesized that the canine GnRH vaccine would safely and effectively suppress estrus (both ovarian cyclicity and subsequent estrous behavior) for a prolonged duration.

Materials and Methods

Animals

ACCEPTED MANUSCRIPT

Eleven mares (mean age 13.36 years) were obtained for experiment 1 and twelve privately-owned mares (mean age 9.91 years) that had histories of displaying unwanted behaviors during the estrous period were recruited for experiment 2. All mares had histories of normal reproductive cyclicity.

Experimental Design

In experiment 1, which began in May (spring in the Northern hemisphere), reproductive tracts were monitored by transrectal palpation and ultrasonography three days a week for four weeks. After initial monitoring, mares were either given 5mL of the canine GnRH vaccine (5 times the labeled canine dose; n=6) or a placebo (n=5) twice four weeks apart. Reproductive tracts continued to be monitored three days a week for 40 weeks after initial vaccination, until spring of the following season, and venous blood samples were collected at each session.

Experiment 2 was a clinical study and began in January-April (winter-early spring in the Northern hemisphere). All mares received 1mL of the canine GnRH vaccine (a similar antigenic mass as the Equity® vaccine; n=12) twice four weeks apart. Venous blood samples were collected prior to vaccination (week 0 and 4) and at weeks 12 and 20. Transrectal ultrasonographic examinations of the reproductive tracts were also performed at week 12.

All experimental procedures were approved by the Institutional Animal Care and Use Committee of Oregon State University (ACUP #3699). For the clinical study (experiment 2), the vaccine was used in an extra-label manner by the attending veterinarian and each owner signed a consent form to participate in the study.

ACCEPTED MANUSCRIPT

Vaccine

The canine GnRH vaccine (Canine Gonadotropin Releasing Factor Immunotherapeutic®, Pfizer Animal Health, Exton, PA) consists of the GnRH peptide conjugated to diptheria toxoid as the protein carrier and combined with a proprietary adjuvant of plant-based origin (Hashimi et al., 2008; Russo, 2008). Each 1 mL dose contains 200μg peptide conjugate (Hashimi et al., 2008). The placebo was a sterile diluent provided by the vaccine manufacturer for use in this experiment. Vaccines were administered into the semimembranosus muscle with not more than 2.5 mL of vaccine or diluent injected at one site (experiment 1) or the middle of the neck (experiment 2).

Vaccine Reactions

In experiment 1, mares were monitored twice daily for two days then once daily for one week for adverse reactions after each injection. The injection site was observed visually and digitally for warmth and swelling, and gait was monitored for lameness. In addition, the general appearance, behavior, and appetite of each mare was observed. If any (even subtle) adverse reactions were present, they were noted by investigators. If no adverse reactions were present at the time of each examination, this was also noted by investigators. In experiment 2, mares were monitored for adverse reactions by their owners using the same criteria as experiment 1.

Hormone Analysis

ACCEPTED MANUSCRIPT

Blood samples from both experiments were collected into Vacutainer® clot tubes (02-685-A, Fisher Scientific Co.) and centrifuged upon clotting. Sera were separated, aliquoted, and frozen at -20°C until analysis.

In experiment 1, GnRH antibody titers were measured monthly from the time of initial vaccination in June until all mares were seronegative. In experiment 2, titers were measured at the four time points blood samples were collected. Titers were determined by ELISA using a technique modified from Elhay et al. (2007). Pooled serum from unvaccinated horses served as the negative control and pooled serum from vaccinated mares with a known high antibody titer served as the positive control. Briefly, 96-well microtiter plates were coated with 100 µL of 5 µg/mL of LH-RH (71447-49-9, Sigma, St. Louis, MO, USA) in sodium bicarbonate buffer (pH 8.0) at 4ºC overnight. After incubation, plates were washed with phosphate-buffered saline containing 0.05% Tween-20 (TPBS) (pH 8.0). Plates were then incubated for 1 hour at 20ºC with serum samples diluted in a buffer containing 0.5% bovine serum albumin (9048-46-8, Sigma, St. Louis, MO, USA) to yield final serum dilutions ranging from 1:8 to 1:1024. After tapping dry, antibodies were detected using horseradish peroxidase protein G conjugate (HRP) (10-1223, Invitrogen, Camarillo) diluted at 1:2000 in serum dilution buffer for 1 hour at 37ºC. After a final wash with TPBS, HRP was visualized with 100 µL of ABTS peroxidase substrate (50-66-01, KPL, Gaithersburg, MD, USA). Absorbances were read at 405 nm using a spectrophotometer (FLUOstar Omega, BMG Labtech Inc., San Francisco, CA, USA) and each serum sample was measured in duplicate. The cutoff for seropositivity, defined in this study as the upper limit of a 99% confidence interval above the mean negative control level, was calculated using the methods of Frey et al. (1998). Serological results were expressed as the reciprocal of the highest

Accepted Manuscript

ACCEPTED MANUSCRIPT

144 twofold serial dilution above the calculated cutoff and linearized using a base-2 logarithmic
145 scale.

146 In experiment 1, progesterone concentrations were measured weekly from the time of
147 initial vaccination in June until the end of the breeding season in October for a total of 17 weeks.
148 In experiment 2, progesterone concentrations were measured at the four time points blood
149 samples were collected. Serum samples were analyzed for progesterone using a commercially
150 available kit (Immulite® Progesterone, Siemens) designed for an enzyme-amplified
151 chemiluminescence assay system (Immulite® 1000, Diagnostic Products Corporation) and
152 performed according to the manufacturer's protocol. The interassay coefficient of variation
153 ranged from 5.8% at 7.2 ng/mL to 16% at 0.81 ng/mL; the intraassay coefficient of variation
154 ranged from 6.3% at 7.9 ng/mL to 16% at 0.81 ng/mL, respectively. The detection limit was 0.2
155 ng/mL.

156

157 *Ovarian Activity*

158 Ovarian activity was monitored in experiment 1 mares three days a week for 44 weeks by
159 ultrasonography and transrectal palpation. In experiment 2, ovarian activity was observed by
160 ultrasonography at week 12, during the spring. At each observation, follicle diameter on both
161 ovaries were measured and the presence of a corpus luteum was noted. In experiment 1, each
162 mare was given a weekly score to reflect cyclicity:

163 Score 0: Anestrus-like. Follicles remain < 20 mm in diameter with no corpus luteum
164 present.

ACCEPTED MANUSCRIPT

Score 1: Diestrus or estrus-like. Follicles reach > 20mm in diameter, corpus luteum or dominant follicle may be present.

Behavioral Analysis

Mares in experiment 2 were evaluated for the presence of estrous behavior. Owners scored their mare's estrous behavior (pre-vaccination score) reflecting the specific number of behaviors each mare exhibited during estrus. At the end of the study, owners again scored their mare's estrous behavior (post-vaccination score) reflecting the specific number of behaviors that were still present through the duration of the study.

Statistical Analysis

In experiment 1, the presence of a GnRH antibody titer was compared between the vaccination and control group using Fisher's exact test (GraphPad QuickCalcs Software, La Jolla, CA, USA). Ovarian activity scores were analyzed using the non-parametric Wilcoxon rank sum test in SAS (Version 9.2, SAS Institute Inc., Cary, NC, USA). Progesterone concentrations were analyzed as a repeated measure in time design using PROC MIXED in SAS. Fixed effects in the model were whether the animal was vaccinated, time after first vaccination, and the interactions between vaccination and time. A first order heterogeneous autoregressive variance-covariance structure was fitted for repeated measurements within animals.

In experiment 2, estrous behavior was analyzed using the non-parametric sign test in SAS. The presence of a GnRH antibody titer and progesterone concentrations were analyzed as a

Accepted Manuscript

ACCEPTED MANUSCRIPT

repeated measure in time design using PROC MIXED in SAS. The fixed effect in the model was time after first vaccination. A first order heterogeneous autoregressive variance-covariance structure was fitted for repeated measurements within animals.

Results

Experiment 1

There were no local or systemic vaccine reactions experienced in either the vaccinated or control mares following the first or second injection. All eleven mares demonstrated normal ovarian cyclicity during the four weeks of monitoring pre-vaccination, and control mares continued to cycle normally for the duration of the breeding season (17 weeks). Circulating progesterone fluctuated throughout the season in control mares as expected. Within days after receiving the booster injection, largest mean follicle size began to decrease in the treated mares (Figure 1). By three weeks post-booster, the largest mean follicle size was consistently < 20mm. In addition, no corpora lutea were present based upon ultrasonographic evaluation and serum progesterone concentrations (Figure 2) for all six vaccinated mares throughout the breeding season. Ovarian activity scores for vaccinated mares were significantly less than controls ($p < 0.0001$).

Of the vaccinated mares, 50% (3/6) resumed normal cyclicity in the following spring, 40 weeks after the initial vaccination. The remaining mares displayed continued cessation of ovarian cyclicity. Control mares resumed cyclicity in the following spring.

Accepted Manuscript

ACCEPTED MANUSCRIPT

All mares were seronegative for antibodies against GnRH prior to the first vaccination and all control mares remained seronegative for the duration of the study. Compared to control mares, antibody titers of vaccinated mares were significantly greater post-vaccination (Figure 3). One mare had an antibody titer until week 20, three mares had an antibody titer until week 32, one mare had an antibody titer until week 36, and one mare maintained an antibody titer for the duration of the study (40 weeks). The three mares that did not resume normal cyclicity the following spring had antibody titers that lasted 32, 36, and 40 weeks, respectively.

Experiment 2

There were no local or systemic vaccine reactions experienced following the first or second injection. Of the 12 mares vaccinated, all but one was examined by transrectal ultrasonography 12 weeks after the initial vaccination, during the spring. All of these mares had follicles < 20mm and no corpora lutea were present based upon ultrasonographic evaluation.

As expected, progesterone concentrations were basal (<1.0 ng/mL) in all mares when they were vaccinated initially during the winter-early spring. However, progesterone concentrations remained basal through the late spring and early summer (weeks 12 and 20). All mares were also seronegative for antibodies against GnRH prior to the first vaccination and all developed a GnRH antibody titer post-vaccination that peaked at week 12 (Figure 4).

Owner pre-vaccination and post-vaccination estrous behavior scoring was available from nine mares (Table 1). Common behaviors reported included poor performance under saddle, distractability, irritability, aggression towards other horses or handler, and frequent attempts to evade work. Estrous behaviors diminished completely in all mares, a significant decrease

Accepted Manuscript

ACCEPTED MANUSCRIPT

227 compared to pre-vaccination (p=0.004) (Table 1). Furthermore, all owners reported that they
228 would be interested in yearly revaccination.

229

230 **Discussion**

231 In the United States, there is a need for a safe, effective, and long-lasting method to
232 suppress estrous ovarian cyclicity and subsequent unwanted estrous behavior in mares. This
233 study demonstrated that immunizing mares against GnRH using a vaccine labeled for dogs safely
234 elicited GnRH antibody formation that suppressed estrus. The clinical study component also
235 demonstrated owner satisfaction with the product.

236 Forty weeks after initial vaccination, 50% of the vaccinated mares in experiment 1
237 returned to normal cyclicity whereas the remaining 50% of mares had sustained estrus
238 suppression. Differences in individual responses with regard to estrus suppression in mares was
239 also observed when using Equity® (Elhay et al., 2007) and Improvac® (Imboden et al., 2006) as
240 well as a non-commercial GnRH vaccine (Dalin et al., 2002). Variation in response to GnRH
241 immunization has also been reported in other female species, including the queen (Levy et al.,
242 2011), heifer (Prendiville et al., 1995), and deer (Miller et al., 2000). It has been speculated that
243 genetic differences among individual animals is responsible for variations in immune response
244 (Miller et al., 2000); however, what these differences are has not yet been elucidated.
245 Regardless, differing individual responses should be expected when immunizing against GnRH.

246 The reversibility and the effect of GnRH immunization on fertility is unknown. Equity®
247 does not recommend vaccinating mares later intended for breeding (Pfizer Animal Health
248 Australia, 2008) considering response to vaccine is variable. One study investigating the

Accepted Manuscript

ACCEPTED MANUSCRIPT

reversibility of Improvac® in mares found that 47/51 mares returned to normal cyclicity by 103 weeks after initial vaccination with a mean of 60 weeks; of the 4 mares that were still not cycling, all were ≤ 4 years of age (Schulman et al., 2013). Another study observed the effect of Equity® on fertility and achieved high rates of pregnancy for the two seasons following the season the mares were vaccinated (Card et al., 2007). While the current study was unable to continue monitoring the vaccinated mares that did not resume cyclicity, the three vaccinated mares that did resume cycling the following spring were artificially inseminated to determine whether their fertility had been compromised. Pregnancy was achieved in all three mares on the first cycle, which was in agreement with the findings regarding fertility following use of Equity® (Card et al., 2007).

With regards to behavior, mares display estrous behaviors even when they are not in the vicinity of a stallion, and these behaviors adversely affect performance (Jorgensen et al., 1996; Spiker, 2009). While these non-reproductive estrous behaviors are variable between mares, individuals have a relatively consistent style of estrus from one cycle to the other (Pryor and Tibary, 2005), allowing for owners to make definitive differentiations between non-reproductive estrous behaviors and other unrelated behaviors. The most frequently reported unwanted estrous behaviors in this study are in concordance with other reported behaviors as a result of estrus in performance mares (Jorgensen et al., 1996). By demonstrating diminished non-reproductive estrous behaviors in multiple mares as recognized by the owners, we were able to establish high owner satisfaction with the product and a desire to continue yearly vaccination regimens.

In conclusion, immunization against GnRH using Canine Gonadotropin Releasing Factor Immunotherapeutic® is a safe, effective, and long-lasting method for suppressing estrus in mares. Variability in duration of suppressed estrus is to be expected.

Effects of prolonged immunocontraception on the breeding behavior of American bison

Calvin L. Duncan, Julie L. King, and Paul Stapp*

Department of Biological Science, California State University, Fullerton, CA 92831, USA (CLD, PS)
Catalina Island Conservancy, Avalon, CA 90704, USA (CLD, JLK)

** Correspondent: pstapp@fullerton.edu*

In late 2009, the Catalina Island Conservancy began using fertility control to replace periodic removals to manage an introduced population of American bison (*Bison bison*) on the island. Through the application of the immunocontraceptive vaccine porcine zona pellucida (PZP), population growth was slowed within 1 year, and halted over time. In response to lingering questions about the use of PZP to manage large, free-ranging wildlife populations, we sought to determine the reversibility of PZP by ceasing the annual application to a subset of 15 bison cows and monitoring for subsequent calf arrival, and to document changes in the timing and length of the breeding season in response to PZP by monitoring breeding behavior and assessing fecal progesterone (FP) levels for all 60 resident cows over a 13-month period. As of June 2017, no new calves had been observed on the island, suggesting that, following repeated annual treatment with PZP (3 or 4 years), bison do not resume normal reproduction for at least 4 or 5 years, and that fewer treatments would be advisable if a faster return to fertility is desired. Based on observations of bull and cow behavior, and FP levels, cows displayed estrous cycles consistently throughout the study period, indicating that bison may ovulate year-round when conception and its consequences, e.g., lactation and presence of calves, are blocked. Because there is little evidence that an extended breeding season would negatively impact the health of bulls or result in large numbers of out-of-season births on Catalina, PZP appears to be a highly effective tool for managing the population of introduced bison on the island. However, the extended period of contraception and breeding activity of both cows and bulls may make PZP less suitable in high-latitude, predator-rich environments where bison conservation remains a top priority.

Key words: *Bison bison*, Catalina Island, immunocontraception, non-lethal population control, PZP, reproductive behavior

Historically, humans have altered wildlife abundance in many ways, including eliminating predators to protect themselves and their livestock, over-harvesting game species, and introducing both non-native and domestic species to new areas where they outcompete or displace native wildlife. The resulting population imbalances require informed management to prevent habitat destruction caused by overgrazing, and the extinction of native species from competition or predation (Asa and Porton 2005). Lethal control, used historically for wildlife species considered pests, is no longer socially acceptable in many parts of the world, and translocation may result in the death of the translocated animals or of other animals in their new range (Conover 2002; Asa and Porton 2005). Translocation efforts can also transport diseases or parasites between populations (Woodford and Rossiter 1993).

Contraception, and especially immunocontraction, is increasingly used for non-lethal control of wildlife populations, especially for species that are non-native or risk overabundance. Using the same principles as disease prevention through vaccination, immunocontraceptive agents are administered in small doses that stimulate the immune system of the target animal to produce antibodies that target and disrupt an essential aspect of reproduction (Kirkpatrick and Turner 1991). Porcine zona pellucida (PZP) vaccine, one of several immunocontraceptive vaccines registered or in development, has been widely used in zoos (Frank et al. 2005) and for free-ranging wildlife (Kirkpatrick and Turner 1991). PZP works by disrupting the zona pellucida, the non-cellular capsule that surrounds all mammalian eggs. This membrane is composed of glycoproteins that act as sperm receptors to facilitate sperm attachment and subsequent fertilization of the egg. When injected into the muscle of the target female, the PZP vaccine (derived from eggs of domestic swine *Sus scrofa domesticus*) stimulates

© 2017 American Society of Mammalogists, www.mammalogy.org

her immune system to produce antibodies against the proteins in the vaccine. These antibodies target the similar protein in the zona pellucida of her eggs, attach to sperm receptors, and thereby block fertilization (Liu et al. 1989; Barber and Fayrer-Hosken 2000). The widespread use of PZP can be attributed to its success in controlling reproduction of wild horses (*Equus caballus*—Kirkpatrick et al. 1990; Turner et al. 1997; Ransom et al. 2011) and white-tailed deer (*Odocoileus virginianus*—Turner et al. 1996; McShea et al. 1997; Miller et al. 1999).

The American bison (*Bison bison*) was nearly driven to extinction by overexploitation (Hornaday 1889). Conservation efforts to recover bison populations continue throughout much of North America, but the growth of localized wild herds in some areas, including locations outside of their native range, has created conflict with human interests and other management objectives (Garrott et al. 1993—Plumb et al. 2009). One such area is Santa Catalina Island (hereafter, Catalina), 1 of the 8 California Channel Islands, United States. In 1924, approximately 14 bison were introduced to the island, and were immediately embraced by the island's residents as a possible draw for tourists. Genetic variation within the herd was supplemented through the addition of a total of 45 bison between 1934 and 1996, and, at its largest known size in 1987, the herd exceeded 520 individuals (Sweitzer et al. 2005; Duncan et al. 2013). However, in response to the cumulative ecological impacts of introduced mammalian herbivores on the island, beginning in 1969 bison were periodically captured and shipped to the mainland, with the aim of keeping the herd relatively small and minimizing their effects on native plants and animals (Sweitzer et al. 2005).

Since 1972, the Santa Catalina Island Conservancy (hereafter, Conservancy) has been responsible for managing ecological resources on the island, including the bison herd (O'Malley 1994). To better understand their ecological effects, in 2002, the Conservancy commissioned a multiyear population study (Sweitzer et al. 2003) to examine multiple management approaches, all of which included the maintenance of a bison population on Catalina at some level. Sweitzer et al. (2003) suggested that approximately 142 bison could be maintained within their current range of 16,200 ha on the island's East End, while "providing an acceptable level of protection for the unique natural resources on the island, including endemic plants and animals" (Sweitzer et al. 2003). In an attempt to balance potential ecological impacts with the demand for public viewing opportunities, the Conservancy set a goal of maintaining the herd at approximately 150–200 individuals on the East End (Duncan et al. 2013). However, maintaining this target herd size through occasional removals became unsustainable due to the high costs, concerns about the potential stress on animals during transport, and the expansion of the herd between shipments (Duncan et al. 2013). Additionally, genetic testing suggested a relatively high prevalence of cattle gene introgression in the Catalina herd, which raised concerns about shipping bison to mainland herds with no historical or genetic evidence of hybridization with cattle (Vogel et al. 2007). Given these circumstances, the Conservancy investigated potential methods of fertility control, including immunocontraception, as an alternative to translocation and culling (Duncan et al. 2013). PZP was selected because decades of research on wild horses had demonstrated its safety in pregnant mares, and because it had been shown to increase body condition and longevity in mares treated chronically (Kirkpatrick and Turner 2002, 2003; Turner and Kirkpatrick 2002). The reversibility of PZP, i.e., the ability of an individual to reproduce after cessation of treatment, had also been documented in multiple species, including horses (Liu et al. 1989; Kirkpatrick et al. 1991; Kirkpatrick and Turner 2002), white-tailed deer (Turner et al. 1996), and African elephants (*Loxodonta africana*—Fayrer-Hosken et al. 2000).

Based on its well-documented safety, efficacy and reversibility characteristics, its low cost, and the ability to deliver the vaccine remotely, PZP was first administered to cows in the Catalina herd during 2 roundups in 2009. The first (September 2009) facilitated a final shipment of 149 bison off the island and reduced the island herd to approximately 120 individuals (Table 1). The second (November 2009) supported sample collection, ear tagging, and the application of PZP to approximately 76% of the remaining bison cows (Duncan et al. 2013). The protocol developed by the Science and Conservation Center (Billings, Montana) for species such as bison, with a fairly well-defined breeding season, required a minimum of 2

Table 1.—Annual calving and adult mortality rates calculated for a free-ranging bison (*Bison bison*) herd on Catalina Island, California, prior to porcine zona pellucida (PZP) vaccination (2010) and post-PZP vaccination (2011–2016). Data from 2010 to 2012 from Duncan et al. (2013).

inoculations during the 1st year of treatment. The 1st inoculation (primer) was administered 1–2 months prior to breeding activity or rut, with the 2nd inoculation 2–6 weeks later, but no later than 1–2 weeks prior to the onset of breeding activity. Infertility could then be maintained by administering a single booster annually, or could be reversed by ceasing booster inoculations (Kirkpatrick and Turner 2002).

By early 2010, all calving-age cows (≥ 2 years old; $n = 43$) in the population had received the vaccine during the roundups or remotely via darting. Pregnancy testing, completed during the November 2009 roundup, confirmed that 67% (29) of these cows were already pregnant when they received their 1st dose and all successfully produced calves in the spring of 2010 (Duncan et al. 2013). The resulting calving rate of 67.4% (29/43) was identified as the pre-PZP calving potential for the herd. The 2010 calving rate was somewhat higher than that estimated by Sweitzer et al. (2003) in 2001 (49%) and 2002 (35%), presumably due to the reduced herd size (120 versus 303–379 animals) and improved resource availability in 2010. By 2011, the calving rate was reduced to 10.4%, and to 3.3% by 2012 (Table 1). The arrival of calves in 2011 and 2012 was attributed to difficulty in identifying unmarked individuals during early vaccine administration efforts, and a single cow that apparently did not respond to the vaccine during her 1st year of treatment. These problems were resolved through follow-up vaccinations, and the efficacy of PZP in bison on Catalina has been consistently 100% since (Duncan et al. 2013). PZP had been shown to be effective in captive bison (Frank et al. 2005), but our study was the 1st time that PZP had been administered to a large, free-ranging bison herd.

Although the bison contraception program met its initial goal of halting population growth by reducing the calving rate, several key problems remained to be addressed to demonstrate that PZP could be an effective method for long-term, population-wide control of fertility in bison. First, the use of contraceptives to manage high-profile species has raised public concerns about the long-term health of treated populations, and their ability to resume reproduction successfully when the vaccine is no longer administered (Kirkpatrick and Turner 2002). Reversibility has been documented in many but not all species treated with PZP, and the length of time required for the resumption of fertility has varied considerably. On Assateague Island National Seashore, Maryland, Kirkpatrick and Turner (2002) assessed reversibility in wild horse mares after 1–7 consecutive years of treatment with PZP. Of the 53 mares treated with PZP for 1, 2, or 3 consecutive years, 100%, 100%, and 69%, respectively, became fertile within 4 years of the cessation of treatment, and all of the mares that received PZP for 4 or 5 consecutive years returned to fertility within 8 years (Kirkpatrick and Turner 2002). Lyda et al. (2013) showed that female Dall sheep (*Ovis dalli dalli*) and domestic goats (*Capra hircus*) maintained high antibody titers to PZP antigens for 3 years after a single year's treatment (primer and booster), but that antibody titers in lowland wisent (*Bison bonasus*) and Javan banteng (*Bos javanicus*), species that are more closely related to bison, returned to relatively low levels within only 9 months. Lyda et al. (2013) emphasized the variability among ungulate species and recommended a conservative approach to the application of PZP if a quick return to fertility is desired. In light of this interspecific variability, it was imperative to determine the reversibility of PZP in bison.

A 2nd concern was that PZP would alter the reproductive behavior of bison, specifically, the timing and duration of the breeding season. Adverse changes associated with social behaviors, aggression, and movement and activity patterns have been documented in animals treated with hormone-based fertility control agents (Powell 1999). However, PZP is not hormone-based and the antigen is extremely specific and does not cross-react with other tissues or hormone proteins (Palm et al. 1979; Barber and Fayrer-Hosken 2000). Further, PZP acts upon physiological processes that occur near the end of the reproductive cycle, and therefore does not interfere with other reproductive events (Kirkpatrick et al. 2011). PZP therefore was not expected to elicit behavioral changes as a direct result of vaccine administration. Nonetheless, it is conceivable that the successful act of blocking conception and the absence of calves in the population might alter the behavior of both males and females. These changes may be subtle or inconsequential in captivity, but may be significant for free-ranging populations. Potential concerns include the belief that prolonged or out-of-season breeding behavior as a result of blocked conception and repeated estrous in female ungulates could reduce energy reserves of competing males, especially in populations subject to periods of resource scarcity (McShea et al. 1997; Nuñez et al. 2009; Delsink et al. 2013). Others have speculated that once PZP antibodies decline, offspring could potentially arrive out of season or asynchronously, leaving them more susceptible to adverse weather or predators (Nuñez et al. 2010; Ransom et al. 2013).

Out-of-season breeding activity has been documented in studies of PZP application to free-ranging elk (*Cervus elaphus*—Heilmann et al. 1998) and white-tailed deer (McShea et al. 1997). However, inferences from the elk study are limited because few individuals were treated with PZP, and, in cervids, the breeding season tends to be more regulated by the testicular-antler rhythms of males and is therefore more finite (McShea et al. 1997). Long-term treatment of wild horse mares on Assateague Island did not significantly alter their social organization or behavior (Powell 1999; Kirkpatrick et al. 2011). In other locations, however, PZP-treated mares changed social bands more frequently outside of the breeding season than untreated mares (Nuñez et al. 2009), had different time-activity budgets than untreated ones (Ransom et al. 2010), and cycled and produced foals outside of the normal season (Nuñez et al. 2010; Ransom et al. 2013). Although these studies have been criticized for their small sample sizes and inadequate controls (Kirkpatrick et al. 2011), at minimum they suggest that PZP might alter reproductive behavior of some wildlife species.

In the continental climatic conditions that characterize their native range in the Great Plains of North America, bison generally breed from late June or early July through September, with the majority of breeding activity or copulations occurring

from mid-July through mid-August (Meagher 1986). Out-of-season births have been recorded in many bison herds, but the calving season generally extends from early April through early June, with births concentrated from late April to mid-May (Meagher 1986; Pac and Frey 1991; Berger and Cunningham 1994). The timing of the breeding season of bison on Catalina has been poorly documented. Lott and Minta (1983) reported that bison on Catalina initiated breeding much earlier in 1975 (30 May–24 July [55 days]) than in most mainland herds, presumably because of California's milder Mediterranean climate and seasonality of available resources. More recently, Sweitzer et al. (2003) identified the 90% calving period (the shortest interval in which 90% of the calves were born) in 2002 as occurring over a 3- to 4-week period from mid-April to early May (approximately 24 days), suggesting that, with a gestation period of about 275 days, conception occurred from about 14 July to 7 August 2001. Using a similar approach in 2010, prior to the administration of PZP, we identified the 90% calving period as occurring from 5 March to 17 May 2009 (73 days), suggesting that most conception occurred from early June to mid-August the previous year. These data suggest a somewhat earlier onset and expanded breeding season compared to bison in other locations and from previous research on Catalina; however, a distinct, synchronous calving season has always been apparent. Given the variability between studies, additional data were needed to determine how cessation of conception using PZP would affect breeding behavior and the seasonality of reproduction of bison on Catalina.

Our goals were to investigate the reversibility of PZP in bison after several years of treatment by ceasing administration of the vaccine to a subset of cows and monitoring for new calves, and to determine if the successful blocking of conception by PZP altered the length of the bison breeding season. We hypothesized that bison cows kept infertile for 3 or more consecutive years through PZP treatment would produce calves within 3 years of cessation of booster inoculations. Moreover, at the population level, we predicted that the administration of PZP would not significantly alter the length or seasonality of the breeding season. We interpreted our results in terms of their implications for the continued maintenance of bison on Catalina, and assessed the relevance of our results for efforts to manage bison populations elsewhere.

Materials and Methods

All animal handling and PZP application procedures were performed under an approved protocol from the Institutional Animal Care and Use Committee at California State University Fullerton, and were consistent with ASM guidelines for research on mammals (Sikes et al. 2016).

Study area.—Santa Catalina Island (194 km^2), located approximately 40 km west of Los Angeles, California, United States, has a rugged mountainous terrain, with a central ridge running its length (Fig. 1). The elevation ranges from sea level to 640 m, and a narrow isthmus (< 800 m wide) separates the island into 2 geographically distinct sides: the larger East End, comprising 84% of the island, and the smaller West End, comprising the remaining 16% (Schoenherr et al. 1999). The island has a semiarid Mediterranean climate, with average annual precipitation from 2013 to 2015 of 146.6 mm (WRCC 2016), most of which falls between November and April. Common plant communities include coastal sage scrub, coastal bluff scrub,

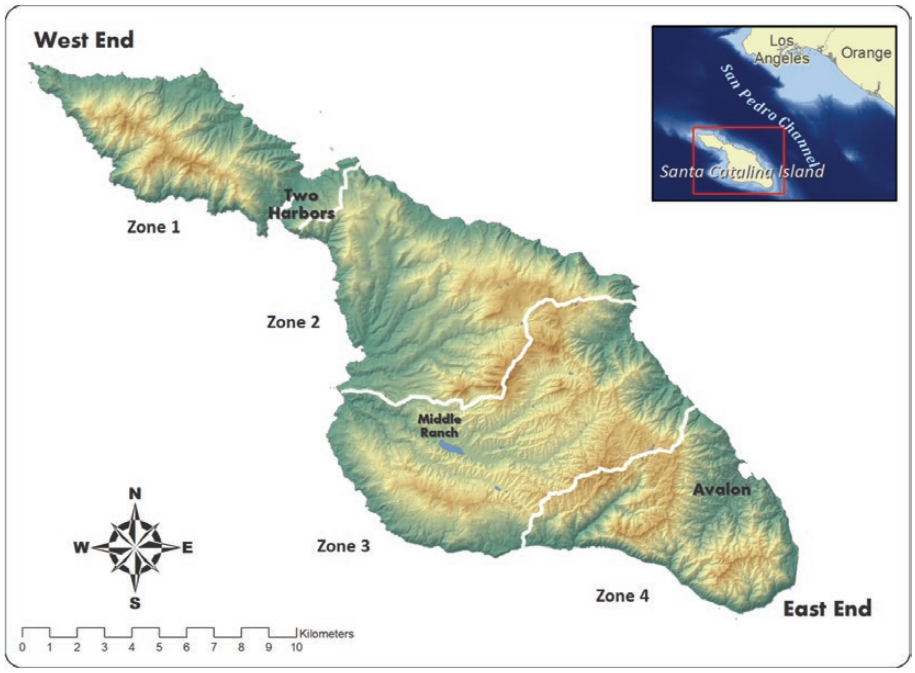

Fig. 1.—Map of Santa Catalina Island, California, illustrating locations of 3 cross-island fences that partition the island into 4 zones. Zone 1 is free of bison (*Bison bison*), whereas Zones 2, 3, and portions of 4 are occupied by bison. Avalon and Two Harbors are the largest human communities on the island. Inset shows the location of Catalina in relation to mainland southern California.

island chaparral, island woodland, riparian woodland, and coastal grassland (Schoenherr et al. 1999). Catalina is home to more than 60 endemic species of plants and animals. It has a resident human population of approximately 4,050, > 90% of which live in the town of Avalon (King et al. 2014), and receives an average of 800,000 visitors annually, making it the most populous of the California Channel Islands.

Although no large mammalian herbivores are native to the island, non-native grazers were introduced over the past 2 centuries. Feral goats were established on the island in the early 1800s, and domestic cattle, horses, and sheep (*Ovis aries*) were present by the 1890s. Feral pigs (*Sus scrofa*) were initially established in the 1930s (Schuyler et al. 1998). Domestic cattle (*Bos taurus*) operations ceased by the 1950s (Schoenherr et al. 1999), and pigs and goats were eradicated between 1990 and 2004 (Schuyler et al. 1998; Sweitzer et al. 2005). Mule deer (*Odocoileus hemionus*) were introduced to the island in 1928 and have been managed since 1998 through a private land management hunting program (Stapp and Guttilla 2006).

Breeding behavior and reproductive physiology of bison.—Bison are sexually dimorphic, with males (544–907 kg) weighing 60–70% more than females (Meagher 1986). The mating system has been characterized as male dominance polygyny (Lott 1981). Sexual maturity in both female and male bison generally occurs at 2–4 years of age; however, bulls usually do not have the opportunity to breed until age 6 (Meagher 1986). Mixed-sex herds comprised of females and young or subdominant bulls (usually the offspring of cows within the group) may be observed throughout the year. Mature bulls often seek solitude or are found in small bachelor groups during the non-breeding season, and then join the larger cow groups during the rut, when herd sizes are at their peak (Lott 1981). Bulls can identify cows in or near estrus by sniffing or licking their urine or anogenital region and performing *flehmen*, a lip curl and inhalation response that exposes the vomeronasal organ to a scent or pheromone (Mahan et al. 1978; Lott 1981; Mooring et al. 2006).

Once a bull becomes interested in a specific cow, he will tend or guard her, remaining in close proximity, often impeding her movement and warding off other bulls until he is either permitted to copulate with her or is displaced by a rival (Lott 1981; Wolff 1998). Bulls communicate their dominance and desire to mate through posturing, bellowing, pawing, rubbing, scent-urinating, and wallowing (Mooring et al. 2006). A tended cow often attracts rival bulls and head-to-head battles may ensue (Wolff 1998). The breeding season or rut can be particularly taxing for bulls as they may forgo feeding, deplete fat reserves through increased activity, and be injured during battles (Lott 1979; Roden et al. 2011).

Immediately following copulation, which lasts only a few seconds, the cow arches her back, voids a small volume of milky secretions from the vulva (presumably semen), and erects her tail (Lott 1981; Berger and Cunningham 1994; Wolff 1998). Cows elevate their tails for other reasons (urination, defecation, or agitation), but this post-copulation 'tail-up' response is distinctive in that the tail is raised at an angle of approximately 135° or higher and is maintained for 1–2 days (Komers et al. 1992; Wolff 1998; Mooring et al. 2006). This behavioral indicator of copulation is very reliable and can be used to infer copulation (Berger and Cunningham 1991; Wolff 1998; Vervaecke and Schwarzenberger 2006). Though uncommon, superficial oval-shaped wounds caused by a mounting bull's hooves scraping the cow's back have been observed in recently bred cows and may also be an indicator of breeding (Lott 1981). Cows remain sexually receptive for 9–28 h (Haugen 1974).

Unlike domestic cattle, bison were initially thought to be monestrous (Rutberg 1986) or to only rarely undergo a 2nd estrus in a given year (Haugen 1974). Kirkpatrick et al. (1991a) used urinary steroid metabolites to document definitive estrous cycles of captive bison and reported that 7 of 8 cows became pregnant during their 2nd cycle and subsequently produced calves. The arrival dates for those calves also supported the occurrence of a 2nd seasonal estrus. Vervaecke and Schwarzenberger (2006) used fecal progesterone (FP) metabolites to identify 3 ovulatory periods, and consequently, bison are now considered seasonally polyestrous.

The reproductive physiology of bison is similar to that of domestic cattle. The estrous cycle, as described by Turner (2014), averages 21 days in length (range 17–24). A period of standing heat or estrus, marked by a rise and peak in estrogen secretion, initiates the cycle. Estrus lasts 12–24 h, and ovulation occurs approximately 12 h after the end of estrus. After ovulation, cells that make up the ovulatory follicle differentiate to form the corpus luteum (CL), which, in turn, produces progesterone. Progesterone levels rise substantially and peak after approximately 15–16 days when the CL is fully mature. After approximately 16 days of elevated progesterone, prostaglandin is released by the uterus, resulting in the lysis of luteal tissue and the regression of the CL. Circulating progesterone begins to decline and the luteal phase of the estrous cycle ends. The decline in progesterone triggers increased pulses of gonadotropin-releasing hormone, which, in turn, stimulates the production of follicle-stimulating hormone and luteinizing hormone (LH). Increases in these hormones support the development of another ovulatory follicle, which results in an increase in estrogen. Once estrogen peaks, a surge of LH is released and ovulation occurs again.

Photoperiod has been identified as a cue for reproduction for many wild ungulates, and plant phenology and predation have been implicated as factors contributing to birth synchrony (Rutberg 1984; Green and Rothstein 1993; Zerbe et al. 2012). The breeding season, or rut, of bison has been estimated several ways, such as recording the timing of specific breeding behaviors (tending, copulations, and post-copulation 'tail-up' responses of cows), by subtracting gestation length (approximately 265–285 days—Haugen 1974; Rutberg 1986) from parturition, or by monitoring changes in reproductive hormones. Each approach has its own challenges and assumptions. For instance, subtracting gestation length from parturition can provide an estimate of the date of successful conception, but does not yield information on unsuccessful copulation attempts. Brief actions or signs associated with breeding behavior may

go undetected when attempting to monitor a large free-ranging population. Assessment of changes in hormones may expand the period of detection, but the collection of adequate blood, urine, or fecal samples systematically from large populations of wild bison can be difficult, dangerous, and expensive. For these reasons, we used a combination of observational and endocrine-based methods to assess changes in the seasonality of breeding behavior in response to PZP application.

PZP vaccine preparation and administration.—The native PZP antigen was prepared at the Science and Conservation Center from porcine oocytes, using the modified method of Dunbar et al. (1980). Antigen samples were shipped to Catalina on dry ice and stored frozen (−10°C) until time of use, under the authority of the Food and Drug Administration Investigational New Animal Drug Exemption (No. 8840-G003-004). The vaccine consisted of 0.5 ml standard phosphate buffer solution containing 100 µg of PZP emulsified with 0.5 ml Freund's Modified Adjuvant (FMA; Calbiochem, La Jolla, California) for all initial (primer) inoculations, and 0.5 ml Freund's Incomplete Adjuvant (FIA; Sigma, St. Louis, Missouri) for all subsequent booster inoculations. The emulsion was prepared within minutes prior to injection using 2 10-ml glass syringes joined with a Luer-Loc connector. After 100 plunger strokes, the emulsion was loaded into 1.0-ml Pneu-Dart type "P" darts with 3.8-cm barbless needles (Pneu-Dart, Williamsport, Pennsylvania) to facilitate remote delivery using an X-Caliber gauged CO_2 rifle (Pneu-Dart). At the beginning of each darting season, the tail fin of each dart was painted red or orange using Rust-Oleum specialty fluorescent spray paint and numbered to facilitate dart recovery and tracking of vaccinations. Immediately after loading the dart a small dab of petroleum jelly was applied to the tip to prevent PZP leakage. Prepared vaccine was stored in a refrigerator and transported to the field in an ice chest. Treated cows were darted in the caudal thigh or gluteus muscle.

Following the roundup and shipment of bison off-island in late 2009, all calving-age (≥ 2 years old) cows were treated with PZP each year from 2010 to 2012 (Table 2). In 2013, the herd consisted of approximately 138 individuals, 61 of which were calving-age cows. Primer inoculations of PZP + FMA were administered in March 2013 to 5 bison cows that were born in 2011. Booster inoculations of PZP + FIA were administered from February to April 2013, to 51 of 61 cows; from March to April of 2014, to 45 of 60 cows; and from March to April 2015, to 45 of 59 cows (Table 2). These represented all breeding-age cows in the Catalina herd each year. Bison cows were identified through a combination of numbered ear tags (Richey Livestock ID, Brighton, Colorado; applied during previous roundups) and photographs highlighting key features such as horn characteristics, pelage color, and natural markings.

Reversibility testing.—To assess the reversibility of PZP in bison, the vaccine was withheld from 10 cows (ages 5–11 years) beginning in 2013, and 5 additional cows (ages 8–14 years) in 2014. All but 1 of the Reversal cows were within the range of ages in which the highest fecundity in bison cows has been documented (3–13 years old—Berger and Cunningham 1994). One of the 10 initial Reversal cows died from a leg injury, naturally caused, in late 2014. The vaccine was withheld from the 14 surviving individuals again in 2015, and no cows received PZP in 2016 (Table 2). Reversal cows had received PZP inoculations for 3 (initial 10 cows) or 4 (additional 5 cows) consecutive years; because of the staggered entry (young cows) and exits (deaths) from the program, PZP-treated cows were

Table 2.—Annual treatment schedule and delivery method of porcine zona pellucida (PZP) to free-ranging, breeding-aged bison (*Bison bison*) cows on Catalina Island, California, from 2009 to 2012 (Duncan et al. 2013) and 2013 to 2015. The number of treated cows was not necessarily the number of cows in the population that year because cows might have died between January and the darting period. FMA = Freund's Modified Adjuvant; FIA = Freund's Incomplete Adjuvant.

Year	Month(s)	Activity	Delivery method	Primer/booster	Adjuvant	Cows
2009	Sep.–Nov.	Roundup	Syringe	Primer	FMA	35
2010	Feb.–May	Field darting	Dart	Primer	FMA	12 of 13[a]
2010	Apr.–Jul.	Field darting	Dart	Booster	FIA	45 of 47[b]
2011	Apr.–Jun.	Field darting	Dart	Booster	FIA	48[c]
2011	Dec.	Roundup	Syringe	Primer/booster	FMA/FIA	13[d]/4
2011	Dec.	Field darting	Dart	Primer	FMA	1[d]
2012	Jan.	Field darting	Dart	Primer	FMA	1[d]
2012	Apr.–May	Field darting	Dart	Booster	FIA	60[e]
2013	Mar.	Field darting	Dart	Primer	FMA	5[f]
2013	Feb.–Apr.	Field darting	Dart	Booster	FIA	51[g]
2014	Mar.–Apr.	Field darting	Dart	Booster	FIA	45[h]
2015	Mar–Apr.	Field darting	Dart	Booster	FIA	45[i]

[a]Additional unmarked adult cow was present but not detected in 2010.
[b]One geriatric cow died early in the year.
[c]One additional adult bison cow was discovered in the population.
[d]Fifteen juvenile cows born in 2010 reached maturity and were added to the program.
[e]Three geriatric cows died between October 2011 and February 2012, and 5 additional geriatric cows died between June and December 2012.
[f]Five juvenile cows born in 2011 reached maturity and were added to the program.
[g]PZP vaccine withheld from 10 adult bison cows (reversibility testing).
[h]One geriatric cow died in late 2013 and PZP vaccine was withheld from 5 additional adult bison cows (reversibility testing).
[i]PZP vaccine withheld from same 14 remaining Reversal cows.

vaccinated annually a total of 6 times (22 cows), 5 times (2 cows), 4 times (16 cows), and 3 times (5 cows) between 2010 and 2015. All cows in the population were monitored regularly from 2013 through November 2016 to document calf arrival. Using Kirkpatrick and Turner's (2002) 8-year study of reversibility in wild mares as a guide, we expected approximately 6 (67%) of the initial 9 cows, last treated in 2012, and 1 (20%) of the additional 5 cows, last treated in 2013, to produce calves by the end of 2016.

Monitoring of breeding behavior.—We monitored behavior and fecal hormone levels of all 60 surviving breeding-aged cows in the Catalina herd as of 1 June 2014. Observations and fecal-sample collections were carried out from a vehicle and on foot over a 13-month period from 1 June 2014 to 30 June 2015. Our aim was to record breeding behavior and signs from all 60 cows every 3–4 days, and to collect a fecal sample from each cow biweekly to determine FP levels. Global positioning system (GPS) collars (G2110E Iridium; Advanced Telemetry Systems, Isanti, Minnesota) were fitted on 5 mature cows on 10–11 May 2014 to assist with locating smaller groups of bison and to assess movement patterns and resource use. Monitoring of the movements of these 5 collared cows allowed us to effectively locate and sample approximately 85–90% of the Catalina herd at all times (Duncan 2017). However, adverse weather conditions, access limitations, safety concerns, and the approachability of the bison all constrained our ability to collect behavioral observations and samples systematically.

For each cow, we recorded the following potential signs of breeding activity (adapted from Vervaecke and Schwarzenberger 2006):

- Tended lightly by bull: A bull, dominant or subdominant but not one of her offspring, remained in close proximity to and followed a cow for longer than 30 min.
- Tended heavily by bull: A dominant bull remained in close proximity to a cow, and often impeded her movements. This activity was accompanied by one or more attempts to mount, cow placing her chin on the bull's back, and frequent nudging, bellowing, pawing, scent urination, as well as defensive behavior against rival bulls. This level of tending behavior occurred for a prolonged period (> 30 min) and continued until copulation or the end of an observation period.
- Tail-up partial: The cow was observed with a slightly elevated, less than horizontal, tail at the beginning of an observation period and maintained it for 1 h or more.
- Tail-up high: The cow held her tail at a horizontal angle or higher, for an extended period of several hours to several days.
- Copulation: The bull mounted the cow with intromission.
- Fresh mounting sores (FMS): The presence of fresh (new, moist, bloody) wounds on the lower back, point of hip region on either side of a cow.
- Healing mounting sores (HMS): The presence of healing (dry, scabbing) wounds, presumably > 2 days old, on the lower back, in the point of hip region on either side of a cow.

Heavy tending, tail-up high, and copulation behaviors have all been confirmed as reliable indicators of ovulation (Kirkpatrick et al. 1991a; Vervaecke and Schwarzenberger 2006), and were used independently to assess the timing of ovulation in monitored cows. Tail-up partial and light tending were not included as subcategories in previous studies, meaning that these less intensive behaviors were either included within the more general categories of "tending" and "tail-up" or were dismissed altogether. These subcategory behaviors were recorded in the field so that they could be examined separately during analysis, and to help identify individuals that were observed close to the date of ovulation.

Collection and analysis of fecal samples.—During behavioral observations, cows frequently voided feces. We marked the location of newly voided feces by fixing the location of the feces in the crosshairs of a rifle scope attached to a tripod. We used a range finder to record the distance between the tripod and the target cow. When it was considered safe to approach (within 15 min, on average, and always within 50 min of deposition), a fecal sample was collected to fill about three-quarters of a 30-ml plastic container (Sarstedt Inc., Newton, North Carolina), and placed in a cooler with ice packs. Each collection cup and lid was labeled with the cow's identification code, date, and time of fecal deposition just prior to sample collection. To ensure a homogeneous sample, fecal material was mixed thoroughly on the ground prior to collection using a single-use wooden tongue depressor. Samples were transferred to a freezer at the end of an observation period and stored frozen (−10°C) until time of shipment. Fecal samples were shipped to the San Diego Zoo Institute for Conservation Research (Escondido, California) within 6 weeks of collection for progesterone radioimmunoassay analysis.

Fecal samples were lyophilized for 72 h in a Flexi-Dry microprocessor manifold lyophiliter (FTS Systems, Inc., Stone Ridge, New York) to reduce variability in water content. Extraneous material was removed from the lyophilized feces by sifting each sample through a copper mesh screen (2 × 2 mm). A 0.1-g sample was weighed and suspended in 5 ml of 90% aqueous ethanol and boiled immediately for 20 min at 80°C. The sample was then centrifuged at 1,000 × *g* for 10 min in a Legend XTR centrifuge (Thermo Fisher Scientific, Waltham, Massachusetts). The supernatant was recovered and the pellet resuspended in 5 ml of 90% aqueous ethanol, vortexed briefly and then centrifuged. The combined supernatants were dried under a stream of filtered air and dissolved in 1 ml of 100% ethanol.

Samples were analyzed using a monoclonal progesterone antibody produced against 4-pregnen-11-ol-3,20-dione hemisuccinate:BSA (Grieger et al. 1990), which cross-reacts 100% with progesterone, 96% with allopregnanolone, and, to a lesser degree, with a number of other progesterone metabolites (Grieger et al. 1990; Wasser et al. 1994). Tritiated progesterone (10,000 cpm/0.1 ml; PerkinElmer, Waltham, Massachusetts) was used to compete against standard progesterone (7–100 pg/0.05 ml; Sigma, St. Louis, Missouri).

One microliter of the fecal extract was assayed in duplicate and incubated overnight at 4°C. After incubation, the

competitive reaction was stopped and the bound and unbound hormone were separated by adding 0.25 ml of char-dex solution to the assay, which was then incubated for 30 min at 4°C. The assay was then centrifuged at 1,000 × *g* for 15 min and the supernatant poured into scintillation vials. Scintillation fluid (3.5 ml; MP Biomedicals, Solon, Ohio) was added to each tube and the assay counted on a Beckman LS 6500 liquid scintillation counter (Beckman Coulter, Brea, California) to determine the FP level.

Data analysis.—We plotted FP levels and breeding behaviors for all 60 cows individually to detect errors and identify possible cycles. For behavioral purposes, a cow was considered to be in estrus if any 1 of 3 characteristic behaviors (heavy tending by bulls, copulation, tail held high) was observed on a given day. To produce a conservative estimate, we considered observations of these behaviors to represent different estrous cycles if they were separated by at least 20 days (Isobe et al. 2005; Turner 2014).

Using the approach of Brown et al. (2001), we estimated a baseline FP value for each cow using an iterative process in which we first calculated the mean and *SD* of all values and then excluded ones that exceeded the mean plus 1.5 *SD*. A new mean was then calculated and these steps were repeated until none of the remaining values exceeded the mean plus 1.5 *SD*. Brown et al. (2001) identified the onset of the luteal phase by the occurrence of FP values that exceeded the baseline by 50% and remained elevated for at least 2 weeks. However, they studied captive animals that were monitored frequently so that increases in FP could be easily identified. To conservatively identify estrous cycles in wild bison cows, we classified FP values as occurring in the luteal phase if they were at least 2 times higher than baseline FP. Given that, in cattle, FP is significantly higher than baseline for approximately 19 days during the estrous cycle (Isobe et al. 2005), we considered elevated FP values to be from different cycles if they were at least 20 days apart.

We were unable to calculate a baseline FP value using the Brown et al. (2001) approach for 8 cows (4 PZP-treated, 4 Reversal). Six of the 8 cows had consistently elevated FP values throughout the study period (71–100% of values > 1,000 ng/g; see "Results"). One cow (Red38) was frequently isolated from the rest of the herd and another (9046) died from a leg injury in December 2014, and so were monitored less frequently. To document the presence of estrous cycles in these 8 cows, we used the mean baseline value (338 ng/g, *SD* = 100) calculated from the other 52 cows. Data from these 8 cows were included in summaries of behavior and FP values, but were excluded from the analysis of temporal patterns in cycles across the herd.

Results

As of 1 June 2017, no calves had been detected in the herd. This included the 9 surviving Reversal cows that had not been vaccinated since 2012 (60–62 months since last booster; treated for 3 years and off for ~5 years) and the 5 Reversal cows that had not been vaccinated since 2013 (50–51 months since last booster; treated for 4 years and off for ~4 years).

For both behavioral observations and FP sampling, the number of days sampled and the number of total observations and samples collected tended to increase over the course of the 13-month study period (see Supplementary Data SD1). The fewest samples and observations were in summer 2014, whereas, except for a peak in October 2014, the most observations and samples were in spring 2015.

Breeding behavior and FP levels were plotted together for all 60 cows. Representative profiles of PZP-treated and Reversal cows (see Duncan (2017) for profiles of all cows) are shown in Fig. 2, and a summary of behavioral observations and FP sampling for all 60 cows is given in Appendix I. On average, PZP-treated and Reversal cows were sampled over similar numbers of days (67 versus 61 days, respectively). Reversal cows tended to be heavily tended and copulated more than PZP-treated ones, but the differences were relatively small. For both groups, tail-up high behavior was observed much more frequently than heavy tending or copulations (Appendix I). Fewer than one-half (43%) of all cows were observed copulating, compared to more than 70% that were tended heavily by bulls or observed with their tails held high. Tending behavior by bulls (including light tending) occurred throughout the study period, whereas most copulations were observed between September 2014 and March 2015 (Fig. 3A). Considering all types of breeding behaviors displayed by bulls and adjusting for sampling effort (number of days of behavioral observations per month), bulls apparently were most responsive to females from June 2014 to January 2015, followed by a decline through May 2015, and then increasing again in June 2015 (Fig. 3B).

The presence or absence of mounting sores was determined to not be a good indicator of breeding or ovulation. Although ovulation and breeding behavior were documented in all 60 cows, 20% (12) never developed sores, and sores were rare on many others, despite abundant evidence of breeding activity. Moreover, sores were often persistent and could not be used to indicate the specific timing of copulation. In many instances, sores were re-aggravated or maintained by scratching on trees or bushes, wallowing, or licking, and by mounting activities that were not associated with breeding.

FP values varied greatly within and among individuals (see Supplementary Data SD2). On average, 18.4 samples (range 7–29, $n = 60$) were collected from each cow (Appendix I). Reversal cows tended to have a lower minimum and baseline, and a higher maximum and range of FP values than PZP-treated cows, although these differences were not statistically significant (*t*-tests, $P > 0.135$).

We tentatively identified estrous cycles first based on behavioral observations and FP values separately. Based on behavior alone, on average, Reversal cows displayed more cycles than PZP-treated ones, but the difference was small (2.9 versus 2.5; Appendix I). Using FP levels, Reversal cows had, on average, 1 more cycle than PZP-treated cows (5.9 versus 4.9; Appendix I), but this difference was not significant ($t_{50} = 2.01$, $P = 0.15$). Fewer cycles were identified using behavior than FP values and the 2 measures only occasionally overlapped (Appendix I).

To estimate the total number of estrous cycles observed for each cow, we summed the number of behavioral and FP cycles

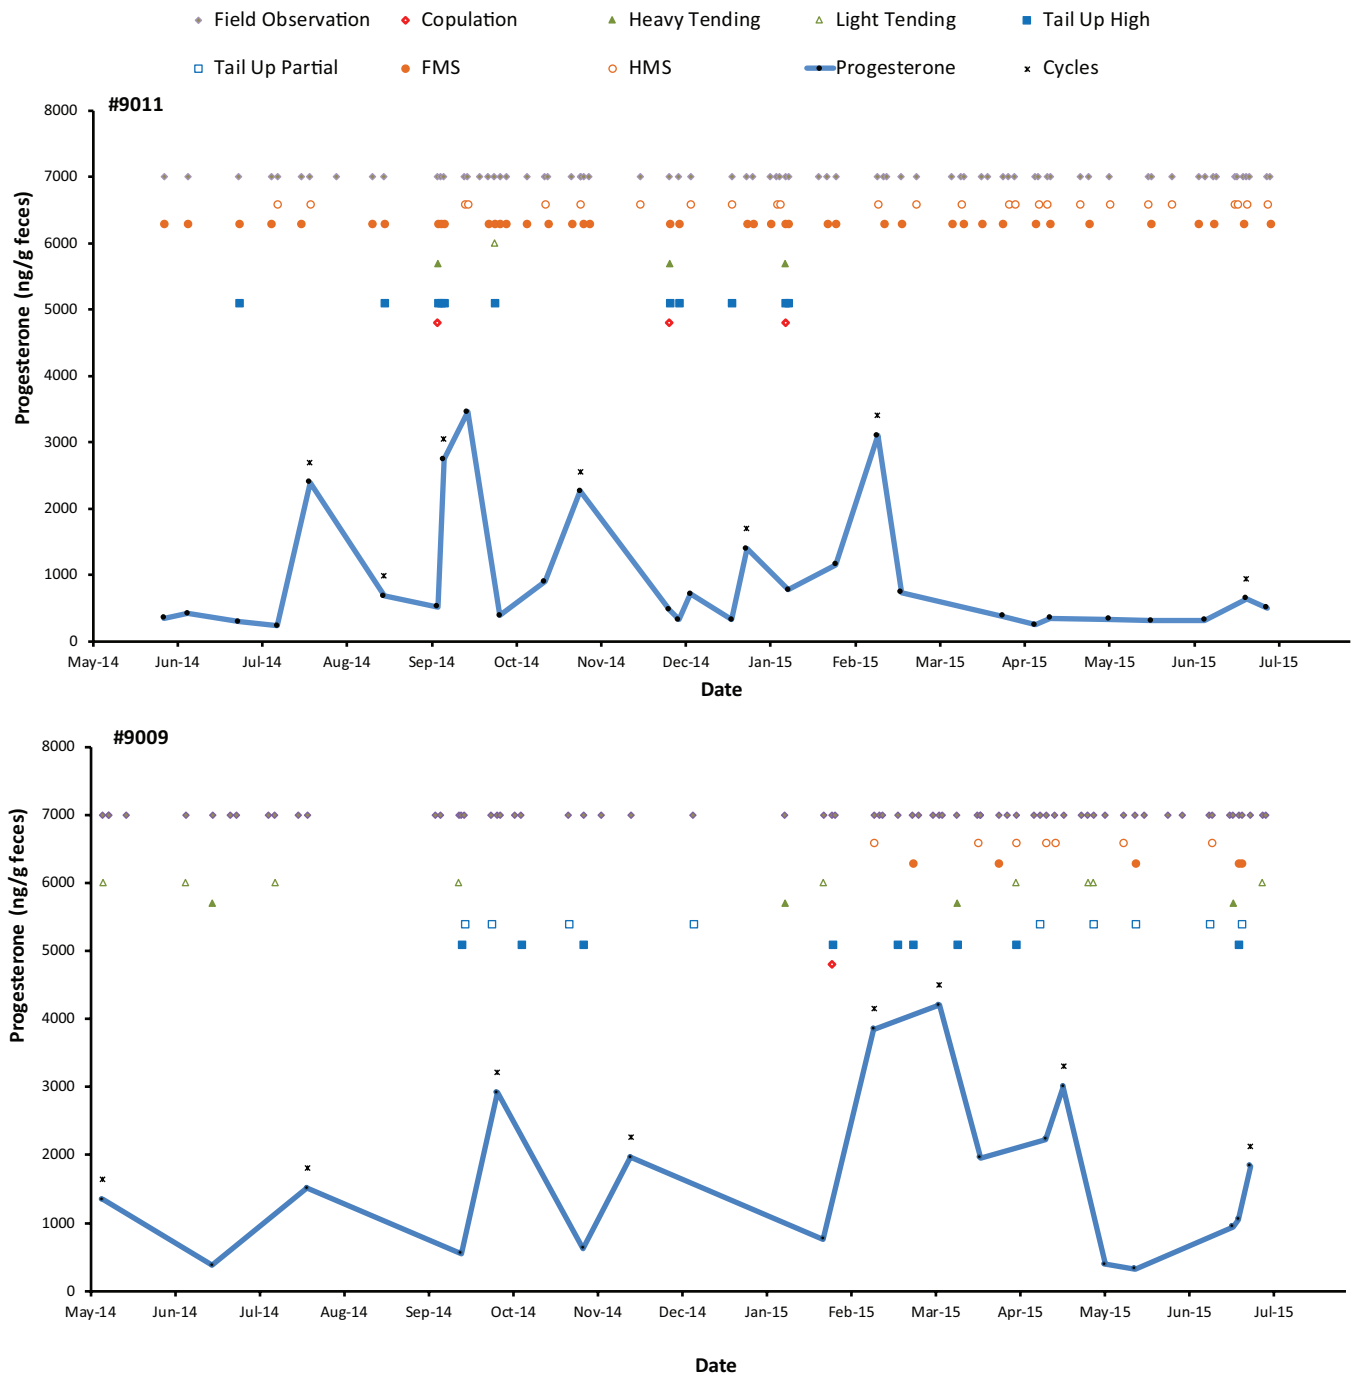

Fig. 2.—Behavioral and FP profiles of representative PZP-treated and Reversal bison (*Bison bison*) cows on Catalina Island. (top) PZP-treated cow 9011, for which 4 cycles were detected based on behavior, 7 cycles were detected based on FP levels (black stars), with 2 occasions in which behavior and FP overlapped. (bottom) Reversal cow 9009, for which 7 cycles were detected based on behavior, 8 cycles were detected based on FP levels (black stars), with 6 occasions in which behavior and FP overlapped. FP = fecal progesterone; PZP = porcine zona pellucida.

and subtracted the number that overlapped. Considering only the 52 cows with reliable FP data, individual PZP-treated cows displayed 2–12 cycles ($\bar{X}$ = 6.2, *SD* = 2.0, *N* = 41), whereas Reversal cows displayed 4–11 cycles ($\bar{X}$ = 7.3, *SD* = 2.2, *N* = 11; Appendix I), a difference of approximately 1 cycle that was not statistically significant (t_{50} = 1.45, *P* = 0.15). Estrous cycles were recorded throughout the 13-month study period (Fig. 4A). Adjusting for the number of cows studied each month (behavior: 18–44; FP: 24–49), a substantial proportion (30–70%) of the resident bison cows were in estrus each month except for April and May 2015 (Fig. 4B).

