Sexual behavior of mares

Sharon L. Crowell-Davis *

Department of Anatomy and Radiology, College of Veterinary Medicine, University of Georgia, Athens, GA 30602, USA

Received 27 March 2007; revised 27 March 2007; accepted 28 March 2007
Available online 1 April 2007

Abstract

The mare is seasonally polyestrus, having an anovulatory period during the short light days of late fall and early winter, and beginning to ovulate as the days become longer during the winter. The complete estrus cycle is typically about 3 weeks, with 5 to 7 days of estrus and approximately 2 weeks of diestrus. When a mare lives within the natural social structure of the horse, i.e. a family band with several adult mares and one or more stallions, estrus is characterized by repeatedly approaching the stallion, frequent urination, deviating the tail away from the perineum, and standing still with the hind limbs spread apart. Diestrus is characterized by avoidance of an approaching stallion, and aggression toward the stallion, such as squealing, striking, and kicking, if he persists in attempting to court the diestrus mare. However, mares and stallions with long-term social relationships will often rest together, graze together and groom each other, all without sexual interactions. Hormonally, estrous behavior in the mare is initiated by estradiol that is secreted by the follicle, while estrous behavior is suppressed by progesterone, secreted by the corpus luteum. Mares are unusual among the ungulates in that they periodically exhibit estrous behavior during the anovulatory period. This is probably due to the release of estrogenic steroids secreted by the adrenal cortex. The display of sexual behavior by the mare throughout the year is thought to facilitate maintenance of the horse's social structure, in which the male remains with a group of females year round, in contrast with most ungulates in which the females and males only come together during the mating season.

Introduction

The sexual behavior of the mare has evolved in the social context of family groups that typically consist of multiple adult mares and their young offspring, plus one or more adult stallions. This long-term cohesive family structure is probably an important factor in the evolution of the unusually long period of estrus in the mare, i.e. 5–7 days versus 1–2 days for other female ungulates. The long period of estrus in all the mares of the herd would facilitate maintenance of proximity to the mares by the herd's stallion. While strong social bonds develop between the mares and the stallion(s), the social core of the group is formed by the mares, and it is not necessary for the stallion to be present for the mares to remain as a cohesive group. Nevertheless, the stability of a mare's consort relationship with a given stallion significantly correlates with her lifetime reproductive success (Kaseda et al., 1995). In the context of sexual interactions with the stallion, however, the mares may become very competitive, and if more than one mare is in estrus at one time, the higher ranking mare will actively disrupt interactions between the subordinate mare and the stallion and drive the subordinate away from proximity to the stallion (Asa et al., 1979).

Normal estrus cycle

The mare is seasonally polyestrus, with estrus cycles beginning in mid to late winter and continuing through the early fall. Increasing daylight length plays a major role in the initiation of cycling, and the use of artificial light can induce a resumption of cycling earlier than would happen under natural conditions (Allen, 1977; Colquhoun et al., 1987; Hughes et al., 1972; Kooistra and Ginther, 1975; Palmer et al., 1982; Sharp, 1980). With an 11-month gestation period, this timing maximizes the likelihood that foals will be born and spend their first few months of life at a time when the weather is warm and food is plentiful. The exact months that a mare will ex-

doi:10.1016/j.yhbeh.2007.03.020

perience estrous cycles depend on the latitude at which she lives. On Assateague Island National Seashore, which lies off the east coast of the United States, most foals born to the feral ponies that live on this island are conceived in May, June, and July and born the following April, May, and June (Keiper and Houpt, 1984). A period of follicular growth and ovulation, accompanied by behavioral estrus, generally lasts 5–7 days. Insemination by a fertile stallion 48 to 72 h before ovulation will generally result in conception (Brinsko and Varner, 1993). While insemination 4–5 days before ovulation can potentially result in conception, rates are much lower. If the mare does not conceive during this period, a period of diestrus, with the development of corpora lutea and an absence of sexual activity, lasting approximately 2 weeks, will occur (Back et al., 1974; Fig. 1). Post-partum mares experience estrus, commonly called "foal heat", during the first week after birth and may conceive at this time. Mares become anovulatory sometime in the fall and remain so until increasing day length triggers a resumption of estrous cycles.

Behavior that identifies mares as being estrous or non-estrous status is arbitrarily grouped into three categories: attractivity, proceptivity, and receptivity (Beach, 1976). As applied to the mare, attractivity refers to the stimulus value of the mare that elicits appetitive sexual responses from the stallion. Thus, attractivity is actually measured by the behavior of the stallion, but is a consequence of various behavioral and non-behavioral attributes of the mare, such as posture and olfactory cues, respectively. Proceptivity refers to appetitive behaviors shown by the mare in response to stimuli received from the stallion. These would include such behaviors as approaching the stallion and rotating the body so that the hindquarters are in front of the stallion. The mare's proceptive behavior occurs as a response to the sexual attractivity of the stallion. Certain attributes of the stallion are more or less likely to elicit proceptive behavior from the mare. For example, stallions that have a high frequency of vocalizations are more attractive to mares than stallions with a low frequency of vocalizations (Pickerel et al., 1993). Finally, receptivity refers to behavior by the mare that facilitates copulation with the stallion, the most important of which is simply standing still so that the stallion can mount and intromit. These three categories are clearly not mutually exclusive. Nevertheless, they can be useful constructs when discussing various aspects of sexual behavior.

The estrous mare will approach the stallion more frequently than the diestrous mare and will turn her hindquarters toward him. The estrus mare will also frequently adopt a posture in which she lowers her pelvis, spreads her hind limbs, and deviates her tail either to the side or straight back from the body, exposing the perineal region (Fig. 2). This posture is accompanied by a rhythmic eversion of the clitoris, called clitoral winking (Asa et al., 1983; Back et al., 1974; Clayton et al., 1981). Estrous mares will also void small quantities of urine very frequently, while diestrous mares void larger quantities of urine less frequently. In a test situation, stallions show no difference in olfactory response, including flehmen, to the urine of estrous and non-estrous mares. Therefore, the stallion appears to be unable to distinguish the two. However, in the field situation, the frequent urination of estrous mares causes an increased frequency of showing flehmen in the stallion. Therefore, the frequent urination of estrous mares may function in chemosensory priming of the stallion for reproduction (Marinier et al., 1988; Stahlbaum and Houpt, 1989).

The estrous mare also has a unique facial expression, with relaxed facial muscles, slightly lowered head and ears turned to the side (Fig. 3). One case has been reported of a mare that exhibited an atypical facial expression when she was in estrus that was similar to snapping behavior, also referred to as champing or tooth-clapping, of immature horses. She exhibited the facial expression when she first noticed the stallion or heard him neighing. When the stallion approached, she would flex her

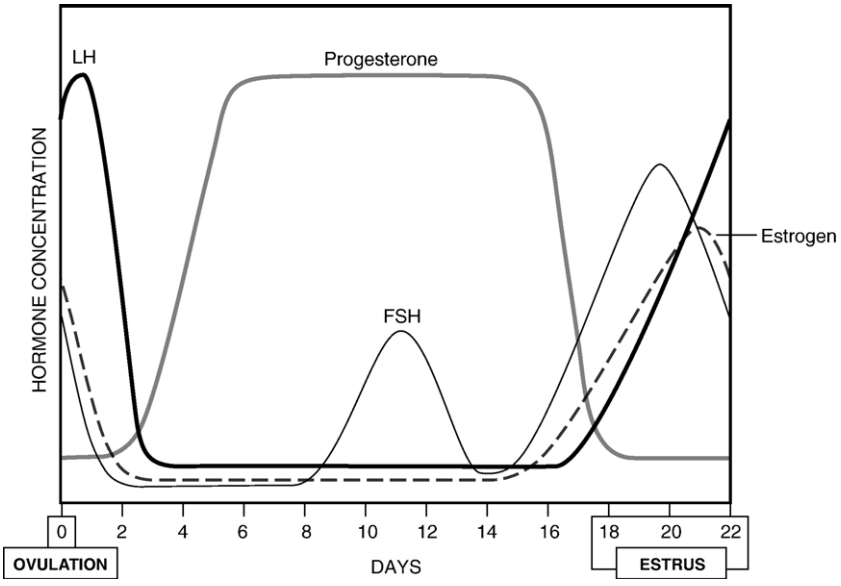

Fig. 1. Changes in the concentration of LH, FSH, estrogen and progesterone over the course of a typical estrous cycle. Behavior of estrus declines rapidly following ovulation and in conjunction with the rapidly rising levels of progesterone, so that the mare will actively reject the stallion 12–48 h after ovulation.