Discussion

Administration of PZP to bison cows quickly reduced and, within 3 years, completely halted calf production on Catalina Island, demonstrating for the 1st time the efficacy of PZP as a method of controlling population growth of a large, free-ranging

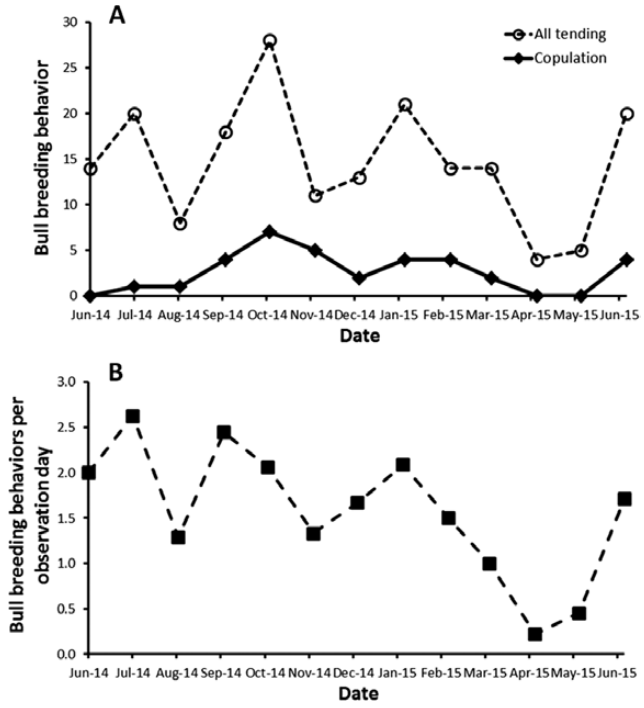

Fig. 3.—(A) Observations of light and heavy tending and copulations by bison (*Bison bison*) bulls, and (B) all bull breeding behaviors (all tending and copulations) per day of observation, tallied by month, in response to PZP treatment in cows on Catalina Island from 1 June 2014 to 30 June 2015. PZP = porcine zona pellucida.

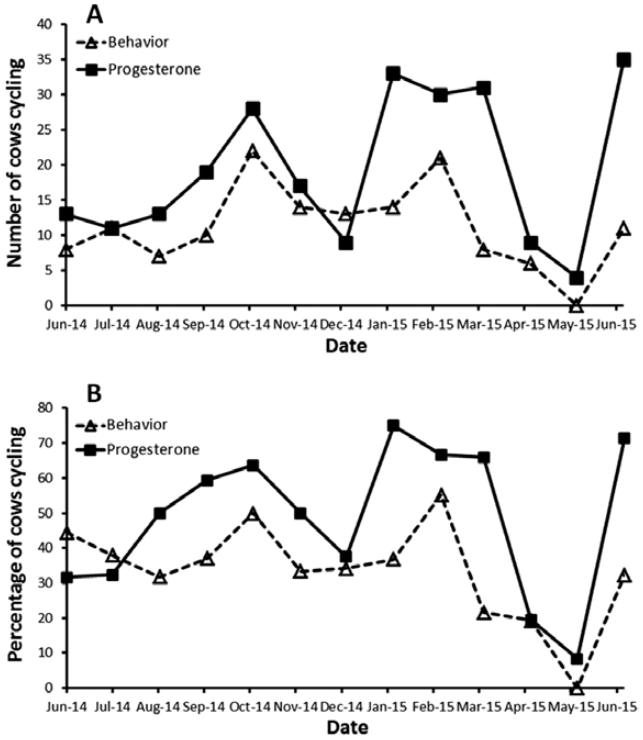

Fig. 4.—(A) Number and (B) percentage of bison (*Bison bison*) cows displaying estrous cycles, tallied by month, on Catalina Island from 1 June 2014 to 30 June 2015 in response to PZP treatment. Percentage was calculated as a fraction of the number of cows sampled in a given month. Prior to PZP treatment, the typical calving season on Catalina was from March to mid-May, indicating breeding from June to mid-August. PZP = porcine zona pellucida.

bison herd. Our success can be attributed in part to the fact that the population was closed demographically, that we were able to consistently identify and treat the entire female population, and that the agent's contraceptive effects were persistent. However, some 4–5 years have passed since PZP was administered to one-fourth (15) of the resident cows and, as of June 2017, no calves have been born on the island. Based on the documented reversibility of PZP in wild horses (Kirkpatrick and Turner 2002), we anticipated that roughly one-half of the Reversal cows would have produced calves by 2016. The shorter (9 months) return to pretreatment PZP antibody titer levels in 2 bovid species closely related to bison (Lyda et al. 2013) also encouraged us that bison might return to fertility relatively quickly. However, Ransom et al. (2013) recently found that the duration of contraception for wild horses increased with the number of years of PZP treatment, such that mares treated with PZP for 3–4 years, like the bison in our study, would not be expected to have their 1st foal until about 5–6 years later. If this pattern applies to bison, calves may not be expected in significant numbers on Catalina for several more years, especially because many cows (24; 40%) were treated for longer (5–6 years) and until as late as 2015. Based largely on our results, the Conservancy elected not to administer PZP boosters to any bison cows in 2016 and will re-assess the administration of PZP when calves are again born on the island.

It is also possible that resumption of fertility in Reversal cows has been delayed because severe drought conditions that persisted on Catalina from 2012 to 2016 reduced the amount and quality of forage. Some of the lowest pregnancy and calving rates recorded in free-ranging bison herds were documented on Catalina Island (35% in 1975 and in 2002) and on Antelope Island, Utah (46% from 1987 to 1997), and in these instances, nutritional deficiencies were suggested as the primary cause (Lott and Galland 1987; Wolfe et al. 1999; Sweitzer et al. 2003). However, the Conservancy provided bison with access to water and modest amounts of supplementary food annually throughout the drought, which should have kept bison in reasonable condition.

Because bison were reported to have at most 2 or 3 estrous cycles in a given year, we anticipated that blocking conception with PZP would, at most, modestly extend the breeding season. Aside from a brief period of low reproductive behavior and progesterone levels in mid-April through May 2015, our results instead suggest that, like domestic cattle (Garverick and Smith 1993), bison are capable of cycling nearly year-round when conception and its consequences, e.g., lactation and presence of calves, are blocked by PZP. This was evident in the behavior of the bulls as well, which continued to copulate with and tend females intensively throughout the year.

Two concerns that have been raised about an extension of the breeding season in PZP-treated ungulates are the potential impacts on the condition of males as a result of an extended rut (Nuñez et al. 2009, 2010; Delsink et al. 2013), and risks

associated with out-of-season calving (McShea et al. 1997; Nuñez et al. 2010; Ransom et al. 2013). A closer examination of the behavior of bison, specifically the frequency of shifts in dominance among bulls, and the survival of offspring born out-of-season in species subject to harsh winters, may help address these concerns, especially in comparison to the consequences of other management approaches such as removals or culling that might be applied to the Catalina herd.

Bison bulls that are 7–13 years old and weigh > 750 kg are the dominant age group, and are responsible for approximately 95% of copulations (Wolff 1998). Both tending and challenging bulls feed less during peak rut than during early rut, lose considerable amounts of weight during rut, and may sustain debilitating or life-threatening injuries during battles (Wolff 1998; Roden et al. 2011). In most herds, dominance rankings among bulls change from year to year as younger bulls mature and grow in size, and begin to challenge older or weaker bulls. Dominance may only be maintained for 2–3 weeks during the rut before an individual is displaced (Wolff 1998). Once a dominant bull is displaced, time off from tending or fighting often allows him to regain enough weight and strength to again challenge for breeding rights (Wolff 1998). Prolonged or continuous ovulation in females therefore may speed up this cycle or the rotation of bulls through periods of dominance, but it may not necessarily affect health or survival of bulls significantly.

Although we did occasionally observe head-to-head battles, in the absence of a long non-breeding period, we speculate that dominance among Catalina bulls was likely maintained through non-contact behaviors such as posturing, bellowing, head swaying, and scent urination, until a challenger reached a size and condition to confidently compete with a tending bull. Abscesses, presumably associated with battles, were occasionally observed, but dominant bulls with more serious injuries were not seen. Due to the high profile of the bison herd on Catalina, and the frequency in which they are observed by Conservancy staff, island tours, and residents, conspicuous injuries, such as a limp or open wound, are unlikely to go undetected. Based on these reports and our own informal observations, we found no evidence that the frequency of injuries or mortalities has increased as a result of the PZP program. Adult bison on Catalina have no predators, and remain brucellosis and tuberculosis free, but they still are subject to marked seasonal variations in the availability of forage and water, which were exacerbated by the drought. Given our close monitoring of the herd since the inception of the PZP program in 2009, any negative effects of an extended rut on Catalina should have been apparent by now.

At the individual level, photoperiod, temperature, vegetation green-up, and female body condition influence the timing of parturition in many ungulate species, whereas resource availability is believed to be the primary driver of birth season length in populations in highly seasonal habitats (Rutberg 1987; Green and Rothstein 1993; English et al. 2012; Zerbe et al. 2012). Because of Catalina's latitude and coastal position, these factors are mitigated to some extent compared to the Great Plains, but strong seasonal variability still occurs, in terms of pronounced wet and dry seasons. During non-drought periods vegetation green-up on Catalina generally occurs in late winter (January–February), with nutritious vegetation persisting until summer (July–August). As a result, the calving season on the island begins sooner than in most mainland herds (March versus April), but lasts about the same amount of time (Meagher 1986; Pac and Frey 1991). Out-of-season births occur in many herds (Meagher 1986; Berger and Cunningham 1994), and birth synchrony and birth season length have been found to vary due to forage availability (Green and Rothstein 1993) and population size (Meagher 1973). On Catalina, calves have been observed occasionally in September and December (Sweitzer et al. 2003) and in 2010, 2 calves were recorded in mid-February. However, the milder winter and lack of predators poses less of a mortality risk to calves born out of season on Catalina than in much of their native range. In some species, PZP application led to more out-of-season births and changes in birth synchrony (McShea et al. 1997; Nuñez et al. 2010; Ransom et al. 2013), whereas, in others, no changes were seen (Kirkpatrick and Turner 2003; Gray et al. 2010). Because we observed breeding-related behaviors and estrous cycles throughout the year, it is conceivable that declining PZP antibody titers would eventually result in more out-of-season calves on Catalina. However, until bison cows on the island again produce calves, we have no evidence that this occurs.

We underscore that bison are not native to Catalina and that some aspects of their biology on the island are quite different than in their natural range. Because of the special cultural significance of bison to island residents, and their possible role in reducing fuel loads and minimizing damage from wild fires (Sweitzer et al. 2005), it is unlikely that bison will be removed from the island in the foreseeable future. However, the bison contraception program represented an opportunity to reduce the ecological damage caused by a large, historically overabundant herbivore on the island, and our research has shown that PZP is much more cost-effective than shipments of bison off-island (Duncan 2017) and less controversial than culling. In similar circumstances elsewhere, the prolonged period of contraception apparently afforded by PZP may represent an advantage over other methods of population control. Nonetheless, we caution that the differences in climate and predators between coastal southern California and most of the native range of bison may have important implications for the application of PZP to herds elsewhere. For example, immunocontraception has been proposed as a method for reducing transmission of brucellosis in the Greater Yellowstone Area because it could prevent bison cows infected with *Brucella abortus* from becoming pregnant and thus spreading the pathogen to other bison, elk, and livestock by the shedding of infected birthing tissues and fluids and aborted fetuses (Rhyan et al. 2013). APHIS (2012) rejected PZP as a potential contraceptive agent for Yellowstone because of concerns that it would prolong the breeding season, resulting in increased activity by dominant bulls and PZP-treated cows during fall and early winter that increased mortality (Miller et al. 2004). Although the high costs associated with out-of-season breeding activity remain to be elucidated fully, our work confirms that PZP treatment does result in year-round breeding

activity of both cows and bulls, making this a legitimate concern in high-latitude, continental climates where large predators are still present.

Acknowledgments

We thank the Catalina Island Conservancy, the Eppley Foundation for Research, the Bernice Barbour Foundation, the Offield Family Foundation, the Harold McAlister Charitable Foundation, and the Department of Biological Science at California State University Fullerton for financial support. T. Dvorak, A. Catalano, B. Coleman, and L. Roll provided field and technical assistance, and Drs. W. Vickers, S. Weldy, and K. Krause provided invaluable veterinary support. B. Durrant and A. Fetter of the Institute for Conservation Research coordinated analysis of fecal samples and provided advice on interpretation of results. B. Hoese and K. Forsgren provided thoughtful advice throughout the project and comments on early drafts of this report. This work is dedicated to the late J. Kirkpatrick, who pioneered the use of PZP in free-ranging large mammals and was instrumental to the success of the bison contraception program on Catalina.

Supplementary Data

Supplementary data are available at *Journal of Mammalogy* online.

Supplementary Data SD1.—Sampling effort (number of days, numbers of observations, and FP samples collected) on Catalina Island from 1 June 2014 to 30 June 2015.

Supplementary Data SD2.—Range of fecal progesterone values for 60 bison (*Bison bison*) cows on Catalina Island between 1 June 2014 and 30 June 2015.

Appendix I

Summary of behavioral and fecal progesterone (FP; ng/g) measurements of 60 bison (*Bison bison*) cows on Santa Catalina Island, between 1 June 2014 and 30 June 2015. Duration is the number of days between the 1st and last behavioral observations. Overlap indicates the number of estrous cycles which were identified by both behavior (Behavior) and FP using the Brown et al. (2001) approach. The total number of cycles detected was estimated by summing the number of behavioral and FP cycles and subtracting the instances of overlap. No baseline FP value could be calculated for the last 8 cows (below the *Baseline*), so the number of FP and overlapping cycles were estimated using the mean baseline FP (338 ng/g) for the other 52 cows.

Suppression of behavioural and physiological oestrus in the mare by vaccination against GnRH

M ELHAY,[a] A NEWBOLD,[a] A BRITTON,[a] P TURLEY,[b] K DOWSETT,[c] and J WALKER[a]

Objective To examine the immunogenicity of an equine immunocontraceptive vaccine and its efficacy in controlling hormone-related behaviour.

Design A total of 24 mares at two sites in Australia were vaccinated with an immunocontraceptive vaccine comprising gonadotrophin releasing hormone (GnRH) conjugated to a carrier protein in immunostimulating complex as an adjuvant. Twelve animals at each site received a placebo of adjuvant alone and served as controls for seasonal oestrus, hormonal and behaviour patterns. Animals were observed for injection site reactions, ovarian and follicular activity, and serum levels of antibody, 17β-oestradiol and progesterone in the weeks following vaccination. Mares were also examined for oestrous behaviour by teasing with a stallion.

Results All mares responded to vaccination. Two weeks following the second vaccination there was a peak in antibody response to GnRH that declined gradually over the following weeks. Commensurate with the elevated anti-GnRH antibody there was a marked effect on ovarian activity with a reduction in 17β-oestradiol and progesterone levels in the 24 vaccinated mares. There was also a reduction of oestrus-related behaviour as determined by a teaser stallion. This effect lasted a minimum of 3 months and correlated with the initial level of antibody response.

Conclusion Following a conventional two-dose immunisation regime this commercially available equine immunocontraceptive vaccine was effective at inhibiting oestrous behaviour for at least 3 months. This vaccine has a high level of safety since there were no significant local reactions nor were there any adverse systemic responses to vaccination.

Key words: vaccination, gonadotrophin releasing hormone, mares, equine reproduction

Aust Vet J 2007;85:39–45 doi: 10.1111/j.1751-0813.2006.00092.x

EIA	Enzyme immunoassay
FSH	Follicle stimulating hormone
GnRH	Gonadotrophin releasing hormone
LH	Luteinising hormone
TU	Titre unit(s)

The onset of oestrus in mares and fillies is often associated with behavioural changes such as leaning, urinating, aggressiveness and responsiveness to nearby stallions that can cause considerable concern to the animal's owner, trainer or handlers. Gonadotrophin releasing hormone (GnRH) has a central role in the control of fertility and sexual behaviour in mammals and thus oestrous behaviour in mares. GnRH exerts this effect indirectly by controlling the release of follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. Disruption of the effects of GnRH by manipulation of GnRH receptor signals either by agonists or antagonists, has raised concerns about their expense and/or longevity of effect.[1] Neutralisation of GnRH by specific antibody elicited by vaccination represents an alternative approach and should lead to a dramatic reduction in levels of FSH and LH and subsequent effects on gonadal function.

Previously, studies with experimental formulations have demonstrated that vaccination against GnRH can have significant effects on reproductive function of colts and stallions[1–6] and prevention of the development of oestrus in the mare.[1,7–11] These studies demonstrated the feasibility of immuno-contraception in male and female horses, confirming significant physical and endocrine effects. The immunocontraceptive effects of these vaccines were often observed only following repeated, prolonged immunisation regimes that were often associated with unacceptable site reactions. There is a need, therefore, for an immunocontraceptive vaccine that would be effective and have an acceptable safety profile for general use in horses.

The feasibility of developing GnRH vaccines for use in domestic species has now been established in the swine[12] where such a vaccine is used to control boar taint in uncastrated male pigs. This vaccine has the additional benefit that it increases production gains and improves carcass characteristics, primarily through its action in suppressing sexual behaviour including fighting. A natural extension of this observation in pigs would be to apply this technology to other species where control of sexual behaviour is desired.

Materials and methods

Animals

Mares aged between 3 and 12 years were obtained at sales in South Eastern Queensland or leased from a horse buyer in Victoria (24 mares per site). The reproductive status of each mare was assessed by rectal examination and ultrasonography, before mares were admitted into the trial, to ensure they were cycling. For teasing, a miniature stallion (Queensland) or a Shetland pony stallion (Victoria) was used.

Experimental location and timing

Two trials were run in the late spring to early summer in two locations. Study 1 was conducted at Woodhill, Queensland (latitude 27°53′S) starting on 5 October 1999. Study 2 at

Woodend, Victoria (latitude 37°21′S) began two weeks later on 19 October 1999.

Experimental design

For both studies the experimental design was identical. In each study 24 mares were identified by neck tag and other markings such as brand or coat colour. Each mare was given one of two treatments in coded syringes, either immunocontraceptive vaccine or adjuvant placebo, randomly, so that there were two groups of 12 at each site. Clinical observations were related to animal number so that those making the observations were unaware of which treatment animals had received. The code was revealed at the end of the study. During the study mares were run together in the same paddock. Each 1 to 2 weeks they were examined by ultrasonography for ovarian structure and teased to elicit oestrus cycle-related behaviour. At key time points (0, 28 and 42 days into the studies) serum samples were taken for antibody and hormone analysis. Mares were assessed for 16 weeks after first vaccination.

Vaccine

The GnRH vaccine examined (Equity™, Pfizer Animal Health P/L, West Ryde, NSW, Australia), comprises GnRH peptide conjugated to a protein carrier and admixed with immunostimulating complex as adjuvant. Immunostimulating complexes are formed from Saponin Quil A (Brenntag Biosector, Frederikssund, Denmark), cholesterol (Avanti Polar Lipids, Inc, Alabaster, Alabama) and dipalmitoylphosphatidycholine (Avanti Polar Lipids, Inc). Each 1 mL dose contained 200 µg peptide conjugate, 300 µg immunostimulating complexes, and 0.01% thiomersal, as preservative, and isotonic buffered solution to volume. The placebo vaccine was similarly formulated but with the omission of GnRH peptide conjugated to a protein carrier.

Vaccines were administered intramuscularly in the middle of the neck on day 0 and day 28.

Injection site reactions

Mares were examined daily for the first 4 days then weekly thereafter for injection site reactions. The area of vaccination was observed by eye and palpated for any swellings undetectable to the eye. Injection site reactions were scored as follows: 0, no observable or palpable reaction; 1, reaction palpable but not visible; 2, visible swelling.

Serum assays

Blood was collected into serum separating tube gel vacutainers (BD, Australia) and serum prepared by centrifugation. Serum anti-GnRH antibody titres were determined by enzyme immunoassay (EIA). Briefly, 96-well microtitre plates (Maxisorb, Nunc, Denmark) were coated overnight at 4°C with 10 µg/mL GnRH peptide in bicarbonate coating buffer pH 5.0. Plates were washed in wash buffer (0.1 M Tris buffered saline containing 0.05% Tween 20). Plates were then blocked for 1 h at room temperature with 1% sodium casein in wash buffer. Plates were washed again then incubated with serial dilutions of test mare serum for 1 h at room temperature. Plates were washed and bound antibody detected by incubating plates for further 1 h at room temperature with goat anti-horse IgG conjugated to horseradish peroxidase (HRP) (Kirkegaard-Perry Laboratories, USA) then washed. Bound goat anti-horse-HRP was visualised with tetramethylbenzidine (TMB) Microwell Peroxidase Substrate System (Kirkegaard-Perry Laboratories). A standard with a nominal titre of 1/45,000 served as a reference for unknown samples. Non-vaccinated mare serum served as a negative control.

Assays of serum progesterone were conducted using the Bioclone Elegance Progesterone EIA kit according to the manufacturer's instruction (Bioclone Australia Limited, Australia). During winter anoestrus, serum progesterone levels are typically between 3 to 6 nmol/L (Elhay and Walker, unpublished observations). Therefore, 6 nmol/L was selected as the cut-off value, below which it was regarded that an individual mare was in anoestrous, with respect to level of serum progesterone.

Serum 17β-oestradiol was measured by Victorian Veterinary Pathology Services (Clayton, Victoria, Australia), using a microparticle EIA technique.

Ovarian and follicular activity

Ovarian and follicular activity were determined by transrectal ultrasonography and palpation. Ovarian activity was measured systematically as follows: follicles and other structures were first recorded for the left ovary, and then for the right ovary. Follicles were recorded as diameter in cm. Other structures were recorded as follows: msf = many small follicles < 1 cm in diameter, mf = many follicles ≥ 1 cm in diameter, CL = corpus luteum present, na = no activity detected in/on the ovary, nd = not determined.

Each mare's cycle status was then summarised as follows:

Score 0. Anoestrus-like: small follicles, < 1 cm, or no palpable or detectable follicles; ovaries generally showing no echogenic structure by ultrasonography.

Score 1. Cycling but not in oestrus: a number of follicles, ≥ 1 cm to 2.5 cm, with no dominant follicle on ultrasonographic assessment; follicles could vary in size, but needed to be distinct and clearly delineated.

Score 2. Oestrus-like: at least one large follicle greater than 2.5 cm in diameter beginning to predominate or a follicle judged to be close to ovulation.

Behavioural activity

Oestrous behaviour was elicited with a miniature stallion or Shetland pony stallion. This induced behaviour was classified as follows:

Score 0. Anoestrous-like: if there was no interest from the mare. Some mares showed a few low-level, positive signs, such as the ears inclined forward, but which were generally passive. These mares were judged as being in an anoestrous-like state.

© 2007 Pfizer Australia
Journal compilation © 2007 Australian Veterinary Association

Score 1. Dioestrus-like: the following behaviours, typical of dioestrus, were recorded: ears held back, aggressive squealing, aggressive kicking, aggressive biting, jamming tail down.

Score 2. Oestrus-like: the following behaviours, typical of oestrus, were recorded: ears to the side, non-aggressive/passive squealing, lifting tail, leaning toward teaser, squatting and urinating, clitoral 'winking'.

Using all of the above parameters, an estimate was then made of an individual mare's oestrous state; whether they were in oestrus (score 2), dioestrus (score 1), or in an anoestrous-like state (score 0). An intermediate score of 1.5 was recorded when a mare's behaviour indicated she was just entering oestrus or had just ovulated. A score of 0.5 was recorded for a mare which had little interest in the teaser or which kicked out at the teaser when forced to stand for teasing.

Return to oestrus

Following completion of the first part of the study, eight mares from the vaccinated group and 4 mares from the placebo vaccinated control group from each site were then kept to observe for return to oestrus activity before the onset of seasonal anoestrus. Duration of this phase of the study was 18 weeks in Queensland and 14 weeks in Victoria. These mares were examined for ovarian activity and oestrous behaviour as described above.

Statistical analyses

Statistical analysis of data was carried out by Beresford Computing and Statistical Services Pty Ltd (Melbourne, Australia). Data for serum progesterone and 17β-oestradiol were analysed by random effects regression analysis and ovarian and behavioural differences by the non-parametric Wilcoxon rank sum test (both using Stata 8.0 statistical package). It was expected that serum hormone levels would rise and fall in unvaccinated animals according to their oestrus cycle therefore random effects regression was used to determine if consistent low hormone levels were associated with vaccination. Also the oestrous cycle length of each mare was not determined and mares were examined on the same day so cycle length variation between mares could not be catered for. The two studies were analysed independently, as there were a number of variables that were different in each study including different lots of vaccine.

Adjustments were made for repeated measures in the same mare; the random effect considered was the mare. The threshold for statistical significance was at the 5% level.

Results

Injection site reactions

In the Woodend (Victoria) trial, injection site reactions were observed in 2 mares 1 week following the first vaccination and consisted of a raised area (score 2) measuring 1 or 2.5 cm in diameter and raised 0.5 cm (mares 11C and 13C respectively). One animal (19C) had a palpable (score 1) reaction, 2 cm in diameter and 0.5 cm high, 1 week following the second vaccination. All three mares were from the treatment group.

In the Queensland study conducted at Woodhill, six mares from the treatment group (mares 1, 7, 8, 9, 11, and 14) had reactions with a score of 2 (slightly raised and flat swelling of the skin approximately 5 cm in diameter) following the first vaccination. These reactions had resolved within a week. Another mare (19), vaccinated with immunocontraceptive vaccine had a reaction that was not visible to the eye though palpable (score 1) at 1 and 2 weeks post first vaccination. Finally, one of the placebo-vaccinated mares had palpable (score 1) reaction that resolved within the week following first detection. There were no injection site reactions in any of the mares at either site following the second vaccination.

Anti-GnRH antibody titres

Serum antibody was measured from samples taken at approximately 2 weekly intervals starting on the day of first vaccination. Antibody was measured by EIA and referenced to standard serum assigned a titre of 45,000 titre units (TU). Mares that received placebo vaccine had no detectable antibody response. All of the mares vaccinated with anti-GnRH vaccine developed an antibody response with maximum titres achieved by 2 weeks following the second immunisation (Figure 1). Maximum antibody levels at 2 weeks after the second vaccination were quite heterogeneous amongst animals, ranging from a low titre of 1064 through to a maximum of 1.8×10^6 TU. More often, the maximum antibody level was between 10^4 to 10^5 TU. Nine of the 24 vaccinated mares developed an antibody response following one injection only (data not shown). This antibody waned quickly and was then masked by the antibody that developed rapidly following the second immunisation.

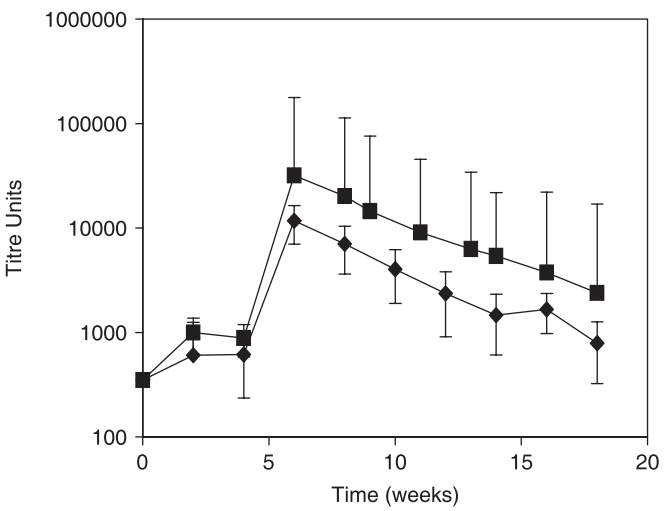

Figure 1. Antibody responses to anti-GnRF vaccination in two sites, Woodhill in SE Queensland (-◆-QLD) and Woodend in Central Victoria (-■- VIC). Twelve mares at each site were vaccinated at week 0 and week 4 with equine immunocontraceptive vaccine. Antibody is presented as the group geometric mean in Titre Units ± SEM.

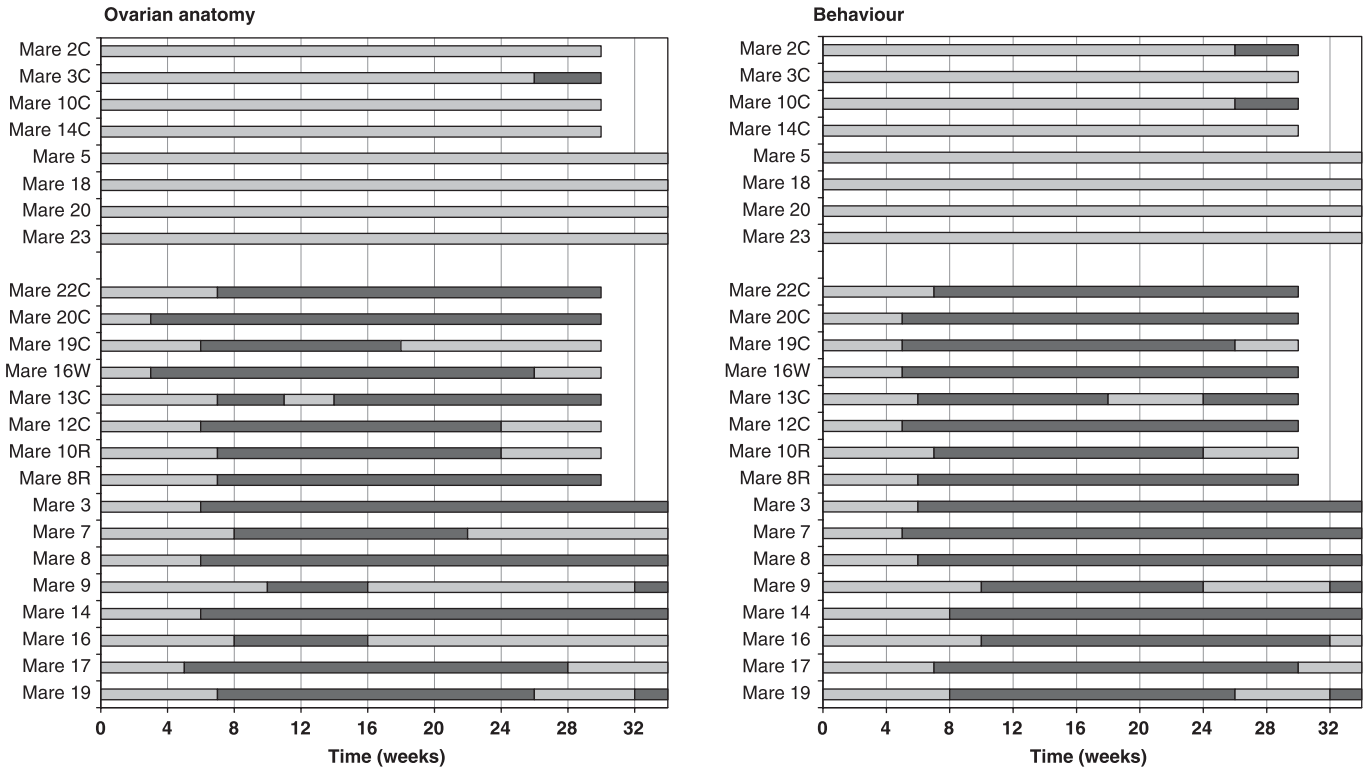

Figure 2. Time in weeks of reproductive activity of individual mares kept for 29 weeks (in Victoria) and 34 weeks (Queensland), after vaccination at Weeks 0 and 4. Each horizontal line represents one mare. Mares shown as having oestrus or dioestrus like activity (light grey) or anoestrus like activity (dark grey). The upper block represents placebo mares (mare numbers 2C to 23) and the lower block represents treated mares (mares 22C to 19). Mares with alphanumeric identification are from the trial run in Victoria.

Ovarian activity

All mares were observed to cycle in both groups during the 2 weeks post first vaccination (Figure 2). Placebo vaccinated controls continued to cycle normally throughout the trial, as expected for the time of year (Figure 3).

The effect of vaccination on ovarian activity was apparent in all treated mares within 2 weeks of second vaccination. In general, there was a significant reduction in the size of the ovaries and any follicles that could be palpated or distinguished by ultrasonographic imaging (Woodhill, Queensland $P < 0.001$, Woodend Victoria, $P < 0.001$). This process of ovarian change continued for several weeks until no folliculogenesis could be detected. For most mares, by 4 weeks post second vaccination, the ovaries resembled those of seasonally anovulatory mares, and no copora lutea were identified.

Oestrous behaviour

A significant (Woodhill, Queensland $P < 0.001$, Woodend Victoria, $P = 0.012$) effect of vaccination on oestrous/dioestrus behaviour was observed following second vaccination (Figure 4). A number of vaccinated mares in the Victorian study were recorded as showing signs of cycling mares. In all cases, these mares showed dioestrus-like signs (kicking out at the teaser) that may have been indicative of forced teasing in the crush.[13] This behaviour stopped once mares were allowed greater freedom in a pen rather than a crush with the teaser separated from them by a fence. For the Queensland study all teasing was conducted within a pen with the mare and miniature stallion on a lead. In this study the onset of anoestrus-like behaviour more closely followed the decline in ovarian activity (Figure 3).

Serum progesterone levels

Results of the serum progesterone assay are shown in Figure 5. Mares vaccinated with GnRH vaccine showed serum progesterone levels below 6 nmol/L from 2 weeks following the second dose of vaccine, and by 4 weeks post boost, none of the 24 GnRH vaccine immunised mares had significant levels of serum progesterone. At no stage thereafter did serum progesterone levels exceed the threshold value of 6 nmol/L.

Placebo vaccinated mares exhibited varying levels of progesterone. Statistical analysis by random effects regression analysis indicated a highly significant difference between the means of the placebo and treated groups at both sites (Woodhill, $P < 0.001$ and Woodend, $P = 0.003$).

Serum 17β-oestradiol levels

Serum 17β-oestradiol levels were reduced from those observed before vaccination, but there was always a detectable level of 17β-

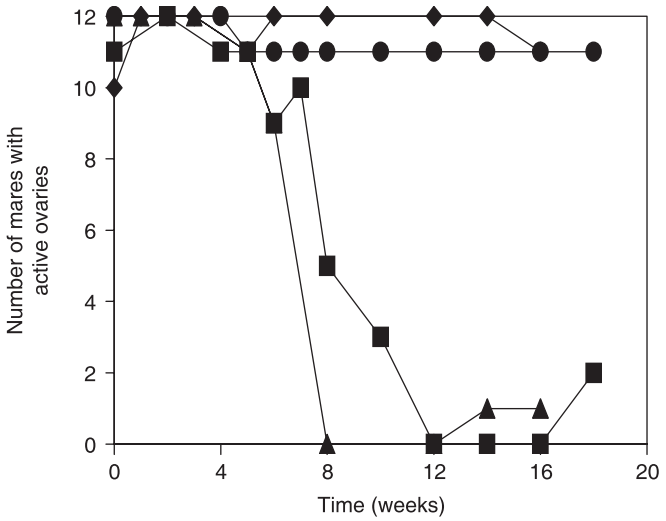

Figure 3. Number of mares with ovarian activity (Score 1 or 2) as measured by trans-rectal palpation and ultrasonography following vaccination with equine immunocontraceptive vaccine. Mares were vaccinated on week 0 and 4 with either vaccine (-■- QLD, -▲- VIC) or placebo (-●- QLD, -◆- VIC).

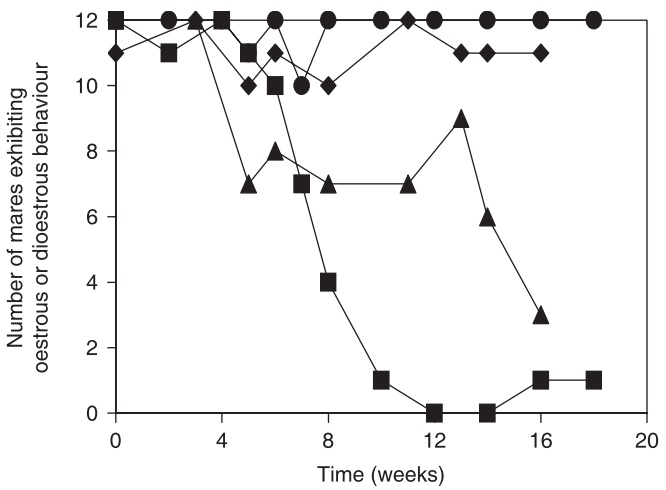

Figure 4. Number of mares exhibiting oestrous or dioestrous behaviour (Score 1 or 2), measured by teasing with a Shetland pony stallion (VIC) or miniature stallion (QLD) following vaccination with GnRH vaccine (-■- QLD, -▲- VIC) or placebo (-●- QLD, -◆- VIC).

oestradiol in some of the vaccinated mares during the period of immune anoestrus. Mean 17β-oestradiol levels were reduced by 16.5 pmol/L for the Queensland trial and 10.9 pmol/L for the Victorian trial. Random effects regression analysis of the differences between the means of the 2 groups indicated a significant effect of vaccination ($P = 0.005$ and $P = 0.02$ for the Queensland and Victorian trials respectively).

Return to oestrus

In the mares that were kept to observe for return to oestrus activity before the onset of seasonal anoestrus, the duration of

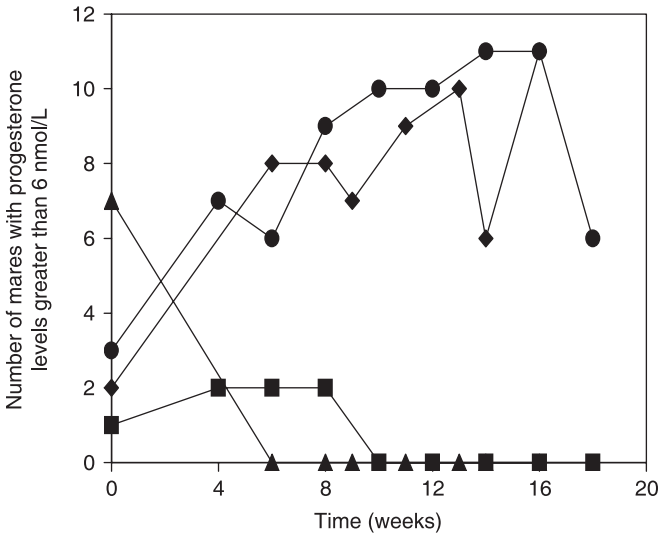

Figure 5. Number of mares with progesterone levels greater than 6 nmol/L. Mares were regarded as being equivalent to anoestrus if progesterone was less than 6 nmol/L. Vaccine treated mares: -■- QLD, -▲- VIC; placebo treated mares: -●- QLD, -◆- VIC).

ovarian shutdown varied from 4 to 23 weeks in 10 of the 16 vaccinated mares (Figure 2). The remaining 6 (3, 8 14, 8R, 20C, 22C) did not return to a cycling status for the rest of the trial.

Three mares (9, 16 and 13C) appeared to have a relatively short period of GnRH vaccine-induced ovarian dormancy lasting approximately 6, 8 and 4 weeks respectively. Thereafter, their ovaries indicated that folliculogenesis and cycling may have begun. These mares also had some of the lowest initial anti-GnRH antibody titres. However, despite this correlation between circulating anti-GnRH antibody and ovarian anatomy, there was no immediate return of sexual behaviour. Sexual behaviour was not observed in these mares for another 8, 14 and 8 weeks following first signs of ovarian activity for mares 9, 16 and 13 C respectively (Figure 2).

The duration of immune anoestrus as measured at the level of behaviour was always longer in duration than the effect on ovarian activity.

The apparent onset of seasonal anoestrus at the level of ovarian anatomy and/or teasing behaviour was observed in three of the mares (mares 13C, 9 and 19). Two of the control mares (2C and 10C) appeared to enter behavioural seasonal anoestrus within the study period, and one (3C) ceased ovarian activity.

Discussion

Immunisation of all 24 mares with two doses of GnRH vaccine elicited antibody to GnRH and significant changes to the levels of ovarian hormones and oestrous behaviour.

The effect of vaccination with the GnRH vaccine was evident in most mares within 2 weeks following second vaccination. Immunological vaccine efficacy was 100%, as reflected in antibody titre, which rose following vaccination to a peak at 2 weeks

© 2007 Pfizer Australia
Journal compilation © 2007 Australian Veterinary Association

post-boost in all animals. Neutralisation of GnRH in all likelihood resulted in the diminished production of FSH and LH,[7] and as a consequence, due to the absence of these hormonal stimulators, there was distinct regression of both ovaries in all vaccinated mares. In fact, their ovaries began to resemble those observed in seasonally anovulatory mares.

Commensurate with the antibody response and ovarian changes, there was a reduction in the levels of sex steroids in serum from vaccinated mares. Progesterone showed the clearest effect indicating lack of FSH dependent folliculogenesis and LH dependent luteal maintenance. At no stage thereafter did serum progesterone levels exceed the threshold value of 6 nmol/L, indicating that the cycle status of the mares had been suspended.

All vaccinated mares showed a significant reduction in their ovarian activity due to vaccination. This was evident as a dramatic reduction in the size of the ovary and a reduction in follicular activity. These results indicate that the effect of vaccination against GnRH was to prevent folliculogenesis and the development of the corpus luteum and thereby prevent progesterone production.

17β-oestradiol levels were not reduced to the same degree as was observed for progesterone. This may indicate that there was an extra-ovarian source for this hormone. The adrenal cortex is a known source of oestrogens and other steroids and may be an alternate source of oestrogen in the mare.[13–16] It has been suggested that adrenal 17β-oestradiol may be responsible for the sexual behaviour displayed by seasonally anovulatory mares as this behaviour can be ablated by dexamethasone treatment of ovariectomised mares.[15]

Another extra-ovarian source of 17β-oestradiol may have been from steroid precursors in the adrenal. The precursor androstenedione is produced by the ovarian cells from 17α-hydroxyprogesterone. Androstenedione is then converted to oestrone or testosterone, either of which are precursors of oestradiol. Pre-antral follicles, arrested in their development by anti-GnRH vaccination,[10] may have served as a source of serum androstenedione which in turn may have acted as a precursor for 17β-oestradiol. Tshewang and coworkers[10] found no effect of vaccination on serum androstenedione levels in mares and fillies. Colts treated with another GnRH vaccine on the other hand had negligible levels of serum androstenedione suggesting a different mechanism of hormonal control of these steroids in mares from colts.[5]

Without further specific investigation, it is not possible to say if one or a combination of these mechanisms may have contributed to the results observed in these studies. Importantly, there was a reduction in the total amount of 17β-oestradiol in vaccinated mares. Oestrous related behaviour, which is believed to be driven by 17β-oestradiol in the mare, was markedly reduced, indicating that this behaviour was inhibited by vaccination.

Sixteen mares (eight from each trial) were retained beyond 4 months post primary course of vaccination. The duration of the effect of treatment, as measured by a return of folliculogenesis detected by ultrasonography, ranged from 6 to 28 weeks with the most frequent duration of immune anoestrus being 23 weeks for 5 of 16 mares (Figure 3).

This reduction in ovarian activity was reflected in the results for oestrous behaviour. Mares vaccinated with GnRH vaccine showed suppressed oestrous behaviour such that their behaviour resembled that of seasonally anovulatory mares. This effect lasted from 12 to at least 29 weeks with 11 of 16 mares clustered around 22 to 29 weeks duration of immune anoestrus.

The observation that the duration of immune anoestrus as measured by behaviour was always longer in duration than the effect on ovarian anatomy, suggests that reactivation of the ovary and folliculogenesis is a necessary precursor to the onset of oestrus-related behaviour.

For those mares that did return to cycling behaviour, as the immune response waned, there was an increase in ovarian activity including folliculogenesis and ultimately, ovulation. For some mares (three in Victoria and four in Queensland), there was a clear return of seasonal oestrous behaviour in late summer or early autumn. One of these mares in Victoria and two in Queensland then proceeded to enter apparent seasonal anoestrus in autumn after having earlier returned to oestrus cycling activity. It is expected that duration of efficacy of the vaccine may have overlapped with the onset of seasonal anoestrus in these mares.

The study described demonstrates that an anti-GnRH vaccine has been developed that is safe and effective. It is unique in that it uses a proprietary adjuvant system, immunostimulating complex, and to our knowledge is the first vaccine of its type for use in horses.

Acknowledgments

We thank Dr Peter Little and Mr Andrew Hodge, Veterinary Medicines Research and Development, Pfizer Animal Health for their helpful comments and discussion on the studies described in this manuscript.

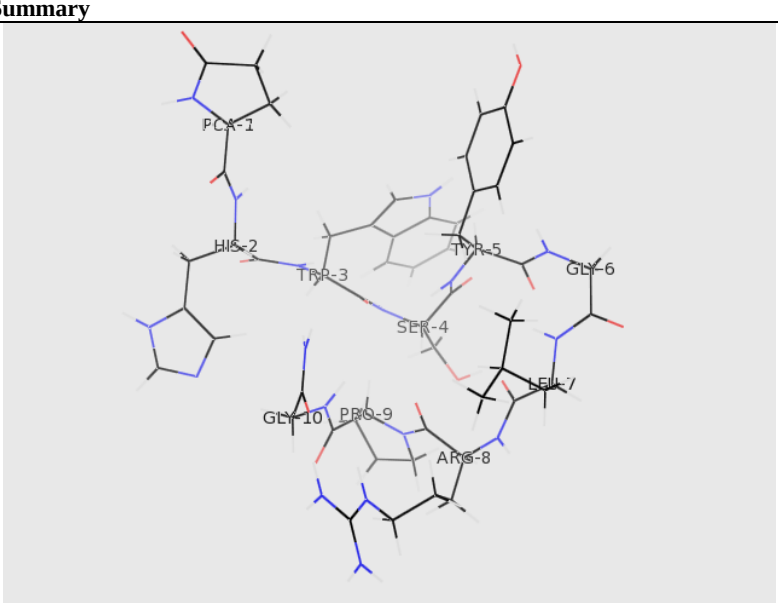
Pesticide Fact Sheet

Name of Chemical: **Mammalian Gonadotropin Releasing Hormone (GnRH)**

Reason for Issuance: **New Chemical**
Nonfood Use

Date Issued: **September 2009**

1. Description of Chemical



Peptide Chain:	pyroGlu1 -His2-Trp3- Ser4 -Tyr5- Gly6 -Leu7-Arg8-Pro9- G ly10NH2 [GnRH]
Common Name:	Mammalian Gonadotropin Releasing Hormone (GnRH)
EPA PC Code:	116800
Chemical Abstracts Service (CAS) Number:	9034-40-6
Chemical Class:	Sterilant/Hormone
Registration Status:	New Chemical, nonfood use
Pesticide Type:	Mammalian Contraceptive
U.S. Producer:	U.S. Department of Agriculture, APHIS, Pocatello Supply Depot 238 East Dillon Street Pocatello, ID 83201

2. Use Pattern and Formulations

Mode of Action	The active ingredient, Mammalian Gonadotropin Releasing Hormone (GnRH) is conjugated into a large protein that initiates an immune response in the animal with its own GnRH resulting in contraceptive effects for a minimum of one year.
Application Sites	GonaCon will be used to control wild white-tailed deer *Odocoileus virginianus*) populations in areas where they have become a nuisance (e.g, urban and suburban settings).
Methods of Application	The vaccine will be administered to restrained female deer using preloaded syringes with an 18 or 19 gauge stainless steel hypodermic needle intramuscularly into a large muscle mass by hand injection only. GonaCon is classified as a Restricted Use Pesticide. Use is restricted to USDA APHIS Wildlife Services or state wildlife management personnel or persons working under their authority.
Application Rate:	Female deer are injected with a single injection containing 1.0 ml of GonaCon at least two to three months prior to the onset of rut for full contraceptive effect. If multi year contraceptive effects are desired, a second vaccination may be given 30 to 60 days after the first injection or during the following year. Two formulations (basic and alternate) are proposed for registration.

3. Science Findings

Available data supporting the use and registration of Mammalian Gonadotropin Releasing Hormone including product chemistry, toxicology, efficacy, and ecological effects and environmental fate are summarized below.

Table 1. Product Chemistry Summary	
Peptide structure	
Common name	Mammalian Gonadotropin Releasing Hormone (GnRH)
CAS Reg. No.	9034-40-6
Color	white
Physical State	Active: solid: powder EU: liquid: somewhat creamy in appearance
Melting Point	N/A Waiver request
Boiling Point	Waiver request: Solid at room temperature.
Odor	Active: odorless EU: odorless
Stability to Normal and Elevated Temperatures, Metal, and Metal Ions	N/A Waiver request
Oxidation/Reduction Action	N/A Waiver request
pH	Active: NA EU: pH = 6.49
Flammability	N/A Waiver request
Explodability	N/A Waiver request
Vapor pressure	N/A Waiver request
Water Solubility	N/A Waiver request
Storage stability	N/A product's shelf life will be $\leq$ 6 months so not necessary
Corrosion Characteristics	N/A product's shelf life will be $\leq$ 6 months so not necessary

TOXICOLOGY SUMMARY

The Registrant submitted the studies listed in Tables 2, which include a number of toxicity studies. The Registrant submitted waiver requests which were granted for acute inhalation and dermal sensitization.

Acute Toxicity Data GnRH

Table 2. Acute Toxicity			
Guideline No.	**Study Type**	**Results**	**Toxicity Category***
OPPTS 870.1100	Acute Oral Rat	All test animals survived 1 mL exposure.	IV
OPPTS 870.1200	Acute Dermal Rat	All test animals survived 1 mL exposure.	IV
OPPTS 870.1300	Acute Inhalation Rat	WAIVED	IV
OPPTS 870.2400	Primary Eye Irritation Rabbit	No corneal opacity or iritis was observed. 1-hour post-instillation: 3/3 treated eyes exhibited conjunctival redness (score 1-2) and discharge (score 1). No "positive" grade irritation was noted at the 24-hour observation. Treated eyes were free of all eye irritation by 72-hours.	IV
OPPTS 870.2500	Primary Skin Irritation Rabbit	No edema was observed at any treated site. Very slight erythema (score 1) was noted at all 3/3 test sites within 1-hour post-pad removal. Irritation severity decreased thereafter. No irritation was noted at the 72-hour observation. The PDII was 0.5.	IV
OPPTS 870.2600	Dermal sensitization	WAIVED	--

- Toxicity Category IV = No precautions required

Chronic toxicity data requirements were waived. There is no human exposure from use of GonaCon, therefore no toxicity endpoints were selected because of the very limited potential worker and dietary exposure.

ECOLOGICAL EFFECTS

Waivers were submitted to fulfill required ecological effects and environmental fate guideline studies for the registration of GonaCon because of the limited potential for environmental releases. Since the product is labeled only for injection to deer by hand and the substance is expected to be rapidly metabolized in treated animals, the limited

potential risks to non-target organisms resulting from the proposed registration of GonaCon are not expected to exceed the Agency's concern levels.

The proposed registration of GonaCon is expected to have no effect on endangered or threatened species

EFFICACY

GonaCon is intended to render a vaccinated female white-tailed deer infertile for a minimum of one year following vaccination. The label claims that GonaCon will not affect existing pregnancies but should cause infertility of the vaccinated animal in subsequent years. If multi-year contraceptive effects are desired, a second vaccination may be given 30-60 days after the first injection or during the following year. The label claims that there is a chance that some vaccinated females will become permanently sterile.

Product performance studies were conducted by APHIS's National Wildlife Research Center (NWRC) both in the field over a two year period and in a laboratory over multiple years to compare two different formulations.

The field test, initiated in 2004 used two sites consisting of fenced federal land near Silver Spring, MD. Female deer in the vaccinated group were dosed with the labeled rate of the vaccine during July and August 2004. All deer were marked with ear tags and radio telemetry collars equipped with mortality sensors. Reproductive status was assessed in the summers of 2005 and 2006 with visual inspection of the udders for signs of lactation.

Results showed 88% efficacy in the summer after vaccination with lactation evident in 3 of the 26 does vaccinated (12%). Of the control group, reproductive status was able to be determined in 13 of the 15 deer and lactation was evident in 11 of those 13 doe (85%).

In the second summer after vaccination lactation was evident in 10 of the remaining 19 vaccinated deer (53%) equating to an efficacy rate of 47%. In the control group, 10 of the 10 remaining deer (100%) had reproductive success.

The lab study results showed the alternate formulation to be more effective than the basic formulation. The alternate formulation had a 100% success rate (5/5 does remained contracepted for two years) compared to the basic formulation with a 60% success rate after two years (3/5 does contracepted). Due to economic and supply reasons however, it is necessary for the product to carry both formulations.

4. Summary of Regulatory Position and Rationale

Available data provide adequate information to support the conditional registration of GnRH as an effective population control method for nuisance white-tailed deer.

White-tailed deer have been classified by EPA as a public health pest because they are a host for deer ticks that may cause Lyme disease and they are a cause of vehicle accidents.

In many urban and suburban areas white-tailed deer populations have become over abundant and are considered a year-round nuisance causing many human-wildlife conflicts. Since these areas are typically non hunting areas, where building and population densities do not allow for safe shooting zones, local laws prohibit guns or shooting or public opinion does not support hunting, there has not been an economically feasible solution to control overabundant deer populations.

In many of these urban and suburban areas, deer have been known to inflict significant economic damage to gardens and landscapes of homeowners associations, golf courses, private residential yards, etc. When deer are in numbers exceeding 20 per square mile, as they are becoming in many areas, they can inflict severe damage to resident flora and fauna. This can adversely affect the ecosystem and the wildlife that depend on that ecosystem.

Since deer in these areas are so well fed, female deer, which normally give birth to twins may be becoming more fertile which is evident by an increase in triplet births. This, and the fact that deer in developed areas appear to be more nocturnal to avoid human contact, is contributing to rapidly increasing populations and problems.

According to a 2006 study, the National Highway Traffic Safety Administration reported that there are about 1.5 million car accidents with deer resulting in over $1 billion of damage and 150 human fatalities annually. GnRH will not only help prevent increases in deer numbers through contraception, but should decrease the number of car accidents during the fall mating season - which is associated with a surge in car collisions with deer as bucks chase fertile does, sometimes for miles.

Deer can also play a role in spreading disease as they are a main host for blacklegged ticks (*Ixodes scapularis*), more commonly known as deer ticks, which are a carrier of Lyme disease. There has been a sharp increase in cases of Lyme disease in suburban/urban areas with significant deer populations.

Contraception of nuisance deer using GnRH is not intended to replace hunting (where it is an option) as a population control method. GnRH is intended to be used in combination with other population management techniques since it cannot alone reduce already over abundant populations. Since GnRH is a nonlethal alternative to population control, many animal rights groups enthusiastically support this registration.

The registration of GonaCon has received letters of support from the Department of Natural Resources at Cornell University and White Buffalo, Inc. a non-profit wildlife organization based out of Connecticut. At Cornell University, deer have caused damages to plants in research and teaching plots as well as dozens of car accidents. Currently, the university attempts population management of deer by capturing and surgically sterilizing deer via tubal ligation. This method however is both time consuming and costly, with expenses of approximately $1,000 per deer along with the impracticality of finding surgery staff and anesthesiologists during the early and late hours that deer are typically captured. The use of GnRH is also supported by the Humane Society of the United States and the Wildlife Society as a humane and “necessary” method of deer population control.

GonaCon was mentioned in an April 2009 article in the Washington Post Magazine as a possible population control method for deer in Rock Creek Park in Washington, DC and suburban Maryland.

5. Labeling Restrictions

To mitigate any risks, the following requirements have been imposed:

- Restricted -Use Pesticide classification due to non-target injection hazard.
- Application is restricted to USDA APHIS Wildlife Services or state wildlife management agency personnel or persons working under their authority only.
- Administration of vaccine is only by hand injection to mitigate any non-target or environmental risks that occur with administration with darts.
- Use restricted to only one species: white-tailed deer (*Odocoileus virginianus*).
- PPE requirements include: long sleeved shirt and long pants, gloves and shoes plus socks to mitigate occupational exposure.
- Children are not allowed in areas where product is used
- A warning that pregnant women should not be involved in handling or injecting GonaCon and that all women should be aware that accidental self-injection may cause infertility.

6. Conditional Data Requirements

Because of the unique chemical nature of GnRH additional preliminary analysis and certified limits data are necessary. The registrant must submit this data to the Agency upon completion.

Conditional data required for GonaCon consists of:

- Guideline 830.1700 Validating the method of analysis of the formulation and additional preliminary analysis
- Guideline 830.1750 Certified Limits

GLOSSARY OF TERMS AND ABBREVIATIONS

ADNT	Acute delayed neurotoxicity
a.i.	Active Ingredient
aPAD	Acute Population Adjusted Dose
ARI	Aggregate Risk Index
BCF	Bioconcentration Factor
CAS	Chemical Abstracts Service
ChE	Cholinesterase
ChEI	Cholinesterase inhibition
cPAD	Chronic Population Adjusted Dose
%CT	Percent crop treated
DAT	Days after treatment
DEEM-FCID	Dietary Exposure Evaluation Model - Food Consumption Intake Database
DNA	Deoxyribonucleic acid
DNT	Developmental neurotoxicity
DIT	Developmental immunotoxicity
DWLOC	Drinking Water Level of Comparison.
EC	Emulsifiable Concentrate Formulation
EEC	Estimated Environmental Concentration. The estimated pesticide concentration in an environment, such as a terrestrial ecosystem.
EPA	U.S. Environmental Protection Agency
FQPA	Food Quality Protection Act
GLC	Gas Liquid Chromatography
GLN	Guideline Number
LC_{50}	Median Lethal Concentration. A statistically derived concentration of a substance that can be expected to cause death in 50% of test animals. It is usually expressed as the weight of substance per weight or volume of water, air or feed, e.g., mg/l, mg/kg or ppm.
LD_{50}	Median Lethal Dose. A statistically derived single dose that can be expected to cause death in 50% of the test animals when administered by the route indicated (oral, dermal, inhalation). It is expressed as a weight of substance per unit weight of animal, e.g., mg/kg.
LOAEL	Lowest Observed Adverse Effect Level
LOAEC	Lowest Observed Adverse Effect Concentration
LOC	Level of Concern
LOD	Limit of Detection
LOQ	Limit of Quantitation
mg/kg/day	Milligram Per Kilogram Per Day
mg/L	Milligrams Per Liter
MOE	Margin of Exposure

MRID	Master Record Identification (number), EPA's system of recording and tracking studies submitted
MTD	Maximum tolerated dose
NA	Not Applicable
NOEC	No Observable Effect Concentration
NOEL	No Observed Effect Level
NOAEL	No Observed Adverse Effect Level
NOAEC	No Observed Adverse Effect Concentration
NPDES	National Pollutant Discharge Elimination System
OP	Organophosphate
OPP	EPA Office of Pesticide Programs
OPPTS	EPA Office of Prevention, Pesticides and Toxic Substances
PAD	Population Adjusted Dose
PAG	Pesticide Assessment Guideline

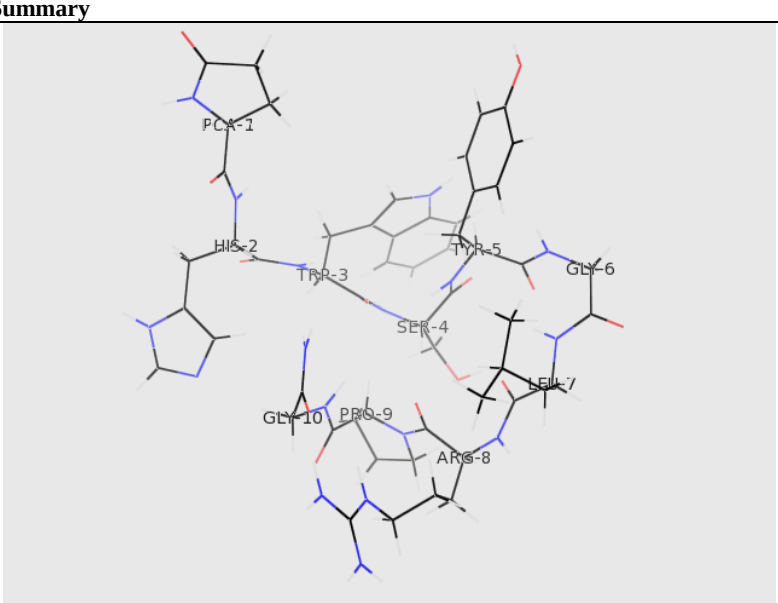
Pesticide Fact Sheet

Name of Chemical: **Mammalian Gonadotropin Releasing Hormone (GnRH)**

Reason for Issuance: **New Chemical**
Nonfood Use

Date Issued: **September 2009**

1. Description of Chemical



Peptide Chain:	pyroGlu1 -His2-Trp3- Ser4 -Tyr5- Gly6 -Leu7-Arg8-Pro9- G ly10NH2 [GnRH]
Common Name:	Mammalian Gonadotropin Releasing Hormone (GnRH)
EPA PC Code:	116800
Chemical Abstracts Service (CAS) Number:	9034-40-6
Chemical Class:	Sterilant/Hormone
Registration Status:	New Chemical, nonfood use
Pesticide Type:	Mammalian Contraceptive
U.S. Producer:	U.S. Department of Agriculture, APHIS, Pocatello Supply Depot 238 East Dillon Street Pocatello, ID 83201

2. Use Pattern and Formulations

Mode of Action	The active ingredient, Mammalian Gonadotropin Releasing Hormone (GnRH) is conjugated into a large protein that initiates an immune response in the animal with its own GnRH resulting in contraceptive effects for a minimum of one year.
Application Sites	GonaCon will be used to control wild white-tailed deer *Odocoileus virginianus*) populations in areas where they have become a nuisance (e.g, urban and suburban settings).
Methods of Application	The vaccine will be administered to restrained female deer using preloaded syringes with an 18 or 19 gauge stainless steel hypodermic needle intramuscularly into a large muscle mass by hand injection only. GonaCon is classified as a Restricted Use Pesticide. Use is restricted to USDA APHIS Wildlife Services or state wildlife management personnel or persons working under their authority.
Application Rate:	Female deer are injected with a single injection containing 1.0 ml of GonaCon at least two to three months prior to the onset of rut for full contraceptive effect. If multi year contraceptive effects are desired, a second vaccination may be given 30 to 60 days after the first injection or during the following year. Two formulations (basic and alternate) are proposed for registration.

3. Science Findings

Available data supporting the use and registration of Mammalian Gonadotropin Releasing Hormone including product chemistry, toxicology, efficacy, and ecological effects and environmental fate are summarized below.

Table 1. Product Chemistry Summary	
Peptide structure	
Common name	Mammalian Gonadotropin Releasing Hormone (GnRH)
CAS Reg. No.	9034-40-6
Color	white
Physical State	Active: solid: powder EU: liquid: somewhat creamy in appearance
Melting Point	N/A Waiver request
Boiling Point	Waiver request: Solid at room temperature.
Odor	Active: odorless EU: odorless
Stability to Normal and Elevated Temperatures, Metal, and Metal Ions	N/A Waiver request
Oxidation/Reduction Action	N/A Waiver request
pH	Active: NA EU: pH = 6.49
Flammability	N/A Waiver request
Explodability	N/A Waiver request
Vapor pressure	N/A Waiver request
Water Solubility	N/A Waiver request
Storage stability	N/A product's shelf life will be $\leq$ 6 months so not necessary
Corrosion Characteristics	N/A product's shelf life will be $\leq$ 6 months so not necessary

TOXICOLOGY SUMMARY

The Registrant submitted the studies listed in Tables 2, which include a number of toxicity studies. The Registrant submitted waiver requests which were granted for acute inhalation and dermal sensitization.

Acute Toxicity Data GnRH

Table 2. Acute Toxicity			
Guideline No.	**Study Type**	**Results**	**Toxicity Category***
OPPTS 870.1100	Acute Oral Rat	All test animals survived 1 mL exposure.	IV
OPPTS 870.1200	Acute Dermal Rat	All test animals survived 1 mL exposure.	IV
OPPTS 870.1300	Acute Inhalation Rat	WAIVED	IV
OPPTS 870.2400	Primary Eye Irritation Rabbit	No corneal opacity or iritis was observed. 1-hour post-instillation: 3/3 treated eyes exhibited conjunctival redness (score 1-2) and discharge (score 1). No "positive" grade irritation was noted at the 24-hour observation. Treated eyes were free of all eye irritation by 72-hours.	IV
OPPTS 870.2500	Primary Skin Irritation Rabbit	No edema was observed at any treated site. Very slight erythema (score 1) was noted at all 3/3 test sites within 1-hour post-pad removal. Irritation severity decreased thereafter. No irritation was noted at the 72-hour observation. The PDII was 0.5.	IV
OPPTS 870.2600	Dermal sensitization	WAIVED	--

- Toxicity Category IV = No precautions required

Chronic toxicity data requirements were waived. There is no human exposure from use of GonaCon, therefore no toxicity endpoints were selected because of the very limited potential worker and dietary exposure.

ECOLOGICAL EFFECTS

Waivers were submitted to fulfill required ecological effects and environmental fate guideline studies for the registration of GonaCon because of the limited potential for environmental releases. Since the product is labeled only for injection to deer by hand and the substance is expected to be rapidly metabolized in treated animals, the limited

potential risks to non-target organisms resulting from the proposed registration of GonaCon are not expected to exceed the Agency's concern levels.

The proposed registration of GonaCon is expected to have no effect on endangered or threatened species

EFFICACY

GonaCon is intended to render a vaccinated female white-tailed deer infertile for a minimum of one year following vaccination. The label claims that GonaCon will not affect existing pregnancies but should cause infertility of the vaccinated animal in subsequent years. If multi-year contraceptive effects are desired, a second vaccination may be given 30-60 days after the first injection or during the following year. The label claims that there is a chance that some vaccinated females will become permanently sterile.

Product performance studies were conducted by APHIS's National Wildlife Research Center (NWRC) both in the field over a two year period and in a laboratory over multiple years to compare two different formulations.

The field test, initiated in 2004 used two sites consisting of fenced federal land near Silver Spring, MD. Female deer in the vaccinated group were dosed with the labeled rate of the vaccine during July and August 2004. All deer were marked with ear tags and radio telemetry collars equipped with mortality sensors. Reproductive status was assessed in the summers of 2005 and 2006 with visual inspection of the udders for signs of lactation.

Results showed 88% efficacy in the summer after vaccination with lactation evident in 3 of the 26 does vaccinated (12%). Of the control group, reproductive status was able to be determined in 13 of the 15 deer and lactation was evident in 11 of those 13 doe (85%).

In the second summer after vaccination lactation was evident in 10 of the remaining 19 vaccinated deer (53%) equating to an efficacy rate of 47%. In the control group, 10 of the 10 remaining deer (100%) had reproductive success.

The lab study results showed the alternate formulation to be more effective than the basic formulation. The alternate formulation had a 100% success rate (5/5 does remained contracepted for two years) compared to the basic formulation with a 60% success rate after two years (3/5 does contracepted). Due to economic and supply reasons however, it is necessary for the product to carry both formulations.

4. Summary of Regulatory Position and Rationale

Available data provide adequate information to support the conditional registration of GnRH as an effective population control method for nuisance white-tailed deer.

White-tailed deer have been classified by EPA as a public health pest because they are a host for deer ticks that may cause Lyme disease and they are a cause of vehicle accidents.

In many urban and suburban areas white-tailed deer populations have become over abundant and are considered a year-round nuisance causing many human-wildlife conflicts. Since these areas are typically non hunting areas, where building and population densities do not allow for safe shooting zones, local laws prohibit guns or shooting or public opinion does not support hunting, there has not been an economically feasible solution to control overabundant deer populations.

In many of these urban and suburban areas, deer have been known to inflict significant economic damage to gardens and landscapes of homeowners associations, golf courses, private residential yards, etc. When deer are in numbers exceeding 20 per square mile, as they are becoming in many areas, they can inflict severe damage to resident flora and fauna. This can adversely affect the ecosystem and the wildlife that depend on that ecosystem.

Since deer in these areas are so well fed, female deer, which normally give birth to twins may be becoming more fertile which is evident by an increase in triplet births. This, and the fact that deer in developed areas appear to be more nocturnal to avoid human contact, is contributing to rapidly increasing populations and problems.

According to a 2006 study, the National Highway Traffic Safety Administration reported that there are about 1.5 million car accidents with deer resulting in over $1 billion of damage and 150 human fatalities annually. GnRH will not only help prevent increases in deer numbers through contraception, but should decrease the number of car accidents during the fall mating season - which is associated with a surge in car collisions with deer as bucks chase fertile does, sometimes for miles.

Deer can also play a role in spreading disease as they are a main host for blacklegged ticks (*Ixodes scapularis*), more commonly known as deer ticks, which are a carrier of Lyme disease. There has been a sharp increase in cases of Lyme disease in suburban/urban areas with significant deer populations.

Contraception of nuisance deer using GnRH is not intended to replace hunting (where it is an option) as a population control method. GnRH is intended to be used in combination with other population management techniques since it cannot alone reduce already over abundant populations. Since GnRH is a nonlethal alternative to population control, many animal rights groups enthusiastically support this registration.

The registration of GonaCon has received letters of support from the Department of Natural Resources at Cornell University and White Buffalo, Inc. a non-profit wildlife organization based out of Connecticut. At Cornell University, deer have caused damages to plants in research and teaching plots as well as dozens of car accidents. Currently, the university attempts population management of deer by capturing and surgically sterilizing deer via tubal ligation. This method however is both time consuming and costly, with expenses of approximately $1,000 per deer along with the impracticality of finding surgery staff and anesthesiologists during the early and late hours that deer are typically captured. The use of GnRH is also supported by the Humane Society of the United States and the Wildlife Society as a humane and “necessary” method of deer population control.

GonaCon was mentioned in an April 2009 article in the Washington Post Magazine as a possible population control method for deer in Rock Creek Park in Washington, DC and suburban Maryland.

5. Labeling Restrictions

To mitigate any risks, the following requirements have been imposed:

- Restricted -Use Pesticide classification due to non-target injection hazard.
- Application is restricted to USDA APHIS Wildlife Services or state wildlife management agency personnel or persons working under their authority only.
- Administration of vaccine is only by hand injection to mitigate any non-target or environmental risks that occur with administration with darts.
- Use restricted to only one species: white-tailed deer (*Odocoileus virginianus*).
- PPE requirements include: long sleeved shirt and long pants, gloves and shoes plus socks to mitigate occupational exposure.
- Children are not allowed in areas where product is used
- A warning that pregnant women should not be involved in handling or injecting GonaCon and that all women should be aware that accidental self-injection may cause infertility.

6. Conditional Data Requirements

Because of the unique chemical nature of GnRH additional preliminary analysis and certified limits data are necessary. The registrant must submit this data to the Agency upon completion.

Conditional data required for GonaCon consists of:

- Guideline 830.1700 Validating the method of analysis of the formulation and additional preliminary analysis
- Guideline 830.1750 Certified Limits

APPENDIX I

GLOSSARY OF TERMS AND ABBREVIATIONS

ADNT	Acute delayed neurotoxicity
a.i.	Active Ingredient
aPAD	Acute Population Adjusted Dose
ARI	Aggregate Risk Index
BCF	Bioconcentration Factor
CAS	Chemical Abstracts Service
ChE	Cholinesterase
ChEI	Cholinesterase inhibition
cPAD	Chronic Population Adjusted Dose
%CT	Percent crop treated
DAT	Days after treatment
DEEM-FCID	Dietary Exposure Evaluation Model - Food Consumption Intake Database
DNA	Deoxyribonucleic acid
DNT	Developmental neurotoxicity
DIT	Developmental immunotoxicity
DWLOC	Drinking Water Level of Comparison.
EC	Emulsifiable Concentrate Formulation
EEC	Estimated Environmental Concentration. The estimated pesticide concentration in an environment, such as a terrestrial ecosystem.
EPA	U.S. Environmental Protection Agency
FQPA	Food Quality Protection Act
GLC	Gas Liquid Chromatography
GLN	Guideline Number
LC_{50}	Median Lethal Concentration. A statistically derived concentration of a substance that can be expected to cause death in 50% of test animals. It is usually expressed as the weight of substance per weight or volume of water, air or feed, e.g., mg/l, mg/kg or ppm.
LD_{50}	Median Lethal Dose. A statistically derived single dose that can be expected to cause death in 50% of the test animals when administered by the route indicated (oral, dermal, inhalation). It is expressed as a weight of substance per unit weight of animal, e.g., mg/kg.
LOAEL	Lowest Observed Adverse Effect Level
LOAEC	Lowest Observed Adverse Effect Concentration
LOC	Level of Concern
LOD	Limit of Detection
LOQ	Limit of Quantitation
mg/kg/day	Milligram Per Kilogram Per Day
mg/L	Milligrams Per Liter
MOE	Margin of Exposure

MRID	Master Record Identification (number), EPA's system of recording and tracking studies submitted
MTD	Maximum tolerated dose
NA	Not Applicable
NOEC	No Observable Effect Concentration
NOEL	No Observed Effect Level
NOAEL	No Observed Adverse Effect Level
NOAEC	No Observed Adverse Effect Concentration
NPDES	National Pollutant Discharge Elimination System
OP	Organophosphate
OPP	EPA Office of Pesticide Programs
OPPTS	EPA Office of Prevention, Pesticides and Toxic Substances
PAD	Population Adjusted Dose
PAG	Pesticide Assessment Guideline
PAM	Pesticide Analytical Method
PHED	Pesticide Handler's Exposure Data
PHI	Preharvest Interval
ppb	Parts Per Billion

Pesticide Fact Sheet

Name of Chemical:	**Porcine Zona Pellucida (PZP)**
Reason for Issuance:	**New Chemical Nonfood Use**
Date Issued:	**January 2012**

1. Description of Chemical

Glycoprotein Complex:	ZP1 (80,000-90,000 KD), ZP2 (60,000-65,000 KD), ZP3 (55,000 KD), and ZP4 (20,000 – 25,000 KD)
Common Name:	Porcine Zona Pellucida (PZP)
EPA PC Code:	176603
Chemical Class:	Contraceptive
Registration Status:	New Chemical, nonfood use
Pesticide Type:	Mammalian Contraceptive
U.S. Technical Registrant:	Humane Society of the United States 2100 L St. NW Washington, DC 20037

2. Use Patterns and Formulations

Mode of Action:	PZP antigen is the glycoprotein layer that surrounds the oocyte and is weakly antigenic by itself. Therefore, PZP is emulsified with an adjuvant (mFCA for the primary vaccination and mFIA for booster

vaccinations) which stimulates a stronger immune response. This results in the creation of anti-zona pellucida antibodies which bind to the zona pellucida of the oocyte, alter their conformation, and block sperm attachment to the zona pellucida receptors.

Application Sites: ZonaStat-H will be used to control female wild and feral horse and burros privately or publicly owned, in areas where they have become a nuisance and are capable of doing environmental damage.

Methods of Application: The vaccine will be injected intramuscularly in hip or gluteus muscles by hand-held syringe, syringe mounted on a jabstick, or by syringe dart fired from a CO_2 or cartridge-powered projection system.

Application Rate: The application rate is 1.0 cc of PZP + adjuvant (modified Freund's complete adjuvant for the initial application, then modified Freund's incomplete adjuvant for follow-up applications). A second administration is given 2 to 4 weeks after the initial priming dose, then annually thereafter.

3. Science Findings

Available product chemistry data supporting the use of ZonaStat-H including product chemistry, toxicology, efficacy, and ecological effects and environmental fate are summarized below in Tables 1 and 1.1.

Table 1. Product Chemistry Summary

Common name	Porcine Zona Pellucida (PZP)
Color	Clear
Physical State	Active: Aqueous solution or powder EU: Thick, white aqueous emulsion
Odor	Odorless
Oxidation/Reduction Action	Denatured by acid or base, no incompatibility
pH	7.0 – 7.04
Flammability	Nonflammable (protein)
Explodability	Not explosive (protein)
Storage stability	Frozen liquid (or powder in desiccant) is viable for 2 years.
Corrosion Characteristics	No corrosive activity.

TOXICOLOGY SUMMARY

The Registrant submitted waiver requests for the acute oral, acute dermal, acute inhalation, primary eye irritation, primary dermal irritation, and dermal sensitization studies. The waiver requests were reviewed and determined to be acceptable.

Table 2. Acute Toxicity Data

GUIDELINE NO.	STUDY TYPE	MRID NO.	RESULTS	TOXICITY CATEGORY
870.1100	Acute Oral Toxicity	47859803	Waived	IV
870.1200	Acute Dermal Toxicity	47859803	Waived	III
870.1300	Acute Inhalation Toxicity	47859803	Waived	III
870.2400	Acute eye irritation	47859803	Waived	III
870.2500	Primary skin irritation	47859803	Waived	III
870.2600	Dermal sensitization	47859803	Waived	Negative

- Toxicity Category III = Precautionary Statements Required

Chronic toxicity data were not submitted. There is no human exposure from use of ZonaStat-H, therefore no toxicity endpoints were selected because of the very limited potential worker and dietary exposure.

ECOLOGICAL EFFECTS

Waivers were submitted to fulfill required ecological effects and environmental fate guideline studies for the registration of ZonaStat-H because of the limited potential for environmental releases. Since the product is labeled only for injection to target animals by hand or dart, is expected to be deactivated in the digestive tract, and has a short half-life in treated mammals, the limited potential risks to non-target organisms resulting from the proposed registration of ZonaStat-H are not expected to exceed the Agency's concern levels.

Risk to Endangered Species

The following table summarizes the conclusions of potential concerns for direct and indirect effects to federally-listed threatened and endangered species (listed species). Because the proposed uses cannot be geographically limited, all federally listed species are assumed to be potentially indirectly affected. The available data suggest that potential exposures to non-target animals is not expected to result in any significant risk concerns to terrestrial or aquatic organisms from the proposed use. However, indirect effects (potentially beneficial or negative) to Listed species could not be precluded.

Table 3. Potential Effects to Federally Listed Taxa

Listed Taxa	Direct Effects	Indirect Effects
Terrestrial and semi-aquatic plants – monocots and dicots	No	Yes
Terrestrial invertebrates	No	Yes
Birds (surrogate for terrestrial-phase amphibians and reptiles)	No	Yes
Mammals	No	Yes
Aquatic vascular plants	No	Yes
Aquatic non-vascular plants	No	Yes
Freshwater fish (surrogate for aquatic-phase amphibians)	No	Yes
Freshwater invertebrates	No	Yes
Freshwater benthic invertebrates	No	Yes
Estuarine/Marine fish	No	Yes
Estuarine/Marine crustaceans	No	Yes
Estuarine/Marine mollusks	No	Yes

EFFICACY

As ZonaStat-H does not bear claims to control pests that may pose a threat to human health, pursuant to OPPTS 810.1000(b)(2), the requirement for demonstration of efficacy is waived. In lieu of efficacy studies, the registrant provided various peer-reviewed published articles demonstrating ZonaStat's efficacy as a contraceptive for wild horses and burros.

The principle of efficacy of PZP in horses was first demonstrated by Liu et al. (1989) by inhibiting fertility in 12 of 14 captive fertile domestic and wild mares (*Eqqus caballus*), which persisted for 7 months. The researchers inoculated the mares with 4 hand injections of PZP with aluminum hydroxide gel. As the aluminum hydroxide gel was found to be only moderately effective in most of the horses, it was therefore substituted by FCA and FIA at 2-4 week intervals. A fifth booster injection was administered 6-9 months after the fourth injection. This study also demonstrated that anti-PZP antibody titers of 64% or greater were associated with effective contraception, and that a decline in contraceptive effect correlated with a decline in antibody titers.

Kirkpatrick et al. (1990) demonstrated PZP effectiveness in a study conducted at Assateague Island National Seashore (ASIS), MD in which 26 mares were remotely injected with a priming dose of 65-100 µg PZP in FCA and either one or two boosters of PZP in FIA at three-week intervals based on the determination by Liu et al. (1989) that at least two inoculations are required in horses so antibody titers are raised high enough for a minimum of 6 months. Upon the first inoculation, antigen recognition is initiated which increases antibody titers temporarily. Then, the second inoculation causes increased titers that last for several months, with each follow-up inoculation prolonging the duration of high titers (Kirkpatrick, et al. 1990).

During this study, 14 of the 26 treated mares were already pregnant upon inoculation and gave birth to healthy foals approximately 1 – 3 months after the last inoculation. By October 1998, there was only one pregnancy out of the 26 treated mares, as indicated by analysis of urinary steroids, with zero pregnancies among the 18 receiving 3 inoculations, and one pregnancy out of the 8 receiving two inoculations. The following spring, August 1989, only one of the 26 treated mares produced foals (Kirkpatrick, et al. 1990). Of the 26 treated mares, 14 were boosted again a year later with a single remotely delivered dart containing PZP in FIA. Only 1 of the 14 boosted mares was pregnant and produce a foal the following year, compared to 10 of 22 "sham-treated and untreated mares (45.5%) (Kirkpatrick, et al. 1991). Additional studies were carried out during the next 6 years which demonstrated foaling rates of 3.8% (4 foals in 105 mare-years) among PZP-treated mares compared to 46.2% in untreated mares (Kirkpatrick, et al. 1991). Zero population growth was achieved in 2 years, with an initial decline in the population becoming apparent in 8 years of inoculations and by year 11, the population declined from 175 to 135 horses, a decrease of 22.8% (Kirkpatrick and Turner 2008).

Turner et al. (1996) conducted a study at Virgin Islands National Park, St. Johns, VI (VINP) on free-roaming feral burros (*Eqqus asinus*) to assess the effectiveness of PZP as a contraceptive with results comparable to those seen in the Assateague Island studies. In this study, 16 female burros were treated with PZP contraceptive. Burros were given an initial one- or two-injection PZP treatment and, after 10 – 12 months, were given a one-injection PZP booster treatment. Initial treatment consisted of: (1) two separate injections (3 weeks apart) of a 1.0 mL emulsion, containing 65 µg PZP plus FCA (first injection) followed by a booster of FIA (n = 13); or (2) a single injection containing 130 µg PZP emulsified in FCA (n = 3). The single injection was a time-released method with release rates projected to be continuous across 4 weeks, with greatest release in weeks 1 and 4 followed by a booster shot at the end of the 4 weeks (Turner et al., 1996).

Zero of 13 females darted with a priming dose of 65 – 100 µg in FCA and a booster of 65 – 100 µg PZP in FIA produced foals in the period 12 – 24 months after treatment, while 1 of the 3 females receiving the single dose produced foals. Furthermore, 6 of 11 control females gave birth in that time period. Unlike wild and feral horses, feral burros are not seasonal breeders, and some of the burros were pregnant at the time of treatment.

The results of this study indicate the two-injection protocol was more effective than the single-injection in preventing pregnancies.

The effectiveness of the adjuvant used is an important factor in how efficacious the PZP epitope is as an immunocontraceptive (Lyda, et al. 2005). Since 1998, PZP has been used in captive free-ranging wild horses with a high degree of efficacy, utilizing Freund's Complete Adjuvant (FCA) as the adjuvant of choice for the initial inoculation and Freund's Incomplete Adjuvant (FIA) for booster inoculations. The use of FCA has resulted in 90% or greater efficacy, however two side effects can occur from its use: 1) Injection site reactions, including open abscesses and 2) false-positive tuberculosis (TB) tests in treated animals. The primary ingredient in the FCA is *Mycobacterium tuberculosis* which can cause antibodies against the TB organism. As a result of these side effects, the United States Department of Agriculture (USDA) has voiced opposition to the use of FCA.

Therefore, modified Freund's Complete Adjuvant (mFCA) has been substituted for FCA in titer trials of captive mares. These trials demonstrated no significant difference between mares hand-injected with 65-100 µg PZP in mFCA followed by a booster shot of 65-100 µg in FIA and mares treated with 65-100 µg PZP in FCA followed by a booster of 65-100 µg in FIA. Lyda et al. (2005) reported that 7 of 8 (87.5%) of mares treated with PZP and mFCA remained above the contraceptive titer threshold 10 months after treatment. The effectiveness of mFCA as an adjuvant was verified with these studies.

4. Summary of Regulatory Position and Rationale

Available data provide adequate information to support the unconditional registration of ZonaStat-H as a tool for management of nuisance feral and wild horses, and burros.

Like other animals (e.g. deer, Canada geese, etc.), horses may be pests in some situations. As a result of Federal protection, lack of natural predators, and fecundity (herd sizes can double in about four years), wild horse and burro herd populations have significantly increased, exceeding the BLM appropriate population levels of 27,200 in BLM managed lands. To help control these populations, BLM removes wild horses and burros and transfers them to private ownership or maintains them in BLM holding facilities.

With high population levels and the inability to sell or adopt out all captured wild horses and burros, the BLM has expressed that there is an explicit need to manage wild horse and burro populations because uncontrolled populations may lead to adverse environmental effects such as degradation of wildlife and native vegetation habitat. Additionally, these populations may lead to conflicts with other rangeland uses such as cattle grazing and recreation.

With these factors in mind, EPA is proposing to register ZonaStat-H and PZP for use to control wild and feral horse and burro populations. The Agency feels that ZonaStat-H will provide BLM a much needed alternative control method for wild horse and burro populations. The Agency believes that ZonaStat-H and PZP meet the standard for unconditional registration in FIFRA § 3(c)(5) including that it will not cause any unreasonable adverse effects on the environment. Therefore, the Agency proposes to grant this registration with the labeling requirements below.

5. Labeling Restrictions

To mitigate any risks, the following requirements have been imposed:

- Restricted-Use Pesticide classification limiting application to Department of Interior, and all its designated agents (i.e., National Park Service, Bureau of Land Management, U.S. Fish &Wildlife Service); State departments of agriculture/livestock and wildlife, and their designated agents; Federally recognized Indian tribes, and their designated agents; Department of Defense and its designated agents; Public and private wild horse sanctuaries and reserves; Humane Society of the United States designated agents; USDA and all its designated agents (i.e., U.S. Forest Service, Animal and Plant Health Inspection Service).

- Use limited to only two animals: Wild and feral horses (*Eqqus caballus*) and feral burros (*Eqqus asinus*).

- Label statement restricting the application of ZonaStat-H to horses or burros that will not be used as food or feed.

- Personal Protective Equipment requirements include: long sleeved shirt and long pants, gloves and shoes plus socks to mitigate occupational exposure.

- A warning that pregnant women must not be involved in handling or injecting ZonaStat-H and that all women should be aware that accidental self-injection may cause infertility.

6. Data Requirements

The registrant has fulfilled all data requirements, resulting in an unconditional registration of ZonaStat-H.

APPENDIX I

GLOSSARY OF TERMS AND ABBREVIATIONS

ADNT	Acute delayed neurotoxicity
a.i.	Active Ingredient
aPAD	Acute Population Adjusted Dose
ARI	Aggregate Risk Index
BCF	Bioconcentration Factor
CAS	Chemical Abstracts Service
ChE	Cholinesterase
ChEI	Cholinesterase inhibition
cPAD	Chronic Population Adjusted Dose
%CT	Percent crop treated
DAT	Days after treatment
DEEM-FCID	Dietary Exposure Evaluation Model - Food Consumption Intake Database
DNA	Deoxyribonucleic acid
DNT	Developmental neurotoxicity
DIT	Developmental immunotoxicity
DWLOC	Drinking Water Level of Comparison.
EC	Emulsifiable Concentrate Formulation
EEC	Estimated Environmental Concentration. The estimated pesticide concentration in an environment, such as a terrestrial ecosystem.
EPA	U.S. Environmental Protection Agency
FQPA	Food Quality Protection Act
GLC	Gas Liquid Chromatography
GLN	Guideline Number
LC_{50}	Median Lethal Concentration. A statistically derived concentration of a substance that can be expected to cause death in 50% of test animals. It is usually expressed as the weight of substance per weight or volume of water, air or feed, e.g., mg/l, mg/kg or ppm.
LD_{50}	Median Lethal Dose. A statistically derived single dose that can be expected to cause death in 50% of the test animals when administered by the route indicated (oral, dermal, inhalation). It is expressed as a weight of substance per unit weight of animal, e.g., mg/kg.
LOAEL	Lowest Observed Adverse Effect Level
LOAEC	Lowest Observed Adverse Effect Concentration
LOC	Level of Concern
LOD	Limit of Detection
LOQ	Limit of Quantitation
mg/kg/day	Milligram Per Kilogram Per Day
mg/L	Milligrams Per Liter
MOE	Margin of Exposure
MRID	Master Record Identification (number), EPA's system of recording and tracking studies submitted
MTD	Maximum tolerated dose
NA	Not Applicable
NOEC	No Observable Effect Concentration
NOEL	No Observed Effect Level

NOAEL	No Observed Adverse Effect Level
NOAEC	No Observed Adverse Effect Concentration

_X_ Registration
___ Reregistration
(under FIFRA, as amended)

EPA Reg. Number:	Date of Issuance:
56228-41	JAN 10 2013

Term of Issuance:
Unconditional

Name of Pesticide Product:
Gonacon - Equine

Name and Address of Registrant (include ZIP Code):

U.S. Department of Agriculture, Animal and Plant Health Inspection Service
Environmental Services, Unit 149
4700 River Road
Riverdale, MD 20737

Note: Changes in labeling differing in substance from that accepted in connection with this registration must be submitted to and accepted by the Registration Division prior to use of the label in commerce. In any correspondence on this product always refer to the above EPA registration number.

On the basis of information furnished by the registrant, the above named pesticide is hereby registered/reregistered under the Federal Insecticide, Fungicide and Rodenticide Act.

Registration is in no way to be construed as an endorsement or recommendation of this product by the Agency. In order to protect health and the environment, the Administrator, on his motion, may at any time suspend or cancel the registration of a pesticide in accordance with the Act. The acceptance of any name in connection with the registration of a product under this Act is not to be construed as giving the registrant a right to exclusive use of the name or to its use if it has been covered by others.

This product is unconditionally registered in accordance with FIFRA section 3(c)(5) provided that you:

1. Submit and/or cite all data required for registration/reregistration of your product when the Agency requires all registrants of similar products to submit such data.

2. Make the following label change before you release the product for shipment:
- Revise the EPA Registration Number to read, "EPA Reg. No 56228-41."

Signature of Approving Official:

for Meredith Laws, Chief
Insecticide-Rodenticide Branch, Registration Division (7505P)

Date: JAN 10 2013

EPA Form 8570-6

3. Submit one copy of your final printed labeling before you release the product for shipment.

If these conditions are not complied with, the registration will be subject to cancellation in accordance with FIFRA section 6(e). Your release for shipment of the product constitutes acceptance of these conditions. If you have any questions, please contact Autumn Metzger at 703-305-5314 or metzger.autumn@epa.gov.

A stamped copy of the label is enclosed for your records.

Meredith Laws, Chief
Insecticide-Rodenticide Branch
Registration Division (7505P)

PRECAUTIONARY STATEMENTS

HAZARDS TO HUMANS AND DOMESTIC ANIMALS

Keep away from humans, domestic animals and pets. Wear protective gloves when handling. If pregnant, do not handle or administer product. Accidental injection may cause infertility in women. Wash all implements used for handling or applying product with detergent and water. Do not use these implements for mixing, holding, or transferring food or feed.

ENVIRONMENTAL HAZARDS

Do not apply this product directly to water, or to areas where surface water is present or to intertidal areas below the mean high water mark

PERSONAL PROTECTIVE EQUIPMENT (PPE)

Applicators and other handlers must wear:

-long sleeved shirt and long pants
-gloves
-shoes plus socks

DIRECTIONS FOR USE

Restricted Use Pesticide

It is a violation of Federal law to use this product in a manner inconsistent with its labeling. A copy of this label must be in the possession of the user at the time that the product is applied.

READ THIS LABEL: Read this entire label and follow all use directions and precautions.

IMPORTANT: Do not expose children, pets, or other non-target animals to this product. To help prevent accidents:

1) Keep children out of areas where this product is used.
2) Store product not in use in a location out of reach of children and pets.
3) Apply product only according to the directions authorized.
4) Dispose of product container and spoiled or unused product as specified in the "STORAGE AND DISPOSAL" section on this label.

GonaCon™ - Equine is used to manage fertility in reproductively mature female wild or feral horses *(Equus caballus)* and burros *(Equus asinus)*.

Use caution to prevent accidental self-injection when administering GonaCon™ - Equine to wild or feral horses and burros.

Pregnant women should not be involved in the handling or injection of GonaCon™. Do not ingest. Avoid contact with eyes.

Do not apply this product to food or feed.

Applicators: Additional State regulations and/or permitting may apply to the use of this product in wild or feral horses and burros. All applicable State authorities must be contacted prior to use. GonaCon™ renders vaccinated reproductively mature female wild or feral horses and burros infertile for a minimum of one year following vaccination.

(See right panel for application instructions)

RESTRICTED USE PESTICIDE

DUE TO NON-TARGET INJECTION HAZARD

For use by employees of USDA APHIS Wildlife Services and Veterinary Services, U.S. Bureau of Land Management, U.S. Fish and Wildlife Service, U.S. National Park Service, U.S. Department of Defense, Federally recognized Indian Tribes, State agencies responsible for wild or feral horse and burro management, public and private wild horse sanctuaries, or persons working under their authority.

GONACON™ - EQUINE

For managing fertility in female wild or feral horses (Equus caballus) and burros (Equus asinus)

ACTIVE INGREDIENT

Mammalian Gonadotropin Releasing Hormone	0.03%
OTHER INGREDIENTS	99.97%
TOTAL	100%

ACCEPTED
JAN 10 2013
Under the Federal Insecticide, Fungicide, and Rodenticide Act, as amended, for the pesticide registered under:
EPA Reg. No: 56228-41

KEEP OUT OF REACH OF CHILDREN

CAUTION

Have the product container or label with you when calling a poison control center or doctor, or when going for treatment

STORAGE AND DISPOSAL

Do not contaminate water, food or feed by storage or disposal.

PESTICIDE STORAGE: Keep preloaded GonaCon™ - Equine in a refrigerator (36 °F to 45 °F) until ready for use. In the field, keep preloaded GonaCon™ - Equine in a cooler on ice as long as possible prior to use.

PESTICIDE DISPOSAL: If not used within 6 months of manufacture when held under refrigeration (36°F to 45°F), or if not maintained on ice in the field, disable and dispose of unused GonaCon™ - Equine material and preloaded syringes as medical waste according to applicable Federal, State, and/or Local regulations.

CONTAINER DISPOSAL: Nonrefillable container. Do not reuse or refill container. Disable and dispose of expired material, preloaded syringes or darts, used syringes, darts and needles as medical waste according to applicable Federal, State, and/or Local regulations.

APPLICATION INSTRUCTIONS

GonaCon™ can be administered at any time throughout the year and should not adversely affect an existing pregnancy, but should cause infertility of the vaccinated animal in the subsequent year and possibly longer.

Administer a single vaccination (2 ml) of GonaCon™ at least two to three months prior to the onset of breeding for full contraceptive effect. If longer contraceptive effect is desired, a second vaccination may be given 30 or more days after the first injection or during the following year with no known adverse health effects to the vaccinated animal. The effects of the vaccine may wear off during the second year or sometimes later and vaccinated females may once again become fertile. However, re-immunization with GonaCon™ can extend infertility.

There is a chance some vaccinated females will become permanently sterile. Accidental injection of males will result in infertility.

Two-milliliter (2 ml) doses of GonaCon™ are packaged in pre-loaded, 3-ml plastic syringes.

GonaCon™ can be administered by hand injection, jab stick or remote delivery (darting). Inject 2.0 ml of GonaCon™ by intramuscular injection (IM) into a large muscle mass (e.g., rump, neck).

Hand Injection: Inject IM 2 ml GonaCon™ using the packaged preloaded syringe and a 1.5-inch 18G or 19G stainless steel hypodermic needle.

Jab Stick Delivery: Transfer 2 ml GonaCon™ from the preloaded syringe into the jab stick syringe. Inject IM using a 1.5-inch 14G stainless steel hypodermic needle.

Remote Darting: Recommended dart specifications for this use are a 2 cc dart with a 1.25- or 1.5-inch 14G gelatin barb needle. Transfer 2 ml GonaCon™ from the preloaded syringe into the dart. Deliver IM using an appropriate projection device.

If remote delivery is used, the applicator must make every attempt to recover all darts. If possible, all darts that are discharged and drop from the horses at the shooting site must be recovered before another darting occurs. In exceptional situations, such as an onset of inclement weather, loss of daylight, applicator safety concerns, or other urgent circumstances, the site of a lost dart may be noted and marked, and recovery efforts made at a later time. Examine all fired darts after recovery to determine if the charge fired and the plunger fully expelled its vaccine content.

Syringes must be individually labeled with the following language:

Restricted Use: Injection Hazards
CAUTION
GonaCon™ - Equine

OFFICE OF CHEMICAL SAFETY
AND POLLUTION PREVENTION

November 19, 2015

David S. Reinhold
Chief
Environmental and Risk Analysis Services
USDA-APHIS
4700 River Road
Riverdale, MD 20737

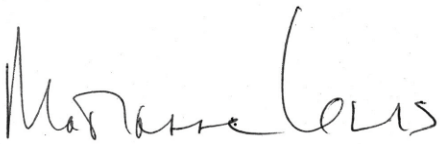
Subject: Label and CSF Amendment – Calculation corrections on CSF and subsequent label changes
Product Name: GonaCon – Equine
EPA Registration Number: 56228-41
Application Date: 7/22/2015, 11/2/2015
Decision Numbers: 508908, 510842

Dear Mr. Reinhold:

The amended label and CSFs referred to above, submitted in connection with registration under the Federal Insecticide, Fungicide and Rodenticide Act, as amended, are acceptable. This approval does not affect any conditions that were previously imposed on this registration. You continue to be subject to existing conditions on your registration and any deadlines connected with them.

A stamped copy of your labeling is enclosed for your records. This labeling supersedes all previously accepted labeling. You must submit one copy of the final printed labeling before you release the product for shipment with the new labeling. In accordance with 40 CFR 152.130(c), you may distribute or sell this product under the previously approved labeling for 18 months from the date of this letter. After 18 months, you may only distribute or sell this product if it bears this new revised labeling or subsequently approved labeling. "To distribute or sell" is defined under FIFRA section 2(gg) and its implementing regulation at 40 CFR 152.3.

Please note that the record for this product currently contains the following CSFs:



- Basic CSF dated 07/22/2015
- Alternate CSF 1 dated 07/22/2015

Should you wish to add/retain a reference to the company's website on your label, then please be aware that the website becomes labeling under the Federal Insecticide Fungicide and Rodenticide Act and is subject to review by the Agency. If the website is false or misleading, the product would be misbranded and unlawful to sell or distribute under FIFRA section 12(a)(1)(E). 40 CFR 156.10(a)(5) list examples of statements EPA may consider false or misleading. In addition, regardless of whether a website is referenced on your product's label, claims made on the

website may not substantially differ from those claims approved through the registration process. Therefore, should the Agency find or if it is brought to our attention that a website contains false or misleading statements or claims substantially differing from the EPA approved registration, the website will be referred to the EPA's Office of Enforcement and Compliance.

Your release for shipment of the product constitutes acceptance of these conditions. If these conditions are not complied with, the registration will be subject to cancellation in accordance with FIFRA section 6. If you have any questions, please contact Jacquelyn Marchese by phone at 703-347-0559, or via email at marchese.jacquelyn@epa.gov.

Sincerely,

Marianne Lewis,
Acting Product Manager 07
Invertebrate & Vertebrate Branch 3
Registration Division (7505P)
Office of Pesticide Programs

KEEP OUT OF REACH OF CHILDREN

CAUTION

Have the product container or label with you when calling a poison control center or doctor, or when going for treatment

STORAGE AND DISPOSAL

Do not contaminate water, food or feed by storage or disposal.

PESTICIDE STORAGE: Keep preloaded GonaCon - Equine in a refrigerator (36 °F to 45 °F) until ready for use. In the field, keep preloaded GonaCon - Equine in a cooler on ice as long as possible prior to use.

PESTICIDE DISPOSAL: If not used within 6 months of manufacture when held under refrigeration (36 °F to 45 °F), or if not maintained on ice in the field, disable and dispose of unused GonaCon - Equine material and preloaded syringes as medical waste according to applicable Federal, State, and/or Local regulations.

CONTAINER DISPOSAL: Nonrefillable container. Do not reuse or refill container. Disable and dispose of expired material, preloaded syringes or darts, used syringes, darts and needles as medical waste according to applicable Federal, State, and/or Local regulations.

DIRECTIONS FOR USE

GonaCon can be administered at any time throughout the year and should not adversely affect an existing pregnancy, but should cause infertility of the vaccinated animal in the subsequent year and possibly longer.

Administer a single vaccination (2 ml) of GonaCon at least two to three months prior to the onset of breeding for full contraceptive effect. If longer contraceptive effect is desired, a second vaccination may be given 30 or more days after the first injection or during the following year with no known adverse health effects to the vaccinated animal. The effects of the vaccine may wear off during the second year or sometimes later and vaccinated females may once again become fertile. However, re-immunization with GonaCon can extend infertility.

There is a chance some vaccinated females will become permanently sterile. Accidental injection of males will result in infertility.

Two-milliliter (2 ml) doses of GonaCon are packaged in pre-loaded, 3-ml plastic syringes.

GonaCon can be administered by hand injection, jab stick or remote delivery (darting). Inject 2.0 ml of GonaCon by intramuscular injection (IM) into a large muscle mass (e.g., rump, neck).

Hand Injection: Inject IM 2 ml GonaCon using the packaged preloaded syringe and a 1.5-inch 18G or 19G stainless steel hypodermic needle.

Jab-Stick Delivery: Transfer 2 ml GonaCon from the preloaded syringe into the jab-stick syringe. Inject IM using a 1.5-inch 14G stainless steel hypodermic needle.

Remote Darting: Recommended dart specifications for this use are a 2 cc dart with a 1.25- or 1.5-inch 14G gelatin barb needle. Transfer 2 ml GonaCon from the preloaded syringe into the dart. Deliver IM using an appropriate projection device.

If remote delivery is used, the applicator must make every attempt to recover all darts. If possible, all darts that are discharged and drop from the horses at the shooting site must be recovered before another darting occurs. In exceptional situations, such as an onset of inclement weather, loss of daylight, applicator safety concerns, or other urgent circumstances, the site of a lost dart may be noted and marked, and recovery efforts made at a later time. Examine all fired darts after recovery to determine if the charge fired and the plunger fully expelled its vaccine content.

Syringes must be individually labeled with the following language:

Restricted Use: Injection Hazard
CAUTION
GonaCon - Equine
Active Ingredient: Gonadotropin Releasing Hormone (0.032%)
KEEP OUT OF REACH OF CHILDREN

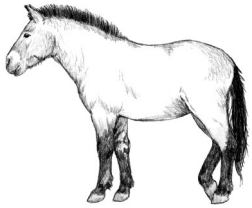
Delayed Reversibility of PZP (Porcine Zona Pellucida) in Free-Ranging Przewalski's Horse Mares



Claudia Feh

Contraception can be important for endangered species management, both in captivity and for reintroductions, reversibility being essential for planned breeding. PZP (porcine zona pellucida) has been successfully employed as a contraceptive in 80 species, in both captive and wild populations. Studies on its efficiency, safety and reversibility show no major detrimental effects. Following 3 years of treatment, feral mares returned to fertility 3.7 years later on average. PZP has been used in Przewalski's horses in zoos, but published data on reversibility is missing. We contracepted 20 Przewalski's mares belonging to two free-ranging subpopulations from the same origin, 8 mares at Le Villaret (France) and 12 re-introduced mares in Khomiin Tal (Mongolia). We administered 65 µg doses of PZP remotely, the primo-injection mixed with Freund's Complete adjuvant, subsequent injections with Freund's Incomplete adjuvant. We treated 9 mares for one year, 7 mares for two years and 4 mares for 3 years. Eight mares were 2 years old at the start of treatment, 1 mare 3, 9 mares between 4 and 8, two mares 11 and 18. All mares were in good to excellent body condition throughout and after treatment. Eleven out of the 20 mares have still not produced a foal after an average time span of 6.7 years following contraception, regardless whether PZP was administered for one, two or three years. The other 9 mares gave birth after an average of 3.2 years. All 12 mares aged 3 years or more at the start of contraception had foaled at least once beforehand. Only 4 of these reversed. The 8 remaining 2 year old mares obviously had no previous foals. All mares were mated regularly throughout the breeding season. All 10 stallions associating with the 20 mares sired foals with other mares. The inbreeding coefficient of mares not producing foals was slightly lower (mean 0.174) compared to mares having foals (mean 0.183). Foaling rate of untreated mares in the same population over 9 years was 0.64 for adults, similar to the 0.72 observed prior to the start of contraception over the same time span. The reaction of Przewalski's mares to PZP seems to differ compared with feral domestic mares, reversibility being delayed and probably compromised in a high percentage of individuals even after a short administration time. Although our study is not experimental and other factors may influence conception, we were able to control for population and previous mare fecundity, mare inbreeding coefficient and stallion fertility. A soft-release approach to reintroductions, including releasing preformed family groups, proved beneficial to survival in many projects. This implies applying contraceptives before shipping to avoid the risk of transporting pregnant females, but PZP seems not ideally suited for Przewalski's mares.

Male infanticide and paternity analyses in a socially natural herd of Przewalski's horses: Sexual selection?

Abstract

The sexual selection hypothesis explains infanticide by males in many mammals. In our 11-year study, we investigated this hypothesis in a herd of Przewalski's horses where we had witnessed infanticidal attacks. Infanticide was highly conditional and not simply linked to takeovers. Attacks occurred in only five of 39 cases following a takeover, and DNA paternity revealed that, although infanticidal stallions were not the genetic fathers in four cases out of five, stallions present at birth did not significantly attempt to kill unrelated foals. Infanticide did not reduce birth intervals; only in one case out of five was the infanticidal stallion, the father of the next foal; mothers whose foals were attacked subsequently avoided associating with infanticidal stallions. Therefore, evidence for the sexual selection hypothesis was weak. The "human disturbance" hypothesis received some support, as only zoo bred stallions which grew up in unnatural social groups attacked foals of mares which were pregnant during takeovers.

1. Introduction

Observations on many species show that some males, after taking over a female group, kill vulnerable infants dependent on their mothers. The sexual selection hypothesis received strong support to explain infanticide by mammalian males, mainly in primates, carnivores and rodents (Van Schaik, 2000a). The overall assumption states that infanticidal males produce offspring at a faster rate than non-infanticidal males. Therefore, if male infanticide is adaptive, the following conditions should be fulfilled (Hausfater and Hrdy, 1984).

1. The probability that the infanticidal male had sired the attacked infants was zero or close to zero.
2. The mother can be impregnated earlier than if the infant had lived.
3. The infanticidal male has an increased probability of siring the next infants relative to the current offspring.

The seven extant Equids should be at a low risk regarding infanticide. In contrast to typical species where infanticide is of high prevalence (Van Schaik, 2000a), foals are precocious, mares only give birth to one offspring at a time, show post partum oestrous and, in the mean, gestation time (11 months in horses) generally lasts longer than mean lactation time (8 months in horses).

Despite being classified as low risk species, male infanticides in relation to takeovers have been reported in Plains zebras (Pluhacek and Bartos, 2000, 2005; Pluhacek et al., 2006), Mountain zebras (Penzhorn, 1984), Przewalski's horses (Ryder and Massena, 1988; Zarkikh, 1999; Kolter and Zimmermann, 1988; Boyd, 1991) and Camargue horses (Duncan, 1982), although all actual observations of stallions killing foals were based on studies with human induced experimental male replacement. Some authors tended cautiously towards favouring the classical sexual selection hypothesis (Duncan, 1982; Pluhacek and Bartos, 2000; Ryder and Massena, 1988), while others did not (Kolter and Zimmermann, 1988; Zarkikh, 1999). Infanticide has never been witnessed in studies on natural freeliving populations of equids (Berger, 1983; Duncan, 1982; Feist and McCullough, 1976), despite the considerable length and intensity of the observational studies.

In this study, we first investigated whether infanticide in stallions was linked to takeovers, a first prerogative, and under what conditions. Indeed, as has been shown in experimental studies on rodents, infanticide rates can be highly conditional. Both mating

UNCORRECTED PROOF

with the future mother and familiarity during gestation, which are thought to enhance paternity probability, reduce infanticide rates regardless of genetic paternity (Huck et al., 1982; Perrigo and Cully Bryant, 1990; Elwood, 1980). Therefore, we studied links between infanticide and the stallions' presence at time of conception, their presence during gestation in general and the gestational stage of the mother. We then tested whether males preferentially attacked unrelated foals, whether the interbirth interval was reduced following infanticide, and whether infanticidal males were the genetic fathers of the foals to be born to the mother of the attacked foals.

Furthermore, we examined the two, somehow contradictory, female defence strategies mentioned in the literature with regard to the influence of male infanticide on mammalian social systems. Do mares whose foals suffered infanticidal attacks subsequently associate with the infanticidal male in an exclusive one-male unit, such as suggested for mountain gorillas and other species (Watts, 1989)? Or do they engage in multi-male matings as a consequence to infanticide, as suggested by many authors (Wolff and MacDonald, 2004)?

Finally, we discuss alternatives to the sexual selection theory for infanticide by males, such as the "social pathology" hypothesis.

Although the sample size of infanticidal behaviour in our study is low, this is the case in most studies on the subject. For example, Van Schaik (2000b) synthesis of this type of behaviour in primates is based on 55 observed cases from 17 species. Moreover, if infanticide brings an evolutionary advantage to males killing unrelated offspring after takeovers of females, situations where infanticide occurs after male takeovers should be compared to situations where this behaviour does not occur, and the reproductive success of males committing infanticide should be compared to that of non-infanticidal males. To our knowledge, this is the first study on a socially natural mammalian population which investigates these aspects of infanticide.

2. Materials and methods

2.1. Study animals

Between 1993 and 1994, we released 11 horses (five subadult stallions, six adult mares) originating from eight different zoos on a 200 ha pasture at Le Villaret, Causse Méjan (Lozère), a high plateau of the Massif Central. The pasture area was increased to 380 ha in 2001. The herd grew to a maximum of 55 animals in 2003. Human intervention was kept to a minimum (e.g. supplementary feeding on two occasions only, no anti-parasite treatment, veterinary care only for severely sick and isolated horses). The sex-ratio was slightly biased towards males in all age-classes. The horses quickly formed one-male family groups (3–5 over the different years), and bachelor male groups (1–2), similar to all feral horses living under natural conditions. Sixty-five foals were born between 1993 and 2003, of which 12 died in the first month. Five of these foals were stillborn, they never breathed, and one other foal was found dead on its day of birth, the cause could not be identified despite an autopsy. These foals were excluded from the infanticide analysis, as they had died before the stallions could potentially attack them.

2.2. Observation methods and definitions

We carried out a systematic individual behavioural follow-up over all 11 years, from 1993 to 2003. Except for weekends, we made observations every other day, 1 h in the morning and 1 h in the evening, for a total number of 2692 h. We recorded group composition at the beginning of every observation period. Groups were defined as spatial units where the diameter of the group was inferior to the distance from the next group. All individual horses then were recorded as belonging to a group. We classified horses that stayed at a distance exceeding the diameter of the group as solitary. During the foaling season, we checked the herd every day, and newborn foals were closely watched for 2 days.

We defined takeovers as observations when we saw a mare or a group of mares together in the same group with a new stallion, who had previously been a member of a different group, or classified as solitary.

Gestation in Przewalski's mares lasts for a mean of 48.6 weeks or 340 days (range 47–50 weeks) (Monfort et al., 1994). We calculated conception time backwards from the day of parturition, and added 15 days in each direction for "presence at conception time" by the stallions, as oestrous can last for 1 week in mares and we wanted to make sure to cover uncertainties with regard to actual fertilisation. We calculated interbirth intervals based on the same data.

Between 290 and 29 days before parturition, oestrogen levels exceed the highest levels found during oestrous (Monfort et al., 1994). This allowed us to separate "high hormone level" gestation periods from "low hormone level" gestation periods. Indeed, it is known from domestic stallions and even geldings that they are able to detect oestrous in mares from olfactory cues (Stahlbaum and Houpt, 1989), so they may well be capable of detecting gestation, at least when hormone levels are high.

2.3. Infanticidal behaviour

Infanticidal attacks on foals cannot be mistaken for any other behaviour. The stallions lunge at the foal and viciously bite it in repetitive actions, often at the head or neck. They then frequently toss the foal in the air and attack it again once on the ground, with teeth and sometimes hooves. These attacks can be repeated many times, sometimes over several days. The inflicted wounds range from open or internal haemorrhages to broken jaws, skulls, vertebrae or limbs. We witnessed five foals being attacked in this way. Two foals survived due to the energetic interventions of their mothers who, at that stage, were older and dominant over the infanticidal stallion. For the three other foals, their mothers tried equally to intervene, in one case helped by the half-sister of the mother. Our observer team tried to keep the stallion at bay during infanticidal attacks on two foals, without much success (the stallion took profit of a short absence). One foal died shortly after repeated attacks, and we euthanised the two others as they suffered from lethal wounds. Similar descriptions of infanticidal

UNCORRECTED PROOF

Please cite this article in press as: Feh, C., Munkhtuya, B., Male infanticide and paternity analyses in a socially natural herd of Przewalski's horses: Sexual selection?, Behav. Process. (2008), doi:10.1016/j.beproc.2007.12.009

attacks by equid stallions are found in the literature (Pluhacek and Bartos, 2000; Ryder and Massena, 1988; Zarkikh, 1999; Duncan, 1982; Kolter and Zimmermann, 1988).

For our analysis on infanticide, we only included witnessed attacks. Thanks to the high observation pressure, it is highly unlikely that we missed out others.

2.4. DNA paternity analysis

DNA was extracted from blood samples or skin biopsies taken mostly with the help of a hypodermic gun. ETH (Swiss Federal Institute of Technology, Zürich) and Labogena (Jouy-en Josas, France) performed the genetic analysis based on the 17 standard commercial microsatellites used for pedigree analysis in domestic horses. We were able to establish the complete pedigree of our herd, including the 11 original horses and the 65 foals born at Le Villaret. We therefore have no uncertainty about paternities despite several adult stallions being present. We checked the paternity of each foal against all potential fathers 2 years or older present in the herd, as this is the age of physiological sexual maturity in Przewalski's stallions in zoos (Monfort et al., 1994).

2.5. Statistical analysis

We analysed infanticidal behaviour from the foals' point of view and therefore treated foals as independent samples. Even if several foals had the same mother or the same father, this should not influence its probability of being attacked or not with regard to takeovers by new males.

We used non-parametric tests for all analyses, as we were unable to test for distribution because of the relatively small sample size. We calculated exact probabilities with the help of StatExact software programme (CYTEL) for the same reason. All tests are two-tailed.

3. Results

3.1. Takeovers and infanticidal behaviour

Twenty live births out of 59 (18 different mothers) were not preceded by male takeovers of the mother between the time of conception and 30 days after parturition. None of these 20 foals were attacked by stallions. Out of the remaining 39 foals, whose mothers had changed their reproductive partner, five foals (three males, two females), were attacked by stallions. There was no significant relation between takeovers and infanticide (Fisher's exact, $p = 0.1558$).

3.2. Conditionality of infanticidal behaviour (paternity probability)

Exclusive mating opportunity with the mother at the time of conception, when followed by a separation during gestation, did not prevent the stallions from attacking foals (Fisher's exact, $p = 0.3716$). We found no relation between infanticidal behaviour and the continuous presence of the stallion during gestation, regardless of his presence at conception time. (Fisher's exact, $p = 0.1558$). A continuous association between the stallion and the future mother during the high level hormone gestation period compared to low hormone level gestation period, without being present at conception, had no influence on infanticide (Fisher's exact, $p = 0.2663$). But then, when stallions were present during the time of conception and during high hormone level gestation periods, or formed a permanent association from the time of conception to the day of birth, foals had a significantly lower probability of being attacked, regardless of takeovers during other periods (Fisher's exact, $p = 0.0036$).

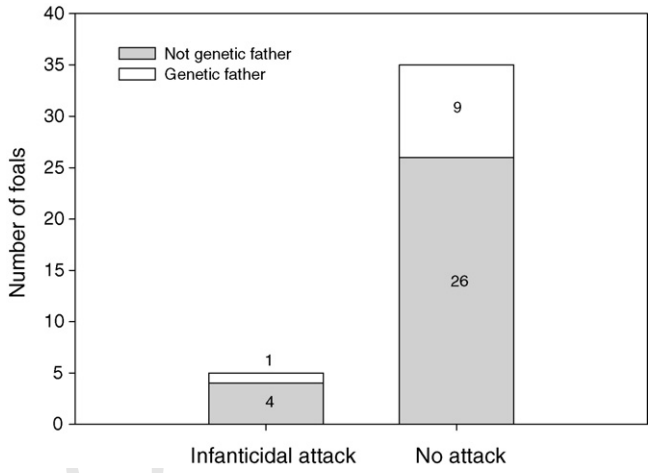

Fig. 1. Number of foals attacked/not attacked by stallions present at birth following takeovers.

3.3. DNA paternity analysis and infanticide

With the exception of two foals out of 59, genetic fathers had associated with the mother during the time of conception, although in 11 cases, two alternate stallions were present. For 26 out of 35 foals, the stallion present from the day of birth to 30 days after parturition was not its genetic father but he did not attack the foal after a takeover (Fig. 1). Although four out of five infanticidal attacks were directed towards unrelated foals (one stallion killed his own foal), unrelated foals were not significantly targeted compared to foals sired by the stallion (Fisher's exact, $p = 0.4165$).

3.4. Interbirth intervals and infanticide

Interbirth intervals following infanticide were not significantly different from interbirth intervals before or after infanticide for the mares whose foals were attacked (Permutation test for paired replicates, $n = 5$, $p = 0.375$).

3.5. DNA paternity analysis of offspring following infanticide

Subsequent to the attack on an infant, only one foal out of five was sired by the stallion which previously had attacked a foal of the same mare.

UNCORRECTED PROOF

Please cite this article in press as: Feh, C., Munkhtuya, B., Male infanticide and paternity analyses in a socially natural herd of Przewalski's horses: Sexual selection?, Behav. Process. (2008), doi:10.1016/j.beproc.2007.12.009

3.6. Characteristics of infanticidal stallions

Out of the nine stallions that formed their own one-male reproductive units over the 11 years, only two attacked foals. Both infanticidal stallions originated from zoos, but then, two other stallions of the same origin were never observed to show infanticidal behaviour. We never saw the five reproductive stallions of the second generation, born at Le Villaret, killing foals, despite forming their units, or increasing their groups, after takeovers of pregnant mares (eight cases) or of mares with vulnerable foals (three cases). The latter stallions were neither the genetic fathers of the foals nor had they associated with the mothers during the time of conception or gestation.

One and a half years after attacking foals, one of the infanticidal stallions died accidentally due to a cause not related to the set-up of the project, so his behaviour could not be monitored further. The other one continued to be a reproductive stallion for 3 years without attacking foals before he was definitely replaced by another stallion and subsequently joined a bachelor group where he still lives, 4 years later. Anecdotally, DNA paternity revealed that the infanticidal stallion which we were able to follow during his whole tenure length had a lower life-time reproductive success (five foals sired, three survived) compared to the two non-infanticidal stallions of the same cohort and the same zoo origin (16 and 9 foals sired, respectively, 12 and 7 survived).

3.7. Female defence strategies

Mothers whose foals had been attacked avoided associating with the infanticidal stallion in the years after (sign-test, $n = 17$, $p = 0.049$). In 11 cases, two stallions were present during the time of conception, but we found no tendency for mothers to engage preferentially in multi-male matings during conception time after one of their foals had been attacked (Fisher's exact, $p = 0.563$).

4. Discussion

Infanticide by males in this herd of Przewalski's horses was highly conditional and not simply linked to takeovers. Attacks on foals were significantly reduced only when stallions associated with the future mother at the time of conception, exclusively or not, and during the high hormone gestation period, whether the stallion was the genetic father or not. Although most infanticidal behaviour was directed against unrelated foals, 74 % of unrelated foals (26 cases out of 35) were not attacked following takeovers by the stallions present at birth. Mothers were not fertilized earlier after infanticides, and the infanticidal stallion was the father of the next foal in one case out of five only. Moreover, mothers whose foals had been attacked avoided associating with the infanticidal stallion in the years after. Therefore, the evidence in support of the classical sexual selection hypothesis was weak at most.

Van Schaik (2000a) summarizes the other hypotheses that were suggested as explanations for infanticide by males, four of which can be excluded for evident reasons. We eliminate

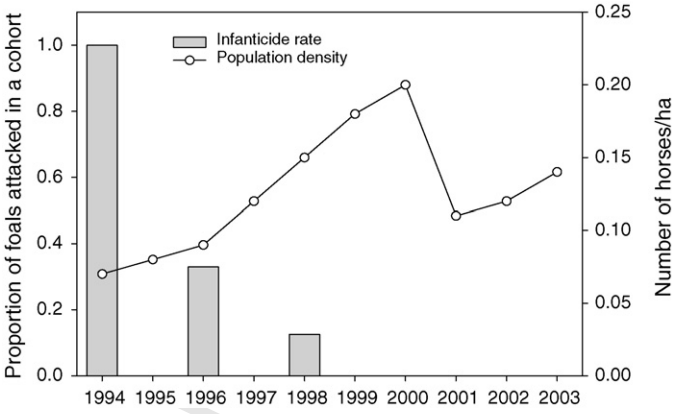

Fig. 2. Infanticide rate and population density.

the "exploitation" hypothesis, as cannibalism obviously never occurred, as well as the "resource competition" hypothesis; in this study, population density and therefore grazing competition increased, while infanticide decreased (Fig. 2). We rule out the "elimination of future rivals", as two out of the five attacked foals were females, an observation confirmed by other studies on equids (Duncan, 1982; Pluhacek and Bartos, 2000; Zarkikh, 1999). Infanticide as a "by-product of male aggression" mainly aimed at females can be rejected. The attacks we observed were without doubt directed towards the foals, not their mothers. The "social pathology" hypothesis states that infanticide is either linked to crowding or to human disturbance. As mentioned above, population density in our herd increased nearly threefold while infanticide disappeared after the first 6 years. However, only zoo bred stallions committed infanticide. Interestingly, all witnessed records of male infanticide in equids concern stallions which have not grown up in socially natural herds, the main difference being that male foals born into a group are separated at a relatively early age from their father and sometimes their mother, before acting as reproductive stallions. Moreover, in all cases of witnessed infanticides, the reproductive partner of the infanticidal stallion, a pregnant mare, was always imposed by humans (Pluhacek and Bartos, 2000; Ryder and Massena, 1988; Kolter and Zimmermann, 1988; Zarkikh, 1999; Duncan, 1982). Infanticide by males in equids therefore seems clearly to contain an element of human "disturbance" or intervention, even if it may have gone unobserved in some populations due to its rarity.

Optimal Control of Wild Horse Populations with Nonlethal Methods

Robert Fonner and Alok K. Bohara

ABSTRACT. *Effective management of wild horse populations has proven difficult for land managers. This paper develops and evaluates dynamic optimization models of wild horse management for three nonlethal population control methods: removals, fertility control, and a hybrid method combining removals and fertility control. Two state variables are included in the models to account for horses on the range and horses in off-range holding facilities. The optimization problems are solved and dynamic simulations are generated for each method. The results indicate that a strategic approach to nonlethal wild horse population control has the potential to significantly improve management efficiency.* (JEL Q28, Q57)

I. INTRODUCTION

Wildlife populations provide a variety of amenities to society, ranging from food and recreation to ecosystem regulation and existence values. Wildlife populations can also impose costs on society through interference with human activities, degradation of habitat, and spreading of disease. Species that both provide a valuable resource and impose societal costs are classified in the literature as multi-use species (e.g., Horan and Bulte 2004; Zivin, Hueth, and Zilberman 2000). Some multi-use species require active management to keep populations from imposing net societal costs. Striking a balance between the costs and benefits of multi-use species can involve active population management. Direct population control is commonly carried out through increased regulated hunting or trapping (Rondeau 2001). However, when multi-use species are endeared to the public, lethal population control methods may not be palatable from a societal perspective. In these cases, wildlife can be captured then relocated, or captured then held in captivity. A third alternative, fertility control, is an emerging nonlethal population control method that can be implemented without displacing animals from their range.

This study evaluates alternative nonlethal strategies for controlling wild horse populations in the American West—a multi-use species for which traditional population control methods are not a politically feasible option. Dynamic economic models of optimal wild horse management are developed for two nonlethal management methods: horse removals and fertility control. A third "hybrid" model is also developed to investigate the effectiveness of using removals and fertility control in tandem. The models account for how management decisions and horse biology influence the dynamics of horse populations on the range, and the population of horses in holding facilities. The objective functions incorporate the costs of on-range management, the costs of off-range holding, and the net benefits associated with wild horse populations. Model parameters are calibrated using published studies on wild horse population biology and Bureau of Land Management (BLM) expenditure data. The value of ongoing status quo management is also estimated, and policy simulations are generated for horse-removal, fertility-control, and hybrid management scenarios. Additional scenarios are developed to assess the sensitivity of model results to shorter time horizons and a cost minimization specification. The simulation results are then examined to glean insights for effectively managing wild horse populations.