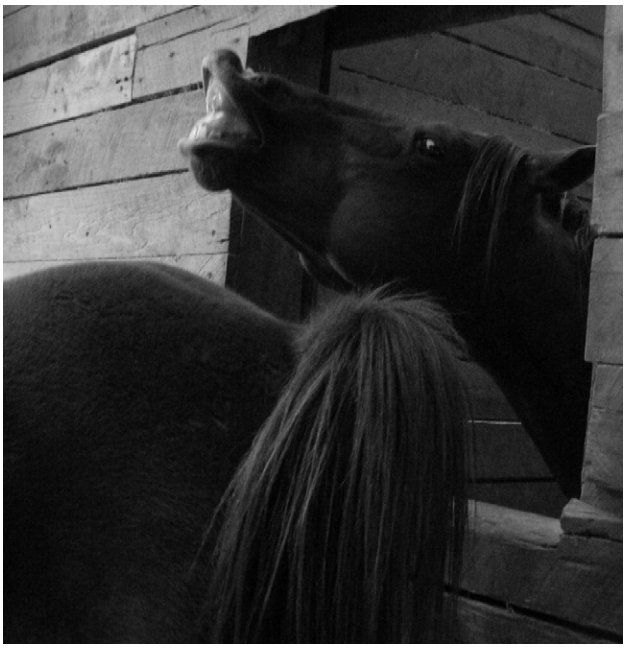

Fig. 2. An estrous mare that has presented her hindquarters to the stallion elevates her tail and deviates it to the side. The stallion is showing flehmen.

limbs, clamp her tail against her perineum, and open and close her mouth (Woods and Houpt, 1986). Snapping has been hypothesized to be a displacement behavior that occurs when foals or, in this case, a mare is in a conflict or approach–avoidance situation (Crowell-Davis et al., 1985). Therefore, in this situation, the mare may have been both attracted to and fearful of the stallion. It is likely that this phenomenon will occasionally be observed in other mares.

The proceptive behavior of the estrous mare is important in facilitating reproduction. If multiple mares are in estrus at the same time, mares that follow the stallion and repeatedly position themselves near the stallion are more likely to be mated repeatedly than estrous mares that follow the stallion less (Ginther et al., 1983). During copulation, the estrous mare demonstrates receptivity primarily by standing still. She may also lean into the stallion once he has mounted and intromitted and may look back at him during copulation.

The most visually notable behavior of the diestrous mare is the fact that, while the estrous mare will stand still when a stallion approaches, licks, and nibbles her, the diestrous mare will squeal, strike, and kick at a stallion that attempts to initiate courtship interactions with her. The relaxed facial expression of the estrous mare is replaced by tension of the facial muscles, turning the ears back and threatening to bite if the stallion is persistent (Fig. 4). Diestrous mares that have a long-term, stable social relationship with a stallion will only engage in these behaviors if he attempts courtship, e.g. prancing, nickering, nibbling, and licking. Stallions and diestrous mares will often graze and rest together and groom each other amicably so long as the stallion does not engage in any courting behaviors.

Yearling fillies (young females) may exhibit estrus, but are less attractive to the stallion at this time than are older mares (Asa, 1986). While the proceptive behavior of yearling fillies is often more exaggerated than that of older mares, they are also likely to run away if the stallion actually approaches. Long bouts of grooming are common between yearling fillies and stallions and may serve to habituate the filly to the proximity of the stallion (Tyler, 1972).

Hormonal control of estrus

During the ovulatory season, the developing follicle releases estradiol, which facilitates the estrous behavior. The corpus luteum releases progesterone which, in the mare, serves to inhibit estrous behavior, resulting in diestrus (Asa, 1986). Injection of 1 mg of estradiol induces estrous behavior in ovariectomized mares. Paradoxically, concurrent injection of 100 mg of progesterone causes more intense exhibition of

Fig. 3. An estrous mare interacts with a stallion. The ears are turned to the side and the facial muscles are relaxed.

Fig. 4. A diestrous mare being held in proximity to a stallion. The ears are back, the facial muscles are tense and the nostrils are flared. The mare also kicks at the stallion, who is protected by a stall wall.

estrous behavior on the first day of treatment, but subsequently causes inhibition of estrous behavior (Asa et al., 1984).