This study fits within a growing body of literature examining the dynamics of multi-use species management. A key characteristic of these analyses is that the shadow price of multi-use species can be either positive or negative, which can lead to multiple potentially optimal equilibria (Rondeau 2001; Zivin, Hueth, and Zilberman 2000). Prior studies have investigated the dynamics of multi-use species management in the context of controlling beaver, deer, and wild pig populations (Huffaker, Bhat, and Lenhart 1992; Rondeau and Conrad 2003; Zivin, Hueth, and Zilberman 2000); wolf reintroductions (Rondeau 2001); and invasive species management with biological controls (Fenichel, Horan, and Bence 2010). This article contributes to the dynamic multispecies management literature an analysis of nonlethal population control using removals with off-site holding, and fertility-control methods.

II. BACKGROUND

Free-roaming horses are an enduring icon of the American West, but an effective and sustainable population management plan has eluded land managers for decades. Western wild horse populations are descendants of the domestic animals that were introduced by Spanish explorers in the early 1500s. Once introduced, the horse populations grew quickly, and by the year 1800 wild horses roamed in large herds from Texas to California (Dobie 1952).

Rapid settlement of the western United States and the subsequent development of western lands led to conflicts with wild horse populations in the 1800s and 1900s. During this time, wild horses were sought out and destroyed or captured for commercial slaughter to prevent their interference with grazing and agricultural activities (Phillips 2012). By 1971, the total U.S. wild horse population was reduced to approximately 9,500 a (Pitt 1984). Some wild horse advocates viewed wild horse management practices as inhumane, and by the mid-twentieth century these advocates had organized to lobby Congress for wild horse protections. The campaign garnered public interest and media coverage; and in 1959 Congress passed legislation to prohibit the use of aircraft or motorized vehicles to hunt horses and burros on public lands (Pitt 1984).

In 1971 Congress passed the Wild and Free-Roaming Horses and Burros Act, legislation that continues to guide the BLM's management of wild horse populations. The act banned private horse gathers and tasked the BLM with "protection, management and control of wild free-roaming horses and burros on public lands" (National Research Council [NRC] 2013). The bill's language guides the BLM to manage horses and burros at "the minimal feasible level" to "achieve and maintain a thriving natural ecological balance on the public lands" (NRC 2013). These directives must be balanced with the BLM's mandate to manage public lands for multiple uses. Without active control, horse populations can become a stress on grazing land (Pimentel, Zuniga, and Morrison 2005). To prevent rangeland degradation, the BLM actively gathers wild horses and removes them from the range with the goal of keeping populations within predetermined appropriate management level (AML) bounds. Adoptive homes are sought for removed horses, and unadopted animals are sent to long-term holding facilities. Current BLM policy does not support selling unwanted horses for slaughter.

In recent years, unwanted horses have been accumulating at holding facilities. During the 2015 fiscal year, 66% of the Wild Horse and Burro Program's (WHBP) $77.2 million budget was dedicated to maintaining captive horses (BLM 2016b). In 2000, by comparison, holding accounted for 46% the $19.8 million total program budget (Government Accountability Office 2008). Furthermore, Garrott and Oli (2013) estimated the total net present value (NPV) cost of caring for the horses currently in holding, if no more were added, at nearly $350 million. Under the existing management program, these authors estimate that the total 2013–2030 costs of maintaining unadopted horses in captivity would total $1.1 billion.

Facing an uncertain future, the BLM requested that the NRC scientifically evaluate the challenges facing the WHBP (NRC 2013). In their report, the council offered guidance for developing dynamic models that could assist the BLM with identifying cost-effective management options. Specifically, a need was

expressed for a model that evaluates the dynamics of on-range and off-range populations, and the costs and consequences of existing and alternative management regimes (NRC 2013).

The findings of the NRC report have not yet led to appreciable shifts in the BLM's wild horse management strategy. Meanwhile, horse populations remain above the AML in most areas, and over 45,000 horses are held in off-range facilities (BLM 2015c). The unsustainable nature of this situation recently garnered coverage by several major media outlets, heightening awareness of wild horse management issues (*The Economist* 2016; Phillips 2016). In September 2016, the citizen-led Wild Horse and Burro Advisory Board recommended euthanizing horses in holding after offering them for adoption. However, following public outcry from animal advocates, the BLM stated that it does not intend to change its policy against wild horse euthanization (Chokshi 2016). Here, we evaluate management alternatives using nonlethal strategies to inform future management actions under current BLM policy.

III. MODELS OF OPTIMAL WILD HORSE POPULATION CONTROL

This section presents dynamic models of optimal wild horse population control for two management methods: removing horses from the range and treating horses with a fertility-control vaccine. A hybrid management regime combining removals with fertility control is then developed. The optimal management policy under a given set of assumptions is to choose a sequence of annual population control efforts that maximizes the net benefits associated with wild horse populations over time.

Both removal and fertility-control methods require that horses be gathered on the range. With removal, gathered horses are transported to short-term facilities where adoptive homes are sought for the animals. Horses that go unadopted are shipped to long-term holding facilities. One of the most promising and practical fertility-control methods for wild horse populations is the long-lasting formulation of porcine zona pellucida vaccine (PZP-22), an imunocontraceptive that is administered through injection after horses are gathered. Treated horses are released back to the range, where the contraceptive remains about 85% effective after 22 months (NRC 2013).

The annual cycle of horse management in the optimization models coincides with the fiscal year. Management actions begin October 1 and continue through the end of February. Wild horse foaling (i.e., birthing) occurs from March 1 to June 30, and the BLM prohibits helicopter gathers during that period (BLM 2010). Net population benefits are assumed to accrue from July 1 through September 30.

Optimal Horse Removal

The NPV of a population of wild horses managed in perpetuity with removal methods is maximized where the chosen sequence of removals $\{Y_0,\ldots,Y_\infty\}$ solves the problem in [1].

$$\max_{\{Y_t\}} \sum_{t=0}^{\infty} \rho^t [B(X_t) - C^{\mathrm{g}}(Y_t) - C^{\mathrm{I}}(I_{t-1},X_{t-1},Y_t) - C^{\mathrm{TR}}(X_{t-1},Y_t) - C^{\mathrm{MISC}}(X_{t-1},Y_t) - CADPT\gamma_t - SC_t], \quad [1]$$

subject to

$$X_t - X_{t-1} = F(X_{t-1}) - Y_t\left[1 + \frac{F(X_{t-1})}{X_{t-1}}\right],$$

$$I_t - I_{t-1} = -I_{t-1}m_{\mathrm{I}} + Y_t\left[1 + \frac{F(X_{t-1})}{X_{t-1}}\right] - \gamma_t,$$

$$Y_t \le \min\{Y^{\max}, \delta X_{t-1}\} \forall t,$$

$$X_{-1} \text{ is given,}$$

$$I_{-1} \text{ is given,}$$

$$X_t^{\min} \ge AML \forall t,$$

$$SC_t = \begin{cases} 0 \text{ if } Y_t = 0 \\ SC \text{ if } Y_t > 0 \end{cases}.$$

Initial population X_{-1} is the population size when the first management cycle begins. The choice variable Y_t is the number of horses gathered during the first five months of period

t. In the absence of management, the horse population grows by $F(X_{t-1})$ during period t foaling. Under optimal removal management, the population transitions to size $(X_{t-1} - Y_t)$ after removals are implemented and then grows to size X_t before benefits are realized in the latter part of period t. Many of the female horses removed from the range are pregnant and give birth off-range rather than on-range. Thus the effective impact of removals on horse population growth is $Y_t[1 + F(X_{t-1})/X_{t-1}]$, where $F(X_{t-1})/X_{t-1}$ approximates the per capita growth increment for horses in a population of size X_{t-1}. This also implies that removing Y_t horses from the range results in $Y_t[1 + F(X_{t-1})/X_{t-1}]$ captive horse births during period t. Furthermore, the total cost of gathering horses, $C^{g}(Y_t)$, depends on the number of horses gathered. Initiating management actions at the beginning of a management period is associated with setup costs $SC_t = SC$.

The inventory of horses in long-term holding at the beginning of period t equals I_{t-1}. These horses are held in long-term facilities until the end of the period when a discrete mortality event occurs at rate m_{I}. The horse inventory in short-term holding during period t equals effective removals in that period, $Y_t[1 + F(X_{t-1})/X_{t-1}]$. Adoptions occur at the end of the period, and the remaining horses are shipped to long-term holding. The costs of off-range holding during time t are given by $C^{\mathrm{I}}(I_{t-1}, X_{t-1}, Y_t)$. The costs of shipping horses from short-term to long-term holding are $C^{\mathrm{TR}}(X_{t-1}, Y_t)$.

The parameter γ_t represents the horses adopted in period t, and γ is the annual state adoption demand. The first γ removed and captive-born horses are adopted and the rest go to long-term holding facilities. Thus, the number of horses adopted in period t equals $Y_t[1 + F(X_{t-1})/X_{t-1}]$ if effective removals (i.e., removed plus captive-born horses) are less than or equal to γ, and equals γ otherwise. The costs associated with administering an adoption are $CADPT$, and total adoption costs in period t equal $\gamma_t CADPT$. When removals plus captive births exceed adoption demand, adoption costs are a fixed cost of management. The miscellaneous costs related to compliance inspections, horse preparation, and additional holding are given by $C^{\mathrm{MISC}}(X_{t-1}, Y_t)$.

Wild horses are associated with economic values beyond the costs of population management. Wild horses provide recreation benefits for wildlife viewers and nonuse benefits for individuals who value knowing that wild horses roam free on the western range. Horse populations can also impose economic costs through displacement of wildlife species and domestic livestock, and through degradation of rangelands. The net economic benefits provided by a wild horse population of size X_t are given by the function $B(X_t)$. It is assumed that $B(X_t)$ is a strictly concave, single-peaked function that reaches its maximum where $X = \bar{X}$. Thus, the marginal benefits function $B_x > 0$ for $X \in [0, \bar{X})$ and $B_x < 0$ for $X \in (\bar{X}, \infty]$.

Several constraints are placed on the optimal horse management solution. During a given period, the horse population is smallest after removals occur but before foaling begins. The models specify that this minimum population level, $X_t^{\min}$, must be above the low-range AML set by the BLM. Wild horse managers may be constrained by the number and proportion of animals that can be gathered in a given year (NRC 2013). Constraint parameter δ is the maximum proportion of the population that can be gathered in a single period. Gathers are also constrained in the model by the maximum total number of horses that can be gathered in a single period, $Y^{\max}$. Finally, the discount factor ρ reflects time preference and is bound between 0 and 1 (inclusive).

Optimal Fertility Control

The optimal fertility-control program is a sequence of fertility treatment choices that maximizes the following problem:

$$\max_{\{Y_t\}} \sum_{t=0,2,4,\ldots}^{\infty} \rho^t \left[B(X_t) + \rho B(X_{t+1}) - C^{\mathrm{g}}(Y_t) - C^{\mathrm{fc}}(Y_t, HMA) - C^{\mathrm{I}}(I_{t-1}) - SC_t \right], \quad [2]$$

subject to

$$X_{t+2} - X_t = F_{t+1}(X_t, Y_t) + F_{t+2}(X_{t+1}, Y_t),$$
$$I_{t+1} - I_{t-1} = I_t(1 - m_{\mathrm{I}}) - I_{t-1},$$
$$Y_t \le \min\{Y^{\max}, \delta \tilde{X}_t\},$$
$$X_{-1} \text{ is given},$$
$$I_{-1} \text{ is given},$$
$$\tilde{X}_t \ge AML \forall t,$$
$$SC_t = \begin{cases} 0 \text{ if } Y_t = 0 \\ SC \text{ if } Y_t > 0 \end{cases}.$$

As in the removals model, the horse population is of size X_{-1} when fertility-control management commences, and Y_t horses are gathered during the first five months of period t. All gathered horses are released back to the range after the mares (i.e., female horses) are treated with contraceptives. Gathers are assumed to occur once every two periods to coincide with the approximate effectiveness duration of PZP-22.

Fertility-control treatments prevent conception but do not interfere with the development of horses in utero (Kirkpatrick and Turner 2003). Thus, fertility treatments applied in period t begin to impact population growth in period $t+1$. Because of this delayed impact, the population grows to size $X_0 = F(X_{-1}) + X_{-1}$ by the beginning of the second period regardless of the initial level of fertility-control effort. The fertility-control formulation considered in this model is effective for two periods, so the treatments applied in period t impact population growth in periods $t+1$ and $t+2$. Fertility-control treatments directly impact the population growth rate. The population growth increments impacted by fertility control undertaken in period t are given by $F_{t+1}(X_t, Y_t)$ and $F_{t+2}(X_{t+1}, Y_t)$. There are no horse removals in the fertility-control optimization model. Thus, the initial horse inventory decays according to mortality rate m_{I} until there are no horses left in holding. The costs of horse holding are determined in the same manner as in the removals model, except that gathers and population size have no impact on holding costs and no are horses held in short-term holding.

Costs specific to fertility-control management (C^{fc}) are assumed to be a function of the number of horses gathered for treatment (Y_t) and the number of BLM herd management areas (*HMA*) where fertility control is undertaken. Gather constraints under fertility-control management mirror the constraints under removals, with one notable exception. The delayed effect of fertility control necessitates a more restrictive gather constraint to facilitate dynamic programming of the solution. The constraint $\tilde{X}_{t-1}$ is the lower bound of the previous period population.

Hybrid Management: Combining Removals and Fertility Control

Horse-removal and fertility-control methods have thus far been considered independently. Each of these approaches has advantages that could be leveraged in a population management regime utilizing both removals and fertility control. The following section discusses the strengths and weaknesses of removals and fertility control and proposes a hybrid management regime that combines both methods.

Compared to removals, fertility control is a more benign method of population management that better aligns with the BLM's mandate to manage horses at the "minimum feasible level." Fertility control may also represent a low-cost population control alternative as it does not require off-range management of horses. However, reducing or stabilizing horse populations with fertility control alone requires that a large share of the population be frequently gathered and treated (NRC 2013).

Removal management directly decreases the base from which a population grows and prevents removed pregnant females from giving birth on the range. Furthermore, removals have an immediate impact on the population compared to the delayed effect of fertility control. These characteristics make removal management a more effective means of reducing horse populations in terms of population reduction per unit of gathering effort. Management with removals also has drawbacks. It requires costly long-term management of off-range horses and is a more intensive management alternative compared to fertility control.

Because removals and fertility each have respective strengths and weaknesses, a management alternative that allows for both removals and fertility control may be preferred to management under a single method. Specifically, a "hybrid" management program could allow for population reductions while reducing the number of horse removals required to maintain populations at a desirable level. Hybrid management may also reduce the intensity of population management subject to maintaining ecological balance on the range.

The NRC's report describes a possible hybrid management scenario (NRC 2013). Following this description, the hybrid scenario is specified to involve several years of intensive removals to reduce the population, followed by a management regime that incorporates fertility control. Specifically, hybrid management involves z consecutive years of removals at the $Y_t = \min\{Y^{\max}, \delta\tilde{X}_t\}$ level until the population is within the AML range. Following the initial reduction phase, horses are managed on a two-year gather cycle with a fixed number of removals and optimally chosen fertility-control effort. The hybrid management model is presented in the Appendix. The number of horses removed at the beginning of each management cycle, q, is the minimum removal effort that maintains a population below carrying capacity in the long term under optimally chosen fertility control.

IV. MODEL CALIBRATION

The objective of this article is to inform wild horse management through development and evaluation of dynamic bioeconomic models. Because the form of the defined optimization problems makes derivation of analytical solutions impractical,[1] we proceed by exploring the problems empirically and develop policy insights through dynamic simulations. This section specifies functional forms, parameters, and assumptions for the optimal horse management models.

[1] These characteristics include having objective functions that are nonmonotone in X, nonlinear transition functions for X and I, and multiple state variables.

Separate models were developed for Nevada and Oregon based on data availability. Thus, all of the herds within in a state were modeled as a single meta-population. This treatment is appropriate given the significant migration that can occur between herds (e.g., see BLM 2015b), but it also imposes no migration between states and equal density dependence (i.e., X/K) across herds.

The biological parameters specified for the models are based primarily on studies of the Beatys Butte herd in eastern Oregon. Due to data limitations, the models do not incorporate burro-specific cost or population biology parameters. Monetary costs and benefits in the models are inflation-adjusted to 2015 dollars. The discount factor (ρ) reflects a 4% discount rate in the base model. The functional forms and associated parameter values specified for the models are summarized in Table 1.

Wild Horse Population Biology

Eberhardt and Breiwick (2012) examined growth data from four wild horse populations, including one in the western United States. They found that the populations grew according to a theta logistic growth function, with the parameter controlling the inflection point equal to two, as shown in equation [3]. The carrying capacity (K) is the maximum population that can be sustained by an environment given available resources, and the intrinsic rate of growth (r) is equal to $b - m$, the birth rate minus the mortality rate.

$$F(X_{t-1}) = X_{t-1} r\left[1 - \left(\frac{X_{t-1}}{K}\right)^2\right]. \quad [3]$$

The theta logistic growth function exhibits properties that add intuition to the equation. The term $X_{t-1}r$ represents the intrinsic increment of growth of the population, and $X_{t-1}r(X_{t-1}/K)^2$ captures the density-dependent population effects. As carrying capacity K goes to infinity, the population is unconstrained by density effects, and population growth is equal to the intrinsic increment of growth. As the population approaches the carrying capacity, growth goes to zero.

For the Beatys Butte herd in eastern Oregon, Eberhardt and Breiwick (2012) estimated an intrinsic growth rate of 0.28 and a carrying capacity of 1,202 horses. The models developed in this study assume that in the absence of management, state horse populations grow according to equation [3] with $r = 0.28$. The states are also assumed to have the same carrying capacity to high-bound AML ratio as the Beatys Butte herd.

The models specify the initial population size based on the BLM's population estimates from March 1, 2016. Because the models require initial population estimates from the beginning of the fiscal year, the BLM population estimates are assumed to grow under model assumptions without management. In the optimization models, $X_{-1} = F(X_{\mathrm{BLM}}) + X_{\mathrm{BLM}}$, where X_{BLM} is the 2016 BLM estimate and X_{-1} is the population at the start of management.

Wild Horse Gather Costs

The annual cost of conducting horse gathers depends on the number of horses gathered. State-level gather expenditure data were obtained from the BLM for fiscal years 2009 through 2015 to parameterize this relationship. The gather expenditure data were escalated to the 2015 fiscal year and then merged with gather statistics from the WHBP website (BLM 2016a). Linear models regressing gather expenditures on the number of horses gathered were estimated for two candidate specifications: a linear specification to represent constant marginal gather costs, and a quadratic specification to represent increasing marginal costs. The quadratic specification provides a superior model fit for the Nevada data, and the linear specification provides a better fit for the Oregon data, as determined by the adjusted R^2 values of the regressions. The final Oregon and Nevada fitted regression lines explain 75% and 87% of the variation in annual gather costs, respectively, according to the final model R^2 values. The model constants are estimates of gather setup costs (SC), and the model coefficients are marginal gather cost estimates. Setting up gather operations is estimated to cost approximately $45,000 Nevada and $155,000 in Oregon. The marginal cost of gathers in Oregon is constant at $490 per horse. In Nevada, marginal gather costs are increasing. The cost of gathering the first horse is $345, and the marginal cost of gathering the 5,000th horse is $1,078. Other potential determinants of state-level gather costs were investigated by sequentially including additional covariates in the regressions described above. However, none of the candidate covariates improved model fit, according to the adjusted R^2, suggesting that gather costs are best predicted by the number of horses gathered without additional covariates.

The gather constraint parameters are specified as follows. The maximum number of horses that can be gathered in a given period ($Y^{\max}$) is set just under the maximum number gathered in a single fiscal year in Oregon ($Y^{\max} = 1{,}250$) from 2009 to 2015. In Nevada, where the current population is a greater share of the AML, the constraint is set to 140% of the maximum number gathered in a single fiscal year in Nevada from 2009 to 2015 ($Y^{\max} = 8{,}000$). Further, no more than half of the pregather population can be removed in a single period in either state ($\delta = 0.5$).

Off-range Horse Inventory

Horses removed from the range are transferred to short-term holding facilities where adoptive homes are sought for them. Horses that go unadopted are transported to long-term holding pastures to live out the rest of their lives. Thus, the inventory of horses in holding over time depends on the number of horses removed from the range, the number of captive-born horses, off-range horse mortality (assuming no reproduction), and the initial inventory of horses.

The models assume zero mortality for removed and captive born horses during the period they were gathered. Mortality for horses in long-term holding occurs as a discrete event at the end of each period. The rate of annual mortality for horses in holding (m_1) was specified as follows. First, inventory accrual was simulated over a 35-year period by looping over 1996–2015 removals and adoptions for Nevada and applying the gender-age-specific survival rates from Garrott and Oli (2013).

The simulations assumed that half of the horses removed were mares and that the age of removed horses is a Poisson process with $\lambda = 2$. The simulations yielded age distributions of horses in holding by gender. The mortality rate for horses in holding, $m_I = 0.095$, was then calculated as the overall annual mortality rate in the 36th year, given the age distributions derived in the simulations and the gender-age-specific survival rates. The initial holding inventories for Nevada and Oregon were approximated as the product of the total number of horses in holding as of September 2015 times the state's share of the total horse population, where $I_{-1}^{NV} = 24{,}335$ and $I_{-1}^{OR} = 2{,}707$.

Off-range Management Costs

Horses removed from the range are transported to short-term holding corrals where they remain until they are adopted or transported to long-term pastures. The models assume that adoptions occur as a discrete event just before the end of each period, and that all unadopted horses are transported to long-term holding facilities before the next period begins. The models also assume that future annual adoption demand remains constant at the 2010–2014 average and that long-term holding capacity is not limiting.

Gathers occur between October and February, and captive-born horses are foaled during the spring of the same period in which their mothers are gathered. To reflect this timing the models assume that I_{t-1} horses are held in long-term holding for the entirety of period t, removed horses are held in short-term holding for 290 days, and captive-born horses are held for 150 days of period t.

Off-range management costs were parameterized with WHBP adoption, horse holding, and expenditure data from the BLM. Per-horse adoption expenditures averaged $2,707 annually for fiscal years 2011–2015, and adopters of wild horses paid a $125 fee (BLM 2016b). Annual adoption demand in Nevada and Oregon averaged 75 and 196 horses, respectively, from fiscal years 2010–2014 (i.e., $\gamma^{NV} = 75$; $\gamma^{OR} = 196$). During fiscal years 2011–2015, long-term holding expenditures averaged $1.52 per day and short-term holding expenditures averaged $5.37 per day.[2] The cost of shipping unadopted horses to long-term facilities is $3.29/mi/40 horses (Arneson, Beutler, and Hurst 2002). The typical distance from short-term facilities to long-term facilities is approximately 1,500 miles, roughly the distance from short-term holding facilities in Reno, Nevada, or Burns, Oregon, to long-term holding pastures the midwestern United States. Horses removed from the range are associated with miscellaneous costs related to compliance inspections, horse preparation, and additional holding. Total miscellaneous costs are $210 for adopted horses and $726 for unadopted horses (BLM 2014).

Fertility-Control Effectiveness and Duration

The relationship between horse population growth and fertility-control effort is specified next. Recall that Eberhardt and Breiwick (2012) estimated the intrinsic growth rate for the Beatys Butte herd at $r = 0.28$ without managment. Another study of the Beatys Butte herd (Eberhardt, Majorowicz, and Wilcox 1982) estimated the average annual survival rate at 0.926. Thus, the intrinsic rate of growth at Beatys butte equals 0.28 with no fertility control, and equals –0.074 when every female in the herd receives effective contraception. In reality, PZP-22 is not 100% effective at preventing horse pregnancy. Bartholow (2007) reports that PZP-22 was 94% effective in the first year after treatment and 82% effective in the second year for Nevada's Clan Alpine herd.

To maintain tractability, the optimal fertility-control model assumes an equal sex ratio in horse populations, homogeneity across gender-specific gather production, and no gender selectivity in gathers. These assumptions yield the simplifying condition that half of the horses gathered are treated with fertil-

[2] For each fiscal year from 2011 to 2015, the number of horses in holding (short and long) is calculated as the average of monthly holding inventories reported by the BLM. The per day holding cost is then calculated as the average number of horses in holding divided by the total (short and long) holding expenditures reported by the BLM for that fiscal year.

ity-control agents and the other half are returned to the range.

Contraceptive applications occur on a biannual cycle in the fertility-control model so that two foaling seasons occur between management actions. In the first mating period after fertility-control application, fertility-control effectiveness is $\pi_1 = 0.94$ and the intrinsic rate of growth is r_{t+1}. In the second mating period after management, fertility-control effectiveness is $\pi_2 = 0.82$ and the intrinsic rate of growth is r_{t+2}. A linear functional form is specified between the growth rate and the proportion of females treated with contraceptive. Combined with the previously defined parameters, a linear functional form yields equations [4] and [5].

$$r_{t+1}(X_t,Y_t) = r_0 - \pi_1 0.354\frac{Y_t}{X_t}, \quad [4]$$

$$r_{t+2}(X_{t+1},Y_t) = r_0 - \pi_2 0.354\frac{Y_t}{X_{t+1}}. \quad [5]$$

The transition of the horse stock over time is then given by the theta logistic population growth function in equation [3], where the intrinsic rate of growth is $r_{t+1}(X_t,Y_t)$ in the second foaling period after fertility-control management and $r_{t+2}(X_{t+1},Y_t)$ in the third foaling period after management.

Fertility-Control Costs

The costs of fertility-control management are parameterized as follows. The combined cost of obtaining contraceptives and administering them on the range is approximately $300 per application (Bartholow 2007). Fertility-control management requires additional population monitoring compared to management with removals. The cost of fertility-control monitoring (M) is approximately $7,000 per HMA per year (Bartholow 2007). There are 18 distinct HMAs on BLM lands in Oregon and 84 in Nevada. Because management is considered at the state level, the models assume all HMAs on BLM lands are monitored for the two years after a fertility control cycle is initiated. The second year of fertility monitoring is discounted, so that if fertility control is initiated in fiscal year t, then monitoring costs per HMA for that management cycle equal $M_t = M + \rho M$. If fertility control is not initiated, then no monitoring costs are incurred during that management cycle.

Horse Population Net Benefits

Wild horse populations are associated with significant societal benefits. On the other hand, large horse populations can impose costs on stakeholders through displacement of alternative land uses and degradation to range lands. Pimentel, Zuniga, and Morrison (2005) estimated that U.S. wild horse and burro populations cause $5 million in forage losses annually. Bastian et al. (1999) found that the marginal opportunity costs of additional horses on the range in excess of target population levels are well over $4,060 in in 2015 dollars. Wild horses also provide use and nonuse benefits to wild horse supporters. However, these benefits are challenging to measure because their value is not revealed through market transactions.

The function describing horse population net benefits, $B(X)$, represents the aggregation of all costs and benefits attributable to that population. The shape of $B(X)$ depends on the shape of the marginal benefits and marginal costs functions. Bastian et al. (1999) found that the marginal costs of adding horses to a population were increasing through the population size associated with the $4,060 figure mentioned above. Intuitively, adding horses to a small population under BLM management (i.e., management subject to an overall grazing limit) would displace less valuable wildlife and livestock resources compared to when the horse population is already large. Conversely, attempts in the economic literature to measure benefit functions for wildlife populations and habitats support decreasing marginal benefits, (e.g., Layton, Brown, and Plummer 1999; Rollins and Lyke 1998), particularly when the wildlife population is above its minimum viable population (e.g., Bandara and Tisdell 2005; Ojea and Loureiro 2009). Decreasing marginal costs and increasing marginal benefits imply that the total net benefits function for horse populations, $B(X)$, is a single-peaked function. This analysis fol-

lows Rondeau and Conrad (2003) in assuming that total net benefits can be represented by a Gompertz function where

$$B(X) = \begin{cases} 0 \text{ if } X = 0 \\ aX\ln\left(\frac{b}{X}\right) \text{ if } X > 0 \end{cases}. \quad [6]$$

The Gompertz function is a single-peaked function that satisfies the characteristics of net horse benefits specified previously (i.e., that $B_X > 0$ for $X \in [0,\bar{X})$ and $B_X < 0$ for $X \in (\bar{X},\infty]$). The high-bound AML is assumed to be the population level $\bar{X}$ that corresponds with the maximum of $B(X)$. The marginal opportunity cost of an additional wild horse at high population levels is approximately \$4,060 (Bastian et al. 1999), and the models assume that this is the marginal net benefit at carrying capacity. The resulting system of equations (i.e., $B_X(\bar{X}) = 0$ and $B_X(K) = -4{,}060$) was then solved for parameters a and b. In the Nevada model, parameters a and b are equal to 2,586 and 34,824, respectively. The resulting function implies that a state population of 10 horses in Nevada produces \$211,000 in annual net benefits, while a population at the high-range AML produces \$33.1 million in annual net benefits. At carrying capacity, the Nevada horse population yields net benefits of −\$90.8 million annually. In the Oregon model, parameter a equals 2,586, and parameter b equals 7,380.

V. RESULTS

This section presents simulations of the specified optimal management models and compares them to current management practices. A 50-year time horizon is used to compare the base scenarios, and sensitivity scenarios with shorter horizons are also explored. A long-term time horizon is appropriate for identifying optimal management strategies because horse removals conducted in the current period are associated with holding costs that extend decades into the future.

Solving the Dynamic Optimization Problem

The solution to the removals problem in [1] is identified by solving the associated Bellman equation in [7], subject to the previously defined constraints and the terminal condition $V(T+1,X_t) = 0$, where T is the finite time horizon.

$$\begin{aligned} V(t,X_{t-1},I_{t-1}) = \max_{\{Y_t\}} \{ & \rho^t [B(X_t) - C^{\mathrm{g}}(Y_t) \\ & - C^{\mathrm{I}}(I_{t-1},X_{t-1},Y_t) - C^{\mathrm{TR}}(X_{t-1},Y_t) \\ & - C^{\mathrm{MISC}}(X_{t-1},Y_t) - CADPT\gamma_t - SC_t] \} \\ & + \rho^{t+1} V(t+1,X_t,I_t). \end{aligned} \quad [7]$$

The function $V(t,X,I)$ is the maximum achievable NPV benefits starting at time t with population level X and given action Y. All subsequent actions are assumed to be taken optimally, given the action taken in the current period. Bellman equations [8] and [9] are the equivalent for optimal fertility-control and hybrid population management, respectively.

$$\begin{aligned} V(t,X_t) = \max_{\{Y_t\}} \{ & B(X_t) + \rho B(X_{t+1}) - \mathrm{C}^{\mathrm{g}}(Y_t) \\ & - C^{\mathrm{fc}}(Y_t,HMA) - C^{\mathrm{I}}(I_{t-1}) - SC_t \} \\ & + \rho^{t+1} V(t+1,X_{t+1},I_t), \end{aligned} \quad [8]$$

$$\begin{aligned} V(t,X_t) = \max_{\{Y_t\}} \{ & \rho^t [B(X_t) + \rho B(X_{t+1}) - C^{\mathrm{g}}(Y_t+q) \\ & - C^{\mathrm{fc}}(Y_t) - C^{\mathrm{I}}(I_{t-1},\tilde{X}_t,q) - C^{\mathrm{TR}}(\tilde{X}_t,q) \\ & - C^{\mathrm{MISC}}(\tilde{X}_t,q) - 2CADPT\gamma - SC] \} \\ & + \rho^{t+1} V(t+1,X_{t+1},I_t). \end{aligned} \quad [9]$$

The Bellman equations were programmed in MATLAB (MathWorks 2015) and solved with a backward induction algorithm. The terminal period (T) was set to 65 years, so that realization of the terminal condition is not taken into account in the optimal management simulations. Robustness checks with longer-horizon models suggest that the solutions are stationary. The problems were discretized to limit their dimensionality and facilitate their solution via dynamic programming.[3]

The Nevada and Oregon scenarios were simulated with a 50-year planning horizon for

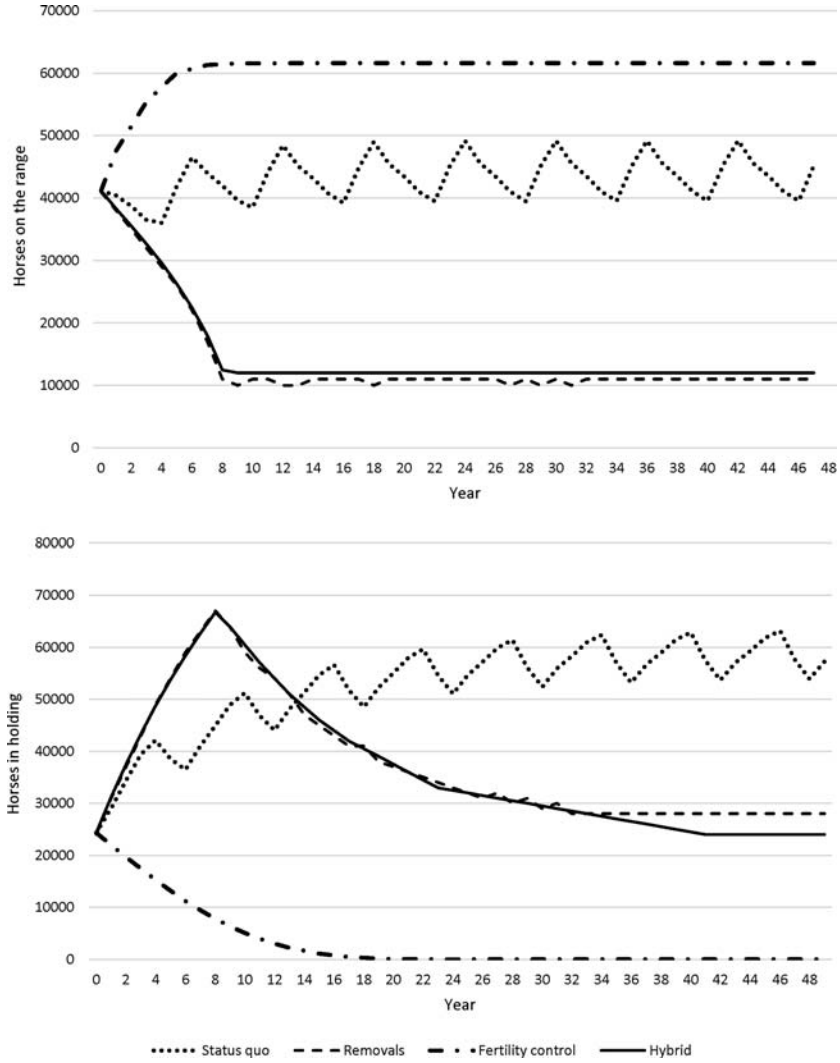
[3] Discretization involved grouping the horses into units and then rounding the state variables to the nearest unit before each value calculation. For removal and hybrid management, the Nevada and Oregon models grouped horses into 1,000-horse and 150-horse units, respectively. The fertility-control models grouped horses into 10-horse units.

both the horse-removal and fertility-control models. The steady-state solutions to the optimal removal and optimal fertility-control models are summarized for Nevada and Oregon in Table 2. The population and holding inventory paths for the optimal solutions and the status quo scenario are presented for Nevada and Oregon in Figure 1 and Figure 2, respectively.

Status Quo Management Scenario

Status quo horse management practices were simulated under model assumptions to provide a baseline for comparison. BLM horse population estimates from 2009 to 2014 and associated management actions from that period were evaluated to characterize current state-level management in Nevada and Oregon. Notably, the intensity of removal efforts varied substantially from year to year in both states. In Nevada, annual gathers ranged from 1.5% to 30.5% of the estimated prefoal population.[4] Annual Oregon gathers ranged from 0.0% to 54.0% of the prefoal population. The status quo management scenarios assume that future gather, removal, and fertility-control efforts reflect a state's recent management practices. Specifically, the scenarios follow a six-year management cycle based on the proportion of horses managed in the six-year period during fiscal years 2009–2014, subject to state gathers not exceeding $Y^{\max}$ or δX_{t-1}.

The periodic nature of removals in the status quo scenarios gives rise to oscillations in horse populations and holding inventories, as displayed in Figures 1 and 2. In terms of long-term trends, populations and inventories increase in the earlier periods before leveling off in the later periods. The cumulative NPV of status quo horse management over a 50-year time horizon is –$1.52 billion in Nevada and –$255 million in Oregon. The cumulative NPV program benefits over time for each scenario are presented in Figure 3, and the cumulative NPV management costs over time are presented in Figure 4.



[4] The status quo gather proportions were constructed with the March 1 BLM population estimate in the denominator and the horses gathered over the subsequent 12 months in the numerator.

TABLE 2
Optimal Steady-State Management Programs and Cumulative Optimal Program Benefits

Scenario	Pregather Population	Removals	Fertility Treatments	Total Gathers	Horses in Holding	Percent Gathered	Cumulative Net Benefits[a]	Change from Status Quo[a]
Nevada								
Removals	11,000	2,000	0	2,000	28,000	18	(230.1)	1,290.5
Fertility control	61,600	0	0	0	0	0	(2,005.5)	(484.9)

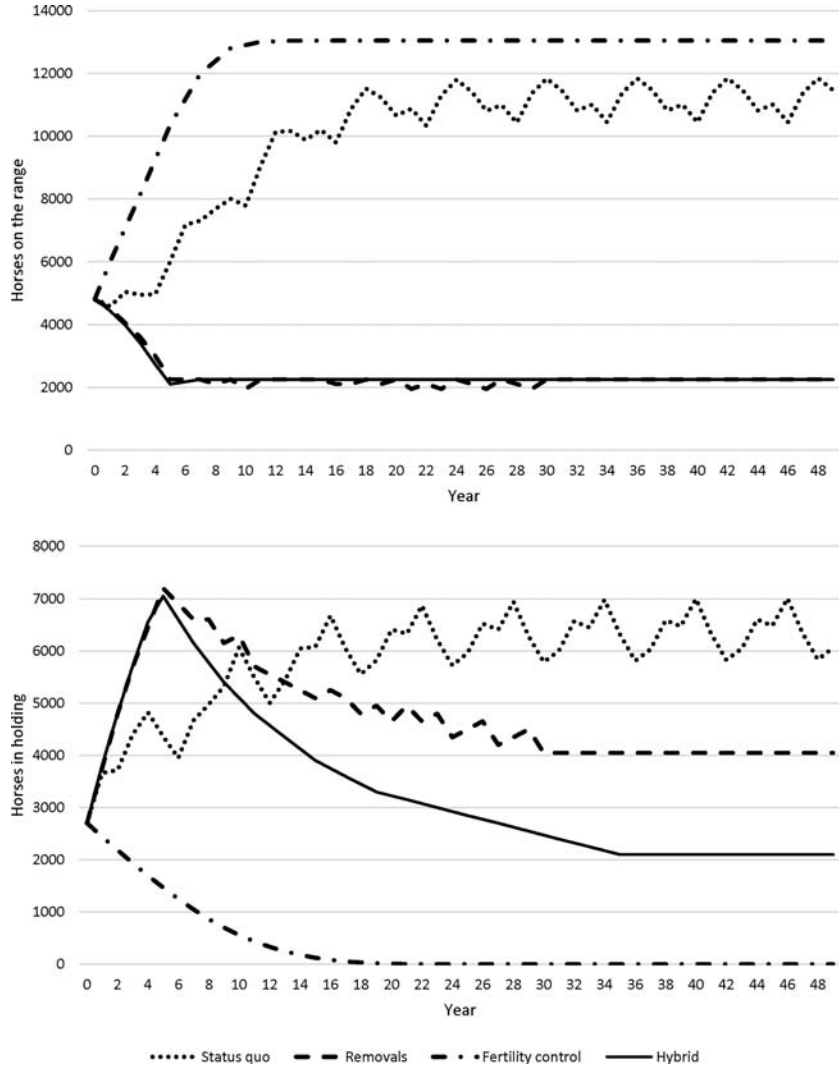
FIGURE 1
Population and Holding Inventory Paths for Nevada Simulations

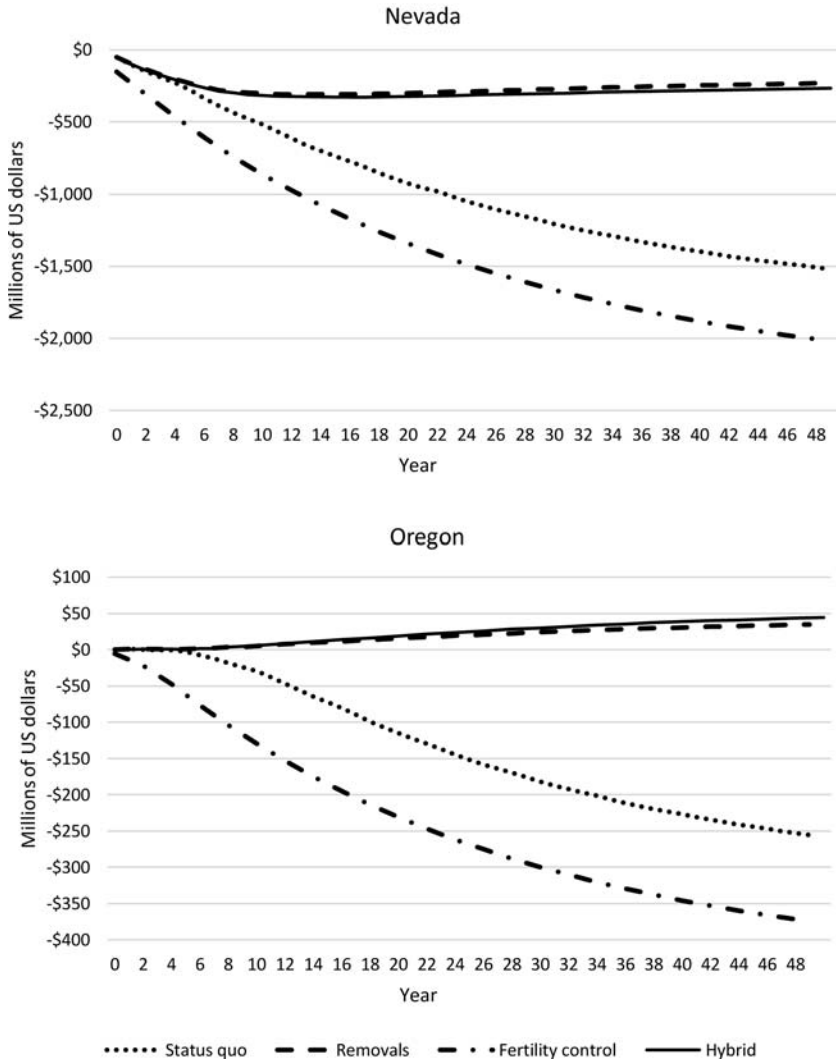


Management Simulations

Horse Removal

The Nevada and Oregon optimal removal scenarios involve an initial reduction of the population to a steady-state equilibrium. In Oregon, the optimal program involves five years of intensive removal effort at or near $Y^{\max}$. At steady-state equilibrium, 450 horses are removed from the range each year to maintain a population of 2,250 horses and a holding inventory of 4,050 horses. The 50-year cumulative NPV of the Oregon optimal removals program is –$34.7 million, a savings of $290.1 million compared to the status quo scenario. Similarly, the optimal removal program in Nevada involves intensive removals over the first eight years of management. Following the initial population reduction, a steady-state management regime commences where 2,000 horses are removed annually to maintain the population at 11,000 and the holding inventory at 28,000. The 50-year cumulative NPV of optimal removals in Nevada

FIGURE 2
Population and Holding Inventory Paths for Oregon Simulations



is –$230.1 million, a savings of $1.3 billion over that period compared to the status quo scenario.

As a check to the dynamic programming solutions, optimal steady-state values for removals, population size, and holding inventory were derived numerically using the discrete-time maximum principle (Canon, Cullum, and Polak 1970). While minor differences in the solutions occur due to rounding errors, the numerically derived steady-state values verify the dynamic programming solutions.[5]

The optimal management scenario results yield insights into the trade-offs involved in maximizing population benefits over time. The absolute gather constraint is binding while the populations are reduced in the initial

[5] The steady-state values derived using the maximum principle are as follows: $X_{SS}^{NV} = 10{,}141; I_{SS}^{NV} = 28{,}242; Y_{SS}^{NV} = 2{,}171; X_{SS}^{OR} = 2{,}175; I_{SS}^{OR} = 4{,}163; Y_{SS}^{OR} = 466$.

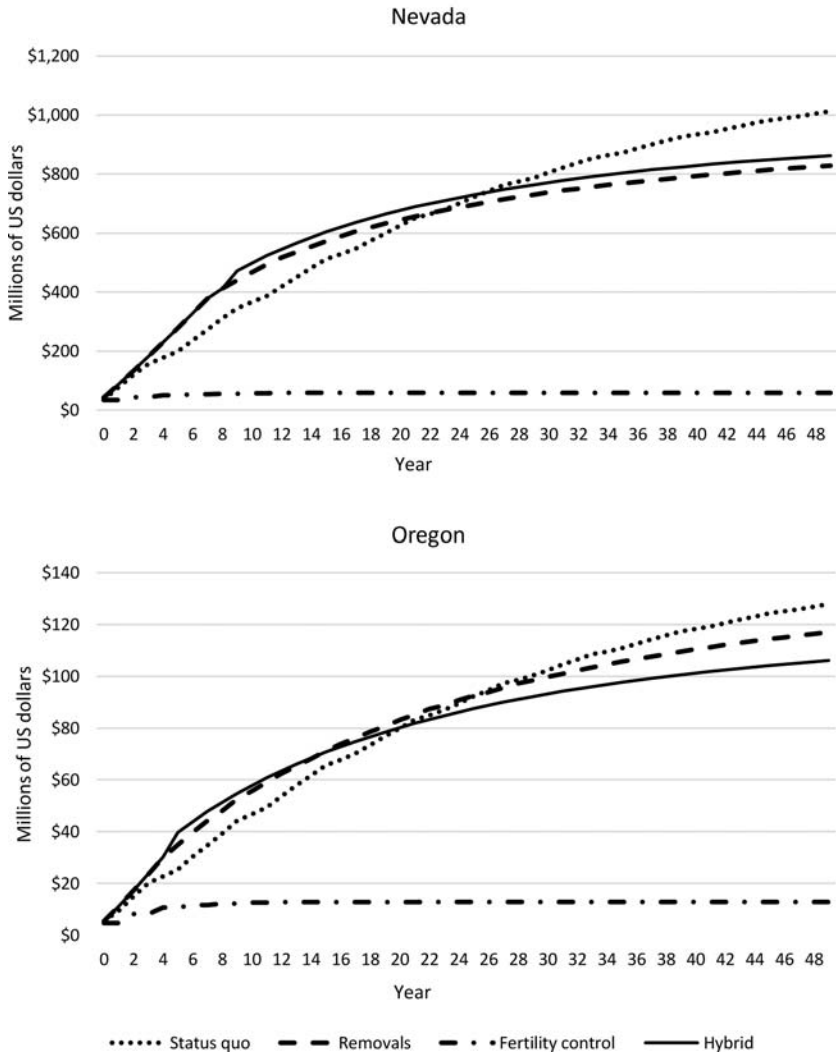


FIGURE 3
Cumulative Net Present Value Net Benefits of Management Programs

periods (i.e., $Y_t = Y^{\max}$). Whereas the removals optimization problem does not meet the sufficient conditions for bang-bang control defined by Spence and Starrett (1975),[6] the removal simulations suggest the optimal management path is indeed to approach a steady state as rapidly as possible. At the optimal steady state, neither the Oregon nor the Nevada optimal removals program is bound by the gather constraints imposed on the model (i.e., $Y^{SS} < \min\{Y^{\max}, \delta X^{SS}\}$). Thus, while the gather constraints regulate the speed with which the population is reduced to steady state, they do not constrain management in optimal steady-state equilibrium.

[6] The Nevada removal model specifies nonlinear gather costs in Y. Both state removal models specify setup costs and stock-dependent variable costs that violate the sufficient conditions of quasi-concavity and separability, respectively.

FIGURE 4
Cumulative Net Present Value of Wild Horse Management Costs

The management costs incurred over a single fiscal year in the optimal removals steady state are higher for the larger Nevada population ($22.4 million) than they are for the smaller Oregon population ($4.3 million). Likewise, in steady state, the larger Nevada population yields higher annual net benefits ($32.8 million) than the Oregon population ($6.9 million). The annual value of net program benefits from optimal removals in steady state is $10.3 million in Nevada and $2.6 million in Oregon.

Horse Fertility Control

The NRC report suggested that fertility control alone cannot address the challenges associated with managing western wild horses. The optimal fertility-control scenarios support this sentiment. The optimal fertility-control management program is to undertake fertility control in early management cycles and then to undertake no management once the population grows toward its carrying capacity. In Oregon, the optimal fertility-control

TABLE 3
Optimal Two-Year Management Cycles at the Steady State (Millions of U.S. Dollars)

Scenario	Net Population Benefits	Management Costs[a]	Net Benefits[a]
Nevada			
Removals	64.3	44.0	20.3
Hybrid	64.1	46.1	18.0
Difference	− 0.4%	4.8%	− 11.3%
Oregon			
Removals	13.6	8.4	5.1
Hybrid	13.2	6.4	6.7
Difference	− 2.7%	− 23.8%	31.4%

[a] Includes costs of off-range holding. For discounting purposes, $t = 0$ in the first year of the optimal management cycle, and $t = 1$ in the second year.

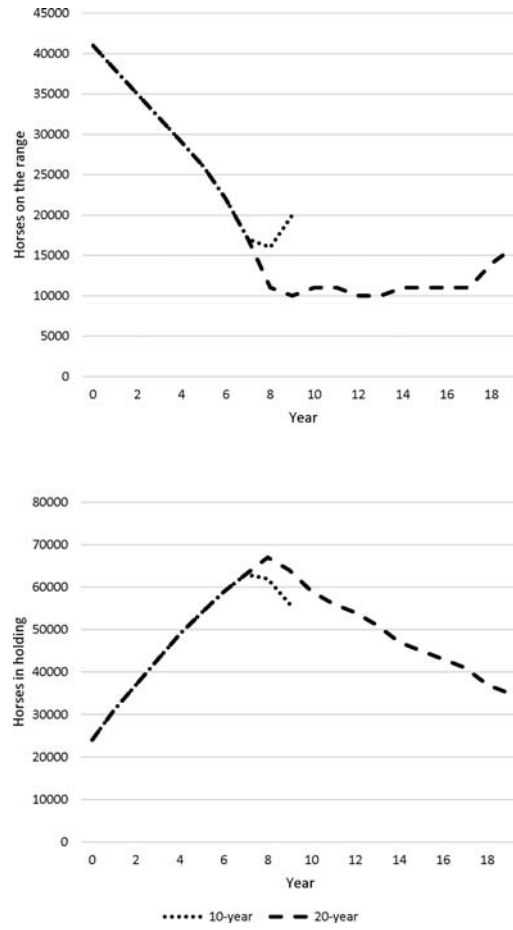
program is to treat around 600 females for the first three cycles and then cease fertility control in all subsequent periods. The optimal fertility-control program in Nevada is to treat 3,940 females in the first period and then undertake no further management actions. Without management, the horse populations grow to their carrying capacity (K) and remain at that level for the duration of the management horizon. The inventory of horses in holding declines to zero deterministically in all of the fertility-control scenarios. Intuitively, it is impossible to reduce the population with fertility control alone given the model gather constraints. Thus, after slowing growth in the initial period(s), it is optimal to just let the populations grow to their carrying capacity instead of applying costly fertility control. Because horse populations are not effectively managed in the fertility-control scenarios, subsequent discussion focuses on the removal and hybrid methods.

Hybrid Management

Fertility-control alone is not a viable population management strategy. The hybrid management scenarios explore the efficacy of fertility control when applied in tandem with horse removals. The hybrid scenarios begin with intensive removals over successive years until the state population is brought within the AML range. Next, a program of fixed removals with optimally chosen fertility-control effort ensues on a two-year cycle. Fixed removals are undertaken at the lowest possible level subject to maintaining a stable population below carrying capacity in the long run. When implemented in concert with removals, fertility control helps stabilize the horse population by decreasing the intrinsic rate of growth. The Nevada hybrid scenario involves nine years of intensive removals followed by a steady-state gather program that stabilizes the population at 12,000. The steady-state program involves gathering 5,750 horses biannually, of which 3,750 are removed and 1,000 are treated with fertility-control agents. Adoptive homes are found for 150 of the removed horses and 3,600 go to long-term holding facilities. A steady-state inventory of 28,000 horses is maintained in holding facilities. The hybrid program in Oregon involves six years of removals followed by a biannual steady-state management program that maintains a pregather population of 2,250 horses. The program involves gathering 977 horses every other year, including 677 removals and 150 horses treated with fertility control. In Oregon, 392 of the removed horses are adopted and 285 are sent to long-term holding facilities. A holding inventory of 2,100 horses is maintained in the steady state.

The NPV costs and benefits of the optimal removal and hybrid management programs over a two-year cycle are presented in Table 3. The steady-state NPV management costs of a two-year hybrid management cycle in Nevada are $46.1 million, an increase of 4.8% compared to the NPV costs removals over the same time period. In Oregon, the NPV of steady-state hybrid management over a cycle is $6.4 million, which represents a 23% re-

duction compared to removals. In terms of program net benefits, a cycle of steady-state hybrid management yields NPV $18.0 million in Nevada and $6.7 million in Oregon. Compared to optimal removals in the steady state, hybrid management decreases two-year net program benefits by 11.3% in Nevada and increases net program benefits by 31.4% in Oregon. The superior performance of the Oregon hybrid scenario is related to Oregon's higher adoption demand, which facilitates a lower steady-state holding inventory.



Time-Horizon Sensitivities

A long-term time horizon is appropriate for capturing the economic impact of wild horse management decisions because removals in the current period result in holding costs for the life span of removed horses. In practice, however, land managers may base their management decisions on shorter time horizons, due to budgetary constraints, management uncertainties, or other factors. Additionally, the models assume that specified parameters remain constant over time, and setting a shorter time horizon makes this assumption more likely to hold. The Nevada removals models were solved under 10-year and 20-year time horizons (i.e., $T = 10$ and $T = 20$) to explore how shorter time horizons influence optimal management. The optimal population and holding inventory paths from these simulations are shown in Figure 5. The paths suggest that even when considered under a shorter time horizon, it is optimal to reduce the population rapidly in the early periods to avoid incurring costs (i.e., negative net population benefits) associated with a larger population. The population uptick at the end of the shortened time horizons occurs to satisfy the terminal condition.

Removals under Cost Minimization

Allowing horse populations to become self-limited can reduce population growth rates, and potentially reduce the number of horses removed and sent to holding compared to current management. On the other hand, larger populations grow from a bigger base and thus produce more horses annually for a given growth rate. If managers determine

FIGURE 5
Optimal Paths for Removal Management in Nevada under Alternate Time Horizon

horse populations should not exceed some maximum level, the question arises as to whether it is cost-effective to maintain self-limited populations just below the threshold, or if it is less costly to maintain smaller, but faster growing populations. To explore this question, the next section examines optimal horse removals under a cost minimization objective, where the net population benefits term is dropped from the objective function. Dropping $B(X)$ from [1] and imposing a maximum population constraint frames management decisions in terms of cost-effectiveness, where management costs are minimized subject to maintaining the horse population under some ceiling.

The cost-effectiveness scenarios were run for optimal removals management in Nevada. If the maximum population constraint is set above 50,000, or roughly 80% of carrying capacity, then it is cost-effective to actively manage a large population at the constraint. If the maximum population is set below this level, then it is cost-effective to manage a population of 11,000 horses, the optimal steady-state solution to the model in equation [1].

VI. DISCUSSION

Dynamic, benefit maximizing models of wild horse management were developed for three nonlethal population control methods using published research on wild horse population biology and expenditure data from the BLM. The optimal model solutions were compared to each other and to a scenario that represents status quo management. Finally, optimal removal models were simulated with shorter time horizons, and with a cost-minimization objective to assess the cost-effectiveness of maintaining populations under a specified level.

The model simulation results provide evidence of how to undertake state-level horse management to maximize benefits for stakeholders. Importantly, the results indicate that societally efficient management programs involve an initial reduction of state horse populations from their 2015 levels. This result is robust to the time-horizon specifications, and to the cost minimization specifications where the maximum population is set less than 80% of carrying capacity. The upshot here is that even in the face of costly removals and holding, efficient management involves reducing populations from current levels and maintaining them within their AML ranges. Moreover, the removal and hybrid management simulations suggest that with current technology nonlethal wild horse management requires maintaining off-range populations comparable to, or greater than, the on-range populations.

A second takeaway from the results is that, as defined, fertility control alone is not an effective method for managing horse populations. The reason is that nearly all of the mares must be effectively treated to reduce horse populations using fertility control only. Further, the gather constraints imposed by the model make reducing or stabilizing horse populations with fertility impossible. If all mares in the population could somehow be effectively treated in each period, fertility control has the potential to slowly reduce the population at the mortality rate. However, it is unlikely all mares could be treated, and even if they could, fertility control would not produce a significant population reduction over the short term.

While fertility control alone is not an effective population management strategy, the hybrid management results indicate that fertility control can reduce the total number of horses removed from the range while maintaining comparable management costs and net program benefits. At the optimal steady state, for example, there are 6% fewer horses removed over each two-year hybrid management cycle compared to optimal removals in Nevada, and 25% fewer in Oregon.

When framed in terms of cost minimization, the models yield the cost-effective solution for keeping populations under some specified maximum level. For removals in Nevada, it is cost-effective to reduce populations and maintain them at the base model steady state unless the population constraint is set above 50,000, or roughly 80% of carrying capacity. Thus, maintaining small populations that are not resource limited is less costly than managing large, resource-constrained populations unless the large populations are near the carrying capacity. Further, managing medium-sized populations is costly because many horses need to be removed to stabilize fast-growing populations that are not resource limited.

As shown in Figure 4, cumulative NPV management costs are higher in the optimal scenarios than in status quo management until at least the twentieth management year across scenarios. Thus, realizing the gains associated with optimal management requires enduring higher initial management costs in return for greater population benefits and lower management costs in the future. Furthermore, while the optimal scenarios involve intensive management in the initial periods, the status quo scenario is the most intensive manage-

ment method across the 50-year management horizon. In the Nevada status quo scenario, over 280,000 horses are taken to long-term holding facilities across the management horizon, compared to around 175,000 with optimal removals and 170,000 with hybrid management.

Overall, the simulation results show that significant economic gains can be realized with a more strategic approach to wild horse population management. Relative to the status quo scenario, the results indicate that implementing optimal removals or hybrid management would result in 50-year NPV program savings of $1.3 billion in Nevada. Undertaking optimal hybrid management would save $300 million compared to the status quo in Oregon. Realizing these savings, however, is a matter of incurring short-term costs to realize future benefits.

Separate models were developed for Nevada and Oregon, and comparison of the results across states yields additional management insights. Oregon contains almost 3 million HMA acres compared to 14 million in Nevada. Likewise, the Oregon models specify a smaller carrying capacity, AML, and initial population to carrying capacity ratio compared to the Nevada models. Adoption demand is greater in Oregon than in Nevada despite Oregon having a much smaller horse population. This allows Oregon to send a smaller proportion of removed horses to long-term holding. These state-specific management differences reflect the difficulties inherent in managing the large Nevada population of horses. Though the larger Nevada population yields nearly five times the population benefits at the optimal steady state, Oregon yields greater 50-year program benefits due to the high costs of managing the Nevada population.

Implementing the optimal management programs identified in this study would require allocating additional resources to the WHBP to fund intensive removals in the early periods and associated increases in the horse-holding inventory. The BLM currently has capacity for around 32,000 horses in long-term facilities. Implementing the optimal management programs would require temporarily increasing that capacity to around 70,000 to handle the Nevada population alone (Nevada's horse population represents roughly half of the overall wild horse population in the west.) Securing the resources to implement these programs would surely be challenging. However, the model results suggest that the investment would yield benefits that outweigh the costs.

While the models developed in this article represent a step toward understanding the economic consequences of alternative wild horse management regimes, they also have some notable limitations. First, the models do not capture potentially significant heterogeneity in biological and economic parameters across the state. More granular models may increase overall precision and provide guidance regarding how to best allocate management effort among state HMAs. Second, the models implicitly assume that specified economic and biological relationships remain constant across time. Aside from uncertain shifts in preferences or management costs, horse habitats are likely to change in the future due to climate change. In the Great Basin, where most of Oregon's and Nevada's wild horses reside, climate change is expected to increase overall precipitation, but also increase interannual precipitation variability. In summer, stream flows are expected to decline (Chambers 2008), which could have limiting impacts for wild horse populations. Beschta et al. (2013) suggest that reducing wild horse grazing is a prudent policy for mitigating the expected effects of climate change on western public range lands. Future research efforts could incorporate emerging climate science and related ecosystem impacts into horse management models. Despite its limitations, this article presents significant evidence that current wild horse management is inefficient, and that significant efficiency gains are possible if management actions are undertaken strategically.

APPENDIX: HYBRID POPULATION CONTROL

$$\max_{\{Y_t\}} \sum_{t=z+1,z+3,z+5,\ldots}^{\infty} \rho^t \big[B(X_t)+\rho B(X_{t+1}) - C^{g}(Y_t+q) - C^{fc}(Y_t,HMA) - C^{I}(I_{t-1},X_t,q) - C^{TR}(X_t,q) - C^{MISC}(X_t,q) - 2CADPT\gamma - SC\big], \quad [A1]$$

Porcine and recombinant zona pellucida vaccines as immunocontraceptives for donkeys in the Caribbean

[1]French, H., [1]Peterson, E., [1]Ambrosia, R., [2]Bertschinger, H., [2]Schulman, M., [3]Crampton, M., [3]Roth, R., [3]Van Zyl, P., [1]Cameron-Blake, N., [1]Vandenplas, M., [1]Knobel, D.

Immunocontraception has been investigated as an alternative to hormone manipulation and lethal methods of fertility control in wildlife for almost 30 years. Porcine zona pellucida (PZP) vaccine has been shown to utilize an animal's immune system to prevent pregnancies temporarily and reversibly in multiple species. This study investigated PZP vaccination as a method of practical population control in feral donkeys (Equus asinus) in the tropics. In addition, the study investigated a novel recombinant zona pellucida vaccine (recZP) as an alternative for fertility management in donkeys.

Twenty-five feral female donkeys of proven fertility were captured on Nevis and transported to Ross University School of Veterinary Medicine (RUSVM). All animal protocols were approved through RUSVM IACUC review. Jennies allocated to Group 1 (n=9) received the recZP vaccine in complete modified Freund's adjuvant (CMFA) and thereafter two booster vaccines in incomplete Freund's adjuvant (IFA) 5 weeks and in sterile saline 10 weeks later. Jennies allocated to Group 2 (n=8) received the PZP vaccine in CMFA and one booster in IFA 5 weeks later. Those allocated to Group 3 (n=8) received an initial injection of CMFA and second injection of IFA 5 weeks later and acted as controls. All treatments were administered intramuscularly by injection into the left and right gluteal muscles (1st and 2nd injections), and the left pectoral muscles (3rd injection in Group 1). Trans-rectal ultrasonography was performed weekly on each jenny to monitor ovarian and follicular development and cyclical reproductive activity. Five weeks after the final injection, one jack was placed with each group of jennies. Estrus detection, mounting behaviors, and breeding were recorded when observed. Weekly trans-rectal observations were continued to visualize the reproductive tracts and ovaries and to identify pregnancies. Jacks were rotated through the groups every three weeks.

All donkeys were cycling normally prior to injection with obvious estrus signs detected when in proximity to a jack. Sterile abscesses at injection sites were observed in 9/9 (100%) jennies in Group 1, 7/8 (87.5%) jennies in Group 2 and 3/8 (37.5%) jennies in Group 3. Three months after the final injection, 7/9 (78%) jennies in Group 1 and 6/8 (75%) jennies in Group 2 had no detectable follicular development nor estrus signs. No pregnancies were found in either of the treatment groups at twelve weeks post-treatment. In contrast, 6/8 (75%) of the control group were pregnant and all had shown follicular development.

Despite the injection site reactions, both PZP and recZP vaccines were shown to be effective as non-hormone based contraceptives with potential for application in fertility management programs in donkeys. Further investigation of these vaccines, using alternative adjuvants providing similar contraceptive efficacy without the associated adverse reactions, may benefit future population control programs for feral donkeys in the Caribbean.

anti-pZP antibody titers

ABSTRACT

Feral and semi-feral donkeys are recognised as a problem in some world regions. The main problem associated with uncontrolled donkey populations is habitat degradation and competition for feed resources, especially in arid climes. Controlling population numbers would reduce the impact of donkeys and other species. While removal by various means is effective, it has been shown to stimulate reproductive rate. Probably the most effective and humane solution is reducing reproduction using minimally invasive methods including immunocontraception. This study tested the immunocontraceptive efficacy and safety of zona pellucida (ZP) vaccines, both recombinant (reZP; three treatments) and native porcine (pZP; two treatments) vaccines formulated with Freund's modified complete (primary) and Freund's incomplete (boosters) adjuvants in donkey jennies. Control jennies received adjuvants only (two treatments). Twenty-five non-pregnant jennies were randomly assigned to reZP (n = 9), pZP (n = 8) or control (n = 8) groups. Weekly monitoring of the reproductive tract and ovaries via transrectal palpation and ultrasound and inspection of injection sites was conducted and anti-pZP antibody titers were measured. Five weeks after last treatment, one donkey jack was introduced to each group and rotated every 21 days. By 232 days after last treatment the number pregnant and median days to pregnancy was 2/9 and 214 (reZP group), 1/8 and 196 (pZP group) and 8/8 and 77 (control group). Median time to ovarian shut-down was 77 (9/9) and 56 (7/8) days for reZP and pZP groups, respectively. This was observed in association with a distinct reduction in mean uterine diameter. The antibody response was equally good for both ZP-treated groups. Incorporation of Freund's adjuvants initially produced a high incidence of side effects from local swelling and intermittent lameness followed weeks later by sterile abscesses (reZP, 9/9; pZP, 7/8; control, 3/8). Both ZP vaccines effectively controlled reproduction in jennies, albeit with a high incidence of adjuvant-associated side effects.

1. Introduction

Feral and semi-feral donkey populations are described as an important emerging global human-animal conflict scenario [1,2]. These perceived conflicts are reported in various countries (Australia, India, Northern Ireland, South Africa, USA, Zimbabwe) and include deleterious environmental impacts such as erosion, damage to crops, competition for resources with livestock or wildlife [3], road and air traffic hazards and as a perceived nuisance in urban areas. Currently, however, there is a paucity of evidence-based reports supporting these perceptions and the available data are often contradictory [4–7]. Methods reportedly employed in attempting to manage these populations to mitigate their impacts include fencing, fertility control, and lethal approaches such as shooting, immobilization followed by lethal injection, and

mustering or trapping for transport and slaughter at abattoirs. These methods vary in their humaneness, efficacy, cost-efficacy and impact on non-target species [8].

Fertility control has proved effective in certain herbivore populations, including African elephants (*Loxodonta africana*), that experience density-dependent increases in reproductive rates following short-term removal programs [9]. In these populations, reducing reproductive rates through fertility control may be more sustainable in the long-term. Current methods of fertility control include surgical sterilization, hormonal (chemical) methods and immunocontraception. In the latter, injection of formulations containing antigenic epitopes results in the production of circulating antibodies or immune effector cells that interrupt reproductive processes, causing variable periods of infertility in treated animals [10]. One target is the zona pellucida (ZP) capsule, a complex glycoprotein matrix surrounding the mammalian oocyte [11]. Zona pellucida proteins are weak antigens requiring inclusion of strongly immunogenic adjuvants in vaccine formulations in order to elicit an effective immune response. For immunocontraception, native porcine zona ZP (pZP) proteins are typically emulsified with modified Freund's complete adjuvant (MFCA) for primary and Freund's incomplete adjuvant (FIA) for booster immunizations, respectively [12]. These formulations have been used successfully for contraception in more than 90 species [13], most notably feral equids in the USA [14–18] and African elephants in South Africa [19,20]. In donkeys, to our knowledge, a single study reported the successful use of pZP immunocontraception [21]. Recombinant ZP vaccines based on the expression of porcine ZP3 and ZP4 in *Escherichia coli* have also been developed [22]. Their potential advantages over vaccines using native pZP include production efficiency and avoiding contamination with non-ZP proteins.

The aims of the current study were to evaluate the contraceptive efficacy, ovarian effects and safety of pZP and reZP vaccines, both formulated with MFCA and FIA, in female donkeys (jennies). Results of this study will help to inform choice of method for humane and sustainable reproductive management of feral and semi-feral donkey populations.

2. Materials and methods

The study was reviewed and approved by Ross University School of Veterinary Medicine Institutional Animal Care and Use Committee (protocol no. 15.12.032).

2.1. Animals and management

The study was conducted at Ross University School of Veterinary Medicine (RUSVM) on the island of St Kitts in the federation of St Kitts and Nevis. Twenty-five feral jennies were caught on the island of Nevis. On capture, all appeared to be in good body condition and estimated to be in late gestation which was confirmed by transcutaneous transabdominal ultrasound (US). No additional history was available. Jennies were subsequently transported to St Kitts via water ferry. On arrival at RUSVM, all were microchipped and individually identified with numbered collars. Individual ages in y varied from three to 13, estimated according to the appearance of the incisors on dental inspection [23]. Jennies were housed in outdoor grass paddocks with free access to water and freshly-cut New Guinea grass (*Megathyrsus maximus*). They were monitored twice daily for signs of impending parturition and weekly by transcutaneous transabdominal US until they had foaled. Three clinically healthy jacks between the ages of three to six y (estimated by dental inspection) with two apparently normal intrascrotal testes assessed by inspection and palpation, were chosen for this study. Jacks were housed in a separate outdoor grass paddock with similar access to water and feed.

2.2. Study design

Inclusion criteria for the study were good physical condition, non-pregnant status, a normal reproductive tract and active ovaries on clinical examination. After foaling, all 25 jennies met these criteria and were randomly assigned to one of three treatment groups (Fig. 1) stratified according to age. The groups were housed in separate, adjacent outdoor grass paddocks. The study commenced after all eligible jennies had shown at least one complete estrous cycle. Day 0 of the study was defined as the day of last treatment. On Day 35, one jack was introduced into each group of jennies; jacks were rotated between groups every 21 days. The primary endpoint for the study was a pregnancy diagnosed by transrectal palpation and US of the reproductive tract. The secondary endpoint was 'ovarian shutdown', defined as the presence of bilaterally inactive ovaries with only small follicles (<10 mm) and no corpus luteum (CL) visible on transrectal US [24,25]. Jennies remained in the study until diagnosed pregnant or Day 232, the last day of the study.

2.3. Treatments

2.3.1. Preparation of vaccines

All three vaccine formulations were prepared less than 30 min before administration.

Recombinant ZP_3 and ZP_4 proteins, supplied by the Council for Scientific and Industrial Research, South Africa, were expressed in *E. coli* according to Gupta et al. [22] with several modifications. The reZP vaccine used in the current study comprised recombinant ZP_3 and recombinant ZP_4, containing the promiscuous T-cell tetanus and bovine RNase epitopes at the N-terminus, respectively. The recombinant ZP_3 and ZP_4 proteins were analysed via SDS-PAGE gels (Fig. 2) and confirmed by LC-MS peptide mapping. ZP3 with the TT epitope had 93.3% coverage at 95% confidence, while ZP4 with the bRNase epitope had 92.6% coverage at 95% confidence, analysed with ProteinPilot Software (AB Sciex). The resultant reZP product was lyophilized in vials, each containing 2 mg of each protein. Before administration, individual vials were reconstituted with 5 mL sterile water for injection providing a final concentration of 400 μg/mL of each protein. For the primary dose (V1), 0.5 mL reZP (200 μg per protein) was mixed with 0.5 mL MFCA to provide a stable emulsion. For the booster doses (V2 and V3), 0.5 mL recZP was mixed with 0.5 mL FIA to provide a stable emulsion.

Native pZP was prepared according to a standard method [14] and was supplied lyophilized in 1 mg vials by Trumpeter Farms and Veterinary Service (Winters, CA, USA). Each vial was reconstituted with 5 mL sterile water for injection providing a final protein concentration of 200 μg/mL. For the primary dose (V1), 0.5 mL pZP (100 μg) was mixed with 0.5 mL MFCA to provide a stable emulsion. For the booster dose (V2), 0.5 ml pZP (100 μg) was mixed with 0.5 mL FIA to provide a stable emulsion.

An adjuvant control consisted of 0.5 mL sterile saline emulsified with 0.5 mL MFCA for the primary dose (V1) and 0.5 mL sterile saline emulsified with 0.5 mL FIA for the booster dose (V2).

2.3.2. Vaccinations

reZP group (n = 9; mean age 6.1 y; age range 3–13 y): the primary dose (1 mL; V1) was administered by injection into the gluteal muscle mass on Day −70, the first booster (1 mL; V2) was similarly administered into the contralateral gluteal muscle mass on Day −35 and the final booster (1 mL; V3) was administered into the pectoral muscles on Day 0; pZP group (n = 8; mean age 6.5 y; range 3–13 y): the primary dose (1 mL; V1) was injected into the gluteal

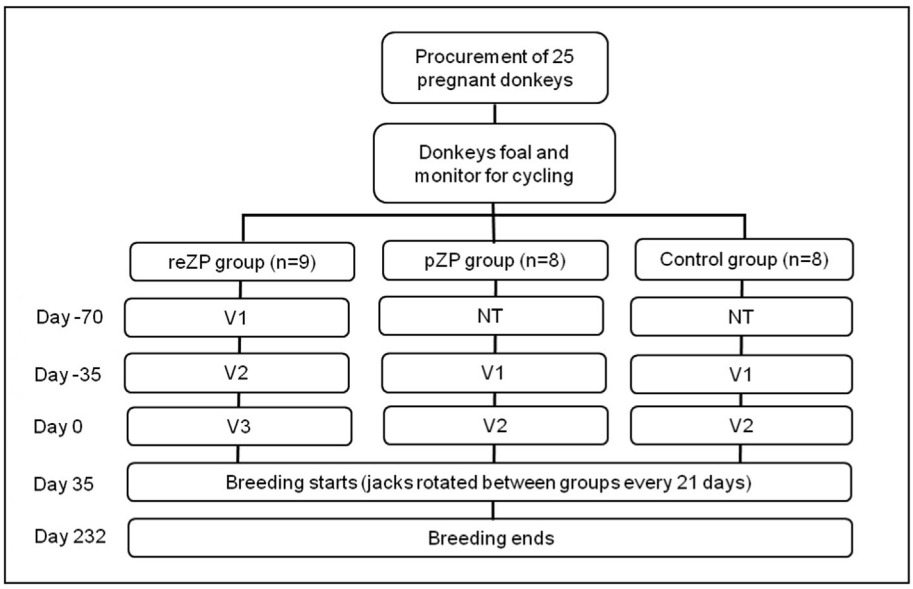

Fig. 1. Overall timeline and treatment protocol for the 25 jennies. NT = no treatment; V1 = primary vaccination; V2 = 1st booster; V3 = 2nd booster.

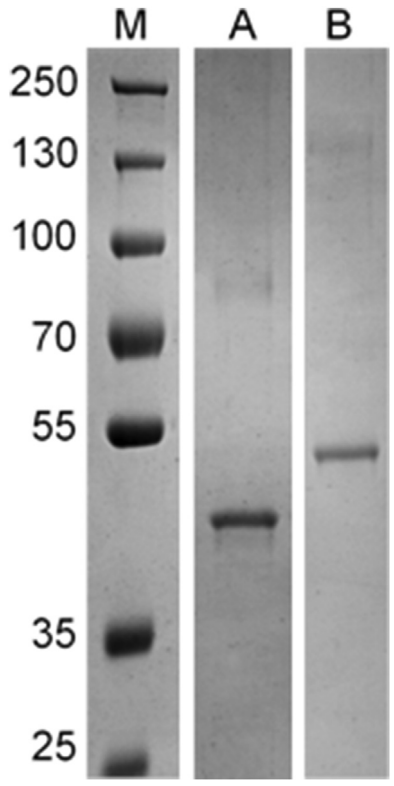

Fig. 2. 10% SDS-PAGE gel of purified (A) ZP3 with the TT epitope and (B) ZP4 with the bRNase epitope. M = PageRuler plus prestained protein ladder (Thermo).

muscle mass on Day −35 and the booster (1 mL; V2), into the contralateral gluteal muscle mass on Day 0; Control group (n = 8; mean age 5.9 y; range 4–10 y): the primary dose (1 mL; V1) was injected into the gluteal muscle mass on Day −35 and the booster (1 mL; V2), into the contralateral gluteal muscle mass on Day 0.

2.4. Observations and sample collection

2.4.1. Transrectal monitoring of the reproductive tract

Clinical examination of the reproductive tract by transrectal palpation and US was performed weekly from Day −105 using a linear 5 mHz probe (Sonosite, Universal). The left and right uterine horn diameters were measured at their base using US. Ovarian findings were recorded as the number of visible follicles (approximate resolution threshold of 5–10 mm) on each ovary and either the presence or absence of a CL. Following introduction of jacks, the jennies were monitored weekly until Day 232 for pregnancy via transrectal US.

2.4.2. Monitoring of injection sites

Jennies were monitored daily for five days after each vaccination for signs of swelling and pain. Thereafter injection sites were monitored weekly until the end of the study.

2.4.3. Serum collection and antibody titer assays

Blood samples from all jennies were collected with plain, evacuated tubes (Terumo™ VENOJECT™ II, Fischer Scientific, Waltham, Massachusetts, USA) by jugular venipuncture at 5-weekly intervals from Day −70 to Day 70 for assessment of anti-pZP antibody titers. Samples were allowed to coagulate at room temperature and serum was separated and stored at −80 °C until assayed. Anti-pZP antibody response was measured by enzyme immunoassay (EIA), using a modification of a method previously described [24]. Positive reference serum consisted of pooled samples collected from the pZP group (n = 8) on Day 35, when maximal antibody responses were anticipated for use as reference standards. Briefly, 96-well plates (MaxiSorp, cat. no. NUN430341) were incubated at 2–8 °C for 16 h with 1 μg purified pZP in 100 μL coating buffer (2.94% NaHCO3, 1.59% Na2CO3, pH 9.6) per well. Plates were washed four times with phosphate buffered saline (PBS) containing 0.05% Tween 20 and then blocked with 0.03% bovine serum albumin in PBS for 16 h at 2–8 °C. Plates were then incubated with serial dilutions of reference standards (1:500–1:64,000) and test samples (1:250–1:32,000) in duplicate at 37 °C for 1 h. Wells containing PBS served as blanks. After washing four times, antibodies were detected by incubating plates with 100μL/well of a

1:10,000 solution (diluted with assay buffer) of a Protein G-horse radish peroxidase conjugate concentrate (1 mg/mL; EMD Millipore Corporation, 28820 Single Oak Drive Temecula, CA 92590 USA) at 37 °C for 1 h. After washing four times, plates were developed with trimethylene blue (SureBlue™, KPL, Gaithersburg, Maryland, USA). The reaction was stopped by adding 50 μL of 2 mol/L H_2SO_4 per well. Absorbance was measured at 450 nm using a microplate photometer (BioTeck ELx800, Winooski, Vermont, USA). Sample antibody response (titer) was expressed as the serum dilution rate which achieved an absorbance 1.

2.5. Data analysis

The proportion of pregnancies and of ovarian shutdowns by Day 232, mean of antibody titers and 95% confidence intervals (95% CI) were computed by treatment group. Comparisons of shutdown and pregnancy proportions were done using a permutation test. Threshold of significance was set at 0.05. Comparisons of antibodies titers were done using Wilcoxon rank-sum test. To take in account multiple comparison, P-value threshold was set up at 0.0056 for these statistical tests (Bonferroni correction). Number of follicles and uterine horn diameter were plotted over time until pregnancy diagnosis or the end of the study (Day 232) using local polynomial regression fitting ('loess') smoothing with 95% CI. Mean of antibodies titers were plotted with an error plot (95% CI). The effect of antibody titers at Day 35 on time to ovarian shutdown was evaluated in the pZP and reZP groups combined using a Cox proportional hazards model. The threshold effect was identified using a penalized spline term. All data analyses were performed in R software [25] using the packages coin, ggplot2 and survival [26–28].

3. Results

3.1. Effects of treatment on pregnancy rate, ovarian function and the uterus

Table 1 summarizes the results for the primary and secondary endpoints for the study. The proportion of pregnant jennies differed across the three treatment groups (P = 0.0004). All in the control group were confirmed pregnant by Day 119. One in the pZP group (Day 196) and two the reZP group (Days 196 and 232) were diagnosed pregnant. The proportion of jennies fulfilling the criteria for ovarian shutdown also differed across the three treatment groups (P < 0.00054). None in the control group, all in the reZP and all but one in the pZP group showed shutdown. The median time (days from Day 0) to shutdown was 56 days for the pZP and 77 days for the reZP group. In the pZP group, the jenny not showing ovarian shutdown was diagnosed pregnant on Day 196. A second jenny in this pZP group had resumed ovarian cyclicity on Day 232. In the reZP group, two jennies resumed ovarian cyclicity after shutdown, by Days 165 and 210, respectively. Both were subsequently diagnosed as pregnant on Days 196 and 232, respectively.

Jennies in both pZP and reZP groups showed a post-treatment reduction in their total ultrasonographically-visible follicle counts compared with those in the control group (Fig. 3). In addition, their mean uterine horn diameter was smaller compared to those in the control group (Fig. 4).

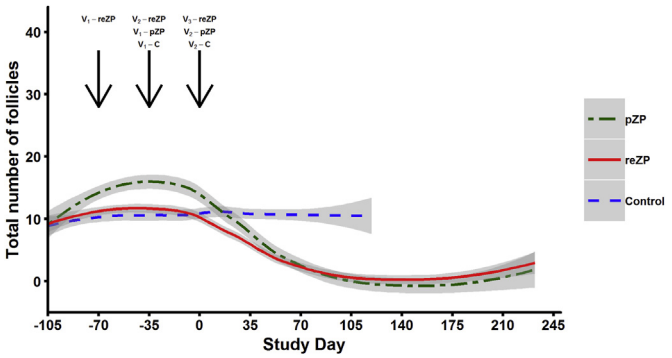

Fig. 3. Total mean follicle counts (≥5–10 mm) of pZP, reZP and control groups from Day −105 (prior to vaccination) to the end of the study (Day 232) after 2 or 3 vaccinations. V_1 = primary vaccination; V_2 = 1st booster vaccination; V_3 = 2nd booster vaccination. Curves were smoothed using loess regression. Grey shading indicates the 95% confidence intervals.

3.2. Injection site reactions

Post-treatment injection site reactions were more frequently observed in ZP-treated jennies than in the controls. Reactions ranged from localized swelling, sometimes accompanied by intermittent lameness during the first five days post vaccination, to abscesses which appeared several weeks later. Subjectively assessed, the swelling and pain exhibited following the primary and first booster treatments was more pronounced in the reZP than the pZP and even more so, the control group. Abscesses were observed in 9/9, 7/8 (87.5%) and 3/8 (37.5%) jennies treated with reZP, pZP and control formulation, respectively. Bacteriological cultures of these abscesses were negative. As a result of the more severe injection site reactions observed after the first booster in the reZP group, a decision was made to substitute FIA with physiological saline for the second booster. As a result, only minor injection site reactions were observed.

3.3. Post treatment antibody titers

The mean antibody titers of each group over time are shown in Fig. 5. Groups pZP and reZP differed significantly from the control group on Days 0, 35 and 70 (P < 0.001 in all cases). There were no significant differences between the mean titers of the pZP and reZP groups on days 0 (P = 0.24), 35 (P = 0.37) and 70 (P = 0.42). Table 2 shows the antibody titers (Day −35 to Day 70) of the jennies that were diagnosed pregnant in the reZP (#10, Day 232; D #23, Day 196) and pZP (#4, Day 196) groups, respectively. It also shows the mean group titers and titers of jennies that were lower (at least on

Table 1
Summary of reproductive outcomes observed in jennies following the final administration (Day 0) of native porcine zona pellucida vaccine (pZP), recombinant zona pellucida vaccine (reZP) or saline control, all formulated with Freund's adjuvants.

Observation	control group (n = 8)	reZP group (n = 9)	pZP group (n = 8)
number (%) pregnant by Day 232	8 (100%)	2 (22.2%)	1 (12.5%)
median time to pregnancy (days)	77 (n = 8)	214 (n = 2)	196 (n = 1)
median time to shutdown (days)	–	77 (n = 9)	56 (n = 7)
Jennies with temporary shutdown - days to resumption of cyclicity (%)	0 (0%)	1 - 165 (11.1%) 1 - 210 (11.1%)	1–232 (12.5%)
Number of jennies with prolonged shutdown	0 (0%)	7 (77.8%)	6 (75%)

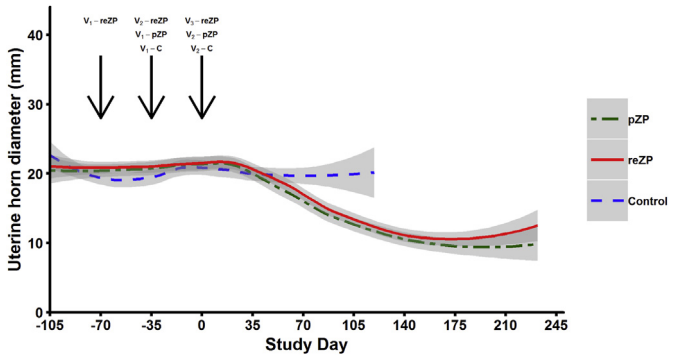

Fig. 4. Mean uterine diameter at the base of the uterine horn in jennies from pZP, reZP and control groups from Day −105 (prior to vaccination) to the end of the study (Day 232) after 2 or 3 vaccinations. V_1 = primary vaccination; V_2 = 1st booster vaccination; V_3 = 2nd booster vaccination. Curves were smoothed using loess regression. Grey shading indicates the 95% confidence intervals.

the last sampling day), than jennies that became pregnant during the observation period. There was a statistically significant negative association between titer at Day 35 and time to shutdown. The "hazard" (instantaneous potential for shutdown) was increased by 13% (95% CI: 2–26%) for every 1000 unit increase in Day 35 titer ($p = 0.02$). This effect varied non-linearly, with a threshold of effect identified at a Day 35 titer of ~17,000 (Fig. 6). This figure excludes the one subject in the pZP group with a very low titer that did not shut down, as the effect of that one subject masked the above threshold effect to a large extent. Donkeys categorized as "high responders" on the basis of this threshold (titers>17,000; n = 10) showed shut down significantly faster than "low responders" (titers<17,000; n = 7), with a median time to shutdown of 59.5 days in high responders and 84 days in low responders (log-rank test p-value = 0.03).

4. Discussion

4.1. Contraceptive efficacy

The most important finding of the study was the contraceptive efficacy of both ZP vaccines. On the last day of the trial (Day 232), 7/9 and 7/8 jennies in the reZP and pZP groups were not pregnant. Compared to the controls, the first conceptions were delayed by more than 100 days. The median time to pregnancy diagnosis from the final treatment was 77 days for the controls, whereas

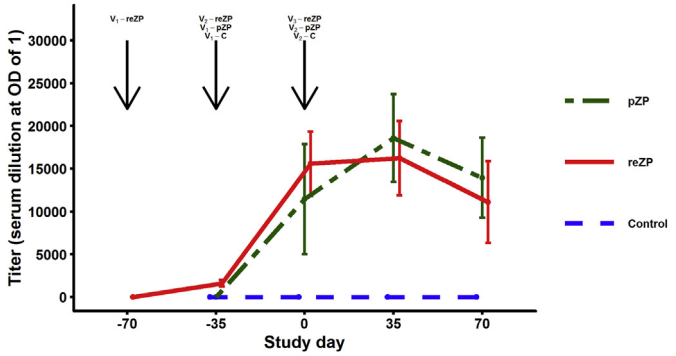

Fig. 5. Mean antibody titers expressed as serum dilution rates of pZP, reZP and control samples which achieved an absorbance of 1 from Day −70 (prior to vaccination) to Day 70 (after 2 or 3 vaccinations). V_1 = primary vaccination; V_2 = 1st booster vaccination; V_3 = 2nd booster vaccination. Vertical bars represent 95% confidence intervals.

Table 2
Antibody titers expressed as serum dilution rates which achieved an absorbance of 1 of pregnant and non-pregnant jennies with low Day 70 titers, and the group means during the study.

Group	ID	Titer			
		Day −35	Day 0	Day 35	Day 70
reZP group	#10 pregnant	2600	8461	19549	9978
	#23 pregnant	1300	13763	12988	6537
	#19 Low not pregnant	1539	8935	7559	4503
	#18 Low not pregnant	1363	18744	8268	4593
	reZP group mean	1604	15577	16229	11103
pZP group	#4 pregnant		7065	7081	9912
	#6 Low not pregnant		1556	13435	7016
	#15 Low not pregnant		18939	19582	7016
	pZP group mean		11437	18574	13941

conceptions in the reZP and pZP groups were recorded on Days 196 and 232, and Day 196, respectively. Given the weekly examination of the jennies, estimated time of conception would have been 2–3 weeks earlier. The contraceptive efficacy was similar to those reported in mares treated using pZP formulated with Freund's adjuvants [14,15,17,29]. In the only other study reporting the immunocontraception of donkeys with pZP in the Virgin Island National Park [21], 16 feral jennies were treated and 11 served as controls. Thirteen jennies were treated by remote delivery of two injections of 65 μg pZP in Freund's complete adjuvant (FCA; primary) and FIA (booster) 3 weeks apart. Another three jennies were treated once with a combination of a 65 μg pZP formulated in a slow-release pellet and 65 μg pZP in FCA. All jennies received another booster in FCA 10–12 months later. The jennies were monitored for pregnancy using a fecal progestogen and total estrogen assays. Of the 16 treated, one was pregnant 12–24 months after the final booster whereas 6/11 control animals were found to be pregnant during the same period. Other than providing definite proof of efficacy, especially during the 12–24 month period, the two studies are difficult to compare. Our jennies were captive whereas theirs were feral. All our females were non-pregnant whereas 4/27 (3 control and 1 treatment) were already pregnant at the commencement of their study. The authors did not report on post-treatment injection site reactions or changes to the reproductive organs.

The current study is novel in that it describes the first successful

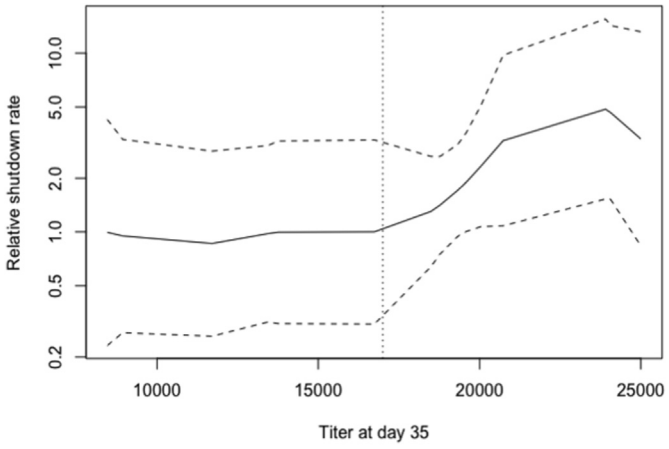

Fig. 6. Effect of antibody titer at Day 35 on time to ovarian shutdown in the pZP and reZP groups combined, excluding one subject with low titers which did not shut down. The solid line shows the shutdown rate relative to the mean antibody titer as the reference. The dashed lines show the 95% confidence intervals. The proposed threshold value of 17,000 is shown by the vertical dotted line.

application of reZP to control fertility in an equid species. This supports reZP as an alternative to native pZP vaccination with its added potential benefits as a non-animal derived product of enhanced production efficacy, antigen protein purity and microbiological safety.

4.2. Ovarian and uterine effects

The previously-presumed mechanism of pZP contraception was largely ascribed to blocking of sperm receptor sites by antibodies in response to ZP_3 protein. Some reports did suggest a limited disturbance in ovarian function, including ovulation failure [15,17] and decreased total urine estrogen concentrations [16]. These consequences were mainly associated with repeated (annual) administration of pZP. It is possible, however, that studies may have overlooked ovarian shut-down because animals were first monitored following a post-treatment delay of ≥3–4 months by which time the presumed ovarian status may have reversed [14,15,17]. Studies in feral mares either did not monitor ovarian function [14,15,29] or did so only indirectly via the measurement of fecal or urinary steroids, and then only for short periods [30].

Recent reports have however associated administration of pZP vaccines in mares with temporary ovarian suppression. Bechert et al. [31] compared two formulations of a single-injection pZP vaccine in MFCA in mares and reported that 93% of mares were non-cyclic 3–4 months after injection. This was associated with basal progesterone concentrations and significantly smaller ovaries with multiple small follicles and no CLs on trans-rectal US. Similarly, Joonè et al. [24] reported that 86% of mares receiving a pZP vaccination protocol similar to this study experienced a period of prolonged anestrus five to 12 weeks post vaccination. Anestrus was characterized by basal serum estradiol and progesterone concentrations and scanty, small follicles on transrectal US. These mares all resumed ovarian activity and reproductive cyclicity by 10 months post-booster injection. On further investigation, it was found that T-helper and cytotoxic cells were associated with the ovarian changes [32]. The current study reports similar findings of ovarian shut-down, thus confirming the findings in the two horse studies. By day 77, all reZP-treated and 88% of the pZP-treated jennies had ceased cyclic ovarian activity. Two reZP and one pZP-treated jenny had resumed ovarian activity by Day 165, 210 and 232, respectively. The pZP jenny diagnosed pregnant on Day 196 had cycled throughout the study.

Although the precise mechanism leading to suppression of ovarian function is currently undefined, these observations suggest that this phenomenon may play an important role in ZP immunocontraception in equids and other species [32]. It would seem that ovarian suppression following ZP immunocontraception is not confined to vaccine formulations using FCMA and FIA, having also been observed in varying levels in mares treated with reZP and pZP formulated with Pet Gel A and Poly(I:C) [33].

The reduction in uterine horn diameter is an interesting hitherto unreported observation in pZP-immunocontracepted mares. These changes were associated with reductions in ovarian size, follicular and luteal activity. We suggest that this change was associated with decreased stimulation of the endometrium by ovarian steroids.

4.3. Anti-pZP antibody titers and infertility

Although good anti-pZP antibody titers are achieved in response to pZP immunocontraception in most species, they vary considerably [35,36]. In general, antibody titers within a species are closely related to infertility [14], but between individuals there is considerable variation. Also, comparison between laboratories is difficult unless universal standards are used. Roelle et al. [37] reported that mean anti-pZP titers of non-pregnant mares treated with a slow release pZP formulation (SpayVac) were 33.7–91.9% higher than those of pregnant mares. However, several mares that developed high maximum titers became pregnant whereas one mare with a maximum titer of only 60.11% failed to conceive. A study by Willis et al. [38] may shed some light on these inconsistencies. Three mares were immunized with pZP (primary and booster after 4.5 weeks). The polyclonal antibodies of each mare were characterized by immunoblots against pZP and equine ZP (eZP). All three mares recognised pZP bands of approximately 90 and 55 kDa. For eZP, one mare reacted to the 75–90 and 40–50 kDa bands while the two others mainly reacted to the 90–106 kDa band, but also the 45–55 kDa band. The differing response may explain why anti-pZP antibody titers are not always accurate in predicting contraceptive efficacy in mares. Speculatively, the same may be true for other species including donkeys. The two pregnant jennies in the reZP group had lower final antibody titers than the group mean. However, there were two other jennies with lower titers on Day 70 that did not fall pregnant within the study period. Similarly, the jenny that was pregnant in the pZP group had a higher titer than two non-pregnant jennies on Day 70. The titers of all three were lower than the group mean on Day 70 (Table 2). From this it would seem that anti-pZP titers can be used as a guideline to predict infertility, however, there is considerable as yet unexplained variation between individuals. On the other hand, antibody titers were found to be significant predictors of ovarian shutdown in mares treated with either pZP or reZP [39]. Similarly, an exploratory analysis in the present study, revealed an apparent distinct threshold of effect at a Day 35 titer of ~17000.

4.4. Injection site reactions

The formulation of reZP and pZP with MFCA for primary and FIA for booster immunizations produced excellent antibody titer responses in this study. The inclusion of Freund's adjuvants in the vaccine formulations was unfortunately also associated with undesirable injection site reactions. The localized swellings and lameness were a common finding in all groups, the tendency increasing after the second treatment. Subjectively assessed, swelling and pain was more pronounced in the reZP group. Subsequently, sterile abscesses developed in many controls, all reZP and most of the pZP jennies. Similar injection site reactions were reported in mares treated with two single-injection pZP formulations [31] and with pZP and reZP formulated with FCMA and FIA [24]. Similarly, these were more common with reZP than pZP treatment [24]. Speculatively, this difference may be partly attributable to the promiscuous T-cell epitopes for tetanus toxoid and bovine RNase in reZP in combination with the Freund's adjuvants. Given the more severe reactions to V1 and V2 in the reZP-group, FIA was substituted with saline for V3. The minor reactions associated with the incorporation of saline may also explain the smaller rise in mean antibody titer following V3.

5. Conclusions

Both immunocontraceptive vaccines successfully reduced pregnancy rates in treated jennies. Significantly, this is the first study reporting the successful application of reZP for fertility control in any equid species. Both vaccines induced ovarian shut-down which may be partly responsible for their observed contraceptive effect. In our opinion the injection site reactions associated with inclusion of Freund's adjuvants with both reZP and pZP are an untenable feature of these formulations. Alternative similarly immunogenic adjuvant formulations without the associated severe local reactions are an essential prerequisite for future application.

The recently-reported use of the commercially-available adjuvants Pet Gel A and Poly (I:C) with pZP and reZP in mares producing antibody titer responses equivalent to those observed with Freund's adjuvants [33,34] may be a suitable alternative for donkey jennies.

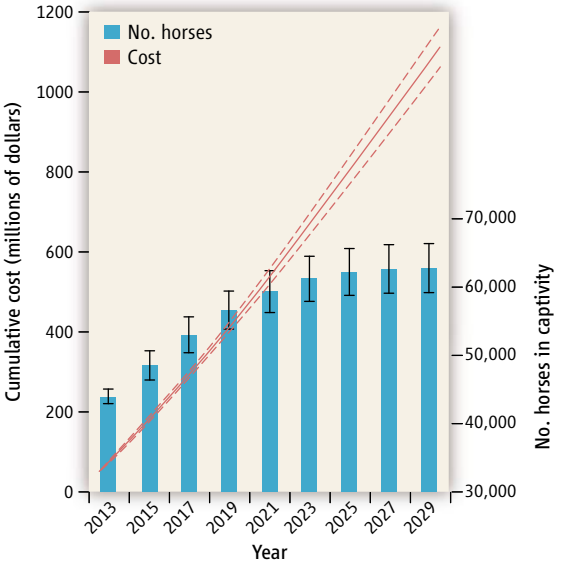
CONSERVATION

A Critical Crossroad for BLM's Wild Horse Program



Captive wild horses will cost the United States over $1 billion by 2030 unless management approaches change

Robert A. Garrott,[1]* and Madan K. Oli[2]

Although horses evolved in North America, they went extinct 10 to 12 thousand years before the present. Spanish conquistadors returned domestic horses to the continent in the mid-1500s, and since then, domestic horses have escaped captivity and also were purposefully released onto western rangelands where they thrive today. Most free-roaming horse populations are managed primarily by the Bureau of Land Management (BLM) of the U.S. Department of the Interior (*1*).

In 1971, the Wild Free-Roaming Horses and Burros Act (*2*) was passed, which establishes public ownership of free-roaming horses and instructs federal agencies to "protect and manage" horses as "an integral part of the natural system of the public lands." The act mandates that BLM and other federal agencies monitor horse numbers, determine appropriate population levels, and remove excess horses from public lands "to preserve and maintain a thriving natural ecological balance." However, at present, tens of thousands of horses are not living the life of "wild mustangs" as Congress intended in passing the Wild and Free-Roaming Horses and Burros Act; instead, they have reverted back to the status of captive, domestic livestock, and the cost of the captive horse program is increasingly unsustainable.

The BLM currently reports ~33,000 free-roaming horses in the western United States. The WHB Program has 179 designated Herd Management Areas, with population objectives for each, and an aggregate maximum goal of 23,622 horses (*3*). Since its inception, the WHB Program has been embroiled in controversy over appropriate population goals, management activities, and the accuracy of its estimates of population size and growth rates (*4*–*7*). The BLM monitors numbers using aerial surveys and captures and removes horses from rangelands when horse numbers exceed target population size. As of 2012, BLM has removed >195,000 horses from public lands under this program (*3*). The act requires BLM to place removed horses into "private maintenance and care for which … an adoption demand exists," with unadoptable, old, and excess animals, beyond the adoption demand, either sold or "destroyed in the most humane manner possible" (*2*). The number of horses BLM removes from public lands routinely exceeds adoption demand (*8*). However, because of pressure from horse advocates, administrative directives and congressional appropriation bills prohibit killing healthy horses (*9*); therefore, BLM is left with large numbers of captive horses that must be maintained indefinitely.

Projections of U.S. captive wild horses and costs (with 95% confidence intervals). (see SM for more details).

These policies have led to a complex and costly system for maintaining captive horses. Horses removed from public lands are processed in short-term holding facilities similar to cattle feed lots and held for several months or more. Many mature females are pregnant when captured and foal in the facilities, which adds to the captive population. Most adult males are castrated. Horses can be adopted from the short-term holding facilities, and some are removed through deaths, sales, or release back onto public lands. Excess animals are eventually transferred to private pastures, primarily in the Midwest, that are contracted as long-term holding facilities. Although small numbers are sold, horses typically remain in these facilities until they die of natural causes. Currently, the ~45,000 horses in captivity exceeded the estimated 33,000 free-ranging horses on public rangelands (*3*).

In a recently released National Research Council (NRC) report (*7*), a committee of 14 scientists concluded that, left unmanaged, horse numbers on public lands would triple every 6 to 8 years until food and water became limited. Under these conditions, horses would be in poor health, reproduction would be suppressed, and deaths from starvation and dehydration would become common, with mass mortality events possible during periods of drought. High horse populations and limited resources would also degrade rangelands, which would affect all native species and public uses of these lands. Thus, although the NRC committee concluded that BLM must actively manage wild horse populations, it asserts that continuing "business as usual" will impede effective management of wild horses on public lands and recommends management changes to put the WHB Program on a more sustainable course (*7*).

Although the NRC report focused on scientific issues, a major impetus for changing the WHB Program is the escalating costs of maintaining increasing numbers of horses in captivity. The WHB Program budget grew from $19.8 million in 2000 (*10*) to $74.9 million in 2012 (*3*). More than 60% of the 2012 budget was used to maintain captive horses, 11% expended to capture and remove animals from public lands, and 10% for adoption programs (*3*). To inform the policy debate, we extend the implications of the NRC report to provide a projection of the captive horse population and associated costs if current policies and management approaches continue.

The Consequences of Business as Usual

We used records of the sex and age of 165,459 horses removed from public lands and placed in captive facilities between 1990 and 2011 to develop demographic projections and associated costs (see the chart) (Fig. 1) [see supplementary materials (SM) for details]. We made two basic assumptions. First, we projected the life span of 33,946 unadoptable horses currently in long-term holding facilities. Under this scenario, BLM will accrue 366,846 horse-years of maintenance costs over a 30-year period before all animals currently in captivity die. Given that $45.9 million was budgeted to maintain 42,835 horses in captivity during 2011 (*10*), annual per-horse maintenance costs would be ~$1074. Thus, the 30-year cost of maintaining horses currently in long-term holding facilities would be ~$394 million ($449 million with 2% annual inflation).

Second, we assumed the current management program would continue, with a mean of 9412 horses in short-term holding facilities and 3803 horses transferred annually to long-term holding facilities. Expenses would be ~$1.1 billion between 2013 and 2030, and annual costs thereafter would be $67 million. Although some citizens may support such expenditures, these projections reinforce assertions (*7*, *8*) that BLM's current approach to managing horse numbers is not sustainable.

A Way Forward

Over 30 years of research on contraceptive agents for feral horses have resulted in the development of effective vaccines that prevent pregnancy in both captive and free-ranging mares for 1 to 3 years (*7*). Experimental application of these vaccines has contributed to the control of a small horse population on an Atlantic Coast barrier island, and limited experiments on western horse herds have also produced encouraging results. The Environmental Protection Agency recently sanctioned two contraceptive vaccines, which enables their routine use for horse population management on western rangelands (*7*). The average life-expectancy of horses entering long-term holding facilities is about 15 years (see SM). Therefore, every horse that does not enter long-term holding facilities would save, because of contraceptive application, $16,110 in maintenance cost (or savings of $1 million for every 62 horses), not considering the modest cost of contraceptive application.

Uncertainties exist when attempting to deliver vaccines to large numbers of horses. Although concerns have been raised regarding behavioral, physiological, and demographic consequences of contraceptive vaccines, none of these concerns preclude their use for managing rapidly increasing populations (*7*). The level of reduction in population growth that can be realistically attained for western horse herds through application of contraceptive vaccines remains unclear. Large-scale management experiments, perhaps within an adaptive management framework, would help address some of this uncertainty (*11*).

We estimate that the typical 15 to 20% annual population increase of western horse herds (*7*) could be halved by means of contraceptive vaccines. If a gather-and-removal effort reduced the western horse population to the BLM's goal of 23,622 horses and aggressive contraception treatment was initiated, then BLM need only remove 2000 to 3000 horses annually to maintain its goal. The number of horses annually removed would then more closely match adoption demand and that would minimize or eliminate the need for long-term maintenance of unadopted animals.

Although broad-scale use of contraceptives can help reduce the number of horses that BLM must remove to control populations, it is not a panacea. Current contraceptive vaccines are most effective when hand-injected, and remote delivery of vaccines via dart is impractical for most free-ranging horse populations (*7*). Accordingly, vaccine delivery will require continuing, and perhaps increasing, the frequency of horse captures. It may also take a decade of experiment and refinement of treatment regimens and contraceptive methods to scale-up management to include the entire population of horses on western rangelands. Furthermore, most populations already exceed management objectives, and population modeling efforts indicate that current contraceptives can only reduce, not stabilize or reverse, population growth. Thus, even with the changes suggested by the NRC report, BLM must continue removing horses from public lands for the foreseeable future.

It is up to society to decide how they want their government to manage wild horses, how many wild horses should be accommodated on public lands, what should be done with excess horses, and how much they are willing to spend. The debate has gone on for many decades; however, we are at a critical juncture. BLM recently announced that because of funding constraints and lack of additional capacity for maintaining captive animals, it will substantially reduce scheduled removals of horses from public lands this year. This decision has been made despite worsening drought conditions that are causing severe shortages of forage and water for horses, wildlife, and livestock (*12*). Terminating or reducing active management will lead to a rapid increase in the number of horses, further exacerbating resource limitations.

The current situation in Australia provides a sobering view of what might be in store for western rangelands in the United States if the current management dilemma is not resolved. The wild horse population in Australia is estimated to exceed 400,000 animals (*13*), and severe drought conditions in central Australia have reportedly forced government agencies to propose shooting 10,000 horses from helicopters to reduce animal suffering and environmental degradation (*14*). One can only hope that there is the political will to change current policy and place BLM's WHB Program on a more sustainable trajectory.

Active Immunization of Intact Mares against Gonadotropin-Releasing Hormone: Differential Effects on Secretion of Luteinizing Hormone and Follicle-Stimulating Hormone

FRANK GARZA, JR., D. L. THOMPSON, JR.,[1] D. D. FRENCH,[2] J. J. WIEST, R. L. St. GEORGE, K. B. ASHLEY, L. S. JONES, P. S. MITCHELL, and D. R. McNEILL

ABSTRACT

Five lighthorse mares were actively immunized against gonadotropin releasing hormone (GnRH) to determine the relative importance of this hypothalamic hormone in the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Five mares immunized against the conjugation protein served as controls. Mares were initially immunized in November and received secondary immunizations 4 wk later, and then at 6-wk intervals until ovariectomy in June. All mares immunized against GnRH exhibited an increase ($p<0.01$) in the binding of tritiated GnRH by plasma, an indication that antibodies against this hormone had been elicited. Concentrations of LH, FSH and progesterone in weekly blood samples were lower ($p<0.05$) in GnRH-immunized mares than in controls after approximately 4 mo of immunization. However, the LH concentrations were affected to a greater degree than were FSH concentrations. All five control mares exhibited normal cycles of estrus and diestrus in spring, whereas no GnRH-immunized mare exhibited cyclic displays of estrus up to ovariectomy. All mares were injected intravenously with a GnRH analog (which cross-reacted <0.1% with the anti-GnRH antibodies) in May, after all control mares had displayed normal estrous cycles, to characterize the response of LH and FSH in these mares; two days later, the mares were injected with GnRH. The LH response to the analog, which was assessed by net area under the curve, was lower ($p<0.01$) by approximately 99% in mares immunized against GnRH than in control mares. In contrast, the FSH response to the analog was similar for both groups. The FSH response to GnRH in mares immunized against GnRH was 85% lower than that in control mares ($p<0.05$), an indication that the antibodies against GnRH did prevent much of the injected GnRH from reaching the pituitary. At ovariectomy, combined ovarian weights of GnRH-immunized mares were 57% lower than those of control mares ($p<0.01$); numbers of follicles and corpora lutea were also lower ($p<0.01$) than those of controls. It was concluded that LH and to some degree FSH secretion, and probably LH production, in the mare are dependent upon the bioavailability of GnRH. However, the lack of effect of GnRH-immunization on FSH response to the analog indicates that FSH stores in the pituitary (and perhaps FSH production) are relatively independent of GnRH bioavailability.

INTRODUCTION

In horses, concentrations of luteinizing hormone (LH) in the blood appear to be tightly coupled in some physiologic states to concentrations of follicle-stimulating hormone (FSH). For example, gonadectomy results in increased concentrations of both gonadotropins in blood (Ginther, 1979; Thompson et al., 1979); administration of gonadotropin-releasing hormone (GnRH) results in a rapid increase in concentrations of both hormones (Ginther, 1979; Thompson et al., 1979, 1983d); and spontaneous, simultaneous peaks in concentrations of both hormones have been reported for both mares and stallions (Thompson et al., 1983a, 1986).

Under other conditions, usually involving gonadal steroids, concentrations of LH and FSH in blood appear to be independent. For example, LH concentrations are stimulated by administration of estrogen to gonadectomized horses whereas FSH concentrations are suppressed (Ginther, 1979; Thompson et al., 1979, 1983d; Garza et al., 1985). Moreover,

FSH production is increased in ovariectomized mares treated with testosterone propionate whereas LH production is not affected (Reville-Moroz et al., 1984).

Another condition under which LH and FSH concentrations in blood differ is seasonal anestrus. Hart et al. (1984) reported that the amount of LH in pituitaries from anestrous mares in winter was only 15% of that in pituitaries of mares in the breeding season. In contrast, pituitary content of FSH did not differ due to season. These results agree well with secretion rates of LH and FSH after administration of GnRH to anestrous mares (approximately 94 times more FSH than LH; Thompson et al., 1986). Hart et al. (1984) suggested that the reduced LH content in the pituitaries of mares in the nonbreeding season was due to the lowered hypothalamic content (and presumably secretion) of GnRH that they found in those same mares.

Given that pituitary content and secretion rates of FSH differ markedly from those of LH during winter, we hypothesized that there is a component of FSH production and/or secretion in the horse that is relatively independent of GnRH's reaching the pituitary. Thus, the present experiment was designed to determine the long-term effects of active immunization of intact mares against GnRH on concentrations of LH and FSH in blood and on their relative responses to exogenous secretagogues.

MATERIALS AND METHODS

Ten lighthorse mares (≥2.5-yr-old) that had exhibited normal estrous cycles during the previous breeding season were used. All mares were kept on pasture and fed grass hay as needed to maintain good body condition throughout the experiment. On November 1, five randomly selected mares were immunized with 4.0 mg of a conjugate prepared from GnRH and bovine serum albumin (BSA) as described by Fraser et al. (1974). The remaining five mares were immunized with 4.0 mg of BSA (controls). The primary immunizations were prepared in Freund's complete adjuvant. Immunizations consisted of multiple intramuscular injections in the neck and/or hip regions of each mare. Secondary immunizations (2.0 mg antigen), similarly in Freund's incomplete adjuvant, were given 4 wk after the primary immunizations, and then every 6 wk thereafter until ovariectomy. Samples (10-ml) of jugular blood were collected from each mare immediately before the primary immunization and then weekly throughout the experiment. The ovaries of all mares were evaluated by rectal palpation once a month for size (length, width and depth) during March, April and May.

Beginning February 1, all mares were checked daily for estrus by exposure to a stallion. After all control mares had exhibited at least two normal estrous cycles in the spring (a normal estrous cycle was defined as at least 3 consecutive days of estrus followed by at least 8 consecutive days of diestrus), each control mare was randomly paired with one GnRH-immunized mare for the timing of all subsequent events. This was because no GnRH-immunized mare exhibited normal estrous cycles during the late winter and spring. Thus, for the following procedures (GnRH-analog administration, GnRH administration, and ovariectomy), one control mare and one GnRH-immunized mare were treated at the same time based on the stage of the control mare's estrous cycle.

On Day 8 or 9 of diestrus in May, one jugular vein of each mare was fitted with a 14-gauge catheter for frequent blood sampling. Three 10-ml samples of blood were collected from each mare at 15-min intervals. Each mare was then administered a GnRH analog (des-Gly^{10}-(im-Bzl-D-His^{6})-LHRH; Sigma Chem. Co., St. Louis, MO) through the jugular catheter at 40 ng/kg of body weight. Blood samples were collected at 15, 30, 45, 60, 75, 90, 120, 150, 180, 210, 240, 270, 300, 330 and 360 min after the injection of analog. The GnRH analog was chosen because it was found in preliminary trials to cross-react <0.1% with the antibodies in the plasma of these mares when tested with tritiated GnRH. The dosage of GnRH analog was also determined in a preliminary trial (with different mares) and was equivalent to 1.0 μg/kg of body weight of GnRH with regard to LH and FSH response (area under the curve).

Forty-eight h after the injection of GnRH analog, the above procedure was repeated for each mare except that GnRH (Sigma) was injected. The dose of GnRH was 1.0 μg/kg of body weight.

On Day 7 or 8 of the subsequent diestrus (in June), each pair of mares was bilaterally ovariectomized via flank incision under local anesthesia. Each ovary was trimmed of connective tissue, weighed, and serially sectioned (approximately 6-mm sections) for the enumeration of follicles and corpora lutea.

For all blood samples, heparinized plasma was harvested via centriguation and stored at −15°C. Concentrations of LH, FSH and progesterone were

measured by radioimmunoassay as described previously (Thompson et al., 1983a,b,c). The binding of tritiated GnRH to diluted plasma was measured and the cross-reactivities of various GnRH analogs (Sigma) were determined as described previously for estradiol (Thompson and Honey, 1984).

Data for measurements taken over time were analyzed by analysis of variance that accounted for the repetitive nature of the sampling (split-plot design; Gill and Hafs, 1971). Differences between groups for each time period were assessed for significance by the lsd-test. Net areas under the LH and FSH response curves for GnRH and analog injections were calculated as described by Thompson and Nett (1984). Data for nonrepetitive variables were analyzed by one-way analysis of variance (Steel and Torrie, 1960).

RESULTS

The binding of tritiated GnRH by 10 μl of plasma from control and GnRH-immunized mares is presented in Figure 1. After the third injection of antigen in January, GnRH binding increased ($p<0.01$) in plasma of GnRH-immunized mares relative to control mares. There was an increase in binding after each immunization thereafter such that binding was gradually increasing up through June 6 when blood sampling ceased.

The cross-reactivities of several commercially available GnRH analogs were as follows (%): (Gly-OH^{10})-LHRH 12.9 ± 7.8; des-Gly^{10},(D-Leu^{6})-LHRH 0.28 ± 0.24; des-Gly^{10},(D-Trp^{6})-LHRH 0.31 ± 0.23; des-Gly^{10},(im-Bzl-D-His^{6})-LHRH 0.097 ± 0.054; and (Ac-D-pCl-Phe^{1,2}, D-Trp^{3}, D-Arg^{6}, D-Ala^{10}) - LHRH 0.078 ± 0.046. Because up to 5 μg of most of these analogs did not inhibit the binding of tritiated GnRH by 50%, the above cross-reactivities were calculated at the greatest percentage of inhibition obtained with a given analog. The amount of unlabeled GnRH that resulted in 50% inhibition averaged 3.92 ± 0.92 ng.

Concentrations of progesterone, LH and FSH were all suppressed ($p<0.05$) in GnRH-immunized mares relative to control mares during the latter periods of the experiment (Fig. 1). Concentrations of all three hormones in control mares varied due to the stage of the estrous cycle as evidenced by the large fluctuations in values in Figure 1. In contrast, hormonal concentrations in GnRH-immunized mares became relatively constant after approximately 15 wk of treatment.

From February 1 until ovariectomy in June, no GnRH-immunized mare exhibited cyclic displays of estrus (Table 1). In fact, during that time, only one GnRH-immunized mare exhibited estrus, and that was on two separate occasions (March 21 and May 16) for one day only. This mare did not exhibit any rise in LH or progesterone concentrations in association with these two displays of estrus. All control mares exhibited normal estrous cycles (Table 1) with an average duration of estrus of 6.4 ± 0.7 days and an average duration of diestrus of 17.3 ± 0.7 days.

During March, ovarian volume, as assessed by rectal palpation, did not differ ($p>0.05$) between the two groups of mares (Table 1). In April and May, ovarian volumes of GnRH-immunized mares averaged only 18 and 8%, respectively, of control values ($p<0.05$). At ovariectomy, ovarian weights, number of follicles >10 mm in diameter and number of corpora lutea were all lower ($p<0.01$) in GnRH-immunized mares than in control mares (Table 1).

When mares were administered GnRH analog in May, the mean concentrations of FSH before injection were lower ($p<0.05$) in GnRH-immunized mares than in control mares (Fig. 2). However, the FSH response to GnRH analog, as assessed by the change in hormonal concentrations and by the net area under the curve, was similar for both groups. In contrast, when

GnRH itself was administered (Fig. 2), the FSH response was reduced ($p<0.05$) in GnRH-immunized mares compared with control mares.

The LH response to GnRH analog (Fig. 3) was essentially nonexistent in GnRH-immunized mares relative to control mares ($p<0.01$). The same lack of response was observed for LH after administration of GnRH. For both LH and FSH, the shape of the response curves differed for the analog and GnRH injections, with the analog resulting in a sustained elevation in concentrations through 6 h after injection.

DISCUSSION

Active immunization of these mares against a GnRH-BSA conjugate resulted in the production of anti-GnRH antibodies, as has been reported for other species (Clarke et al., 1978; Fraser and Baker, 1978; Chappel et al., 1980; Shettigara et al., 1981). Moreover, repetitive injection of antigen at 6-wk intervals resulted in high GnRH binding in plasma of GnRH-immunized mares such that the long-term effects of immunization could be determined. Although the specificity of the anti-GnRH antibodies could not be exhaustively assessed (and was not attempted), it appears from the analog data that minor deviations from the GnRH structure greatly reduced the cross-reactivity of an analog when it was in competition with GnRH. If this apparent specificity was also present in vivo, then we would conclude that only GnRH or closely related compounds in plasma were

affected by the antibodies generated against the GnRH moiety of the conjugate.

Because horses are seasonal breeders, the mares in the present experiment were first immunized in the autumn so that they received several secondary immunizations before the onset of the next breeding season. Our goal was to study the long-term effects of immunization on characteristics of LH and FSH secretion, thereby minimizing the importance of pituitary stores and/or turnover rates that could mask any real effects of treatment in the short term. The failure of GnRH-immunized mares to return to normal estrous cycling in the spring is similar to the cessation of normal reproductive activity observed in other species immunized against GnRH (Clarke et al., 1978; Fraser and Baker, 1978; Shettigara et al., 1981). Thus, it appears that the generation of anti-GnRH antibodies in these mares resulted in a biological inactivation of endogenous GnRH. This concept is also supported by the data in Figure 2; i.e, immunization against GnRH reduced the GnRH-induced release of FSH by 85% but did not affect analog-induced FSH release.

Concentrations of both LH and FSH in plasma were suppressed in the long term in GnRH-immunized mares relative to control mares. However, it must be noted that LH concentrations in GnRH-immunized mares were suppressed to undetectable levels (0.3 ng/ml in our assay) whereas FSH concentrations were still easily detectable after 32 wk (approximately 10 ng/ml as compared with the limit of detection of 3.9 ng/ml in the FSH assay). Thus, we conclude that normal secretion of these two gonadotropins is dependent upon GnRH's reaching the pituitary; however, there appears to be a component of FSH secretion that is relatively independent of GnRH. This is in agreement with previous observations in seasonally anestrous mares in which concentrations of plasma LH are generally undetectable whereas concentrations of FSH are not nearly as suppressed (Thompson et al., 1986). A similar dichotomy was reported for LH and FSH secretion in geldings after suppression with testosterone or estradiol (Thompson et al., 1979).

The effect of GnRH-immunization on apparent amount of hormone released in response to injection of GnRH analog differed markedly for LH and FSH. Essentially no LH was secreted by GnRH-immunized mares. In previous studies, the apparent amount of LH secreted in response to exogenous GnRH was closely coupled with the mean amount of LH in the pituitary (Thompson et al., 1979; 1986; Hart et al., 1984). If this relationship had persisted in the present experiment, the amount of LH in the pituitaries of GnRH-immunized mares would have been proportionally lower, which would be indicative of a long-term suppression of LH production. Such a suppression would be similar to that reported for LH in seasonally anestrous mares (Hart et al., 1984).

The FSH response to the injection of GnRH analog was virtually identical in both groups of mares. Again, if this analog-induced change in blood levels of FSH is indicative of pituitary stores, then we conclude that the amount of FSH in the pituitary was relatively independent of GnRH's reaching the pituitary. Because concentrations of FSH in blood in the long term were suppressed by approximately 50%, it might be expected that a concurrent and proportional reduction in FSH production would have to occur to prevent a large accumulation of FSH in the pituitary. Given that FSH secretion after injection of the GnRH analog was not indicative of such an accumulation, we conclude that some reduction in FSH production likely occurred. One possible interpretation of these data is that the production of FSH in the pituitary is coupled to the amount within the gland such that accumulation would not occur. It must also be noted that this FSH was released by the GnRH analog, thus its secretion per se was GnRH-dependent.

The overall characteristics of LH and FSH secretion in the mares immunized against GnRH were analogous to those in seasonally anestrous mares. Thus, our results agree with the speculation by Hart et al. (1984) that the low LH content in the pituitary of mares in the winter is due to the low concentration (and probably secretion) of GnRH in the hypothalamus. Moreover, continued low concentrations of LH resulted in a failure of the mares in the present experiment to return to estrus and to ovulate, which is similar to the seasonally anestrous state.

It is not known whether LH and FSH are produced by one, two or perhaps three cell types within the pituitary of the horse. In rats, at least three cell types appear to be involved with LH and FSH storage (Dada et al., 1983). This important basic information is needed to develop a model of gonadotropin secretion by the equine pituitary. The complexities of the LH vs. FSH data in the present experiment and in previous reports (Thompson et al., 1979, 1986; Hart et al., 1984; Reville-Moroz et al., 1984) tend to refute the

argument that a single cell type is responsible for both LH and FSH secretion in the horse.

In conclusion, long-term immunization against GnRH produces a reproductive state in mares analogous to seasonal anestrus. It appears that LH secretion, and probably production, in mares is highly dependent upon the bioavailability of GnRH from the hypothalamus, because immunization against GnRH markedly reduced LH concentrations in the long term and the LH response to secretagogues. In contrast, FSH concentrations were less affected by immunization, and there appear to be components of FSH secretion and perhaps production that are relatively independent of GnRH bioavailability.

ACKNOWLEDGMENTS

We thank the National Hormone and Pituitary Program, Baltimore, Maryland, for supplying purified human FSH; Dr. Harold Papkoff, University of California at San Francisco, for supplying equine gonadotropins; and Dr. Leo E. Reichert, Jr., Albany Medical College, for supplying purified ovine LH.

ABSTRACT We evaluated the health effects of GonaCon™ Immunocontraceptive Vaccine in individual white-tailed deer (*Odocoileus virginianus*) on a fully fenced corporate office campus in suburban New Jersey, USA. We captured and vaccinated adult females, fawns of both sexes, and yearling and adult males, and evaluated their health status through field and necropsy observations, assessment of blood chemistry, and histopathological examination of selected tissues. One 1.0-mL intramuscular injection of vaccine was delivered by hand to the hind limb of each GonaCon-treated deer. Control deer received sham injections (ad F) or no injections (yearling and ad M). Mean body-condition scores of GonaCon-treated adult females and males were greater than those of corresponding control groups. No evidence of limping or impaired mobility was noted in study deer during the 2-year study. No adverse effects of vaccination were detected in major organs, organ systems, body condition, fat deposits, or blood chemistry. Injection-site lesions (granulomatous nodules and sterile abscesses) occurred in the deep hind-limb musculature of >85% of GonaCon-treated and sham-injected deer but were not detectable externally. Reactions at injection sites and in lymph nodes were typical responses to injection of vaccines formulated as water-in-oil emulsions, especially those, like GonaCon, that contain mycobacteria. The formation of injection-site lesions may be a necessary component of the immune response that causes infertility in treated animals. Natural resource managers who use GonaCon to manage deer in settings such as developed areas and public parks will ultimately determine its value and applicability. © 2011 The Wildlife Society.

KEY WORDS contraception, gonadotropin releasing hormone, granuloma, infertility, *Odocoileus virginianus*, overabundance.

Management of overabundant populations of white-tailed deer (*Odocoileus virginianus*) has become a major challenge for natural resource managers in many urban, suburban, and public park settings in the United States. Traditional management methods cannot be used in many such settings because of safety issues, conflicting views regarding the social acceptability of hunting, or laws prohibiting the discharge of firearms (DeNicola et al. 1997). Fertility control may offer a nonlethal management alternative, especially for deer subpopulations that are isolated by fencing or natural barriers. Immunocontraception and other nonlethal methods are increasingly advocated by the public (Stout et al. 1997, Lauber et al. 2007) and hold promise as a means of reducing reproduction in overabundant wildlife populations (Hobbs et al. 2000, Curtis et al. 2002, Fagerstone et al. 2010).

GonaCon™ Immunocontraceptive Vaccine (National Wildlife Research Center, Fort Collins, CO) is a gonadotropin releasing hormone- (GnRH-) based water-in-oil emulsion that has safely induced temporary infertility in many mammalian species, including free-ranging California ground squirrels (*Spermophilus beecheyi*; Nash et al. 2004), captive Norway rats (*Rattus norvegicus*; Miller et al. 1997), domestic cats (*Felis catus*; Levy et al. 2004), domestic and feral swine (*Sus scrofa*; Miller et al. 2003; Killian et al. 2006*c*), wild horses (*Equus caballus*; Killian et al. 2006*a*), bison (*Bison bison*; Miller et al. 2004*a*), elk (*Cervus elaphus*; Killian et al. 2009), and white-tailed deer (Miller et al. 2008*b*; Gionfriddo et al. 2009). It can be administered as one intramuscular injection that suppresses reproduction in treated animals of both sexes for multiple years (Miller et al. 2004*b*). GonaCon was registered by the United States Environmental Protection Agency in September 2009 as a restricted-use product for the contraception of adult, female, white-tailed deer via hand injection (Fagerstone et al. 2010).

We assessed the health effects of GonaCon treatment in white-tailed deer adults and fawns of both sexes. Adult females were the primary focus of the study because they will be the targets of operational applications of GonaCon vaccine by natural resource managers. Fawns were tested because a GnRH immunocontraceptive agent could potentially be delivered orally in the future, and treated bait might be consumed by deer of all ages. We also tested GonaCon in yearling and adult males. Although GonaCon is not registered or recommended for use in male deer (Killian et al. 2005, Curtis et al. 2008), antlerless males could inadvertently be treated during winter management activities because they can be mistaken for females. Inadvertent treatment of males could also occur if a new GnRH vaccine is registered for remote injection or oral delivery in bait.

This research was part of a larger investigation that also evaluated GonaCon's contraceptive efficacy, which is addressed separately in another manuscript (Gionfriddo et al. 2011). The objective of the research covered in this manuscript was to evaluate the health effects of GonaCon Immunocontraceptive Vaccine in wild white-tailed deer through field observations, necropsy examinations, laboratory assessment of blood chemistry, and histopathological analysis of selected reproductive and other tissues. We tested several hypotheses to determine whether mean body condition scores were higher in some groups of study deer than in others. In addition, we tested a series of hypotheses to determine whether mean values for blood-chemistry parameters differed between treatment groups (GonaCon-injected ad F vs. sham-injected control F) and between years (pretreatment vs. posttreatment). We also tested the hypotheses that the incidence of injection-site lesions was higher 1) in GonaCon-treated than in sham-injected control adult female deer, and 2) in GonaCon-treated adult female deer that became pregnant than in those that did not, for each year. Finally, we tested the hypothesis that the GonaCon-injected rear leg of each deer was greater in circumference near the injection-site location than the other rear leg.

STUDY AREA

The study was conducted on a fully fenced (2.4-m-tall chain-link), 123-ha corporate office campus near Madison in New Jersey, USA. Habitat types included hardwood forest (about 20%), old fields reverted to grasslands and savannah (about 20%), lawns (about 40%), and landscaped areas around buildings. Deer were easily observed from paved and gravel roads located throughout the study area. During the 2-year study, a few deer emigrated or immigrated by running through security gates opened briefly by guards to allow ingress and egress of motor vehicles.

Northern New Jersey experienced a continental type of climate, with cold, damp winters and hot, humid summers. At Morris Plains, about 8.5 km northwest of the study area, mean monthly temperatures (1945–1990) ranged from −2.4° C (January) to 22.4° C (July). Mean annual precipitation (1941–1990) was 128.8 cm, with an annual growing season of about 142 days (Office of the New Jersey State Climatologist 2011; U.S. Department of Agriculture Natural Resources Conservation Service, National Water and Climate Center 2011).

METHODS

Capture and Treatments

All study deer.—We captured deer at night with tranquilizer darts fired from a Pneu-Dart rifle (Model 171; Pneu-Dart, Inc., Williamsport, PA). We used a mixture of Telazol® (4.5 mg/kg; Fort Dodge Animal Health, Fort Dodge, IA) and xylazine hydrochloride (2.5 mg/kg; Bayer, Leverkusen, North Rhine-Westphalia, Germany) to immobilize deer. One of us (AJD) estimated deer body masses in the field by handling deer and by palpating body contours strongly influenced by fat deposits (Riney 1960, Robinson 1960, Audigé et al. 1998). We fitted deer with numbered ear tags and radiotelemetry collars equipped with mortality sensors (Model M2520; Advanced Telemetry Systems, Isanti, MN). We delivered a 1.0-mL injection (GonaCon vaccine or a sham material; see below) by hand to the deep musculature of the upper hind limb of each deer. If a deer had been darted in a hind limb we hand-injected the opposite hind limb. We administered tolazoline hydrochloride (3.0 mg/kg; Lloyd, Inc., Shenandoah, IA) intravenously to reverse anesthesia and hasten recovery of deer before we released them at their capture sites.

Adult females.—During July and early August 2005, we captured all adult females present on the study area ($n = 47$) and collected a blood sample from the jugular or femoral vein of each animal to measure pretreatment blood-chemistry parameters. We injected each female with GonaCon Immunocontraceptive Vaccine ($n = 32$; each 1.0-mL dose of vaccine contained 1,000 μg of conjugated GnRH–mollusk protein) or with a sham material ($n = 15$). The sham material consisted of AdjuVac™ adjuvant (National Wildlife Research Center, Fort Collins, CO) and mollusk stabilizing buffer (i.e., GonaCon vaccine without GnRH and without the mollusk protein that usually serves as the carrier molecule to which GnRH is conjugated).

Fawns and males.—We captured and vaccinated 8-month-old female fawns ($n = 4$) in February 2006 to determine the health effects of vaccination with GonaCon vaccine on young deer treated during their first winter. To evaluate the health effects of treating young fawns with GonaCon, we captured and vaccinated 3- to 4-month-old fawns ($n = 16$) during September–October 2006. We captured and vaccinated yearling and adult males ($n = 10$) during March 2007 to assess the health effects of wintertime treatment of male deer with GonaCon. To provide baseline data on untreated (control) males, we killed (via gunshot to head or neck) and necropsied previously uncaptured males (yearlings and ad; $n = 13$) during October 2007.

Evaluation of Health Effects of Vaccination on Treated Deer

We used field observations, necropsy examinations, laboratory assessment of blood chemistry, and histopathological evaluation of selected reproductive and other tissues to

identify potential health and safety problems associated with GonaCon treatment. We observed all study animals during spring(s) and summer(s) between their capture and October 2007. During field observations we looked for evidence of limping, impaired mobility, reduced range of motion of limbs, other abnormal behavior, and externally visible injection-site reactions. In October 2007, at the conclusion of field activities, we collected 62 deer (including representatives of all of the above treatment and control groups) after shooting them in the head or neck with a high-powered rifle. We shot deer as they foraged or rested, without a chase. We collected blood from each deer via cardiac puncture within 1 min of the animal's death, and we stored blood samples in a cooler or refrigerator before we isolated the serum via centrifugation and shipped it to a laboratory for analysis of blood chemistry. For the original group of adult females (the only experimental deer from which we collected blood at the time of initial capture), we used analysis of variance (ANOVA; mixed model) to compare mean values of blood-chemistry parameters of vaccinated versus control deer. Treatment group and year were treated as fixed effects and individual deer were treated as a random effect in the mixed-model analysis.

An experienced wildlife veterinarian performed standard necropsy examinations (Munson 2010) in the field immediately after deer were killed and blood samples were collected. We fixed and preserved tissue samples in formalin before we shipped them to Colorado, USA, for histopathological evaluation (Colorado Histo-Prep, Fort Collins, CO). Samples collected included ovaries, fallopian tubes, uteri, hypothalami-anterior pituitary glands, mammary glands, and the injection-site tissues and their draining (popliteal and iliac) lymph nodes. We also submitted other apparently abnormal tissues, if present, for histopathological analysis. We used Fisher's exact tests to determine whether the incidence of injection-site lesions was greater 1) in GonaCon-treated than in sham-injected control adult female deer, and 2) in pregnant than in nonpregnant GonaCon-treated adult female deer for each year.

Fat stores and general body condition were evaluated for each deer at necropsy to provide information on individual and general herd health, which may have influenced vaccine efficacy. We measured (to the nearest 0.5 mm) the thickness of the thickest fat layer at the base of the heart and on the ventral surfaces of the kidneys; of the 6 indicator sites used by Kistner et al. (1980), these are the most predictive of body composition (Cook et al. 2001). Based on thickness, we assigned a value of 1–5 to each heart or kidney fat deposit (0.0–2.0 mm = 1, 2.5–4.5 mm = 2, 5.0–7.0 mm = 3, 7.5–9.5 mm = 4, $\geq$10.0 mm = 5). For each deer, we categorized general fat deposits as "little," "little to moderate," "moderate," "moderate to abundant," or "abundant," and we assigned values of 1–5 for these categories ("little" = 1, "abundant" = 5). In addition, the necropsy veterinarian classified each animal's general body condition on a scale of 1 through 4, based upon body size (relative to age), muscularity, and externally perceptible fat stores (1 = poor poor condition, with ribs, spine, and all bony prominences starkly visible, and with no fat cover in the concave rump; 2 = thin condition, with the spine, ribs and bony prominences clearly but not starkly visible, with no muscle development, and with little palpable fat in the flat rump; 3 = fair condition, with the spine visible, the ribs and bony prominences palpable but only slightly visible, and with little muscle development; 4 = good condition, with spine, ribs, and prominences not visible, and with at least moderate muscularity, but not a "fat" animal). None of the deer on this study site was considered "fat" or in "excellent" body condition. For each deer, the 4 values for fat stores and body condition were summed to produce a body condition score that took into account body size, musculature, and both externally apparent and deep internal fat stores. If one of the values was missing, we replaced it with the mean of the other 3 values, rounded to the nearest integer. We used these body condition scores, which ranged from 4 to 16, to assign each deer to a body condition class (4–5 = "poor," 6–8 = "thin," 9–11 = "fair," 12–16 = "good"). Body condition scores usually vary among males, females, and fawns due to differences in their ability to store fat and in their need to metabolize fat stores as the autumn breeding season proceeds (Kistner et al. 1980). Accordingly, we calculated a mean body-condition score for each of the following groups: GonaCon-treated adult females, control adult females, GonaCon-treated adult males, control adult males, male fawns vaccinated at 3–4 months of age, female fawns vaccinated at 3–4 months of age, and female fawns vaccinated at 8 months of age (Table 1). Modified Kistner scores have been used successfully to evaluate body condition in many cervids (e.g., Cook et al. 2001, 2007; Stephenson et al. 2002; Peterson and Messmer 2007). Although our body condition scores may not provide an absolute measure of fat deposits or body condition, they do provide standardized relative measures of these variables that permit valid comparisons of treatment–demographic groups within our study.

To determine whether injections had caused a swelling of hind limbs, or whether limb disuse had caused muscular atrophy, we used a standard vinyl tape measure to determine the circumference of each thigh of each deer at necropsy. We held the end of the tape at the top edge of the patella at the insertion of the quadriceps muscle group and wrapped the tape around the thigh at the narrowest point caudal to the stifle. Although this point was very slightly distal to the injection site, it provided a practical, standardized location for comparative measurements that would detect differences in girth at the injection sites. We used a paired t-test to compare the left and right thigh circumferences of each deer. For all statistical analyses, we used $\alpha = 0.05$. The Institutional Animal Care and Use Committee of the National Wildlife Research Center approved all aspects of this research.

RESULTS

All Study Deer

With one exception, no overt signs of limping, restricted range of motion of limbs, or impaired mobility were observed

Table 1. Body condition scores* of GonaCon-treated and control white-tailed deer in New Jersey, USA, 2005–2007.

Treatment group	Body condition				*N*	Group mean	SEM
	Poor	Thin	Fair	Good			
Ad F: GonaCon	2	7	4	3	16	8.8	0.8
Ad F: control[a]	3	5	2	0	10	6.8	0.6
3- to 4-month-old F fawns: GonaCon	1	1	2	1	5	8.8	1.4
3- to 4-month-old M fawns: GonaCon	1	3	2	0	6	7.7	1.1
8-month-old F fawns: GonaCon	0	1	1	0	2	8.0	1.0
Ad M: GonaCon	0	0	1	3	4	12.0	1.2
Ad M: control[b]	0	3	2	0	5	8.4	0.9
Totals	7	20	14	7	48		

* Body condition scores were based on evaluation of body size (relative to age), musculature, and both externally apparent and deep internal fat stores.
[a] Each control ad F received a sham injection of AdjuVac adjuvant and mollusk stabilizing buffer (i.e., GonaCon vaccine without the GnRH and mollusk hemocyanin).
[b] Control ad M received no injections.

in any vaccinated or control deer in this study. No externally visible evidence of injection-site reactions was observed in live deer in the field or in dead deer prior to dissection of the musculature at injection sites during necropsies. Hind limb circumferences measured at the injection sites did not differ ($P > 0.05$) in any animal in this study.

Major organs and organ systems were normal in most study deer, although several abnormalities (apparently unrelated to capture, handling, and treatment) were noted at necropsy. Livers of 5 (4 GonaCon-treated and 1 control) deer and spleens of 2 (1 GonaCon-treated and 1 control) deer showed evidence of current or previous parasitic infection. Several small nodules were found in the lungs of 2 (1 GonaCon-treated and 1 control) deer and in the parenchyma of the pancreas of 1 (control) deer.

Field estimates of deer body weights at initial capture ranged from 32 kg to 57 kg. Skin was normal on all examined deer, with either no external parasites or a few ticks present. Ovaries and uteri in many GonaCon-treated females (ad and fawns) were small and inactive. Ovarian and uterine quiescence is a normal response to GonaCon because the vaccine disrupts the synthesis of reproductive hormones.

Dissection of the deep musculature (semimembranosus, semitendinosus, and biceps femoris muscles) at injection sites revealed lesions of 2 types within muscles and in fascia between muscles: hard nodules and abscesses. Nodules were partially or fully encapsulated, yellowish-white globular masses that occurred singly or in groups; most were 3–6 mm in diameter. Histopathologic examination confirmed that these nodules were chronic inflammatory granulomas of long duration, characterized by macrophages, multinucleated giant cells, vacuoles, and mineralized and/or necrotic centers. Most abscesses were small (0.5–4 cm^3; $n = 6$) or moderate (30–100 cm^3; $n = 5$) in size, but one was very large (about 1,000 cm^3). During histopathological examinations, abscesses were identified as granulomas that had progressed to sterile abscesses.

Adult Females

Of the 30 adult female deer (18 GonaCon-treated and 12 control) that were collected in October 2007, 26 were assigned body condition scores based on necropsy evaluation (Table 1). None of the 10 control females and only 3 of the 16 GonaCon-treated females were in "good" condition. The mean body condition score for all GonaCon-treated adult females (regardless of pregnancy outcomes) was higher than that of controls ($t_{24} = 1.92$, $P = 0.034$; Table 1). The mean body condition score for GonaCon-treated adult females that became pregnant during the study (1 or both yr) did not differ from that of control females ($t_{16} = 0.47$, $P = 0.323$).

Fat reserves in necropsied study deer generally were meager. Ten of 16 GonaCon-treated and 6 of 8 control females had "little" general body fat and 3 others (1 GonaCon-treated and 2 control) had "little-to-moderate" fat. Only 3 deer (all GonaCon-treated) had "moderate" or "moderate-to-abundant" fat, and none had "abundant" fat. Fat reserves on the heart and kidneys ranged from 0 mm to 10 mm in thickness; most deer had 2–4 mm of fat.

None of the 15 blood-chemistry parameters we measured differed ($P > 0.05$) between GonaCon-treated and control adult female deer at the time of initial capture in July–August 2005 or when deer were collected in October 2007 (Table 2). Although 2005 and 2007 mean values of some blood-chemistry parameters differed, all values were within the normal ranges for adult white-tailed deer (Seal et al. 1981, Kie et al. 1983) except creatinine phosphokinase (CPK), potassium, and phosphorus values for 2007, which were abnormally high.

Injection-site lesions (hard nodules, or hard nodules and abscesses) were found at necropsy in 17 (94%) of 18 adult female deer that had been vaccinated with GonaCon, and in 9 (82%) of 11 adult female deer that had received sham injections (Table 3). The incidence of lesions was not higher in GonaCon-treated females ($P = 0.316$) than in controls. Of the 17 GonaCon-treated females with hard nodules at injection sites, 8 (47%) also had abscesses (2 small, 5 moderate, 1 large). Two (22%) of the 9 sham-injected control females with hard nodules also had abscesses (both small). Among GonaCon-treated adult females, the incidence of lesions was not higher in pregnant ($n_{2006} = 6$; $n_{2007} = 8$) than in nonpregnant ($n_{2006} = 12$; $n_{2007} = 13$) animals for either year ($P_{2006} = 0.333$; $P_{2007} = 0.619$). Injection-site tissue samples from 12 adult females (7 GonaCon-treated

Table 2. Means and standard errors of the means for blood chemical parameters of adult, female, white-tailed deer in GonaCon-treated groups and control groups in New Jersey, USA, 2005–2007. Values marked with different letters (A and B) within a row differed significantly from each other. Note that some values are marked with both A and B. Values for 2005 are pretreatment values. ALK, alkaline phosphatase; CPK, creatinine phosphokinase; ALT, alanine aminotransferase; BUN, blood urea nitrogen.

and 5 control) were submitted for histopathological examination. Chronic granulomatous inflammation was detected in 11 of these 12 samples, and the remaining sample had a chronic abscess. Necrosis of muscle fibers at injection sites was common.

Injection sites of tranquilizer darts used at initial capture (summer 2005) were found in 7 (24%) of 29 adult female deer (GonaCon-treated and controls) at necropsy in October 2007. A tissue sample from the tranquilizer-dart injection site of an adult female was examined histopathologically and found to have chronic granulomatous inflammation.

At necropsy, the popliteal lymph node in the hind leg that was hand-injected was enlarged or hard in 11 (61%) of 18 GonaCon-treated adult female deer and in 6 (50%) of 12 sham-injected control females. The iliac lymph node associated with the injected hind leg was enlarged or hard in 6 (35%) of 17 GonaCon-treated females and in 6 (50%) of 12 sham-injected females.

Twenty-five popliteal or iliac lymph nodes from 14 (10 GonaCon-treated and 4 control) adult study females were submitted for histopathological examination. Chronic granulomatous inflammation was found in 4 unidentified (popliteal or iliac) lymph nodes from 3 (2 GonaCon-treated and 1 control) deer. Chronic hyperplasia was detected in 2 popliteal lymph nodes (from 2 GonaCon-treated deer) and 1 unidentified lymph node (from a control deer). Acute hemorrhage was noted in 2 unidentified lymph nodes (from 1 GonaCon-treated and 1 control deer). Foreign material was found in one unidentified lymph node (from a GonaCon-treated deer). No significant findings were reported for 5 popliteal, 4 iliac, and 7 unidentified lymph nodes.

In several lymph nodes in our study deer (both sexes), vacuoles were found among the macrophages and multinucleated giant cells or within their cytoplasm. These vacuoles were probably mineral oil droplets from the AdjuVac in GonaCon.

Table 3. Occurrence of injection-site lesions in wild white-tailed deer injected with GonaCon Immunocontraceptive Vaccine or a sham material in New Jersey, USA, 2005–2007.[*,**]

Treatment group[a]	Deer examined	Deer with injection-site lesions	Deer without injection-site lesions
Ad F: GonaCon	18	17 (94%)	1 (6%)
Ad F: sham	11	9 (82%)	2 (18%)
3- to 4-month-old fawns: GonaCon	12	8 (67%)	4 (33%)
8-month-old fawns: GonaCon	2	2 (100%)	0 (0%)
Ad M: GonaCon	6	6 (100%)	0 (0%)
Totals	49	42 (86%)	7 (14%)

[*] Sham material consisted of AdjuVac adjuvant and mollusk stabilizing buffer (i.e., GonaCon vaccine without the GnRH and mollusk hemocyanin).
[**] No injection-site lesions were found in 13 ad M control deer that received no injections.
[a] Ages in this column are ages at time of injection.

Fawns (F, 8 Months Old)

Two of the 4 fawns vaccinated in February 2006 were collected for necropsy in October 2007. Deer number 76 was "thin" based upon body condition score, with "little" general body fat. Deer number 78 was in "fair" body condition, with "little-to-moderate" general body fat (Table 1). Heart and kidney fat deposits were 3–5 mm thick in these 2 deer.

Lesions were found at vaccine injection sites in both deer at necropsy (Table 3). An intramuscular scar caused by a tranquilizer dart also was found in the hind leg of deer number 78. The popliteal and iliac lymph nodes were hard in deer number 78; only the popliteal lymph node was hard in deer number 76.

Fawns (M and F, 3–4 Months Old)

Twelve of the 16 (8 M and 8 F) fawns we captured and vaccinated in September–October 2006 were collected and necropsied in October 2007. Although body condition varied substantially, half of these deer were in "poor" or "thin" condition, and only one was in "good" condition (Table 1). General fat deposits were "little" in half of these deer, and no deer had more than "moderate" fat stores. Heart and kidney fat stores were $\leq$2 mm in thickness in 4 of the 12 necropsied deer, and from 3 mm to 10 mm in the remaining deer ($n = 7$) that we evaluated.

Vaccine injection-site lesions (hard nodules, no abscesses) were found in 8 (67%; 5 [100%] of 5 F and 3 [43%] of 7 M; Table 3), and tranquilizer dart scars were found in 7 (58%) of the 12 GonaCon-treated deer for which these data were recorded. Histopathological examination of tissue samples taken from the vaccine injection sites of 2 deer detected chronic granulomatous inflammation in both cases. One of these 2 deer also had chronic granulomatous inflammation in its other hind limb from the tranquilizer dart injection.

Enlargement of the popliteal lymph node was observed at necropsy in 3 (27%) of 11 examined deer for which data were recorded, and enlargement of the iliac lymph node was detected in 1 of these 3 deer. The popliteal and iliac lymph nodes from 2 (1 M and 1 F) of these 3 deer were examined histopathologically. One (unidentified) lymph node from the male had chronic granulomatous inflammation, and acute hemorrhage was found in one lymph node from the female. The remaining lymph node from each animal showed no signs of pathology.

Adult Males

Of the 10 adult males that were captured and vaccinated with GonaCon during March 2007, 2 died of unknown causes and 2 left the study site before October 2007. Body condition scores were determined for 4 of the 6 remaining males; the mean was higher than that for 5 noninjected control males ($t_5 = 2.31$, $P = 0.032$; Table 1). Heart and kidney fat deposits were 4–8 mm thick in 3 males that had "moderate" general fat deposits, and they were 2–4 mm thick in a male that had "little-to-moderate" general fat deposits.

Vaccine injection-site lesions were observed in all 6 males at necropsy (Table 3), but no tranquilizer dart wounds or scars were found. Two (33%) of these 6 males had small abscesses in addition to hard nodules. Popliteal lymph node reactions were evident at necropsy in 5 (83%) of these males. Enlargement of the iliac lymph node was seen in 2 (33%) of the males. Relatively small testes and delayed or abnormal antler development were observed in 2 of the adult males and in males that had been vaccinated as 3- to 4-month-old fawns (J. P. Gionfriddo, unpublished work).

Control Males

Thirteen previously untreated males (12 of which had never been captured) were collected for necropsy during October 2007 for comparison with GonaCon-treated males. Heart and kidney fat deposits were $\leq$5 mm, and general fat deposits were "little" to "moderate" in 5 control males we evaluated at necropsy. Necropsy observations and photographs of the other 8 control males indicated that they also were generally in "thin" to "fair" body condition (J. P. Gionfriddo, unpublished work).

DISCUSSION

Treatment with GonaCon Immunocontraceptive Vaccine caused no serious adverse effects on deer mobility, major organs and organ systems, or general health and welfare. Intramuscular injection-site lesions were the only adverse effect of vaccination that we detected via field observations, necropsy examinations, laboratory assessment of blood chemistry, and histopathological evaluation of selected reproductive and other tissues collected from study deer. These results are consistent with those of earlier studies of GonaCon vaccination of white-tailed deer (Killian et al. 2006*b*, Gionfriddo et al. 2009). In New York, USA, Curtis et al. (2008) detected no adverse health effects (except injection-site lesions) associated with hand- and remote-vaccination of female white-tailed deer with 2 early formulations of GonaCon. Instead of AdjuVac, Freund's complete adjuvant (FCA) was used in the primary dose and Freund's incomplete adjuvant (FIA) (Freund 1956) was used in the booster injection.

Although transitory limping can be common among animals that receive intramuscular vaccinations that produce injection-site inflammation and granulomas (Macy 1997), we saw no limping or decreased mobility in injected deer in this study. Although histopathological evaluation found chronic granulomas in both rear legs of one of the adult males (from the tranquilizer dart and a GonaCon hand injection), the animal was never seen limping during many field observations in 2007.

Body Condition and Fat Reserves

Prior to the start of our field research, deer had not been actively managed on the study site for many years, and the herd had increased to about 95 animals by early spring 2005 (A. J. DeNicola, White Buffalo, Inc., unpublished data). At capture in July 2005, most deer were noticeably thin, as reflected in their low body masses. Sustained and severe overbrowsing by deer was evident in the condition of native and ornamental vegetation throughout the study site. Thus it was not surprising that fat reserves of study deer at necropsy generally were meager.

GonaCon-treated adult females, especially those that had not been pregnant during the field study, were in better body condition at necropsy than control females. By relieving females of the annual energetic burdens of gestation and lactation, immunocontraception may have enabled treated deer to maintain better body condition than control females that produced and raised fawns (McShea et al. 1997). Body condition was not evaluated in previous GonaCon studies. The effects of porcine zona pellucida (PZP) immunocontraception on body condition have been equivocal. Adult female white-tailed deer contracepted with a PZP vaccine in Connecticut, USA were not in better condition than untreated controls after a 3-year field study (Walter et al. 2003). Among captive white-tailed deer in Pennsylvania, USA, no differences in annual autumn body weights were detected between PZP-treated and control females during a 4-year vaccine trial (Miller et al. 2001). On the other hand, female deer successfully contracepted with PZP in Virginia, USA were heavier 1 year posttreatment than untreated control females that had become pregnant (Kirkpatrick et al. 1997). Many deer treated with PZP undergo repeated estrous cycling that is energetically costly and may adversely affect body condition (Miller et al. 2009). In addition, fertilization during later estrous cycles can produce fawns whose late birthdates could reduce their survivorship during their first winter (McShea et al. 1997). GonaCon does not cause repeated estrous cycling.

The better condition of GonaCon-treated males when compared to control males may be related to the rut and to the relatively short interval between vaccination and necropsy. Control males may have lost body condition through seasonal rut-associated behavior such as fasting, sparring, and chasing. Although GonaCon-treated males generally do not grow as large as untreated males (Killian et al. 2005), males in our study were injected with GonaCon in March 2007 and killed in October 2007, perhaps before some effects of the vaccine (such as reduced muscle development) were manifested.

Blood Chemistry

Blood-chemistry parameters may be influenced by many factors, including sex, age (Johnson et al. 1968), season, reproductive status (Klinger et al. 1986), nutrition (Sams et al. 1998), and capture-related factors such as capture and handling methods (Mautz et al. 1980, Kock et al. 1987*b*, DelGiudice et al. 1990), including the use of immobilizing agents (Marco and Lavín 1999, Poljičak-Milas et al. 2006, Vengušt et al. 2006). Several aspects of our blood-sampling procedures may have affected blood parameters and could have contributed to differences between treatment groups or years. At initial capture in 2005, blood was drawn from the jugular veins of live deer, whereas cardiac puncture of lethally gunshot deer was used at the end of the field study in 2007. The latter collection method may have affected the poststudy (2007) values of some blood parameters (White and Cook 1974). For example, cardiac puncture of a dead animal tends to yield higher values for CPK, potassium, and phosphorus than venipuncture of a live animal, and trauma associated with lethal shooting also can elevate these parameters (Savignano et al. 1969, Seal et al. 1981, Latimer et al. 2003). Creatinine phosphokinase, potassium, and phosphorus were the only blood-chemistry parameters in our study with values outside the normal ranges for adult white-tailed deer. A second potential capture-related source of variation in blood-chemistry results was our use of immobilizing agents in 2005 but not in 2007. These compounds may affect blood parameters and could have influenced our results (Seal and Bush 1987). Finally, observed differences in the values of some blood parameters could be due to seasonal (July vs. October) variation in nutrition and physiology (Seal et al. 1981, Waid and Warren 1984).

Despite the above limitations, our data show that GonaCon caused no serious adverse health effects that were reflected in blood parameters. Other researchers have reported similar results. Curtis et al. (2008) measured 28 standard blood parameters in white-tailed deer in New York and found no differences between GnRH-treated and control animals. Killian et al. (2006*b*) used standardized methodology under carefully controlled conditions to handle captive, GonaCon-treated, white-tailed deer and to sample their blood. Their comparison of the blood chemistry and hematology of 19 captive adult females detected no statistically significant treatment effects for any of the 33 blood parameters tested. As expected, however, seasonal changes in some variables were detected via repeated sampling over a 20-week period (Killian et al. 2006*b*).

Posttreatment values for CPK, potassium, and phosphorus were abnormally high in our study deer (Table 2). Elevated CPK values usually reflect stress or trauma to heart, brain, or skeletal muscle. Lethal gunshot wounds to the head or neck, and cardiac puncture for blood collection immediately after death could have caused CPK to increase dramatically. Stress and tissue damage associated with chronic inflammation at injection sites and in lymph nodes (reactions to injection) also could have contributed to the elevation of CPK. Evaluation of CPK values may not be useful due to the extreme fluctuations that commonly occur. For example, 200-fold increases in serum CPK were observed in penned white-tailed deer 24 hr after deer were physically restrained (Seal et al. 1972).

Elevated concentrations of potassium and phosphorus, like CPK, often are associated with excess destruction or necrosis of cells, and may reflect the extent of tissue (especially muscle) damage (Kock et al. 1987*a*, Latimer et al. 2003). Wilber and Robinson (1958) collected Maryland, USA white-tailed deer via lethal gunshots to neck vertebrae and then immediately sampled blood via heart puncture. They found consistently high concentrations of plasma potassium (similar to our values) and phosphorus, which they attributed to "shock." Using similar methods in Oklahoma, USA, Sams et al. (1998) found very high serum phosphorus concentrations in white-tailed deer. Elevated potassium and phosphorus concentrations in our study deer were likely due to muscle necrosis associated with collection of deer and blood samples.

Mean posttreatment alkaline phosphatase (ALK) values showed a 6-fold increase from pretreatment values in our

study, but they remained within the ranges of values reported for white-tailed deer (e.g., Sams et al. 1998, Curtis et al. 2008) and for our sample of noninjected control male deer ($\bar{x} = 221.3$, SE = 48.5, $n = 13$). A published range of normal values for white-tailed deer could not be found for this variable, but the range is very broad for large mammals and, therefore, ALK is not a sensitive indicator (Latimer et al. 2003).

Injection-Site Lesions

The occurrence of intramuscular injection-site lesions in 5 (29%) of 17 GonaCon-treated deer in a previous field study (Gionfriddo et al. 2009) alerted us to the possibility that deer in the current study might develop such reactions. Necropsy observations and histopathological evaluation revealed that >85% of the GonaCon-treated and sham-injected deer in New Jersey had injection-site granulomas or sterile abscesses in the deep musculature of the hind limbs in October 2007. The similarity in the incidence of injection-site lesions in GonaCon-treated and sham-injected adult female deer strongly suggests that the causative agent(s) was present in both inocula.

Adjuvants and vaccines often cause localized reactions at injection sites, including pain, local inflammation, swelling, necrosis, granulomas, ulcers, and sterile abscesses (Aguilar and Rodríguez 2007). For example, adjuvants that include alum (Gupta et al. 1995, Valtulini et al. 2005, Reed et al. 2008) or *Mycobacterium* spp. (Broderson 1989) often cause reactions at injection sites. Larger amounts of mycobacteria cause proportionately more inflammation and necrosis (Broderson 1989). Water-in-oil emulsions, especially those containing mineral oil, also induce local inflammation and granuloma formation at injection sites (Humphrey 1982, Straw et al. 1985, Yamanaka et al. 1992, Macy 1997, Petrovsky and Aguilar 2004). Injection-site granulomas and other lesions are routinely encountered in livestock, from which they are excised at slaughter (George et al. 1995, Van Donkersgoed et al. 1997, Valtulini et al. 2005). They also commonly occur in humans (Hay 1995, Bordet et al. 2001, Marsee et al. 2008).

GonaCon Immunocontraceptive Vaccine contains AdjuVac, a mineral-oil-based adjuvant developed from a USDA-approved Johnes disease vaccine called Mycopar™ (Fort Dodge Animal Health). AdjuVac contains killed *Mycobacterium avium*, which is needed for GonaCon vaccine to induce a rapid, strong (Miller et al. 2008*a*), and sustained (Perry et al. 2008) contraceptive effect. *Mycobacterium* spp. are commonly used in adjuvants to strengthen the immune response (Gupta et al. 1993, Aguilar and Rodríguez 2007). Like Freund's complete adjuvant (which contains *Mycobacterium paratuberculosis* and has been used extensively in laboratory animals), AdjuVac's combination of water-in-mineral-oil emulsion and killed mycobacteria results in a highly potent adjuvant that stimulates both humoral and cellular immunity (Warren et al. 1986). Freund's complete adjuvant, however, cannot be used in human or veterinary vaccines because it may cause severe pain, fever, abscess formation, and the possibility of permanent organ damage (Edelman 1980). Leenaars et al. (1998), for example, found extensive intramuscular lesions in rabbits (*Oryctolagus cuniculus*) and mice (*Mus musculus*) after injection with FCA and FIA (as prime and boost, respectively), although palpation had detected no swelling or nodules. Wild horses injected with an early formulation of a PZP immunocontraceptive vaccine that contained FCA developed externally visible nodules, swelling, and abscesses at injection sites (Roelle and Ransom 2009). Porcine zona pellucida and GnRH vaccines (early formulations of GonaCon that contained FCA or FIA instead of AdjuVac) also caused granulomas at hand-injection (PZP) and dart-injection (PZP and GnRH) sites in nearly all treated white-tailed deer in New York (Curtis et al. 2007, 2008). The intramuscular injection of large doses of FCA or FIA can cause diffuse necrosis and extensive atrophy of functional muscle groups, impairing function (Broderson 1989). Such severe reactions have not been observed in animals injected with GonaCon (containing AdjuVac), possibly because of the relatively small amount of mycobacteria it contains (Miller et al. 2008*a*), or because GonaCon uses a different mycobacterial species.

Necrosis of muscle fibers at injection sites was observed in many of our study deer in New Jersey and in Maryland (Gionfriddo et al. 2009), and in captive white-tailed deer (Killian et al. 2006*b*) and rabbits (Powers et al. 2007) treated with GonaCon. Exposure to necrotic cells may be necessary for the maturation of dendritic cells and the initiation of an immune response (Gallucci et al. 1999, Sauter et al. 2000). Moreover, the strength of the immune response may be proportional to the extent of local tissue damage caused by the inoculum at the injection site (Schijns 2000). Thus the necrosis of muscle fibers at the injection site by adjuvants containing alum (Walls 1977), mineral oil (Straw et al. 1985, Yamanaka et al. 1992), or mycobacteria (Broderson 1989) may yield important immunological benefits.

Vaccines that contain alum or mycobacteria, or that are formulated as water-in-oil emulsions, also may induce strong immune responses because they form a repository ("depot") at the injection site (Glenny et al. 1931, White 1967, Fukanoki et al. 2000). The vaccine depot slowly releases antigen, which is carried by maturing, migratory dendritic cells via afferent lymph vessels to the paracortical regions of the local draining lymph node, where it is presented to resting, antigen-specific T cells that are activated by the now-mature dendritic cells (HogenEsch 2002). Antigen has been detected in lymph nodes as early as 3 hr after peripheral injection (Dupuis et al. 1998). Antigen may be protected and retained for months or even years on follicular dendritic cells in draining lymph nodes where antibody formation continues (Greene et al. 1975, Tew and Mandel 1979, Burton et al. 1994). Subsequent release of antigen from the depot acts as a secondary stimulus (similar to a booster injection) to the sensitizing action of the antigen released previously.

In response to the presence of the vaccine depot, a granuloma develops as the immune system attempts to wall off the irritating foreign material by enclosing it in a fibrous capsule of thick connective tissue. Granulomas that develop

at injection sites contribute substantially to antibody synthesis because they harbor large numbers of antibody-producing plasma cells (White 1967, World Health Organization 1976). The release rate of antigen from an injection-site granuloma decreases as the granuloma develops and becomes encapsulated, and eventually it becomes insufficient to maintain an optimal antibody response (Herbert 1968, Lascelles et al. 1989). After the granuloma is completely walled off and antigen release stops, excision of the granuloma does not affect antibody formation in the draining lymph node because antigen is already present there (Lascelles et al. 1989, Schijns 2000). Active but unused antigen remains trapped inside the encapsulated granuloma, as demonstrated by researchers who excised material from injection-site granulomas and injected it into the same or different animals, thereby inducing immune responses in the recipients (Harrison 1935, Holt 1950, Herbert 1968).

Lymph Nodes

Popliteal and iliac lymph nodes are the draining and regional lymph nodes for the hind limb area where hand injections were delivered to deer in our study. Enlargement of local lymph nodes is a normal response to infection or other types of antigenic stimulation, and also can be caused by injection of oil emulsions (Yamanaka et al. 1992). Stronger antigens and adjuvants induce greater inflammation of draining lymph nodes (Taub et al. 1970).

In our study, popliteal and iliac lymph nodes of noninjected control male deer were normal, as expected. Many of the lymph nodes of GonaCon-treated and sham-injected deer, however, were enlarged, hard, or otherwise reactive, indicating the involvement of these nodes in the drainage of the intramuscular injection site. These results demonstrate that the material that caused reactions in lymph nodes was present in both GonaCon vaccine and in the sham material (which contained AdjuVac adjuvant and mollusk stabilizing buffer). The mineral oil (Aucouturier et al. 2001) or the *M. avium* (Herbert 1968, Lind 1968) in AdjuVac could have caused the draining lymph nodes to react. Enlargement of draining lymph nodes also was reported in captive rabbits (Powers et al. 2007) and in captive (Killian et al. 2006*b*) and wild (Gionfriddo et al. 2009) white-tailed deer treated with GonaCon vaccine.

In $\geq$6 of our study deer, secondary granulomatous inflammation and hyperplasia occurred in draining lymph nodes to which the irritant at the injection site had been transported by lymph. Similarly, one of 13 captive adult female white-tailed deer vaccinated with GonaCon in Pennsylvania developed granulomatous lymphadenitis in a draining lymph node (Killian et al. 2006*b*). Development of granulomas in draining lymph nodes is common when alum-absorbed adjuvants (Humphrey 1982), FCA (Yamanaka et al. 1992), or FIA (Gaafar and Turk 1970) are used. In extreme cases, granulomatous lesions may replace the majority of the tissue in lymph nodes (Yamanaka et al. 1992). Unanue and Benacerraf (1973) demonstrated that granulomatous reactions may be passively transferred between animals by intravenously injecting lymph node cells from a granulomatous lymph node in one animal into a second animal.

The oil droplets detected in the lymph nodes of several of our study deer probably originated in the inoculum and were transported via lymphatic vessels to the draining lymph nodes. Previous studies have documented the presence of paraffin or mineral oil (used as an adjuvant) in lymph nodes after subcutaneous or intramuscular injection (White et al. 1955, Freund 1956, Broderson 1989). Long-term (probably lifelong) retention of oil in body tissues may result from the use of mineral oil adjuvants (World Health Organization 1976).

MANAGEMENT IMPLICATIONS

GonaCon Immunocontraceptive Vaccine provides a safe and humane way to reduce reproduction in individual adult female white-tailed deer, especially in demographically closed (e.g., fenced or otherwise spatially isolated) populations. The only adverse reactions to vaccination in our field study were normal inflammatory responses at injection sites and in associated draining lymph nodes. These responses were natural and essential expressions of the strong immune response that is required to induce temporary infertility. Safety issues should not impede acceptance of GonaCon as a deer management tool. Operational use of GonaCon Immunocontraceptive Vaccine and other wildlife contraceptives will likely be limited by efficacy, practicality, and politics to settings where traditional management methods cannot be applied. The widespread occurrence of such settings suggests that the potential contribution of contraceptive agents to deer management in developed landscapes is substantial. In addition to its contraceptive effects, GonaCon may improve deer body condition without the PZP-associated disadvantages of repeated estrous cycling and delayed birth of fawns to vaccine nonresponders. Although public demand for safe, humane contraceptive agents like GonaCon will continue to drive their research and development, wildlife management agencies and personnel will ultimately determine the value and applicability of these products.

ACKNOWLEDGMENTS

We are very grateful to S. F. Timm for field necropsies, P. K. Hildebrandt and J. C. Rhyan for histopathological evaluations, C. A. Yoder for help with statistics, R. Rodts, D. Cuddy, V. DeNicola, and C. Collier for field assistance, K. A. Crane, J. M. Kemp, C. M. Denny, and L. E. O'Dell for laboratory assistance, and J. D. Eisemann for manuscript review. We also thank Associate Editor C. Nielsen and 2 anonymous reviewers for providing constructive comments that improved the manuscript.

ABSTRACT Safe and effective contraceptive agents are needed to manage overabundant populations of cervids in settings where traditional management methods such as hunting are prohibited or impractical. We used GonaCon™ Immunocontraceptive Vaccine to reduce reproduction in individual white-tailed deer (*Odocoileus virginianus*) on a fully fenced corporate-office campus in suburban New Jersey, USA. In July–August 2005, we captured, marked, injected, and released 47 adult females and then monitored their reproductive performance for 2 years. Thirty-two of these females each received a 1.0-mL injection of GonaCon vaccine, and 15 control females were given sham injections. Field observations of udder condition during summers of 2006 and 2007 were used to determine which adult female deer were lactating; lactation was used as an indicator of imminent or recent parturition. During summer 2006, 8 of 24 GonaCon-treated deer were pregnant, in contrast to 12 of 13 control deer. During summer 2007, 2 years after injections were given, 13 of 23 GonaCon-treated and 10 of 12 control animals were pregnant. We also captured, vaccinated, and released fawns (both sexes) and yearling and adult males and then monitored their reproductive status. Immunocontraception of fawns was unsuccessful. In some GonaCon-treated males (all age classes), serum testosterone concentrations and development of testes and antlers were reduced. Higher anti-gonadotropin-releasing-hormone antibody titers were associated with greater infertility in females and with lower values for reproductive parameters in males. GonaCon reduced reproduction in wild adult female white-tailed deer, but greater contraceptive efficacy may be required for it to gain widespread acceptance and use by natural resource managers. © 2011 The Wildlife Society.

KEY WORDS contraception, gonadotropin-releasing hormone, infertility, *Odocoileus virginianus*, overabundance.

Local populations of white-tailed deer (*Odocoileus virginianus*) have become overabundant in many regions of North America, where they are causing problems for residents and natural resource managers (Crête and Daigle 1999). Deer–motor-vehicle collisions (Etter et al. 2000), severe overbrowsing of native and ornamental vegetation (Rooney and Waller 2003), and adverse effects on local avian communities (McShea and Rappole 2000) are among the problems caused by overabundant deer. Hunting is prohibited in many urban, suburban, and public park settings, and other deer management tools must be used. Contraception and other nonlethal deer management approaches are increasingly preferred by many urban and suburban residents (Stout et al. 1997, Lauber and Knuth 2000). Immunocontraception offers natural resource managers another tool to reduce reproduction in overabundant wildlife populations (Fagerstone et al. 2002).

Although efforts to develop safe and effective wildlife contraceptive agents have been underway for about 50 years (Davis 1961, Vandenbergh and Davis 1962, Balser 1964), only 2 contraceptive products have been registered in the United States for wildlife: GonaCon™ Immunocontraceptive Vaccine (National Wildlife Research Center, Fort Collins, CO) for adult female white-tailed deer, and a nicarbazin-based contraceptive bait ("OvoControl") for Canada Geese (*Branta canadensis*), certain domestic ducks, and pigeons (*Columba livia*; Innolytics, Rancho Santa Fe, CA). Among the obstacles to the development and registration of wildlife contraceptives is the achievement of objectives related to safety, efficacy, practicality, and humaneness of treatment. To be registered by the United States Environmental Protection Agency (EPA) and to gain widespread acceptance among wildlife management professionals, a contraceptive agent must: 1) not adversely affect the health, social behavior, or population structure of the target

Received: 20 December 2010; Accepted: 4 April 2011

[1]*E-mail: james.p.gionfriddo@aphis.usda.gov*

species; 2) not adversely affect nontarget species; 3) provide a complete, long-lasting (but ideally, reversible) contraceptive effect; 4) be cost-effective; and 5) not cause treated food animals to become unfit for human consumption (Fagerstone et al. 2010).

GonaCon Immunocontraceptive Vaccine is a gonadotropin-releasing hormone (GnRH)-based wildlife contraceptive agent that has safely induced temporary infertility in many mammalian species (see refs in Gionfriddo et al. 2011). One intramuscular injection of GonaCon suppresses mammalian reproduction (M or F) for multiple years (Miller et al. 2004). GonaCon was registered with the United States EPA in September 2009 as a restricted-use product for the contraception of adult, female, white-tailed deer via hand injection (Fagerstone et al. 2010). Regarding potential risk associated with consuming deer treated with GonaCon vaccine, the EPA (Farwell 2009:2) has stated "There is little likelihood of exposure to hormonally active compound from deer meat because GnRH is a protein that is digested and not absorbed intact. Like other proteins, GnRH is too large and polar to pass through the membranes of the gastrointestinal tract. Proteins are digested into their component amino acids in the stomach and small intestines."

We tested GonaCon's contraceptive efficacy in white-tailed deer adults and fawns of both sexes. Adult females were the primary focus of the study because they will be the targets of real-world applications of GonaCon vaccine by natural resource managers. Fawns were tested to determine whether their immune systems were sufficiently mature to mount and maintain the strong immune responses to vaccination that are required to achieve and sustain a contraceptive effect. We also tested GonaCon in yearling and adult males. Although GonaCon is not registered or recommended for use in male deer (Killian et al. 2005, Curtis et al. 2008), deer-management field activities in North America often occur during winter when ambient temperatures are lower, deer are more visible (due to reduced vegetative cover), and deer occur in larger groups than at other times of year. Male deer lack antlers during late winter and can be mistaken for females. We vaccinated males to determine the effects of GonaCon treatment on male deer that might inadvertently be treated during winter management programs (if a GnRH vaccine is registered for remote injection or oral delivery in bait).

The objective of this 2-year field study was to evaluate the efficacy of GonaCon Immunocontraceptive Vaccine in individual wild white-tailed deer by determining the proportion of treated individuals that became infertile and the duration of induced infertility. For each year, we tested the hypothesis that pregnancy rates of adult females did not differ between GonaCon-treated and control deer. For male deer, we tested hypotheses to determine whether serum testosterone concentrations or testicular circumferences differed among treatment groups or age classes.

This research differs from our previous studies of GonaCon immunocontraception of white-tailed deer in several ways. Most studies involved captive deer at Pennsylvania State University where optimal diets and veterinary care (including de-worming) were routinely provided. In contrast, our field studies in Maryland, USA (Gionfriddo et al. 2009) and New Jersey, USA (Gionfriddo et al. 2011) involved wild deer subpopulations that lived independently of humans and ranged freely on very large, fenced, partially forested sites where forage was extremely overbrowsed, deer were exposed to natural environmental conditions, and deer received no veterinary care. Important differences between the Maryland and New Jersey field studies included the occupation of a single site by all study deer in New Jersey (GonaCon-treated and control deer occupied adjacent but different fenced sites in Maryland, for political and logistical reasons) and the injection of New Jersey control females with a sham material (controls in Maryland were not injected, again for political and logistical reasons). In addition, only adult female deer were tested in the Maryland study.

STUDY AREA

The study was conducted on a 123-ha corporate office campus near Madison, New Jersey, USA. Vegetation on the site consisted of hardwood forest (about 20%), old fields in various stages of secondary succession (about 20%), lawns (about 40%), and landscaping near buildings. A 2.4-m-tall chain-link fence surrounded the property. Although the site was bounded by public roads on all 4 sides, public access to the campus was prohibited, and security gates and guards controlled access of authorized personnel. Despite the presence of the fence, a few deer entered or left the study area by running through gates opened briefly by guards for vehicular traffic. Most of the study area was accessible via a network of paved and gravel roads that was used during deer capture and observation activities. Limited food availability in forested areas caused deer to forage heavily on lawn areas where they were easily observed with binoculars and spotting telescopes. Long-term patterns of temperature and precipitation for the study area are summarized elsewhere (Gionfriddo et al. 2011).

METHODS

Capture and Treatments

General.—We captured deer at night with tranquilizer darts and fitted each animal with numbered ear tags and a radiotelemetry collar before reversing anesthesia and releasing deer at their capture sites, as described by Gionfriddo et al. (2011). We gave each deer a 1.0-mL injection by hand to the deep musculature of the upper hind limb (see below); if a deer had been darted in a hind limb, we delivered the hand injection to the opposite hind limb. We observed all study deer during the summer(s) between their capture and October 2007, when deer were collected and necropsied.

Adult females.—During July and early August 2005, we captured all adult females ($n = 47$) present on the study area. We injected each female with GonaCon Immunocontraceptive Vaccine ($n = 32$; each 1.0-mL dose of GonaCon contained 1,000 μg of conjugated GnRH-hemocyanin in a water-in-oil emulsion) or with a sham material ($n = 15$) that consisted of AdjuVac™ adjuvant (National Wildlife Research

Center) and mollusk stabilizing buffer (i.e., GonaCon vaccine without GnRH and without mollusk hemocyanin, which usually serves as a carrier molecule for the GnRH). We collected a blood sample from the jugular or femoral vein of each female for measurement of pretreatment serum anti-GnRH antibody titers. Four GonaCon-treated adult females that became pregnant during autumn 2005 were recaptured in October 2006 and given a second vaccine injection to determine the effects of a booster dose on contraceptive efficacy. We assumed that these 4 females would (without boosting) have become pregnant during autumn 2006, and we classified them as pregnant for the 2007 efficacy analysis. Four other GonaCon-treated females were recaptured and reinjected with GonaCon in June 2007, after their reproductive status for spring 2007 had already been determined through observations of udder condition (1 of 4 had lactated in 2007; status was confirmed at necropsy).

Fawns and males.—To investigate the effects of GonaCon vaccination on young deer treated during their first winter, we captured, vaccinated, and released 8-month-old female fawns ($n = 4$) in February 2006. To determine whether GonaCon would elicit strong enough immune responses to induce infertility in 3–4-month-old fawns, and to establish the duration of such responses via evaluation of antibody titers, we captured fawns (8 F and 8 M) during September–October 2006, vaccinated them with GonaCon, and released them. We captured, vaccinated, and released yearling ($n = 3$) and adult ($n = 7$) males during March 2007 to investigate the effects of wintertime vaccination with GonaCon on antibody and testosterone levels, testis size, and antler development in male white-tailed deer. Finally, to provide baseline data on untreated males, we collected previously uncaptured males (4 yearlings and 9 ad) during October 2007 for necropsy evaluation.

Evaluation of Contraceptive Efficacy

We evaluated the contraceptive efficacy of GonaCon vaccine in experimental female deer during 2006 and 2007 by using spring and summer field observations of udder condition in vaccinated and control deer to identify animals that were lactating. Lactation was used as an indicator of imminent parturition (i.e., current pregnancy) or recent pregnancy (Whitten 1995, Pojar and Bowden 2004, Gionfriddo et al. 2009). By repeatedly observing the udders of deer throughout the fawn-bearing and fawn-rearing seasons in 2006 and 2007, we were able to determine which individuals became pregnant, although we were unable to tell how many fawns were born to each female, or whether the fawn(s) survived. We used 1-tailed Fisher's exact tests ($\alpha = 0.05$, 1 df) to compare, for each year, the proportion of GonaCon-treated females that lactated with the proportion of control females that lactated. The experimental unit was the individual deer.

Serum concentrations of anti-GnRH antibodies also can be used to assess immunocontraceptive efficacy (Miller et al. 2000). We used enzyme-linked immunosorbent assays (ELISAs) to measure serum antibody titers (Muller et al. 1997) in blood collected from vaccinated and control deer of both sexes at the conclusion of field activities in October 2007. We collected blood samples by cardiac puncture within 1 min of death after deer were shot in the head or neck with a high-powered rifle as they rested or foraged (no chase). We stored blood samples in a cooler or refrigerator until we isolated serum by centrifugation and shipped it to the National Wildlife Research Center in Fort Collins, Colorado, USA for analysis. An experienced wildlife veterinarian conducted field necropsies by following standard procedures described by Munson (2010). Examination of reproductive tracts during necropsy provided additional information on the reproductive status of study deer.

We investigated GonaCon's effects on reproductive status in male deer through necropsy observations and evaluation of blood serum in GonaCon-treated and noninjected control males. At necropsy in October 2007, we measured testicular circumferences to the nearest 0.5 cm and characterized the development of antlers (e.g., "buttons," "spikes," "2 × 2"). Later, we evaluated serum anti-GnRH antibody levels and testosterone concentrations via ELISAs. We then used 1-tailed, 2-sample t-tests ($\alpha = 0.05$) to compare mean testosterone levels and testicular circumferences of vaccinated and control males. All aspects of this research were approved by the Institutional Animal Care and Use Committee of the National Wildlife Research Center.

RESULTS

Adult Females

By June 2006, 8 of 32 GonaCon-treated and 2 of 15 control females had died or left the study site (Table 1). Field evaluations of udder condition were conducted during the summers of 2006 and 2007 by 2 independent observers. Because their conclusions were 100% in agreement when the same deer was studied ($n = 55$), the findings were considered conclusive when only one observer was able to

Table 1. Reproductive status of GonaCon-treated and control adult, female, white-tailed deer in New Jersey, USA, 2006–2007.

Treatment group	n (2005)	n (2006)[a]	Pregnant (2006)	Not pregnant (2006)	n (2007)[b]	Pregnant (2007)	Not pregnant (2007)
GonaCon	32	24	8 (33%)[c]	16 (67%)	23	13 (57%)[d]	10 (43%)
Control	15	13	12 (92%)[c]	1 (8%)	12	10 (83%)[d]	2 (17%)

[a] By Jun 2006, 8 GonaCon-treated and 2 control deer were no longer on the study area. Three deer (2 GonaCon-treated and 1 control) had been killed by collisions with motor vehicles, and 5 (4 treated and 1 control) deer had died of unknown causes. In addition, 2 treated deer had apparently left the study area.

[b] By Jun 2007, 2 additional deer (1 treated and 1 control) had died of unknown causes. The treated deer that died was 1 of the 2 treated deer (mentioned above) that had left the study area before summer 2006. The other treated deer that had left the study area could not be located in 2007. All 8 deer given booster vaccinations in Oct 2006 and Jun 2007 were included in the 2007 analysis (5 were pregnant).

[c] Rates of pregnancy were higher in control F than in GonaCon-treated F during 2006 (Fisher's exact test, $P < 0.001$).

[d] Rates of pregnancy were not higher in control F than in GonaCon-treated F during 2007 (Fisher's exact test, $P = 0.112$).

study a deer ($n = 14$). During summer 2006, 8 (33%) of the 24 remaining vaccinated females and 12 (92%) of the 13 control females lactated (Table 1). The pregnancy rate among control deer was nearly 3 times that of GonaCon-treated deer (Fisher's exact test, $P < 0.001$).

During summer 2007, 13 (57%) of 23 GonaCon-treated females and 10 (83%) of 12 control females lactated (Table 1). Necropsy observations in October 2007 confirmed the lactational status of these deer, except female number 14, who had stopped lactating by October. Although the pregnancy rate among control deer during 2007 was more than 45% higher than that of GonaCon-treated deer, the difference was not significant (Fisher's exact test, $P = 0.112$).

Anti-GnRH antibody titers ranged from 0 ($n = 2$) to 1:128,000 ($n = 5$) in GonaCon-treated adult females 2 years after treatment. Fifteen (83%) of the 18 vaccinated adult female deer we evaluated had titers $\geq$1:16,000, including 3 females that were given booster injections during the field study (deer no. 17 and 29 in Oct 2006, and deer no. 16 in Jun 2007, all of which had antibody titers of 1:128,000). All 12 control females had titers of 0.

Both ovaries were small and inactive in 8 (31%) of 26 adult deer at necropsy in October 2007; 7 of these 8 deer had been injected with GonaCon, and 6 of the 7 vaccinates had not lactated during 2006 or 2007. (Two of these 7 deer had received booster injections after summer 2006.) Ovaries of all but one control deer were normal in size and contained small follicles. Uterine size was within normal limits at necropsy in all 16 examined GonaCon-treated adult females and in 9 of 10 examined control adult females.

Fawns (Females, 8 Months Old)

Of the 4 female fawns treated in February 2006, 1 left the study site soon after vaccination and did not return. None of the other 3 lactated as a yearling in 2006. Two did not lactate as 2-year-olds in 2007; only 1 of these 2 deer (no. 76) was necropsied in 2007 and it had small, inactive ovaries, an enlarged uterus, and an anti-GnRH antibody titer of 1:128,000. The third deer (no. 78) lactated in 2007 and had normal ovaries with small follicles, a small, inactive uterus, and an antibody titer of 1:64,000.

Fawns (Females and Males, 3–4 Months Old)

Of the 8 female fawns treated in September–October 2006, 2 died of unknown causes before summer 2007. The remaining 6 females did not lactate as yearlings during summer 2007. Five of these 6 females were collected in October 2007, when they had anti-GnRH antibody titers ranging from 0 to 1:64,000. Necropsies of 4 of these deer revealed that ovaries were small and/or inactive at necropsy in 2 deer, and ovaries contained small follicles in 2 other deer. Two of these 4 deer had small, inactive uteri (one had small ovaries and one had normal ovaries with small follicles).

Seven of the 8 males treated as 3–4-month-old fawns survived to the end of the study and were collected and necropsied in October 2007. Testicular circumferences and serum testosterone concentrations did not differ between these males and control yearling males (circumferences: $t_5 = 1.75$, $P = 0.070$; testosterone: $t_7 = 0.01$, $P = 0.494$), or between these males and GonaCon-treated adult males (circumferences: $t_7 = -1.01$, $P = 0.172$; testosterone: $t_5 = -1.70$, $P = 0.073$).

Adult Males

Of 10 yearling and adult males treated during March 2007, 2 died of unknown causes and 2 left the study site before October 2007. One of the deer that left the site was observed with large, normal-appearing antlers during late June 2007. Four of the 6 males that remained on site had normal, hardened antlers, and testes of normal size (16.0–19.5 cm in circumference). In contrast, 2 others had antlers that were still in velvet and smaller testes (2-sample t-test, $t_3 = -10.55$, $P < 0.001$; testicular circumferences: 9.0 cm and 9.5 cm). Overall, however, mean testicular circumferences did not differ ($t_5 = -1.43$, $P = 0.102$) between males treated as adults in March 2007 and a group of control adults. Mean serum testosterone concentrations also did not differ ($t_9 = -0.13$, $P = 0.449$) between these 2 groups. Anti-GnRH antibody titers were consistently low ($\leq$1:8,000) in males that had hardened antlers, normal testes, and moderate testosterone levels, and they were consistently high ($\geq$1:32,000) in males that had antlers retaining velvet, small testes, and relatively low testosterone levels.

Control Males

Thirteen previously untreated males were collected for necropsy during October 2007 for comparison (see above) with GonaCon-treated males. Nine were adults with antlers normal in appearance and scrotal circumferences ranging from 15.5 cm to 20.0 cm. The other 4 males were yearlings with normal spiked ($n = 3$) or button ($n = 1$) antlers. All antlers lacked velvet and had hardened. Testicular circumferences in control yearlings ranged from 13.5 cm to 17.0 cm and did not differ ($t_3 = -1.42$, $P = 0.126$) from those of control adults. Serum testosterone concentrations were lower in control yearlings than adults ($t_7 = -2.55$, $P = 0.018$). Anti-GnRH antibody titers were not measured, but were assumed to be 0 in these noninjected males.

DISCUSSION

Induced Infertility in Female Deer

GonaCon Immunocontraceptive Vaccine induced temporary infertility in a large proportion of treated adult female white-tailed deer. The strength and duration of immune responses to immunocontraceptive treatment varied among treated individuals in this study and in previous studies (Miller et al. 2008*a*; Gionfriddo et al. 2009). In the current study, 67% of GonaCon-treated adult female white-tailed deer were infertile 1 year after vaccination, and 43% were infertile after 2 years. In a similar field study in Maryland, 88% of GonaCon-treated white-tailed females were infertile after 1 year, and 47% were infertile after 2 years (Gionfriddo et al. 2009). Captive adult female white-tailed deer ($n = 5$) treated with GonaCon at Pennsylvania State University remained infertile for 2 years, and 4 of 5 deer were infertile 5 years after treatment (Miller et al. 2008*a*). Six of 10 captive adult female black-tailed deer (*Odocoileus hemionus hemionus*) in Washington State, USA, were infertile for 3 years after

each received an injection of GonaCon vaccine (Perry et al. 2008).

Treatment of young (3–4-month-old) female fawns in our study did not induce a strong, sustained immune response required for contraception, a finding supported by Miller et al. (2008*b*). This result suggests that the immune systems of fawns may be insufficiently mature for immunocontraception, and that operational treatment of deer with GonaCon vaccine should focus on adult females. Nonetheless, experimental treatment of fawns to determine contraceptive efficacy is important because future wildlife contraceptive agents could be delivered orally, and treated bait may be consumed by deer of all ages.

The level of circulating anti-GnRH antibodies is a good indicator of the fertility status of an animal treated with an immunocontraceptive agent (McShea et al. 1997). Other than infertility, no side effects are associated with the presence of antibodies against GnRH (Delves 2002). In most treated animals, fertility is naturally regained after a decline in antibody titers (Keeling and Crighton 1984).

The immune response must reach and maintain a threshold level for contraception to occur (Adams and Adams 1990, Zeng et al. 2002). In white-tailed deer, infertility is normally associated with anti-GnRH antibody titers $\geq$1:64,000 (Miller et al. 2000, 2008*a*; Gionfriddo et al. 2009). In the current study, 27 months after vaccination, titers were $\geq$1:64,000 in 4 (29%) of 14 nonboosted GonaCon-treated adult females, all of which were infertile in 2006 and 2007. Of the 5 examined females that were vaccinated in September–October 2006 as 3–4-month-old fawns, 1 (20%) had a titer $\geq$1:64,000. Although these 5 deer were vaccinated too late in the 2006–2007 reproductive cycle to affect reproduction that year, they were likely too young to breed until (at least) autumn 2007. Both of the females that had been vaccinated at 8 months of age and remained alive on the study site had titers $\geq$1:64,000, although one of them was pregnant in 2007.

Severe overbrowsing was evident throughout the study area when the study began. Most deer captured in July 2005 were noticeably thin, with body masses estimated at 32–57 kg. Healthy adult female white-tailed deer in the northeastern United States generally weigh 41–96 kg (Whitaker and Hamilton 1998). Fat reserves in study deer at necropsy in 2007 were generally meager (Gionfriddo et al. 2011). The relationship between nutrition and immune response has long been recognized (Homsy et al. 1986, Chandra and Amorin 1992), and it is possible that stronger immune responses (and greater contraceptive efficacy) may have been achieved if study deer had been in better physical condition. As a practical matter, however, most overabundant deer populations that would be candidates for treatment with contraceptive agents would likely have experienced suboptimal nutrition.

Small and inactive ovaries and uteri, as observed in many of the GonaCon-treated females in this study, are commonly associated with GnRH immunocontraception and are indicators of successful contraception. GonaCon induces the production of anti-GnRH antibodies that bind to endogenous GnRH and prevent the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. In the absence of LH and FSH, the gonads remain quiescent, production of sex hormones is sharply reduced, and the animal remains in a nonreproductive state.

The administration of booster vaccine injections to several of our adult female study deer provided an opportunity to evaluate the effect of such injections on contraceptive efficacy. For example, females numbered 17 and 29 were each given a 1.0-mL booster injection of GonaCon in October 2006 after lactating during summer 2006. Neither female lactated in 2007; both females had very high anti-GnRH antibody titers (1:128,000) when collected in October 2007, suggesting that the booster injections had stimulated strong immune responses. Deer number 28 followed a similar pattern. After her pregnancy in summer 2006, she was boosted in October and then did not lactate in 2007. Unfortunately her carcass was too badly decomposed when it was found in September 2007 to permit blood collection or necropsy examination. In contrast to these examples, a booster injection did not seem to be effective in deer number 5. She lactated in summer 2006, was boosted in October 2006, and lactated again in 2007. Her antibody titer was 1:32,000 in October 2007. Booster vaccine injections seem to increase or extend contraceptive efficacy in some, but not all, cases.

Responses of Male Deer to Vaccination

Although mean values for testicular circumferences and serum testosterone concentrations did not differ between GonaCon-treated and control males, vaccination with GonaCon affected reproductive parameters in some adult males (no. 81 and 82), which, 12 months after vaccination, had small testes, negligible testosterone concentrations, and antlers that retained velvet into October. In contrast, treated adult males 87, 88, and 90 had "normal" values for these parameters when compared with control adult males. Anti-GnRH antibody titers in males treated with GonaCon as 3–4-month-old fawns were similar to those of same-aged females and support the hypothesis that immunocontraception of young fawns may not be feasible.

In our study, deer were collected for necropsy in early October when testosterone concentrations normally increase as the rut approaches (Mirarchi et al. 1977). Treatment with GonaCon vaccine typically reduces the production of testosterone and growth of testes (Killian et al. 2005), and produces males that resemble morphological castrates. Thus it was not surprising that 2 treated deer had smaller testes and lower testosterone concentrations than untreated deer. Curtis et al. (2008) reported similar results for free-ranging male white-tailed deer treated with GnRH vaccines. We agree with Killian et al. (2005) and Curtis et al. (2008) that male deer should not be treated with GnRH vaccines because of potential social consequences for treated individuals.

MANAGEMENT IMPLICATIONS

Successful management of overabundant suburban deer populations requires an initial reduction in numbers to a desired

density, and then maintenance of that density (Merrill et al. 2006). Contraceptive efficacy rates demonstrated for GonaCon vaccine in New Jersey support the contention that the most efficient approach to managing overabundant suburban deer populations may be to combine culling (for initial population reduction) and contraception (for population stabilization; Bomford 1990, Hobbs et al. 2000). Once deer numbers have been reduced to a desired level, population stability can be achieved by preventing about 60–80% of the breeding females from reproducing each year (Garrott 1995, McCullough 1996). Such levels of infertility should be achievable through rigorous application of GonaCon vaccine. Timely reduction of overabundant deer populations using contraception alone, however, is not feasible at current efficacy rates.

The need for safe, effective, practical, and humane wildlife contraceptive agents to manage overabundant wildlife populations in situations where traditional management methods cannot be applied will continue to drive the development of contraceptive products. Immunocontraception of white-tailed deer shows promise as a tool for stabilizing demographically closed populations, but improvements may be needed if this technology is to be accepted and applied widely in real-world settings by natural resource professionals. Greater contraceptive efficacy (i.e., a higher proportion of treated animals rendered infertile and a longer duration of contraceptive effect) is a goal of ongoing research.

ACKNOWLEDGMENTS

We are very grateful to S. F. Timm for field necropsies, C. A. Yoder for help with statistics, R. Rodts, D. Cuddy, V. DeNicola, and C. Collier for field assistance, and K. A. Crane, J. M. Kemp, C. M. Denny, and L. E. O'Dell for laboratory assistance. We thank Associate Editor Nielsen and 2 anonymous reviewers for comments that improved the manuscript.

IMMUNOCONTRACEPTION OF FERAL AND CAPTIVE HORSES USING AN ANTI-LHRH VACCINE[1]

[1]Goodloe, R.B., R.J. Warren, D.C. Sharp, and S.R. Davis. To be submitted to Journal of Wildlife Management.

Abstract: We injected captive mares (n = 4 per treatment group) in 1988 with a microencapsulated anti-luteinizing hormone releasing hormone (LHRH) vaccine that either was precipitated on alum (AP) or emulsified with a triple adjuvant (TA). Control mares (n = 4 per group) received placebos containing vaccine without LHRH. The AP vaccine was less effective than the TA vaccine and was eliminated from further study. Mares treated with the TA vaccine produced elevated antibody titers against LHRH and demonstrated less follicular development during 11-13 weeks after treatment; all treated mares ovulated after LHRH antibody titers declined, and 3 mares that were bred produced at least 1 conceptus each. Treatment appeared only to delay onset of breeding in treated mares compared to controls. Mares that received the microencapsulated TA vaccine in 1988 produced slight elevations in antibody titers when the 1989 booster vaccines were adminstered remotely via biobullet. Little antibody production was observed in a third group of captive mares (n = 4) that received initial vaccine and a single booster administered via biobullet in 1989. Based on preliminary results from the corral study, we treated 21 feral mares with a series of 2-3 biobullets containing TA vaccine from 1988-1989. No differences in foal production or mortality were noted between treated and untreated feral mares. We suggest that our TA vaccine and other vaccines that require a number of boosters to maintain high antibody titers are not suitable

for use in field sterilization programs at their current level of development. We provide recommendations for future immunocontraception reseach and suggest long-acting sterilization techniques that could be implemented in feral horse populations until more efficient, reversible, remotely-delivered vaccines are developed.

J. WILDL. MANAGE. 00(0):000-000

Key words: barrier islands, conservation biology, Equus caballus, feral horses, immunocontraception, immunosterilization, LHRH, biobullets.

A number of barrier islands along the U.S. Atlantic coast support feral livestock that forages on dune and marsh vegetation. Excessive grazing on sea oats (Uniola paniculata) and other dune-stabilizing vegetation can result in poorly developed frontal dunes and produce conditions that favor movement of sand landward from previously stable secondary dunes (Hillestad et al. 1975). Such dune changes can affect nesting habitat of loggerhead sea turtles (Caretta caretta) and deplete wetland habitat leeward of the dunes (Hillestad et al. 1975). Grazing and trampling by feral horses in salt marshs can alter primary production of smooth cordgrass (Spartina alterniflora), affect detritus production, reduce fiddler crab (Uca pugnax) densities, and change successional patterns (Ranwell 1961, Riemold et al. 1975, Turner 1988).

Feral cattle, sheep, and goats have been removed from most coastal islands. However, feral horses are maintained on Assateague Island, Virginia and Maryland (Chincoteague National Wildlife Refuge and Assateague Island National Seashore); Ocracoke Island, North Carolina (Cape Hatteras National Seashore); Shackleford Banks, North Carolina (Cape Lookout National Seashore); Carrot Island, North Carolina (Rachel Carson National Estuarine Research Reserve); and Cumberland Island, Georgia (Cumberland Island National Seashore). Currently, only the corralled population on Ocracoke Island and the privately owned population on the Chincoteague National Wildlife Refuge are managed.

Shooting, poisoning, and other lethal methods are banned on many public lands or may not be acceptable to the public to control feral horse herds. Corralling or relocating excess animals, as practiced with feral horses in the western U.S. and on the Chincoteague National Wildlife Refuge, is costly and may be highly stressful to the animals. Recently, fertility control has been suggested as an alternate, non-lethal method of feral horse regulation.

A male-based method of fertility control could be effective if dominant stallions retain herds for relatively long periods and if subordinate and bachelor males have limited access to harem females. Kirkpatrick et al. (1982) successfully reduced feral mare productivity in harems

controlled by stallions treated with microencapsulated testosterone propionate. Immobilized animals were injected with the treatment by hand; remote delivery, via dart, has not been successful (Kirkpatrick et al. 1990a). Vasectomy also has been used to control population growth rates in feral equids without affecting libido of the treated stallions (McCort 1980). In many horse populations, however, the effectiveness of male sterilization may be limited by unstable band composition and the potential for breeding by subordinate or bachelor males (Nelson 1980).

In most female mammals, reproductive processes dependent on a dynamic hormonal balance can be blocked by treatment with specific chemicals that affect release of reproductive hormones, ova fertilization, or embryo emplantation. In feral mares, silastic rods containing ethinylestradiol (EE_2) or EE_2 and progesterone reduced foal production over a 3-year period (Vevea et al. 1987, Plotka et al. 1989). Intraperitoneal implantation of the compounds, however, required animal immobilization and field surgery, which are costly and stress the animal. More recently, Kirkpatrick et al. (1990a) suppressed feral mare fertility for a year through active immunization against zonae pellucidae antigens. Vaccine was delivered remotely, via dart.

Active immunization against endogenous LHRH successfully blocked ovulation in laboratory rats and rabbits; one immunization was sufficient to stimulate

production of LHRH antibodies to LHRH, resulting in highly reduced or nondetectable levels of LH and FSH in the serum and anterior pituitary (Fraser 1975, Fraser and Gunn 1973, Fraser et al. 1975, Fraser and Baker 1977). Similar immunizations against LHRH before or at the onset of the breeding season prevented ovulation in sheep (Crighton and Foster 1977, Clarke et al. 1978, Adams and Adams 1986), gilts (Esbenshade and Britt 1985), and cattle (Johnson et al. 1988).

Domestic mares treated with LHRH conjugated to bovine serum albumin and emulsified in Freund's Complete Adjuvant (FCA) demonstrated reduced ovarian weights, number of follicles > 10 mm, and number of corpora lutea (Garza et al. 1986). Safir et al. (1987) treated domestic mares with LHRH conjugated to human serum albumin and emulsified in FCA. Three of 5 treated mares ovulated, despite receiving 4 boosters within 29 weeks after the study began. Schanbacher and Pratt (1985) administered a similar vaccine to a cryptorchid stallion, followed by 3 boosters within 2 months; antibody titers were sufficient to block testosterone production 4-6 months after the last booster.

None of the sterilization methods developed to date for feral horses meet the major criteria established by Turner and Kirkpatrick (1986) for an ideal fertility control method: seffective, safe, long-lasting but reversible, inexpensive, and delivered remotely. Our study was initiated to meet 2 major objectives: (1) to develop

and evaluate the immunological and physiological effects of selected contraceptive vaccines in captive mares, and (2) to evaluate the feasibility and effectiveness of these vaccines administered with a biobullet delivery system in a field situitation.

We thank J. Earle, C. Ford, G. Goodrich, D. Hoffman, M. Lyda, B. Mallard, and A. Mead for assistance in immobilizing and treating feral animals. Special thanks to C. Hall of the University of Georgia and W. Grubauth, J. Weithenauer, P. Sherin, and M. Seroussi of the University of Florida for extensive sample and data collection. S. Hendricks, C. Ruckdeschel, J. Ernest, L. Foster, the Ferguson family, the Dubose family, and other residents allowed access to private property and provided information on the feral horses. We thank National Park Service (NPS) personnel, particularly, K. Kacer and K. Morgan, for their support of the field research. Technical guidance was provided by W. Lance, Wildlife Laboratories (Ft. Collins, Colo.); D. Ruth and A. Mia, Pitman-Moore, Inc. (Terre Haute, Ind.); and S. Sandburg, BallistiVet, Inc. (Minneapolis, Minn.). Adjuvant was donated by T. Rudbach, Ribi ImmunoChem Research, Inc. (Hamilton, Mont.). Analysis of fecal and urine samples was kindly conducted by J. Kirkpatrick, Eastern Montana College (Billings, Mont.). Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) antisera and purified gonadotropins were donated by G. Niswender (Colo. State Univ.), D. Thompson (La. State

Univ.), and H. Papkoff (Univ. of Calif.-San Francisco). Financial support was provided by the NPS, University of Georgia, University of Florida, and McIntire-Stennis Project No. GEO-0030-N.

METHODS

Study Areas

Corral studies were conducted at the Horse Research Center, University of Florida, Gainesville. Field studies were conducted on the feral horses of Cumberland Island, the largest and most southern of Georgia's barrier islands. Cumberland Island is about 28 km long, 0.8-4.8 km wide, and covers an area of 95.5 km^2. Eighty percent of the island is organized as the Cumberland Island National Seashore and includes a large area of federally designated wilderness.

Lenarz (1983) counted 144 horses on Cumberland Island in July 1981 and estimated that the population could increase 5-21% annually. A minimum of 154, 181, and 197 horses were counted in the March 1983, May 1985, and May 1987 censuses, respectively (Ambrose et al. 1983, Finley 1985, Koontz 1989). The population increased to an estimated 220 horses by September 1990 (Goodloe 1991).

Treatment Selection and Preparation

Our primary objective when evaluating potential immunocontraception methods was selection of a compound that provided long-term sterility and that could be delivered remotely via biobullet to enhance applicability and safety in field situations. Of secondary importance

was use of an adjuvant that did not cause adverse reactions at the injection site. Freund's Complete Adjuvant (FCA) has been used in most previous studies to enhance immune response to the antigen, but it is known to stimulate potentially life-threatening pyogenic abscesses that may affect survival of free-ranging animals.

The most promising technique we considered that met these requirements was active immunization against endogenous LHRH. Anti-LHRH vaccines, when conjugated to a variety of adjuvants, have successfully inhibited estrus and/or ovulation in domestic horses (Schanbacher and Pratt 1985, Garza et al. 1986, Safir et al. 1987) and a variety of other species (see Fraser 1985 for review). Our vaccine incorporated either alum or a lyophilizable triple adjuvant (100 mg each of monophosphoryl lipid A, trehalose dimycolate, and BCG cell wall skeleton; prepared by Ribi ImmunoChem Research, Inc., Hamilton, Mont.) to reduce the possibility of injection site abscesses and allow biobullet delivery.

Our immunogen was prepared with the carbodiimide reaction (Fraser et al. 1974) to conjugate LHRH to keyhole lempet hemocyanin (KLH) (prepared by Pitman-Moore, Inc., Terre Haute, Ind.). Two different vaccines were created by either precipitating the immunogen on alum (AP) or combining the immunogen in a 2% oil-in-water emulsion with the triple adjuvant components (TA). Two methods of vaccine delivery were used to treat corralled mares--hand

injection of microencapsulated (MC) vaccine in 1988 and biobullet (BB) implantation of vaccine in 1989. All feral horses were administered vaccine via biobullet.

Biobullets, which delivered a single-dose treatment that provided 15 mg LHRH immunogenic activity, were prepared by inserting the lyophilized vaccine into the tip of a 6.53-mm (0.25 caliber) hollow biodegradable bullet and sealing with a lactose plug (prepared by BallistiVet, Inc., Minneapolis, Minn.). Microencapsulated formulations were prepared by the solvent-evaporation process as described by Tice and Gilley (1985). The reservoir microcapsules were designed to release 1 vaccine dose immediately upon injection, 1 dose in 2-3 months, and a final dose in 6-9 months. Placebo treatments consisted of vaccine without LHRH. The microencapsulated vaccine exceeded the biobullets' weight capacity (500 mg) and was injected by hand.

Treatment and Sampling of Corralled Animals

1988.--Sixteen mares were assigned randomly to 1 of 4 experimental groups that were administered the following microencapsulated vaccines or placebos: (1) triple-adjuvanted LHRH-KLH treatment (MC88-TA-LHRH-KLH); (2) alum-precipitated LHRH-KLH treatment (MC88-AP-LHRH-KLH); (3) triple-adjuvanted KLH placebo (MC88-TA-KLH); and (4) alum-precipitated KLH placebo (MC88-AP-KLH). On 31 January 1988, each animal was injected at a single location in the

hindquarters with the microencapsulated, triple-dose formulation suspended in 3 ml of sterile injection vehicle.

1989.--On 13 April 1989, the 4 mares previously treated with MC88-TA-LHRH-KLH in 1988 received a single booster of vaccine, injected into the hindquarters via biobullet (BB89-MC88-TA-LHRH-KLH group). No placebo biobullets were administered to the control horses (MC88-TA-KLH group). In addition, a new treatment group (BB89-TA-LHRH-KLH) was established in 1989 to evaluate the effectiveness of biobullet administration of vaccine. Each of 4 mares (3 mares from the MC88-AP-KLH placebo group and 1 previously untreated mare) received a single biobullet containing TA-LHRH-KLH on 13 April 1989, followed by a booster bullet on 3 June 1989.

Sampling Procedure.--Blood samples were collected from all mares by venipuncture at about weekly intervals from 24 January-27 August 1988 and 13 April-14 July 1989. Samples were refrigerated until plasma could be separated and frozen. Plasma titers of LHRH antibodies were determined by indirect ELISA tests using LHRH-coated plates. Antibody titers in samples collected during the first 11 weeks after the 1988 treatments initially were assayed as serial dilutions to compare the AP and TA vaccines and select the most effective for use in the field portion of the study. All blood samples collected from TA-LHRH-KLH and TA-KLH mares during the 2 years of the study, including those samples tested previously, were analyzed for antibody titer

in a single run at the conclusion of the study to standardize results; titers were measured in units of optical density to allow more efficient statistical analysis of antibody data. Plasma concentrations of LH and FSH were quantified by radioimmunoassay using anti-ovine LH antisera and anti-equine FSH antisera, in conjunction with purified equine LH and FSH for radioiodination and standard preparation (Thompson et al. 1983a, 1983b). Insufficient blood was available from 1988 samples for hormone analysis.

From 5 June through 5 September 1988 and 6 May through 19 July 1989, mares were teased daily with a stallion to detect estrus and palpated rectally when estrus was detected to assess ovarian follicular growth and incidence of ovulation. Most mares were inseminated artificially or bred to stallions of known fertility upon display of estrus or detection of ovarian follicles $\geq$ 30 mm in diameter. Daily breeding continued until ovulation occurred, and all mares were checked for pregnancy with ultrasound echography daily beginning on Day 10 after ovulation. Conceptuses were flushed from the uterus on either Day 12 or Day 14 after ovulation was confirmed, and mares were administered 5 mg prostaglandin F2α (Lutalyse; Upjohn Co., Kalamazoo, Mich.) to regress the corpus luteum.

Treatment and Observation of Feral Horses

Treatment.--We conducted an initial survey of the Cumberland Island feral horse population in 1986 and 1987 to census the population, identify and age animals, and

determine pretreatment reproductive rates. Animals were identified by face and body markings and scar patterns. In addition, 10 feral mares, primarily on the northern half of the island, were immobilized between November 1986 and February 1987 (Goodloe 1991) and fitted with radio collars to assist in identification and location of herds. Ages assigned to animals in 1986 were based on body size, tail length, and muscle mass. Young horses (excluding known foals) were aged as yearlings if body size was small and the tail did not extend past the hocks. Larger, more muscular horses were considered to be 2 years old if the tail did not reach the hoofs.

Between 10 March and 2 May 1988, 21 mares were treated with biobullets containing single doses of TA-LHRH-KLH. Booster biobullets were administered to 20 of 21 mares between 19-26 July 1988 (1 mare was on private property during the treatment period), and to 19 of 21 mares between 3 February and 4 March 1989 (1 severely injured mare was not treated and another mare was not located during the treatment period).

Throughout the study, untreated mares thought to be $\geq$ 3 years old in 1987 were considered as controls but were not administered placebo biobullets. Nineteen mares treated with TA vaccine in 1988 and 1989 and 2 untreated control mares were administered unadjuvanted LHRH-KLH immunogen in 1987. However, identical treatments given to corralled mares in 1987 failed to stimulate detectable

levels of LHRH antibody or to reduce ovulation and productivity rates (Goodloe et al. 1991). Therefore, we included feral mares present on Cumberland Island in 1987 in pretreatment tallies of reproduction.

Observation after Treatment.--After initial surveys of the Cumberland Island population, we observed island feral horses intensively from March through September 1988 and March through August 1989 to document foal production and survival rates. Data also were collected during 0.5-2-week-periods in January, October, and December 1988 and February, November, and December 1989. Estimates of 1990 foal production were based on observations conducted in May and September 1990 and were augmented by analysis of fecal and urine samples collected from late July through December 1989, as described by Kirkpatrick et al. (1988, 1990c). Fecal and urine samples were collected immediately after deposition and subsequently frozen.

Information on total annual production and foal survival was collected through direct counts of live foals and searches for carcasses when foal death was suspected. We assumed that foals were born, but died before being tallied, if a mare had a fully distended udder at any point during the foaling season or appeared visibly pregnant up to a given time, particularly if a foal carcass was found in the herd's home range. Unproductive mares that were not located at frequent intervals during a given year were excluded from calculations of foal production, because the

possibility of foal death could not be eliminated. Mares that died during the study were included in counts of total foal productivity if a necropsy was conducted or if they were visibly pregnant at death; however, foals that died in utero were not included in mortality calculations. Date of foal birth was estimated as the midpoint between the dates when the mare was seen last without, and for the first time with, a foal; if this interval was > 2 weeks, then the foal was not included in estimates of mean date of birth. When foal death was suspected, date of birth was considered to be the last day the mare was observed with a full udder or the day when a fresh carcass was found. We observed a total of 21 treated and 39 untreated mares during the 4-year study (21 and 38 in 1987, 21 and 29 in 1988, 21 and 26 in 1989, and 20 and 23 in 1990.

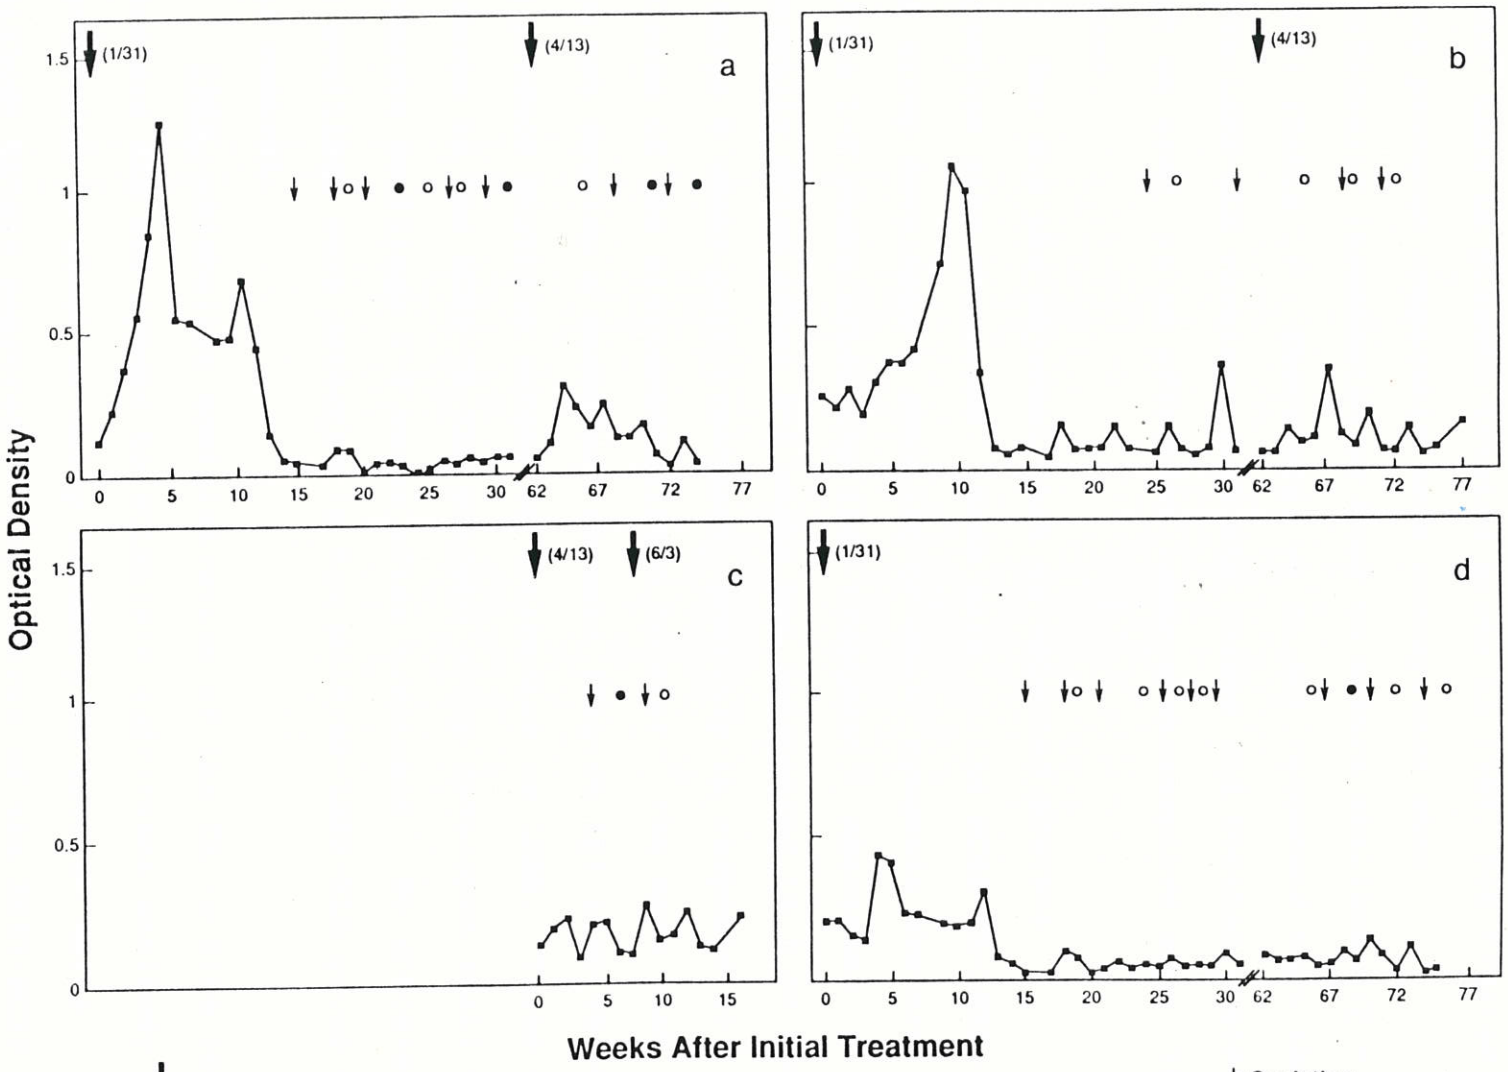
Statistical Analysis

Antibody titers of corralled horses, measured in units of optical density (OD; from mares administered TA vaccines), were analyzed by repeated measures analysis of variance (Gill and Hafs 1971); the mean pretreatment values for each horse were designated as covariances in the model. Student's t-tests were used to compare mean date of first follicle $\geq$ 30 mm, mean date of first ovulation, and mean number of ovulations between treatment groups and the control group.

Differences between conceptus production in treated and untreated corralled mares and foal production and

survival in treated and untreated feral mares were evaluated by 2X2 contingency tables with Chi-square tests (Sokal and Rohlf 1969). Student's t-tests were used to compare mean dates of foal birth between treated and untreated groups. Statistical significance was indicated at $P \leq 0.05$.

RESULTS AND DISCUSSION



Corral Study

1988.--Preliminary results during the first 11 weeks after treatment indicated that the AP vaccine was less effective in stimulating LHRH antibody production than the TA vaccine. Antibody levels in mares treated with MC88-AP-LHRH-KLH rose to maximum titers of 1:200-1:300, which were only 2-6 times greater than levels produced by mares administered the MC-AP-KLH placebos. Peak titer levels (maximum titers of 1:300-1:3200) for the MC88-TA-LHRH-KLH group were 2-42 times higher than those produced by their controls (MC88-TA-KLH horses) during the same period. Three of the mares in the MC88-AP-LHRH-KLH group produced follicles $\geq$ 30 mm on average 50.3 days (SD = 22.5) after initial treatment, compared to a mean of 44.5 days (SD = 12.1) for MC88-AP-KLH control mares and 111.5 days (SD = 29.0) for mares treated with the TA-LHRH-KLH vaccine. The fourth mare in the MC88-AP-LHRH-KLH group first ovulated when the follicle was < 30 mm. Based on these preliminary results, the AP treatment was eliminated from the study, and all further efforts focused on the TA-LHRH-KLH vaccine.

Mares treated with MC88-TA-LHRH-KLH tended to produce higher antibody titers (expressed in units of optical density) than did mares administered placebos (P = 0.075) through Weeks 11-13 after treatment (Fig. 1a, b, and d). Differences in antibody production were not significant (P = 0.880) during Weeks 14-26 after treatment or when antibody production was compared over the entire 28 weeks of the 1988 study (0.121). Mean titers for the 4 MC88-TA-LHRH-KLH horses during the 13-week period after treatment were 0.351-0.726 OD (SE = 0.171; minimum - 0.041-0.084; maximum - 0.808-1.361). Three mares produced bi- or tri-phasic elevations of antibody levels > 0.69 OD at 1-7-week intervals (Fig. 1a), although the response of one was lower and more transitory than in the other animals. The fourth horse produced only a single surge of antibody at Week 9 (Fig. 1b). Similar variation in horse response to anti-LHRH vaccines was reported by Safir et al. (1987). Mean antibody titers for control mares during the first 13 weeks after treatment (Fig. 1d) ranged from 0.195-0.239 OD (SE = 0.018; minimum - 0.030-0.047; maximum - 0.414-0.524).

Despite the relatively high titers of LHRH antibodies after treatment, all mares in the MC88-TA-LHRH-KLH group cycled during the 1988 breeding season, and each of the 3 mares that were bred or artificially inseminated produced at least 1 conceptus. At best, our treatments only delayed breeding--the MC88-TA-LHRH-KLH mares tended to produce large follicles $\geq$ 30 mm later (P = 0.051) and to first

Figure 1. Antibody production by corralled mares treated with TA-LHRH-KLH vaccine in 1988 and 1989. Figure 1a and 1b represent mares treated with MC-TA-LHRH-KLH on 31 January 1988, followed by a booster administered via biobullet on 13 April 1989; Figure 1c represents a mare treated with single biobullet injection of TA-LHRH-KLH vaccine on 13 April and 3 June 1989; and Figure 1d represents a mare administered a microencapsulated placebo (MC-TA-KLH) on 31 January 1988 but no placebo in 1989. Large arrows annotated with dates indicate time of treatments, smaller arrows indicate ovulation dates, open circles indicate administration of 5 mg PGF, and closed circles indicate flushing of a conceptus.

ovulate later (P = 0.060) than did control mares (Table 1). We detected fewer ovulations in the treated mares (P = 0.045) than in placebo-treated mares in 1988, but treated mares produced comparably more conceptuses when artificially inseminated or bred to mature stallions (P = 0.036) (Table 1). Therefore, we do not recommend that the MC-TA-LHRH-KLH vaccine, with the dosage and booster regime that we used, is an effective immunocontraceptive agent in horses.

Nor did the adjuvant that we selected prevent injection site abscesses. Each mare in the MC88-TA-LHRH-KLH group developed a swelling or small pyogenic abscess within 1-2 weeks after the 1988 treatment. Abscesses generally dried after 3-4 weeks but reappeared in 3 of the 4 mares 8 weeks post-treatment, possibly in response to release of the microencapsulated booster; the mare that did not develop a secondary abscess (Figure 1b) also failed to produce multiple surges of antibodies to LHRH. Three of 4 mares in the MC88-TA-KLH placebo group developed small to moderate swellings 1-2 weeks after treatment. No abscesses or swellings were detected in the MC88-AP-LHRH-KLH group or its control.

1989.--Biobullet administration of the TA vaccine and boosters did not appear to stimulate sufficient antibody production to block or delay breeding in treated mares. Antibody titers measured in the 4 mares of the BB89-MC88-TA-LHRH-KLH group after a booster treatment of TA vaccine

Table 1. Follicular development, ovulation, and production by corralled mares at the University of Florida that were treated in 1988 and 1989 with a TA-LHRH-KLH vaccine.

[a] Means are based on data collected from 24 January through 27 August 1988.

[b] Means are based on data collected from 13 April through 14 July 1989.

[c] Mares were injected with a microencapsulated form of the TA-LHRH-KLH vaccine in January 1988 and administered a single booster via biobullet in April 1989.

[d] Control mares were injected with a microencapsulated placebo containing only the adjuvant and KLH in January 1988. No placebos were administered in 1989.

[e] Mares were administered biobullets containing single doses of TA-LHRH-KLH in April and June 1989.

[f] Differences between mares treated with BB89-MC88-TA-LHRH-KLH and MC88-TA-KLH were significant in 1989 ($P = 0.019$). Other differences were not significant (MC88-TA-LHRH-KLH vs. MC88-TA-KLH in 1988, $P = 0.051$; BB89-TA-LHRH-KLH vs. MC88-TA-KLH in 1989, $P = 0.308$).

[g] No differences in means were significant (MC88-TA-LHRH-KLH vs. MC88-TA-KLH in 1988, $P = 0.060$, BB89-MC88-TA-LHRH-KLH vs. MC88-TA-KLH, $P = 0.640$; BB89-TA-LHRH-KLH vs. MC88-TA-KLH in 1989, $P = 0.287$).

[h] Differences between mares treated with MC88-TA-LHRH-KLH and MC88-TA-KLH in 1988 were significant ($P = 0.045$). Other differences were not significant (BB89-MC88-TA-LHRH-KLH vs. MC88-TA-KLH in 1989, $P = 1.0$; BB89-TA-LHRH-KLH vs. MC88-TA-KLH in 1989, $P = 0.134$).

[i] Differences between mares treated with MC88-TA-LHRH-KLH and MC88-TA-KLH in 1988 were significant ($\underline{P}$ = 0.036). Differences among treatment groups in 1989 were not significant ($\underline{P}$ = 0.271).

via biobullet ranged from a maximum of 0.113-0.489 OD to a minimum of 0.028-0.160 OD (Fig. 1a and 1b), much lower than maximum titers the same horses produced in 1988 after treatment with microencapsulated TA vaccine (maximum - 0.808-1.361; minimum - 0.041-0.084). Little response to the TA vaccine was noted in the 4 animals that received initial biobullet treatment in April 1989 followed by a booster biobullet in June (BB89-TA-LHRH-KLH group; Fig. 1c). Maximum titer levels in the BB89-TA-LHRH-KLH animals ranged only as high as 0.112-0.278 OD; these titers were similar to values recorded for 3 of 4 control animals (maximum values of 0.102-0.183 OD; Fig. 1d). The other control mare, in contrast, produced 2 distinct surges of LHRH antibodies that exceeded 0.63 OD.

Overall, LHRH antibody titers produced by the 2 treatment groups did not differ ($P = 0.884$) from the MC88-TA-KLH control group. Mares in the BB89-MC88-TA-LHRH-KLH group produced follicles $\geq$ 30 mm later in the 1989 breeding season than did mares in the MC88-TA-KLH control group ($P = 0.019$) (Table 1). There was no difference between treatment groups and controls for date of first ovulation, number of ovulations, or percentage of mares that produced conceptuses ($P = 0.134-1.0$). Fluctuations of LH and FSH levels in all groups were similar to those described in other studies (Evans and Irvine 1975. Nett et al. 1976).

No abscesses were noted in either treatment group after biobullet delivery. Biobullet administration

appeared successful; entry wounds were observed on all corral mares treated with biobullets, and 64.3% of the mares bled freely after bullet entry.

Field Study

Our conclusion that the TA vaccine had little effect on ovulation and foal production, particularly when delivered by biobullet, was supported by results from the field study on Cumberland Island. Foal production did not differ (Table 2) between mares treated or not treated with TA vaccine during any of the 4 years of observation (1987, $\underline{P}$ = 0.268; 1988, $\underline{P}$ = 0.924; 1989, $\underline{P}$ = 0.258; 1990, $\underline{P}$ = 0.625). In addition, the proportion of productive mares within treated or untreated groups did not differ between years ($\underline{P}$ = 0.128-0.594; the contrast of untreated mares in 1987 vs. 1989 approached significance, $\underline{P}$ = 0.058).

Mortality of foals produced by treated mares in 1987 ($\underline{P}$ = 0.032) and 1988 ($\underline{P}$ = 0.089) was greater than for foals produced by untreated mares. However, more untreated mares (15 of 39; 38.5%) died during the 4-year study than did treated mares (2 of 21; 9.5%) ($\underline{P}$ = 0.037), particularly between September 1987 and March 1988. Mean date of foal production did not differ between treated and untreated mares within years or among years within groups ($\underline{P}$ = 0.125-0.732), indicating that treatment did not significantly delay onset of breeding.

Table 2. Annual production data for feral mares on Cumberland Island, Georgia, before and after treatment with a TA-LHRH-KLH vaccine administered via biobullet in 1988 and 1989. Only females ≥ 3 years old in 1987 are included in these totals.

[a] Determination of production based, in part, on analysis of steroids in fecal and urine samples collected August-December 1989.

[b] Mares were treated with TA-LHRH-KLH via a biodegradable bullet in March-May 1988, and most received booster injections in July 1988 and February-March 1989.

[c] Control mares (no placebo administered).

[d] Differences between mares treated or not treated with TA vaccine were not significant during any year (1987, $P = 0.268$; 1988, $P = 0.924$; 1989, $P = 0.258$; 1990, $P = 0.625$), nor did the proportion of productive mares within treated or untreated groups differ between years ($P = 0.128$-0.594; the contrast of untreated mares in 1987 vs. 1989 approached significance, $P = 0.058$).

[e] Differences between treated and untreated mares within years or among years within groups were not significant ($P = 0.125$-0.732).

[f] Mortality rates of foals produced by treated mares in 1987 ($P = 0.032$) and 1988 ($P = 0.089$) were significantly different from mortality rates of foals produced by untreated mares. Other differences were not significant ($P > 0.05$).

[g] Only those foals that died before 31 August or that were assumed to have been produced by mares observed with full udder development or pregnant during the breeding season were included in estimates of total mortality.

MANAGEMENT RECOMMENDATIONS

We do not recommend that our TA vaccine should be recommended for use in field immunocontraception programs. Corralled mares treated with MC-TA-LHRH-KLH produced elevated anti-LHRH antibody titers that apparently blocked significant follicular development for 11-13 weeks, but all treated mares ovulated after antibody titers declined, and each mare that was bred produced a conceptus. These mares responded only minimally to biobullet boosters administered in 1989. Feral and captive mares that received initial treatment with TA vaccine via biobullet demonstrated no response to the vaccine, either in antibody production or reduced foal production. Our vaccine, therefore, failed to meet the 2 major criteria that we considered were necessary for a field sterilization program--provision of a compound that provided long-term sterility without the need for a number of booster inoculations and delivery of the vaccine effectively via biobullet.

We do not know why the TA vaccine administered via biobullet was less effective at stimulating antibody production than microencapsulated TA vaccine administered by hand. Failure of the majority of the bullets to implant due to poor shooting or inability to penetrate the skin does not seem probable. We observed blood at the implantation site of 57.6% of feral mares administered biobullets; blood was seen on the hindquarters of only 64.3% of the corral mares after treatment, although

biobullet entry holes were observed on all mares upon close examination. It is possible that vaccine was lost from some biobullets before implantation or was flushed from wounds when animals bled. However, the biobullet system has been used successfully by veterinarians for a number of years to deliver vaccines and other chemicals to domestic animals. In addition, it has been applied in field situations to vaccinate free-ranging elk (Cervus elaphus) and bison (Bison bison) against brucellosis (Herriges et al. 1990, Davis et al. 1991). We think that differences in antibody production stimulated by the microencapsulated TA vaccine in 1988 and the biobullet TA vaccine in 1989 were caused by other, vaccine-related factors.

The need for repeated boosters to maintain high antibody titers is a major limiting factor in the use of existing immunocontraception agents. Administration of boosters remotely requires accurate identification of previously treated animals and the ability to approach animals within the range of the delivery system. To avoid these problems, we think that future research should focus on immunization against proteins that are sufficiently large to stimulate "self-boosting" of the immune response when a treated animal is reexposed to the antigen naturally. Recent studies indicated that fertility in a number of species can be suppressed through immunization against proteins located on the acrosomal cap of spermatozoa. Natural boosting of the immune system

probably could be achieved with each successful mating (Talwar 1986, Alexander and Ackerman 1988).

Currently an effective, reversible sterilizing agent that can be delivered remotely without the need for repeated boosters is not available for use in field situations. Two techniques, however, have been tested that provide long-term sterility in equids--vasectomy of stallions (McCort 1980) and steroid implantation in mares (Vevea et al. 1987, Plotka et al 1989). Silastic rods containing EE_2 implanted in captive feral mares were 75% effective for at least 3 years (Plotka et al. 1989). The initial cost, manpower required, and animal stress incurred during immobilization would be higher than that for remotely delivered vaccines, but may be an acceptable tradeoff for long-term sterility in most treated mares.

At this time, sterilization of dominant stallions may be a more efficient method of population control, since fewer animals would need to be immobilized and treated than would be in a control program directed at mares. Concern has been expressed about the removal of permanently sterilized animals, particularly alpha males, from the gene pool (Nelson 1980). However, similar management practices on Chincoteague National Wildlife Refuge, where the majority of male foals are removed annually, have not reduced genetic variability within that feral population compared to other island horse populations or mainland breeds (Goodloe 1991). In addition, permanent corralling

of excess horses, which is the major management technique currently practiced in western states, also is genetically limiting but does not provide long-lasting population control.

Sterilization of the dominant stallions would reduce, but not eliminate, foal production in bands with treated males. Some mares probably will be bred by subordinate or bachelor males (Nelson 1980) or will move from 1 herd to another during the breeding season. Band fidelity, however, varies within and among feral horse populations (Nelson 1980, Berger 1986, Kirkpatrick et al. 1990a, Goodloe 1991), and this technique may provide relatively efficient population control in some areas until an effective, remotely delivered technique is developed.

ABSTRACT

Context. Management of wild horses (*Equus caballus*) on public lands in the western United States by gathering and removing surplus animals has historically failed to keep up with annual population growth. Research has yielded several effective contraceptive agents but these agents have not been widely applied, especially on difficult-to-access horses occupying expansive ranges. **Aims.** This study examined wild horse population growth reduction associated with controlled-release PZP-22 immunocontraceptive vaccine treatments in two challenging herd management areas (HMA) in the western United States. **Methods.** Populations of wild horse herds at Cedar Mountain HMA, Utah (CM), and Sand Wash Basin HMA, Colorado (SWB), USA, were primed with PZP-22 in gathers conducted in 2008 and 2012 (CM only) and boosted with PZP-22 or native PZP administered by dart (SWB in 2010) or by hand (CM in 2012). The two herds were intensively observed between 2008 and 2015. Population size, mortality, reproductive rates and growth rates were calculated from exhaustive inventories of known individuals. **Key results.** Adult and foal mortality were low at both sites. Consequently, both reproductive rates and population growth rates were strongly predicted by a fertility control index, the product of proportion of mares treated and vaccine efficacy. Following the 2012 CM gather, at which 69% of the mares present were treated, only 20% of mares in the herd foaled, and population growth rate decreased by 74% relative to baseline levels, emphasising the importance of treating a large majority of mares. **Conclusions.** Contraception can significantly reduce rates of population growth in wild horse herds that occupy large areas and are challenging to access. Multiple-year efforts and recruitment of new mares into the treatment population beyond the initial application are needed to achieve a biologically significant impact. **Implications.** The strong quantitative relationship between proportion of mares treated and vaccine efficacy and population growth rates should allow managers to better forecast the effort and number of removals (if any) needed to cost-effectively regulate wild horse population numbers and protect the range ecosystem.

Keywords: feral horse, fertility control, population dynamics, population management, wild horse, wildlife contraception.

Introduction

Management of free-roaming unowned horses and burros is a global challenge (Nimmo and Miller 2007; National Research Council 2013; Hobbs and Hinds 2018; Scasta *et al.* 2020). Among the concerns raised by abundant populations of wild horses and burros are undesirable ecological impacts (Nimmo and Miller 2007; Beever *et al.* 2008; deVillalobos and Zalba 2010; Davies and Boyd 2019), competition with livestock (Scasta *et al.* 2016; Danvir 2018), and the welfare of the animals themselves under harsh and changeable environmental conditions (Garrott 2018). Complicating these challenges are sharp divergences among stakeholders and members of the public in how wild horses and burros are perceived and valued (Nimmo and Miller 2007; Nimmo *et al.* 2007; Beever *et al.* 2018; Scasta *et al.* 2020). As a result, government agency actions to manage these populations

are frequently challenged publicly, in the press, and in court (Rikoon 2006; Nimmo and Miller 2007).

Population management options are limited and include direct and indirect lethal reduction by shooting or capture and transportation to slaughter, capture and removal for adoption or transfer to sanctuaries or other long-term holding facilities, and fertility control. In the USA, Australia, New Zealand, and other countries, killing wild horses or burros by any means to manage their populations is deeply unpopular with the public, especially with highly visible populations (Nimmo and Miller 2007; Scasta *et al.* 2020). Because of the high value that the public places on the lives of equids, often the only feasible solutions open to managers are removal for adoption or long-term holding and/or fertility control.

To manage wild horse and burro populations on US public lands, the Bureau of Land Management (BLM) and US Forest Service (USFS) have relied primarily on gathering, removing, and transporting wild horses and burros for adoption or long-term holding. This practice has been in place since shortly after the passage of the federal Wild Free-Roaming Horses and Burro Act in 1971 (USA; Boyles 1986; Garrott and Oli 2013; National Research Council 2013; Danvir 2018; Garrott 2018). The effectiveness of this approach to stabilising populations is undermined by the high population growth rates of wild horses and burros, which may even be accelerated by the gather-and-removal management strategy (National Research Council 2013). Annual population growth rates vary with environmental conditions and may be lower where predators are present, but most estimates for wild horses on US public lands range from 15% to 27%; estimates from removal data suggest system-wide growth rates to be about 15–20% (Garrott *et al.* 1991; Turner and Morrison 2001; Roelle *et al.* 2010; National Research Council 2013; Garrott 2018). Population growth rates in burros are less well known, but pregnancy rates are known to be high (Johnson *et al.* 1987; Wolfe *et al.* 1989). Linklater *et al.* (2004) estimated population growth rates for wild horses in the Kaimanawa Ranges, New Zealand, to be 9.8%, a bit lower than those reported for the USA.

The BLM began funding research into wildlife fertility control in the 1970s and has continued to do so to the present day (Kirkpatrick *et al.* 1982; Plotka *et al.* 1992; Turner *et al.* 1997, 2007). Since 1990, studies of contraceptives on wild horses have yielded more effective and longer-acting contraceptive agents (Massei and Cowan 2014; Roelle *et al.* 2017; Baker *et al.* 2018). Whereas the native PZP emulsion first tested on free-roaming horses at Assateague Island National Seashore in Maryland, USA, required two initial treatments and annual boosters (Kirkpatrick *et al.* 1990), the more recent PZP-22 preparation offers 1–2 years of effectiveness with a single initial treatment, with effectiveness extended three or more years by a single booster delivered 2–3 years after the initial treatment (Turner *et al.* 2007; Rutberg *et al.* 2017; Carey *et al.* 2019). Similar multi-year effectiveness with a single booster has been demonstrated in initial field tests of GonaCon™, and SpayVac® also shows promise of single-shot, multi-year effectiveness (Roelle *et al.* 2017; Baker *et al.* 2018).

While contraceptive agents were being developed and tested, other work modelled population effects of hypothetical contraceptives, either alone or in combination with other population-control strategies (Massei and Cowan 2014). Although employing diverse methods, most models concluded that combining removals and contraception reduces costs (especially if disposal of removed horses through adoption or holding is costly), lengthens gather cycles, and yields population levels that fluctuate less and remain closer to the target than do all-removal strategies (Garrott *et al.* 1992; Garrott 1995; Gross 2000; Hobbs *et al.* 2000; Bartholow 2007; de Seve and Griffin 2013; Garrott 2018). Incorporating contraception may also improve genetic outcomes relative to removals, especially if focused on younger individuals (which extends generation times and slows allele loss through genetic drift; Gross 2000). Several authors have recommended relying on removals to initially reduce the population to a target level, and then applying contraception to maintain population size (Hobbs *et al.* 2000; Massei and Cowan 2014; Garrott 2018; Hobbs and Hinds 2018). However, Bartholow (2007) suggested that maximum long-term cost reduction will be best achieved by pursuing multiple gather cycles of contraception and selective removals. Several studies have concluded that contraception will have little effect on population growth below a threshold proportion of mares treated (40–50%), and that a very high proportion of mares treated (60–90%) would be needed to stabilise populations in the absence of removals.

Empirical studies of the population effects of fertility control in wild horses are scarce (Massei and Cowan 2014). At Assateague, the population impacts of native PZP have been traced since the National Park Service (NPS) started applying it as a management tool in 1994. The Assateague horses showed an initial population stabilisation phase that lasted 10 years, followed by a slow decline that met progressively lower NPS population targets in 2008 and 2015 (Kirkpatrick and Turner 2008; National Park Service 2008, 2016). At Assateague, population control is enabled by the relative approachability of resident horses and their confinement on the narrow barrier island, which means that they can be reliably and repeatedly treated with PZP via dart and monitored regularly.

In western North America, wild horse herds vary widely in their size, density, spatial dispersion, detectability, and approachability in the field. Although horses in some BLM herd management areas are accessible for regular darting (e.g. Little Bookcliffs Wild Horse Range, CO, McCullough Peaks HMA, WY, and Pryor Mountains Wild Horse Range, WY/MT; Ransom *et al.* 2011), most are not. For these three sites, Ransom (2012) demonstrated that PZP treatments were associated with a reduction in mean population growth

from 15.6% pre-treatment to 8.2% post-treatment. Selection and number of horses treated at each site varied according to the site-specific management plans, with a mean of 32.2% treated across populations and across years. At the 234 703 ha Sheldon National Wildlife Refuge, NV, Collins and Kasbohm (2017) reported that, with annual helicopter roundups, the wild horse population was reduced by approximately 72% over 7 years, using a combination of removals, sterilisation of stallions with vasectomies or chemical epididymectomy, and surgical ovariectomy of mares by using colpotomy.

Annual helicopter round-ups are generally infeasible for BLM and USFS wild horse ranges, but longer-acting contraceptive vaccines such as PZP-22 and GonaCon^{TM} open possibilities for measurable population impacts on more difficult-to-access wild horse herds in North America and elsewhere (Garrott 1995; Hobbs *et al.* 2000; Bartholow 2007).

Extending the results on PZP-22 efficacy on individual mares reported by Rutberg *et al.* (2017), this paper reports the impacts of the management-level application of PZP-22 on the population dynamics of two wild horse herds occupying expansive herd management areas (HMAs) in the western USA, namely, Cedar Mountain HMA, Utah, and Sand Wash Basin HMA, Colorado.

Materials and methods

Study areas

Cedar Mountain herd-management area, Utah

Cedar Mountain HMA (CM) comprises 1666 km^2 located 80 km west of Salt Lake City and is part of the Great Salt Lake Desert and Great Basin Desert ecosystem. CM consists of alkali salt flats and playas, sagebrush and grassland benches and steep juniper woodland slopes. Elevation is approximately 1400–2460 m. Rainfall is 20–25 cm at lower elevations and 25-38 cm at upper elevations. Within CM lies the 402 km^2 Cedar Mountain Wilderness Area. In part because of the ban on vehicles in the wilderness area, there are few access roads within the mountain range, and only two passes traverse the range east–west. CM is bordered to the west and south by the US Army Dugway Proving Ground (DPG), part of which lies within the HMA boundaries. Downed or cut fences allow horses to access DPG, and some horses from the HMA utilise areas of DPG that are not part of the HMA. Cattle graze on CM, including parts of the wilderness area, approximately November–May.

Most water sources at CM consist of roadside cattle troughs, although there are also a few seeps and intermittent springs fed by spring runoff from snow that accumulates in the mountains. DPG water consists primarily of spring seeps. The CM population stays close to water sources, primarily during hot weather when water is scarce. Movement of DPG horses into off-HMA areas varies with water availability and season. The southern boundary line of DPG borders the Onaqui wild horse herd where cross-over is possible. CM horses also occasionally take advantage of open or downed fences to move off range to the east.

Horses in CM were wary of people on foot and in vehicles. DPG horses were more accustomed to vehicular traffic and could sometimes be observed roadside.

Appropriate management level (AML) for wild horses at CM is 190–390.

Sand Wash Basin herd-management area, Colorado

Sand Wash Basin HMA (SWB) comprises 638 km^2 in northwestern Colorado, 72 km west of Craig. The topography and vegetation encompass mesas and ridges interspersed with desert washes and salt desert shrub plant communities consisting of sagebrush/bunchgrass, saltbush and a small amount of juniper woodlands. Rainfall is approximately 18–30 cm yearly and elevation ranges from 1900 to 2600 m. The herd area is easily accessible with a network of dirt and primitive roads. Domestic sheep are grazed on the land in spring and fall.

Sand Wash Basin HMA incorporates a network of artificial water sources created for livestock use that are scattered throughout the range, along with intermittent springs and seeps. Horse movements are strongly influenced by water availability and can vary from season to season. Horses may enter and leave the HMA by jumping low fences or passing through southern range entrances lacking cattle guards, snow-covered cattle guards, and boundary gates when they are inadvertently left open. Domestic horses from a neighbouring ranch were observed occasionally on the HMA. Most were quickly removed, but one mare remained for up to 2 years.

Horses in SWB showed some initial wariness but became more approachable throughout the study as the HMA became increasingly popular with visitors and horses grew accustomed to human activity. AML for wild horses at SWB is 163–362.

Observations and demographics

Ground surveys to identify horses pre-gather (2008) and monitor population trends and contraceptive efficacy (2009–2015) were conducted on CM and SWB. Because 2008 pre-gather observations were limited and permission to conduct surveys on the CM HMA section of the Dugway Proving Grounds (DPG) was not obtained until July of 2009, pre-gather (2008) data are omitted from the results. Between 2010 and 2014, only 10 previously unobserved adults were identified at SWB (four in 2010 and six for the remaining 4 years of the study). Only five previously unobserved adults were identified at CM from 2010 to 2015 (four in 2010 and one in 2011). At both sites, new adults represented $<1\%$ of total horses observed, suggesting that our population inventories at both sites were substantially complete.

Observers averaged 990 field-hours per season (2008–2015) and 435 data-logging hours per season in CM and

711 field-hours per season and 350 data-logging hours per season in SWB (2008–2014). Time spent in the field depended on weather and road conditions. In the year prior to gathers (2008), 608 individual horses were identified at CM and 377 at SWB (Tables 1, 2). Observations of horses were concentrated at many of their main water sources, seeps and springs, as well as the various grass and sage landscapes in which they were located. Aside from the DPG groups, which mostly congregated during hot months, the CM horses were frequently observed in a large herd in which horses remained in their respective breeding groups. Elusive horses that were not consistently observed with other main groups of horses were identified and observed throughout the course of the study.

Field activities were performed from pre-dawn to twilight. In both herd areas, observations were made from vehicles, on foot, and at water sources. Infrared motion-detecting trail cameras were utilised during darting efforts in SWB to determine horse activity patterns and in CM to determine activity patterns, assist in individual identification, and monitor bait sites during baiting activities. To facilitate identification and relocation, CM was divided into four to six areas and SWB into six areas on the basis of water resources and landmarks. Observations were made weekly at each defined area and opportunistically to observe as many horses as possible. Individual horses and groups were recorded and photographed whenever sighted.

Horses were individually identified on the basis of their group associations, location, gender, age, colour, face and leg markings, unique identifiers, and mane and tail characteristics. Each positively identified individual was assigned a unique identification number, and for each study population, a horse-list inventory was updated weekly to reflect changes in population composition and group associations. Identification and association information was incorporated into summary spreadsheets and the Wild Horse Identification Management System (WHIMS; ©2010, Wildwise Solutions), which also catalogued photographs of individual horses.

Foals were matched to mares on the basis of nursing and other behavioural indicators of association. Population counts were finalised at the end of the observation season. CM estimates included horses that moved on and off the HMA into the part of DPG not included in the HMA, whereas SWB off-range populations were not reliably observed from year to year and therefore were not included in the population. Horses that cycled on and off range but were consistently observed were counted in the population.

Mortality was confirmed if a carcass was located or a euthanasia was reported by BLM personnel. Date of death was recorded if known. Carcasses and/or skeletal remains

found were investigated for cause of death but did not always yield sufficient information to reach a conclusion. Generally, a horse was classified as 'missing' when it was not observed for that observation year. Dependent foals not observed with their mothers and older horses that had been observed in poor health were presumed dead if they went missing. Otherwise, unless there was specific knowledge to the contrary, horses were assumed to be dead or dispersed if, at the end of the field season, they had not been sighted on or adjacent to the HMA for at least 2 years.

Gathers and PZP treatments

Helicopter gathers took place at CM 9–17 December 2008 and 21–27 February 2012, and at SWB 17–22 October 2008. During the December 2008 CM gather, 447 horses were removed, and 70 mares were treated with PZP and released along with 55 stallions. In the February 2012 CM gather, 75 horses (including 69 yearlings) were removed, and 143 mares were treated with PZP and released along with 130 stallions. (An additional 19 study animals were removed from DPG during a 2012 gather at the adjacent Onaqui HMA immediately before the CM gather.) During the October 2008 SWB gather, 280 horses were removed, 62 mares were treated with PZP and released along with 55 stallions.

PZP treatments are described in detail in Rutberg *et al.* (2017). Mares gathered in 2008 were hand-injected in the left hip with 'PZP-22' primers, consisting of 100 μg PZP antigen in 0.5 mL phosphate buffer solution emulsified with 0.5 modified Freund's complete adjuvant (mFCA) plus 450 μg PZP and 900 μg QA-21 (Agenus, Lexington, MA, USA) incorporated into lactide–glycolide pellets engineered to release at 1, 3, and 12 months ($N = 70$ at CM and $N = 62$ at SWB). Mares gathered at CM in 2012 were injected with either PZP-22 primers if they had not been treated previously ($N = 85$) or, if they had been treated in 2008 ($N = 58$), boosters of PZP-22 (with Freund's incomplete adjuvant, FIA) or simple emulsions of PZP in FIA.

Darting horses was attempted by approaching on foot or vehicle, stalking, sitting behind vegetation or creating natural blinds where no permanent structures were allowed. PZP booster treatments were administered by dart at SWB between 11 September and 17 November 2010, by using Dan-Inject® CO2 Pistol (Dan-Inject Dart Guns, Austin, TX, USA) and PneuDart X-Caliber® rifles (Pneu-Dart Inc.) firing barbless PneuDart darts. Mares previously treated in 2008 received either PZP-22 boosters ($N = 34$) or PZP-FIA emulsion only ($N = 16$). In addition to the 2008 and 2010 treatments, BLM management at SWB re-boosted 23 previously treated mares with PZP/FIA emulsions (one was boosted twice because of misidentification) between 4 April and 9 May 2013.

Data analysis

For the purposes of analysis, treated mares were defined in general as a mare that had received a PZP treatment, primer or booster, within the prior 3.5 years. Because the CM and SWB horses typically mate in April–June and the gestation period of horses is approximately 11 months, mares treated in October (SWB) or December (CM) of 2008 would already have been pregnant for the 2009 foaling season at the time of treatment. Therefore, these horses were first considered as treated in 2010. Likewise, mares treated in February 2012 (CM) would also have been pregnant at the time of treatment and the effects of the 2012 treatments would have first appeared in 2013.

Annual population growth was defined as end-of-year population size for year ($T + 1$) divided by the end-of-year population size for year (T). The effect of the 2012 removals at CM was removed from the 2011–2012 population growth estimate by subtracting the number of animals gathered from the end-of-year 2011 estimate.

In preliminary analysis, linear modelling (Automatic Linear Modeling, SPSS Statistics 26), using proportion of mares treated, adult sex ratio, annual precipitation, and vaccine effectiveness to predict annual population increase identified the model including only a proportion of mares treated and effectiveness as the best fit on the basis of Akaike's information criterion adjusted for small sample sizes (AIC_C). Similar results were found in stepwise regression ($P = .05$ for inclusion), in which location (CM vs SWB), method of administration (hand versus dart), mare age (proportion of mares greater or equal to 4 years old), and adult sex ratio were excluded as predictors, leaving only proportion of mares treated and vaccine efficacy as significant predictors of annual population growth. Consequently, only the last two variables are used to predict annual population growth below.

Analysis was performed with Microsoft Excel and IBM–SPSS. Vaccine efficacy is defined as the proportion, $(P_{untreated} - P_{treated})/P_{untreated}$, where P = proportion of mares foaling in a given year (following Baker *et al.* 2018). For purposes of analysis, we defined a fertility control index (FCI) as the proportion of mares treated times vaccine efficacy. Linear regression was used to test proportion of mares treated and the FCI as predictors of population reproductive rate and annual population growth.

Results

Mortality and disappearances

Mortality was low at both sites. At CM, 23 foals died from 2009 to 2015, averaging 2.9% of foals born each year (range: 0–4.4%; Fig. 1*a*). Among 1 + -year-old horses, mortalities and disappearances averaged 2.7% per year (range: 1.9–4.8%), with 2 + year-old stallions representing 52 of 129 (40%) known deaths and disappearances. At SWB, 23 foals died from 2009 to 2014, averaging 6.1% of all foals born (range: 2.4–12.7%; Fig. 1*b*). There were 36 deaths and disappearances among horses 1 + years old, averaging 2.1% of all known individuals in those age classes (range:

0.6–3.9%). Of the 22 deaths and disappearances, 61% were 2+-year-old males.

Where cause of death could be determined, deaths were associated with injuries, broken legs, old age with deteriorating body condition, loss of access to water (including one group of CM horses that was trapped in a rancher's fenced pasture), lightning strikes, complications during foaling, and vehicle strikes. Aside from scheduled population management gathers, horses were removed infrequently; these included one orphaned foal and four horses that moved off the HMA at CM and one bachelor male that found its way into a corral on a private ranch adjacent to SWB.

Herd sex ratios

Adult sex ratios in CM were stable with a slight male bias throughout the study, whereas foal sex ratios varied from year to year but averaged very close to 1:1 (adult SR, 1.1 m:f; foal SR, 0.98 m:f; Table 1). At SWB, adult sex ratios were somewhat male biased following the 2008 gathers, but a female-biased foal crop in 2009 restored the adult sex ratio to about 1:1 and both foal and adult sex ratios averaged very close to 1:1 for the remainder of the study (adults, 1.02 m:f; foals, 0.98 m:f; Table 2).

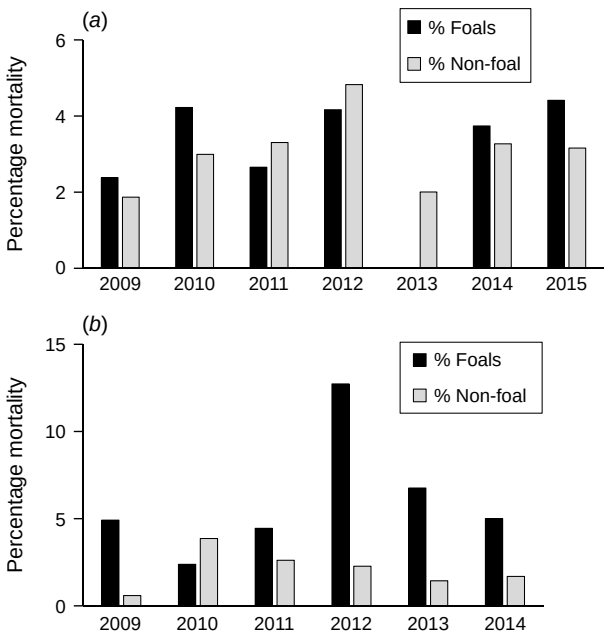

Fig. 1. Annual percentage mortality at (*a*) Cedar Mountain herd-management area, UT, 2009–2015, and (*b*) Sand Wash Basin herd-management area, CO, 2009–2014.

Application of contraception and herd reproductive rates

Efficacy of PZP-22 primers was lower than expected in 2008, with modest reduction of foaling rates in the initial 2 years after treatment at both sites (Table 3; Rutberg *et al.* 2017). Efficacy of the 2012 CM primers was high in the initial year after treatment (2013) but fell in 2014. Booster treatments were highly effective at both sites for at least 3 years after treatment. Of the 21 SWB mares initially treated in 2008, remotely boosted in 2010, and remotely boosted again in the spring of 2013, four (19%) foaled in 2014. Two mares treated only in 2008 and boosted in 2013 did not produce foals in 2014.

At CM, 51% of the mares known to be present in the population were hand-treated with PZP-22 in 2008 (including in the population 51 new mares identified and documented in 2009 on DPG after treatments had been administered). In February 2012, 69% of the mares known to be in the herd were treated, including 58 mares (92% of previously treated mares) that received boosters and 85 new mares that received initial injections of PZP-22. Both the primers and the boosters were highly effective that year, with only 11.4% of all treated mares foaling in 2013. The proportion of mares treated declined slowly after 2013 (Fig. 2*a*).

At SWB, 62 mares representing approximately 79% of the mares known to be present on the HMA at that time were hand-treated with PZP-22 in October 2008. By the time boosters were dart-delivered to a subset of 50 mares in autumn 2010, the herd had expanded, and treated mares represented only approximately 54% of adult SWB mares present. That proportion of treated mares continued to fall slowly through 2014 (Fig. 2*b*).

Overall, the proportion of mares treated following initial treatments averaged 51.4% at CM (2010–2015; range: 32.1–69.0%) and 46.6% at SWB (2010–2014; range: 30.6–76.9%).

Population foaling rates averaged 44.1% at CM (vs 61.6% pre-treatment (2009); range: 21.2–62.4%; Fig. 2*a*) and 49.2% at SWB (vs 78.2% pre-treatment (2009); range: 40.2–58.2%; Fig. 2*b*). In regression analysis with both study areas pooled,

Table 3. Summary of PZP-22 vaccine efficacy: foaling rates of treated and control mares (from Rutberg *et al.* 2017).

Treatment	Untreated controls (%)	Year 1 (%)	Year 2 (%)	Year 3 (%)
Cedar Mountains Primer 2008	63.9	26.1	55.9	–
Cedar Mountains Primer 2012	68.4	14.5	51.3	–
Sand Wash Basin Primer 2008	73.3	47.5	41.0	
Cedar Mountains Booster 2012	–	7.0	17.9	20.0
Sand Wash Basin Booster 2010	–	22.0	24.5	32.1

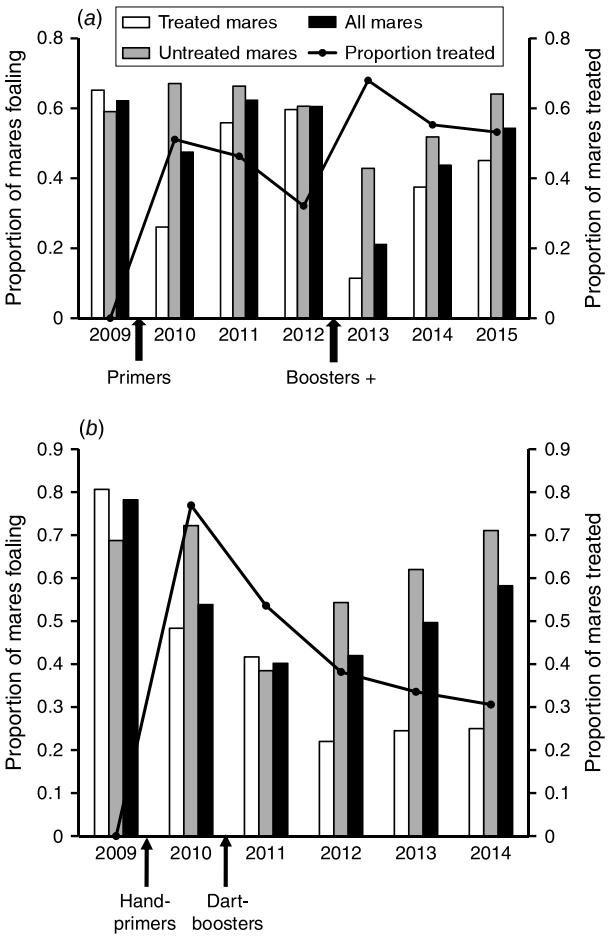

Fig. 2. Foaling rates and PZP treatments at (*a*) Cedar Mountains herd-management area, UT, 2009–2015, and (*b*) Sand Wash Basin herd-management area, CO, 2009–2014. Proportion of mares treated is defined as those mares that had received a PZP injection within 3.5 years.

the proportion of mares foaling was significantly lower when higher proportions of the mares were treated (Fig. 3*a*; $Y = -0.411X + 0.689$; $R^2 = 0.461$, $t = 3.07$, d.f. = 12, $P = 0.011$). Proportion of mares foaling in the two populations was more strongly predicted by the FCI, which also took into account vaccine efficacy (Fig. 3*b*; $Y = -0.841X + 0.675$; $R^2 = 0.756$, $t = 5.84$, d.f. = 12, $P < 0.001$).

Population growth

Including the effects of the removal at the 2012 gather, the CM population grew at an average annual rate of 11.8% from 2009 to 2015 (vs 1997–2000 rates of 24.4%; Fig. 4*a*). The lowest annual growth rate (5.8%, calculated from post-removal data and therefore not including the impact of the removals) was observed in 2013, one year after the 2012 administration of boosters to previously treated mares and of primers to new mares.

No animals were removed from the SWB herd after the gathers and removals were conducted in October 2008.

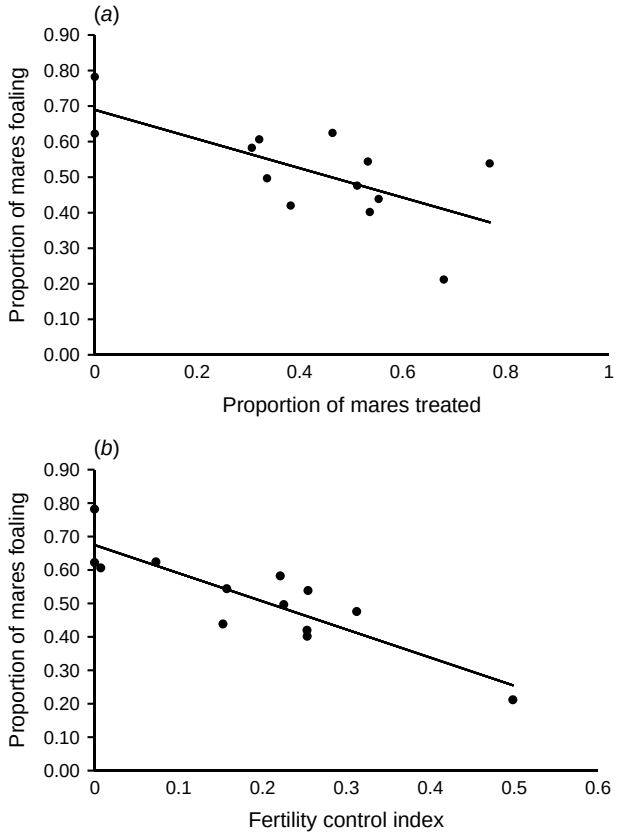

Fig. 3. Population foaling rate, both study sites pooled, versus (*a*) proportion of mares treated ($Y = -0.411X + 0.689$, $R^2 = 0.461$, $t = 3.07$, d.f. = 12, $P = 0.011$), and (*b*) fertility control index ($Y = -0.841 + 0.675$, $R^2 = 0.756$, $t = 5.84$, d.f. = 12, $P < 0.001$).

Between 2009 and 2014, population size grew at an average rate of 17.0% per year (compared with 2001–2004 annual growth of 22.0%), with the lowest rate of growth (13.3%) in 2012, the first year after the dart-delivered PZP boosters administered in fall 2010 took effect (Fig. 4*b*).

Because mortality and dispersal were low in both herds, population growth was mostly driven by foaling rate, and the predictors of population growth were similar to those of foaling rate. Proportion of mares treated significantly predicted annual population growth rate (Fig. 5*a*; $Y = -0.163X + 1.241$; $R^2 = 0.550$; $t = 3.80$, d.f. = 12, $P = 0.0025$), but population growth was better predicted by FCI (Fig. 5*b*; $Y = -0.300X + 1.229$; $R^2 = 0.734$; $t = 5.51$, d.f. = 12, $P \ll 0.001$).

Discussion

Independent corroboration of population inventories

Simultaneous double-count aerial surveys were independently conducted by the BLM and U.S. Geological Survey

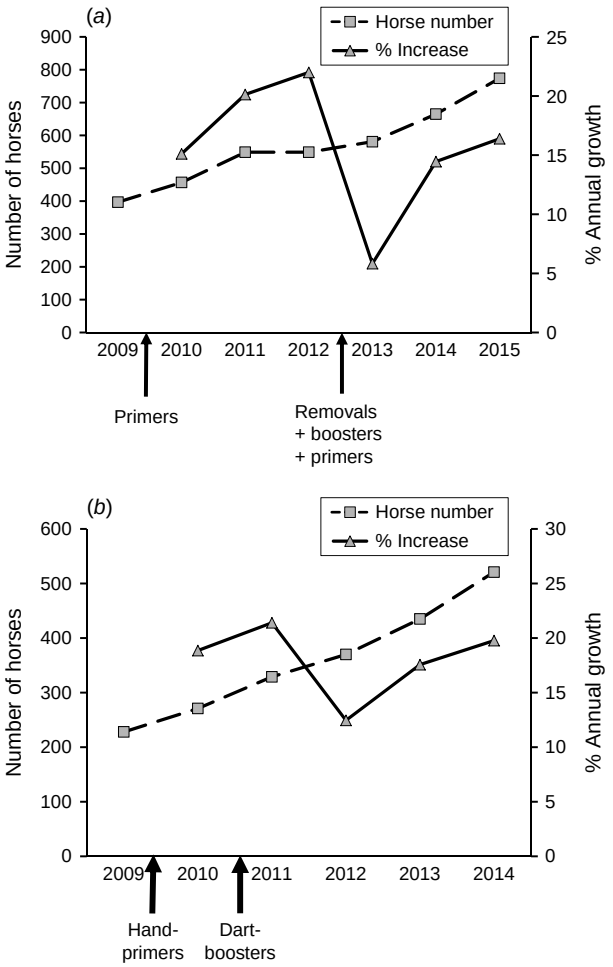

Fig. 4. Population size and growth rate at (*a*) Cedar Mountain herd-management area, UT, 2009–2015, and (*b*) Sand Wash Basin herd-management area, CO, 2009–2014. Arrows on *X*-axis indicate timing of when PZP treatments would take effect. To display the effects of contraception on growth rates more clearly, we calculated population growth rates in 2011–2012 at CM by subtracting the number of animals removed in 2012 from the 2011 baseline and used the post-gather 2012 numbers to calculate the rate of increase from 2012 to 2013. This produces the apparent discrepancy between absolute population size and population growth rate in 2011–2012.

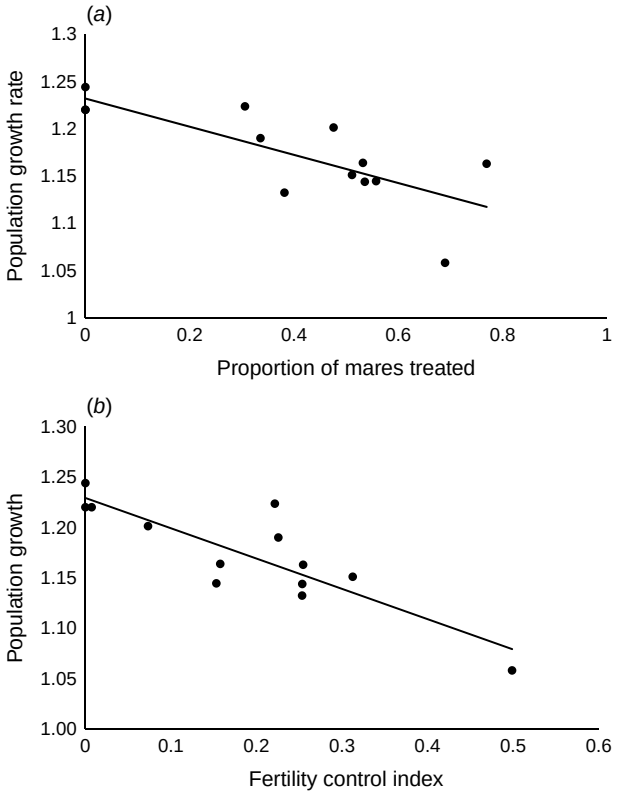

Fig. 5. Population growth rate and PZP treatments, both study sites pooled, versus (*a*) proportion of mares treated, and (*b*) fertility control index (FCI). Proportion of mares treated is defined as those mares that had received a PZP injection within 3.5 years. FCI is defined as the proportion of mares treated multiplied by vaccine efficacy.

post-gather on SWB and CM in February of 2009 (Lubow and Ransom 2016). Our SWB ground estimates fell within or close to the 95% CIs of the aerial survey estimates (aerial surveys, 133; 95% CI, 95–206; 128, 95% CI, 79–166; ground inventory, 169 adults and yearlings); low sightability associated with snow patches may in part account for the lower aerial survey count. Our 2009 CM end-of-year inventory number for adults and yearlings (315) plus the six adults known to have died or disappeared in 2009 (thus totalling 321) was very close to the CM aerial survey estimate (342) and well within the 95% CI (232–521). This corroboration adds confidence to our ground inventory numbers.

Population growth rates at SWB and CM

The regression of population growth rate versus FCI (fertility control index) permits a data-based prediction of what levels of population control will be obtained with a given proportion of mares treated and a given contraceptive agent efficacy (Fig. 5*b*). To achieve zero population growth in these two herds (annual growth = 1), the regression predicts FCI = 0.763, so that at 90% efficacy, for example, 85% of the mares would need to be treated to achieve ZPG.

This regression applies specifically to these two herds, in both of which reproduction and adult and foal survival are relatively high for wild horse herds generally (Garrott 1991; Linklater *et al.* 2004; Ransom 2012; National Research Council 2013), and movement of horses on and off range is modest. Herds with lower natural reproductive rates in untreated mares and lower survival will likely yield stronger population impacts for a given level of contraceptive effort, i.e. the regression line will be pushed downward. Mare age, which is known to influence reproductive rate (Linklater *et al.* 2004; Ransom *et al.* 2011; Rutberg *et al.* 2017), also is likely to influence the rate of population growth, despite the absence of statistically significant impacts in preliminary

modelling of population growth in this study. With those caveats, the regression should provide managers with a rough estimate of what effects on wild horse population growth a given level of contraceptive effort will provide.

The impact of contraception on population growth was most evident at CM, following treatments associated with the February 2012 gathers. In contrast to the 2008 gather, in which about half of the mares were gathered and treated, 69% of the mares remaining on the HMA following the 2012 gather received either a primer or a booster, and the booster proved to be more effective and long-lasting than the primer (Table 3; Rutberg *et al.* 2017). Population growth rate from 2012 (post-gather) to 2013 was only 5.8% in 2013 and remained slightly below the 15% threshold in 2014. This observation supports Bartholow's (2007) recommendation that managers think in terms of multiple cycles of contraceptive application.

The predictions of the impacts of contraception on wild horse population growth yielded by the current data-based relationship are generally in line with those of theoretical models (Garrott 1995; Gross 2000; Bartholow 2007). Empirically, Kirkpatrick and Turner (2008) reported that treating an average of 68% (range 52–95%) of mares annually stabilised and then reduced the population of wild horses at Assateague Island National Seashore, MD, although they effectively underestimated the proportion of females treated because the native PZP preparation they used showed some multi-year effectiveness among mares treated for three or more consecutive years.

Challenges to darting, monitoring, and management

Every free-roaming wild horse herd will yield its own specific management challenges.

In general, groups of horses at our sites tended to stay within their own established areas when water was plentiful. However, wild horses did move within and outside the HMAs in response to human activity, season, and especially water scarcity. Downed fences and other openings contributed to intermittent movements, such as, for example, allowing horses to move between CM HMA and adjacent Dugway Proving Grounds (DPG) to bordering water sources. Horses were also observed jumping low boundary fences; a neighbouring horse ranch that borders the western side of SWB would frequently find bachelor stallions inside their fences as domestic mares came into estrus during spring.

In 2008, when only about half the mares in the CM population were gathered, horses were scattered in small groups, and helicopter contractors struggled to capture them. Our inventory data also suggested that under these conditions, contractors underestimated the number of horses remaining on the range. CM gather efforts in 2012 were more successful in part because more horses were concentrated in open areas.

An additional risk of gathers was noted when contractors failed to return horses to the areas from which they were captured. Following the 2012 CM gather, eight horses became trapped inside a pasture without adequate resources (three died), six stallions disappeared, and three treated mares failed to return to their home range. These incidents account in part for the elevated non-foal mortality and disappearances observed in 2012.

Where feasible, remote darting of free-roaming animals is the safest, least expensive, and least invasive means to deliver immunocontraceptive vaccines. After initial administration of PZP-22 to mares gathered via helicopter round-up, remote darting of study subjects with PZP boosters was attempted at both CM and SWB. Success depended on wild horse wariness and gregariousness, the influence of water distribution on wild horse movements, vehicle access, and administrative restrictions placed on baiting and trapping (see also Naugle and Grams 2013). Remote darting at SWB was successful; at CM it was not.

Darting was unsuccessful at CM for multiple reasons. CM wild horses were generally unapproachable on foot, and the field environment was extremely challenging. Within the central 402 km^2 block of wilderness area inside CM, permanent structures such as blinds and trailers were prohibited or sharply restricted and vehicle movement was limited to a few designated roads. When, in late autumn 2010, the research team set up bait stations at CM to attract horses for trapping and darting with PZP boosters, horses failed to locate and habituate consistently to the bait sites before baiting was ended in November by a major snowstorm. In a follow-up baiting attempt in April, increased disturbance by range visitors and the wider availability of resources prevented horses from regularly visiting and concentrating at bait sites. Whereas concentration of horses in large groups in open areas helped helicopter contractors be more efficient (as noted above), such concentration discourages darting, and effectively confounded attempts to dart in CM in spring and summer of 2011.

Darting at SWB was also challenging; however, because SWB wild horses were less wary than were CM horses and more of the range is accessible by vehicle, darters ultimately succeeded by approaching horses on foot. However, unpredictability of water availability and horse movements hindered trapping at water sources, and access to SWB was inconsistent during winter months because significant precipitation quickly made roads impassable.

Management implications

This study is the first to demonstrate that the population growth rates of wild free-roaming horses in large herd-management areas (in the Western USA) can be substantially reduced by administration of contraceptives in the context of normal management activities. These studies also offer

managers a rough data-derived empirical guide to the magnitude of population impacts that can be expected when a given proportion of mares is treated with a contraceptive of known efficacy, whether it be PZP, GonaCon, or other agent. Application of data such as those presented here offers managers a useful approach to developing site-adapted projections of efficacy, cost, and outcome, and indicates what level of removals, if any, might be needed to supplement contraception to achieve population targets.

Strategies for administering contraceptive vaccines to wild horses will vary from site to site (Naugle and Grams 2013). In some herds, such as SWB, a majority of mares may be accessible and approachable enough to be treated via darting alone, whereas in others, gathers or bait-trapping (e.g. Carey *et al.* 2019) will be needed to ensure that a high enough proportion of mares will be treated to manage horses effectively.

Regardless of population targets, management goals, or means of access, one round of contraceptive treatments and/or removals will not yield effective management. Long-term planning, adaptive management, and persistence are necessary.

An infanticide attempt by a free-roaming feral stallion (*Equus caballus*)

Meeghan E. Gray*

Program in Ecology, Evolution and Conservation Biology, University of Nevada, Reno, NV 89557, USA
**meeghang@unr.nevada.edu*

Infanticide by adult males occurs in a variety of species. While infanticidal attacks have been documented in several equid species in captivity, it has never been witnessed in free-roaming feral horses. I report an infanticide attempt by a free-living feral stallion on a recently born female foal. The stallion picked up the foal by the shoulders, tossed it around twice and bit in on the neck several times. The dam of the foal charged the stallion and successfully protected her foal from additional attacks. The foal survived the attack and later weaned successfully. The stallion recently took over the band and was excluded as the sire through genetic analysis. While this type of attack is rare, this case lends support to the sexual selection hypothesis and further demonstrates that equids have evolved with the risk of infanticide. Furthermore, it shows that maternal protectiveness can be successful against attacks by infanticidal males.

Keywords: feral horse; maternal protectiveness; sexual selection hypothesis

1. INTRODUCTION

Infanticide, while rare, is a widely documented phenomenon in several mammal species including primates (Hrdy 1977; Crockett & Janson 2000; Watts *et al.* 2002), carnivores (Packer & Pusey 1983; Swenson *et al.* 1997) and rodents (Coulon *et al.* 1995; Vom Saal *et al.* 1995; Blumstein 2000). Male infanticide is generally considered to be an adaptive strategy whereby the interbirth interval is reduced, and the male can sire the subsequent offspring (Van Schaik 2000). Sexual selection infers a benefit to the reproduction of infanticidal males provided that only unrelated infants are killed, since infanticide is costly to males if related offspring are killed (Van Schaik 2000). Thus, recognition of paternity plays a key role in the evolution of this strategy.

With the exception of red deer (*Cervus elaphus*; Bartos & Madlefousek 1994) and the hippopotamus (*Hippopotamus amphibius*; Lewison 1998), the majority of cases of infanticide involving ungulates are reported in equids, including the horse (*Equus caballus*; Duncan 1982), Przewalski horse (*Equus przewalskii*; Ryder & Massena 1988; Feh & Munkhtuya 2008), mountain zebra (*Equus zebra*; Penzhorn 1984) and Burchelli's zebra (*Equus burchelli*; Pluhacek & Bartos 2000). Feral horses are unusual among ungulates in that they form stable harem-type groups year-round, consisting of one or more mares and usually one but sometimes several stallions (Linklater 2000). Band stallions are known to obtain high paternity within their band (Bowling & Touchberry 1990), but sneak copulations occur and mares change bands, which can result in paternity differences between foals (Miller 1981). In feral horses, infanticide has never been documented in the wild, but feticide may occur (Berger 1983). Feral mares have been shown to increase maternal protectiveness in response to paternity uncertainty (Cameron *et al.* 2003), which suggests that females have evolved to protect their foals from attacks against males. Here, I document a case of a resident band stallion attacking a young foal shortly after birth in a free-roaming situation.

2. MATERIAL AND METHODS

A feral horse population in the Virginia Mountain Range outside Reno, Nevada, was observed intensively from 2004 to 2008 for the purposes of another study. The total population fluctuated from over 1200 horses down to 1000 horses over the course of those years. The Nevada Department of Agriculture is responsible for managing the horses and the population size was and is still controlled by removals and contraception. The study included approximately 300 known individuals. Horses were habituated to human observers. The band in which the attack occurred was seen on a weekly basis to determine band membership and fidelity. At the time of the attack, the band consisted of two adult stallions, two adult mares, one juvenile male and one male foal. The band was being observed due to a recent birth of a foal and from that time, ad libitum observations were recorded until the end of the incident. All aggressive behaviours were documented and a description of these behaviours can be found in an equid ethogram (McDonnell & Haviland 1995).Genetic data were taken from faecal samples from the foal, dam and band stallion. Paternity was assessed using 12 polymorphic horse-specific microsatellites.

3. RESULTS

During routine behavioural observations on 12 April 2005, an infanticide attempt was witnessed. The band was passed at 15.40, while observing another band. At that time, the foal was not born. At 16.14, while passing the band again, the mare had recently given birth. A new female foal was covered with mucous and lying on the ground next to her dam. The foal was estimated to be no more than 1 hour old when the attack occurred and had not attempted to stand up. The rest of the band, including the dominant band stallion (stallion A), were all resting near the mare and newborn foal. At 16.20, a stallion (stallion B) from a nearby band called out and approached the mare. She immediately gave a head threat towards stallion B. The foal attempted unsuccessfully to stand up. The band stallion (stallion A) lunged towards the mare and foal and immediately bit the foal on the neck several times. Stallion A subsequently picked the foal up by the shoulders twice and shook it around several times. The foal was dropped to the ground and subsequently bitten and kicked by the front legs of stallion A several times. The attack lasted approximately 1 min. During the attack, the mare defended her foal by charging, biting and kicking stallion A, which led to the end of the attack. After the attack, stallion A had several aggressive interactions with stallion B and continued to try to herd the mare away from the area. The mare continued to charge and head threat stallion A when he came near her and she remained in her position over the foal. Stallion B called out again, which led to

another aggressive interaction between stallion A and the mare. While the foal appeared to be in shock, there was no visible major damage, but she suffered minor superficial wounds. The foal stood up at 17.39 and nursed at 17.47, and at that time the observations ended. The band was observed over the course of the next year and the foal successfully weaned.

The attacker (stallion A) was excluded as the father of the foal through microsatellite DNA analysis.

4. DISCUSSION

The attack was unmistakably an infanticide attempt as it was similar to other reported attacks in equids (Duncan 1982; Feh & Munkhtuya 2008). Most infanticidal attacks by stallions occur before the foal reaches one month (Pluhacek & Bartos 2000) and in this case, the foal was recently born. Infanticide imposes direct fitness consequences on the parents of the offspring, especially the mother. Such costs include decreased inclusive fitness, energy expenditure and the loss of investment (Ebensperger 1998). Females should adopt counterstrategies against infanticide in order to maximize their lifetime fitness (Ebensperger 1998). These counterstrategies include fighting back, having close associations with males for infant protection, prolonged receptivity, territoriality, avoidance and termination of infant care (Ebensperger 1998). In horses, mares will defend against infanticidal attacks (Feist & McCullough 1975; Ryder & Massena 1988) by generally positioning themselves between their foal and another approaching horse, even if no direct threat is apparent (Crowell-Davis & Houpt 1986). This protective behaviour was witnessed during the attack, as the mare defended her foal by charging and biting the stallion. She also tried to position herself between the stallion and foal and stood over the foal after the incident. All of these actions appeared to stop the attack and prevent further assaults.

There were several factors that possibly led up to this attack. First, genetic analysis confirmed that the band stallion was not the sire. Second, the band stallion had recently taken over the band and shared the band with another adult stallion. Owing to these factors, there was a high level of paternity uncertainty that may have influenced the decision to attack. Little is known about how males detect paternity, but evidence in primates suggests that males detect paternity by consort time, phenotypic matching or the amount of time spent within the troop during the mating season (Buchan *et al.* 2003). In this case, the male did not have a consortship with the female, nor did he spend anytime with this female during the previous mating season. The uncertainty of paternity has been postulated as proximate cause of an infanticide attempt (Borries *et al.* 1999) and is believed to be the major cause in this particular case.

Recently, infanticide in equids was suggested to be in response to human intervention (human disturbance hypothesis), as most cases have been associated with unnatural environments and introductions of foreign males (Feh & Munkhtuya 2008). While humans may influence infanticide attacks, most documented cases have also been associated with foreign males. For example, in equids, attacks end after males and females have been housed together for longer periods of time (Ryder & Massena 1988), suggesting that the unnatural conditions do not explain infanticide. In addition, many infanticidal events in the wild are associated with contact with foreign males, and attacks are generally attributed to these males. In this case, the male was relatively foreign in the band and several factors increased the level of uncertainty of paternity (i.e. multi-stallion band, recent takeover, no consortship before the foal was born). In addition, the similarity of attacks between equid species, maternal protectiveness and genetic data all suggest that equids have evolved with and respond to infanticide risk. Furthermore, infanticide has been postulated as a main explanation for primate social structure and the evolution of year-round male–female associations (Kappeler 1997; Van Schaik & Kappeler 1997). Feral horses have similar social structure to primates and male harassment plays a primary role in social structure (Linklater *et al.* 1999).

This was the only attack witnessed during 3 years of behavioural observations. Several studies suggest that feticide may be more adaptive in horses (Berger 1983), and there are some suggestions that infanticide is low risk in equids (Feh & Munkhtuya 2008). However, several foals go missing and are found dead every year in all populations, even when no predators are present. While these deaths could be due to numerous factors, infanticide is a possible cause of some deaths. Furthermore, foals not sired by the band stallion have lower survival rates to weaning (M. E. Gray 2008, unpublished data). All of this makes a witnessed event and possible causes important to document. To my knowledge, this is the first documentation of this type of attack in feral horses in a free-living situation and lends support to the role of infanticide in social structure.

ABSTRACT

Sex and reproduction influence mating systems and both are important for maintaining long-term associations between males and females. The mating decisions of females can have consequences for their reproductive success as females decide who to mate with and how often to mate. Females can mate with several males, but risk increasing chances of infanticide by having an offspring not sired by the behavioral father. Sexual interactions can also have social consequences, whereby females may engage in consortships that result in protection from harassment by other males. Thus, both sex and reproduction have important functions in the maintenance of male-female bonds in many mammalian species. Feral horses exhibit a rare social structure among ungulates in that they stay in year-round bands with several females and usually one male. Bands function to decrease harassment by other males and females in stable bands have higher reproductive success by forming consortships with harem stallions. Paternity analysis confirmed that most mares remain loyal to the band stallion and these foals have higher survival than those born in a band without their sire, indicating the importance of band fidelity for infanticide risk. I found females that changed bands suffered higher aggression rates, spent more time traveling and avoided the band stallion, further demonstrating the costs of male harassment. The socio-sexual behavior of females has been postulated as the proximate cause for the long term associations between mares and stallions. I found that fertility manipulation with two contraceptive formulations did not change male-female relationships, sexual behaviors or band fidelity. In addition, lack of foal production did not alter band fidelity. The two contraceptive formulations worked for multiple years with one injection, but were not as efficacious as other tested formulations. However, the

lower efficacy may be explained by the high intensity of research, resulting in high detection of contraceptive failure. Furthermore, there were individual differences in responsiveness as there was more contraceptive failure when females were in poor body condition. A meta-analysis of other studies on contraceptives confirmed that behavioral side effects occur after contraceptive treatment in a variety of species, suggesting the importance of experimental studies on the behavior and welfare of contracepted individuals.

ACKNOWLEDGEMENTS

This PhD is dedicated to my best friend, husband, and love of my life John Gray. This work would not have happened without his love and support. He gave me the courage to follow my dreams and kept me going when I realized how hard they were to accomplish. My life is better for knowing you.

This project was largely funded by the Hatch Grant and the Nevada Arid Rangeland Initiative from the University of Nevada, Reno. Financial support was also provided by American Society of Mammalogists, Animal Behavior Society, the UNR Graduate Student Association and EECB small grants. I thank my committee members, Stephen Jenkins, David Zeh, Mike Ashley and Kim Rollins for all of their valuable input during the entire process. I had the unique experience of having three advisors, so I must thank them individually. Mary Peacock was instrumental for taking me on as a student and forcing me to critically think about my work. I am grateful to David Thain for always having the time and resources to support me. It has been a pleasure to work for someone who has so much passion and integrity for his job. I will never be able to thank Elissa Cameron enough for everything. Elissa gave me the inspiration to keep going many times, and shared my passion for my research. I will never be able to repay all of her kindness and support. I thank the Cameron Lab for lots of laughs and support, especially in Finland!

This research would not have been possible without the support and collaboration with the Nevada Departments of Agriculture and Corrections and USDA/APHIS Veterinary Services, especially from David Thain, Holly Pecetti, Gary Cole, Jerome Peterson, Kitty Dominguez, Chris Collis, Anette Rink, Tim Bryant and Keith Forbes. I

want to express gratitude to Mike Holmes, the range manager, who was always there to assist in the project, was invaluable to the logistics and always treated me like one of the guys (even when I wanted to cry)! I need to acknowledge several Carson City Correctional Facility inmates who worked very hard to help with gathers, treatments, and captive studies. I thank the National Wildlife Research Center for providing the contraceptive formulations, especially Lowell Miller. I want to thank Gary Killian who provided valuable discussions about my research. I am grateful to USDA/APHIS Wildlife Services, including Scott Jenson, for conducting aerial horse counts twice a year during my study and especially Jack Spencer for all of his help and support on this project. I am eternally grateful to several private landowners who graciously gave their permission to work on their private property, especially Sherry O'Mahoney, Jay and Iris Campbell, Bill and Anita Henderson and several others who wish to remain anonymous. I thank the Virginia Range Wildlife Protection Association (VRWPA) for helping to get the project started and introducing me to many bands. A special thanks to Tony West for always kept me safe in the field and was there to help whenever I needed it.

I want to acknowledge the entire Ecology, Evolution and Conservation Biology Program and all of the students and faculty for support, especially the Tracy lab, Bridgette Hagerty, Murrelet Halterman, Juliana Almeida, Larry Hillerman, Lou Christensen, Pauline Jasper, Lucy Morris, Kerrie Medeiros and Heidi McConnell. I would especially like to thank my best friends Natalie Marioni and Angela White for being such wonderful friends and supporters. I would have never made it without you! I thank Christie Howard for being an amazing mentor to me when I first arrived in graduate school. I would like to express gratitude to Janita Jerup, Susie Yamamoto and

Esmail Zanjani from the Animal Biotechnology Department for logistic support. I thank several volunteers including Sarah Medill, Karen Orchard, Tracy Kipke, Matt McMillian and Ryan Cody. I am grateful to Wayne Linklater for help with manuscripts and allowing me to use some of his data and Ania Panorska for help with statistical analyses.

I appreciate the Nevada Genomics Center for all of the help with genetic analysis, especially Kris Kruse. The genetics would not have been possible without the substantial help of Veronica Kirchoff. I thank the St. Louis Zoo Endocrinology Lab, especially Joan Bauman and Corrine Kozlowski, who were extremely helpful with the fecal hormone analysis. I thank the McNair Scholarship Program for getting me interested in biology and field work and helped me to make the decision to pursue graduate school.

I am especially indebted to my parents, Kathryn Windsor and Charles Simmons, who raised me with a strong work ethic and ambition, and fostered a curiosity of all animals. I thank my mother who gave me the inspiration to pursue a career and higher education and always encouraged every aspect of my life! I thank both of them for all of their love and support. I am grateful to my in laws, Tom and Andrea Gray, for both mental and financial support. I thank my "second" parents Debe and Randy Clerc for all of their comic relief and tremendous amount of love and support (50/50!). I am eternally grateful for the companionship I received from Doobie, Kayla, Pepper, Millie, Peeps, Rudy and Tripp.

Lastly, I would like to thank my research subjects, the feral horses. They provided me with countless hours of entertainment and allowed me to observe their lives for several years. I will always remember my field work as some of the best moments of my life.

INTRODUCTION

"The wind of heaven is that which blows between a horse's ears."
Arabian proverb

Photo caption: G Band, subordinate stallion (DBS)

INTRODUCTION

Selection pressures on group living mammals have been traditionally linked with resource distribution and predation (Krause and Ruxton 2002) and yet social factors may have a stronger influence on the formation and maintenance of groups (Clutton-Brock et al. 1992). There is increasing evidence that male harassment and infanticide risk are important influences that determine social structure, suggesting that group living may have benefits beyond predation risk and availability of resources (Williams et al. 2004, Muller et al. 2007, Cappozzo et al. 2008). For males, living in stable groups with females can increase mating opportunities and subsequent paternity of offspring (e.g., Huck et al. 2005, Kappeler and Schäffler 2008). Females benefit from lower rates of harassment, lowered risk of infanticide, and higher body condition, all of which can increase their reproductive success (Linklater et al. 1999, van Schaik and Kappeler 1997).

Within groups, the mating strategies of females can have implications not only for their own reproductive success, but also for the males living in their groups. For example, females can form consortships with males during fertile stages of estrous and throughout pregnancy and offspring dependency (Dixson 1998). Females can benefit from these associations by decreased harassment from other males and increasing their offspring survival (Smuts and Smuts 1993, Dixson 1998, Linklater et al. 1999). The maintenance of these associations has been linked to affiliative and sexual behaviors. However, females may mate with other males both within and outside the group, which can decrease offspring survival, particularly through infanticide (van Schaik 2000).

Hypotheses concerning the role of social factors in group formation and maintenance have been tested primarily in primates and carnivores (Packer and Pusey

1984, van Schaik 2000) and have yet to be tested in wild ungulates with similar social systems. In addition, it is unknown if the manipulation of fertility impacts sexual behavior and social behavior of females and ultimately the fidelity of these long term associations.

Feral horses as a model

Feral horses are ideal for testing hypotheses on the influence of social factors (e.g., male harassment, paternity, mating, and pregnancy) on social behavior and group fidelity. They are unusual among ungulates in that they live in harem bands and maintain stable year-round social relationships over long time periods (Klingel 1979, Berger 1986, Linklater 2000). Harassment by males has been proposed as a factor that strongly influences feral horse social structure, with one of the primary roles of a harem stallion being to minimize harassment by non-band males (Linklater et al. 1999). Since band stallions defend their females from other males, dominant males are expected to achieve high paternity of offspring within their band. Thus, if paternity is high within a band, infanticide should be rare and only occur when a male can shorten the time to a female's next estrous cycle. The rarity of infanticide does not imply absence of these events or that it is not a strong selective force since infanticide has been reported in all equids [horse, *Equus caballus* (Duncan 1982); Przewalski horse, *Equus przewalskii* (Ryder and Massena 1988; Feh and Munkhtuya 2008); mountain zebra, *Equus zebra* (Penzhorn 1984); and Burchell's zebra, *Equus burchelli* (Pluháček and Bartoš 2000, 2005)], and mares are more protective of foals in situations where paternity is uncertain (Linklater et al. 1999, Cameron et al. 2003). Under such circumstances, females are expected to be

more protective of foals not sired by the band stallion. While changes in female behavior are known to occur when paternity is uncertain, there have been no studies that directly link actual paternity with these behaviors and how paternity is correlated with offspring survival.

Feral horses are also ideal to test predictions about the importance of reproduction and fertility on the social behavior of females and band fidelity. Females often stay in bands for long periods of time or for most of their lives after natal dispersal (Klingel 1979, Berger 1986, Linklater 2000). There appears to be strong selection for mate fidelity and band loyalty by females so as to decrease harassment by other males because females that change bands have higher parasite loads, lower body condition, and higher harassment rates (Linklater et al. 1999). The social structure of long term harem bands is thought to be supported by the socio-sexual behavior of mares (Asa 1986). Female horses are unlike most ungulates in that mares display sexual behavior throughout the year (Asa 1986). Thus, sexual behavior, regardless of whether mares become pregnant, may be important to the maintenance of band stability. As a result, the manipulation of fertility of females may have important behavioral and social consequences. Recently, contraception has been proposed as a viable, alternative management strategy to removals for feral horse populations. The manipulation of fertility is a way to test the role of sex and reproduction in male-female consortships and band fidelity.

My study investigated the influence of social factors on the stability and maintenance of harem bands by asking the following questions:

1) Is paternity reliable in stable harems bands, do females change maternal behavior in response to the paternity of their offspring and does paternity influence foal survival?

2) If sexual interactions and reproduction are important for maintaining mare-stallion relationships, what happens to band fidelity and consortships when fertility is manipulated?

3) Does fertility manipulation alter behavior in other species?

Study population

The feral horse population was located in the Virginia Range (145,000 ha) in Storey County, outside of Reno, Nevada (Figure 1). Since the mountain range was declared “wild horse” free by the US Bureau of Land Management in the 1980’s and is private land, the horses are legally defined as estray horses by Nevada statute and are managed by the Nevada Department of Agriculture. Currently, the total population is about 1400 horses, but the study population consisted of 300 individuals including 74 mares from 49 bands that were intensively observed for the duration of the study (2005-2008). The study population was located in the northwest section of the mountain range.

This study was initiated in June 2005 when females were treated with two different contraceptive formulations and were followed until August 2007. We used two different formulations that decrease fertility in significantly different ways. First, SpayVac® is a porcine zona pellucida (PZP) formulation that acts to block fertilization and allows for continued and sometimes increased cycling (Brown et al. 1997, Fraker et al. 2002, Killian et al. 2008). In contrast, GonaCon-B™ is a gonadotropin-releasing hormone (GnRH) vaccine that acts to block cycling altogether by significantly reducing the production of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Miller et al. 2000, Killian et al. 2006, 2008). During the course of the study, horses were

easily indentified by coat color and white markings and adult mares were freeze branded with a unique mark. Most bands habituated to human observers, making behavioral observations easy. Lastly, the study was done blind, so all behavioral observations took place before contraceptive treatment and paternity status of offspring was revealed.

The Study

I was interested in the social factors involved in harem band formation and maintenance, especially offspring paternity and the influence of mating behavior and pregnancy in maintaining long term associations between males and females. I investigated how social behavior can be changed by fertility manipulation and paternity of offspring. My dissertation is organized into five separate papers intended for publication. Consequently, there is some repetition among chapters, particularly in the methods sections.

In the first chapter, I look at how often females have offspring sired by the band stallion and under what circumstances females seek extra-band copulations. I also investigate if females are more protective of foals sired by an extra-band stallion and if foal survival is related to paternity. Previous research indicates that females may be more protective of foals when paternity is uncertain (Cameron et al. 2003), but linking such behaviors to actual paternity has not been done previously. Furthermore, band stability and the tenure of consortships have been shown to increase reproductive success of females (Kaseda et al. 1995, Linklater et al. 1999) and here I investigate additional benefits of not only staying in a band, but having a foal sired by the band stallion. In

addition, I document the first reported case of an infanticide attempt in feral horses and investigate the circumstances under which this attack occurred (Chapter 2).

The next chapter examines how fertility can be manipulated with contraceptive treatment. I compare two contraceptive treatments, SpayVac® and GonaCon-B™, to controls in order to test if these formulations reduce foaling rates in females. Previous studies have shown that these formulations can last up to five years with one injection (Killian et al. 2008), but this is the first test in free-roaming feral horses. I also show how efficacy can be influenced by body condition at time of treatment and discuss some issues with methodologies for evaluating efficacy rates in horses. Since concerns have been raised about the potential side effects of contraceptive treatment, I investigate how treatments could impact foal sex ratio and foal survival in mares for which the contraception failed. Previous studies have raised theoretical concerns about the side effects of contraception (e.g., Nettles 1997). However, the potential role of contraception as an experimental tool to manipulate fertility has been largely overlooked. Therefore, in Chapter 4 I consider whether contraceptive treatment results in changes in physiology, ecology and particularly behavior by reviewing the literature on contraceptive side effects and performing a meta-analysis. I then consider the utility of contraception as an experimental tool.

In Chapter 5 I examine how contraceptive treatment can impact the behavior of mares in relation to band stability and consortships with stallions. Few studies have investigated behavioral side effects of contraceptive treatment, especially in wild social mammals (but see Nuñez et al. 2009). Consortships are important to reproductive success of mares and are thought to be maintained by copulations and other sexual interactions

(Asa 1986, Kaseda et al. 1995, Linklater et al. 1999). Furthermore, mares show receptive behaviors during anestrus and during the nonbreeding season, which have been proposed to maintain stallion interest and strengthen the bonds between males and females year-round. I look at how fertility manipulation can change sexual interactions and social behavior of mares and how both could influence band stability.

Finally, I discuss behavioral consequences of contraceptive treatment and paternity of offspring in feral horses. I further discuss the management implications of contraceptive treatment in feral horses.

CHAPTER 1

Low occurrence of extra-band copulations and parental behavior in response to actual paternity in free-ranging feral horses

“Maternity is a matter of fact; paternity is a matter of opinion.”
American Proverb

Photo caption: Thunder band; band stallion and mare (1/M) mating

Abstract: A growing number of studies conducted on diverse taxa have shown that extra-pair/group paternity is higher than what would be predicted from behavioral observations alone. While the benefits outweigh the costs for females to mate with multiple males in many situations, this often results in offspring not sired by the behavioral father, which could influence offspring survival, especially in social mammals. Feral horses (*Equus caballus*) maintain stable social relationships over several years, usually with one stallion defending a harem band of unrelated mares against other males. Sneak copulations by subordinate males have been observed and mares sometimes change bands, both of which can result in foals sired by males other than the socially dominant band stallion. We measured mare fidelity in free-ranging feral horses in 23 bands, with 51 foals over 4 foaling seasons and tested offspring paternity against parental behaviors. Genetic samples were obtained from both blood and feces. We used 12 polymorphic microsatellite loci and the program CERVUS 2.0 to determine and exclude potential sires. The majority of mares remained stable in the band with the sire of their foal resulting in most foals being sired by the band stallion. Most offspring not sired by the band stallion were the result of mares changing bands and not extra-band copulations. Foals born in a band without their sire had lower survival and suffered more aggression from stallions. Mothers were significantly more protective of foals not sired by the dominant stallion. These findings show the benefits of band stability to the reproductive success of mares and appear to support the importance of harassment and infanticide risk in equid social structure.

Introduction

Selection theory predicts that individuals should attempt to maximize lifetime reproductive success in terms of both offspring survival and numbers, but optimal strategies could vary markedly between the sexes, because the costs of producing gametes differ between males and females (Andersson 1994). For males, gametes are generally cheap and easy to produce (Bateman 1948, Trivers 1972). Consequently, males are predicted to maximize their reproductive success by mating with as many fertile females as possible (Andersson 1994). This occurs directly through male-male competition by either controlling females or excluding other males from territories or indirectly by controlling access to critical resources (Emlen and Oring 1977). Conversely, female gametes are more costly, limiting the number of offspring that females can produce (Bateman 1948, Trivers 1972), with a single mating being sufficient to produce an offspring (Trivers 1972). Furthermore, in mammals, females are the primary caregivers due to the constraints of lactation. Therefore, since females invest heavily in individual offspring, they should be the choosier sex in mate selection and select high quality males to maximize their reproductive success (Andersson 1994). Such sexual selection leads to male and female reproductive tactics that differ in ways that create conflict over who to mate with, how often to mate, and levels of parental investment (Andersson 1994).

Female choosiness does not imply that females will not seek additional matings from males other than the behavioral father or dominant group male since they might receive benefits by mating with the highest quality male (Jennions and Petrie 2000). However, the costs of sneak copulations to females can be substantial due to increased

risks of sexually transmitted diseases, aggression, and increased predation risk due to conspicuousness (Daly 1978, Arnqvist and Rowe 2005). Nonetheless, numerous studies have shown that there are potential advantages to females who seek extra-pair/group matings including direct benefits such as nuptial gifts (e.g., Wedell 1997), increased parental care (Nakamura 1998), confusion of paternity (Hrdy 1979, van Schaik et al. 2000), or increased litter size (Dewsbury 1984), as well as indirect benefits. Indirect benefits appear to explain a large proportion of cases, and include genetic advantages that increase offspring performance, diversity or viability (e.g., Andersson 1994, Endo and Doi 2002, Cohas et al. 2007, Suter et al. 2007, Dreiss et al. 2008), inbreeding avoidance (Tregenza and Wedell 2002), guarding against male infertility (Preston and Stevenson 2001), and genetic compatibility (Zeh and Zeh 2001, reviewed in Stockley 2003). While the benefits often outweigh the costs of mating with multiple males, this often results in offspring not sired by the behavioral father, which could influence offspring survival, especially in social mammals and particularly through infanticide (van Schaik 2000).

Several mammalian species have long lasting social bonds in which several females and males remain in groups beyond the mating season. Males secure matings by defending females (female-defense polygyny) or resources to attract females (resource-defense polygyny) (Emlen and Oring 1977). In these groups, male reproductive success is usually heavily skewed in favor of a few, often dominant males, although other males do get some mating opportunities (e.g., Huck et al. 2005, Brauch et al. 2008, Kappeler and Schäffler 2008). If females mate with males from other groups or subordinates within the group then males may lose opportunities to maximize reproductive success, or even expend valuable resources on females raising offspring sired by other males, thus

creating another conflict between the sexes. The most extreme form of conflict can result in the death of an offspring (infanticide, van Schaik 2000). Males from many species kill young conspecifics that are not genetically related to them (e.g., lions, Packer and Pusey 1984; primates, reviewed in van Schaik 2000; rodents, Cicirello and Wolff 1990, Coulon et al. 1995, reviewed in Blumstein 2000; equids, reviewed in Gray 2009). Males will benefit from infanticide only if certainty of paternity is high, so as to minimize the risk of killing their own offspring, and if the female becomes reproductively active earlier without dependent offspring (Packer and Pusey 1984; Sommer 1994, Borries 1997, Borries et al. 1999). Females however, would benefit from raising their current offspring regardless of paternity, and have adopted counter-strategies to protect offspring from such infanticidal attacks (Ebensperger 1998). Females then benefit from tactics to maximize protection against males, or confuse males about paternity (Hrdy 1979, van Schaik and Kappeler 1997, van Schaik et al. 2000). Hypotheses concerning mating strategies, paternity, infanticide, and female protectiveness have been tested primarily in primates and carnivores (Packer and Pusey 1984, van Schaik 2000), yet many of these hypotheses have yet to be tested in wild ungulates with similar social systems.

Feral horses (*Equus caballus*) are female-defense polygynous mammals that maintain stable year-round social relationships over long time periods (Feist and McCullough 1976, Klingel 1979, Berger1986, Linklater 2000). They group in harem bands with usually one, but sometimes several males defending a harem of unrelated females and their offspring from other males in the population (Feist and McCullough 1976, Klingel 1979, Berger1986, Linklater 2000). The adult sex ratio is usually even, so males without harems join ephemeral bachelor groups (Berger 1986, Khalil and Kaseda

1998). All male and female offspring disperse from their natal band, usually before reproductive age; therefore inbreeding remains low is most populations (Feist and McCullough 1975, Klingel 1979, Berger 1986, Monard et al. 1996). Females are limited to one foal per year and typically give birth in the spring (Feist and McCullough 1975, Keiper and Houpt 1984, Crowell-Davis and Houpt 1986). Since band stallions defend their females from other males, dominant males are expected to achieve high paternity of offspring within their band. Previous studies have shown that band stallions appear to attain a high fraction of paternity within their bands, but these results were only based on blood typing and do not have the level of accuracy of genetic methodologies present today (Bowling and Touchberry 1990, Feh 1990). These improved methodologies for determining paternity, specifically microsatellites, have shown that females from a wide variety of taxa engage in extra-pair/group copulations (e.g., Griffith et al. 2002, Lane et al. 2008, Munshi-South 2007). In feral horses, sneak copulations by bachelors and subordinates are observed, and mares sometimes change bands, all of which can result in foals sired by males other than the dominant band stallion (Miller 1981).

Since paternity is expected to be high within a band, and bands stay together for multiple reproductive seasons, paternity should be relatively predictable. Under such circumstances, infanticide would be favored if foal-killing enhanced the mother's return to fertility. Infanticide has been reported in all equids [horse, *Equus caballus* (Duncan 1982); Przewalski horse, *Equus przewalskii* (Ryder and Massena 1988; Feh and Munkhtuya 2008); mountain zebra, *Equus zebra* (Penzhorn 1984); and Burchell's zebra, *Equus burchelli* (Pluháček and Bartoš 2000, 2005)], including feral horses (Gray 2009). In addition, mares are more protective when paternity is uncertain, such as in multi-

stallion bands (Linklater et al. 1999, Cameron et al. 2003), with mares positioning themselves between their foals and other horses and actively defending their foals against attacks (Crowell-Davis and Houpt 1986). Stallions are also more protective of foals that are born within their bands than they are of other foals (Berger 1986, Boyd 1991), suggesting that both males and females assess paternity and change their behaviors accordingly. While changes in female behavior are known to occur when paternity is uncertain, there have been no studies that directly link actual paternity with these behaviors.

The aim of this study was to assess male reproductive success in free-ranging feral horses over 4 foaling seasons using DNA from fecal samples. We therefore asked (1) how often band stallions sire offspring in their bands, (2) what is the rate of mate fidelity by females, (3) what is the frequency of occurrence of extra-band copulations and (4) under what circumstances do females seek extra-band copulations. In horses, some of the major hypotheses that predict extra-band mating would not apply (e.g., decreased harassment, confusion of paternity, inbreeding avoidance, Wolff and MacDonald 2004). Therefore, we predict a low occurrence of extra-band copulations since bands are stable over long periods of time and both harassment and infanticide by foreign males would be extremely costly to females (Linklater et al. 1999). Sexual harassment influences feral horse social structure, with one of the primary roles of harem stallions being to minimize harassment by non-band males (Linklater et al. 1999). In addition, as females disperse from their natal bands, the risk of inbreeding is low. Under all of these circumstances, we predict the costs would be high and outweigh the benefits of this behavior in females. We hypothesize that sneak copulations may occur when females are seeking increased

male quality, thus most sneak copulations would occur with other band stallions as opposed to bachelors.

In addition to quantifying male reproductive success, we tested whether stallion aggression and harassment toward foals and mare protectiveness of foals were related to paternity, and tested whether there was any difference in foal survival in relation to whether the resident stallion was their father. We predicted that foals not sired by the band stallion would have an increased risk of infanticide, suffer higher rates of aggression by the band stallion, and have lower overall survival rates. We also predicted that females would increase their protective behavior as a counter-strategy to infanticide risk by maintaining more contact with their foals not sired by the dominant stallion. Here we present results of the first study investigating paternity with microsatellites in feral horses and how both maternal and paternal behaviors are linked to actual paternity.

Methods

Study Site

The study was conducted in the Virginia Range centered at 39°26'N and 119°30'W, located southwest of Reno, Nevada. The range is approximately 145,000 hectares and is mostly privately-owned land. The population size of the free-roaming horses was around 1400 individuals, and these horses were managed by the Nevada Department of Agriculture. Other ungulates in the range included mule deer (*Odocoileus hemionus*) and pronghorn (*Antilocapra americana*). The mountain range is dominated by sagebrush (*Artemesia tridentata*) at lower elevations. Other common species in this community include rabbitbrush (*Chrysothamnus nauseosus*), bitterbrush (*Purshia*

tridentata), bluegrass (*Poa secunda*), cheatgrass (*Bromus tectorum*), blue mustard (*Chorispora tenella*) and fiddleneck (*Amsinckia intermedia*). Jeffrey pine (*Pinus jeffreyi*), singleleaf pinyon (*Pinus monophylla*) and Utah juniper (*Juniperus osteosperma*) are found in higher elevations on top of ridges.

Subjects and Sampling Regime

We gathered horses (N=222) into purpose-built yards with the aid of helicopters by the Nevada Department of Agriculture in June 2005 for the purposes of a contraception trial. All females were individually freeze-branded with a unique code for future individual identification and blood was taken from every adult horse. At that time, most adult horses were aged using tooth eruption and wear patterns (Tutt 1968), which were used to classify mares into age categories. We classified mares from 3-5 years old as young since mares do not reach their full reproductive potential until the age of 5 (Berger 1986), and in our study, no mare younger than three gave birth to a foal. We classified mares from 6-8 years as medium age and because aging becomes inaccurate for wild horses 10 years and older (Richardson et al. 1995), we classified all females 9 and older in the old category.

We collected behavioral data on 23 focal bands that were located on a weekly to monthly basis from 2005-2007. Bands were encountered randomly and behavioral observations were evenly distributed during daytime hours. Behavioral sampling periods lasted for up to one hour or until the focal animal moved irretrievably from view. Adults were identified by individual freeze brands or by coat color and unique white markings on the face and legs. Observations were done from a vehicle or on foot within an

approachable distance to habituated bands or with binoculars from greater distances. Mares with foals born in 2006 and 2007 foaling seasons were studied to maximize information known about each foal. Behavioral data were collected during the period of offspring dependency until foals were weaned, died, or the end of the study. The sex of each foal was recorded shortly after birth by sighting external genitalia and the type of band the foal was born in (single stallion vs. multi-stallion) was recorded.

Behavioral Data Collection