Estrus detection

In modern domestic management, there are three primary categories of techniques for horse breeding. In pasture breeding, the mare(s) and stallion are housed together on the same pasture. In this situation, the stallion repeatedly approaches the mares, often prancing and nickering. The diestrous mare will ignore or avoid him and will become aggressive if he persists in approaching, while the mare entering estrus will watch him and will often interact with him, e.g. engaging in mutual grooming. Regular courtship will occur over a period of days, progressing to the point where the mare stands still, adopting the mating posture described above while the stallion licks and nibbles her, especially in the withers (base of the crest of the neck) and in the perineal region. Once this occurs, the stallion will mount. Because estrus is readily detected both by dramatic behavioral changes and by rectal palpation (see below), measurements of hormone levels in urine or saliva are not used for routine detection of estrus. Mares and stallions kept in a pasture breeding situation will typically copulate multiple times and engage in long periods of courtship interactions. In Icelandhorse herds with a ratio of 1 stallion to 10–23 mares, each mare mated approximately 6 times (Steinbjörnsson and Kristjansson, 1999). Conception rates are highest in this context, as compared to herds with a higher mare to stallion ratio, in hand breeding or artificial insemination.

In "in hand" breeding, the mare and stallion are likely to meet only for copulation. The mare and stallion are both restrained via halter and lead rope. In addition, the mare may be twitched and/or hobbled, while a stallion that becomes aggressive in this context may be muzzled to prevent his injuring the mare. Twitching involves applying a chain or rope to the mare's upper lip and twisting it, while hobbling involves tying two or more of her limbs together with a length of rope in between so that her ability to move is limited. In hand breeding requires that some means be used in advance to determine if the mare is in estrus. Rectal palpation can be conducted to determine if the mare is developing follicles. However, there is always some degree of risk in conducting rectal palpation in this species, in which the rectum is very easy to tear. Rectal palpation is therefore not typically done as a routine, daily means of assessing a mare's estrous status. Instead, a technique called "teasing" is used in which the mare exposed to one or more stallions that are separated from the mare so that they cannot fully interact with her, i.e. they can only interact over a fence, a stall door, or a chute designed specifically for this purpose. The mare's behavioral responses to the stallion are then observed to assess her estrous status. If the mare attempts to avoid the stallion and shows aggressive responses, such as squealing and striking, she is presumed to be in diestrus. If the mare assumes the estrous posture, urinates, and/or develops the relaxed musculature of the mating face, she is probably in estrus.

Teasing is not 100% accurate in detecting estrus. Teasing one mare at a time is more accurate than teasing a group of mares, an arrangement in which the observer determines whether mares approach the stallion or not. Usually, 40 to 50% of estrous mares will not approach the stallion (Ginther, 1979, as reported in Asa, 1986). More intense aggression is exhibited by the diestrous mare when she is restrained near the stallion than if she is loose with the stallion in a paddock. In the latter case, the mare can simply avoid the stallion, and low intensity aggression is sufficient to signal the stallion to keep his distance. Depending on the standards of the particular farm, she may or may not be palpated per rectum at this point to determine her ovulatory status. While the conception rate is lower in hand breeding, it is a popular method because it minimizes the chance that the stallion will be injured by the mare kicking him.

While the normal mare does not exhibit stallion-like sexual behavior, mares with ovarian tumors that secrete androgen will do so (Fretz, 1977; Stabenfeldt et al., 1979). Stallion-like behavior can also be induced by injecting the anabolic androgenic steroid boldenone undecylenate at 0.55 mg/kg IM q7days. Such mares fail to elicit signs of behavioral estrus in fence line trials with estrous mares, but do sometimes elicit estrous behavior when allowed to interact with normally cycling mares at pasture (McDonnell et al., 1986).

Finally, artificial insemination is allowed in some breeds. In this case, a mare is teased as described above to determine if she is in estrus or not and will probably be palpated. If appropriate, she is then inseminated by intrauterine infusion of semen that has been collected in an artificial vagina. Stimulation that mimics the courtship behavior of the stallion may facilitate detection of estrus. Specifically, playing a recording of the vocalizations of a courting stallion, and manual tactile manipulations of the withers, the flank and the external genitalia has been shown to elicit estrous behavior in the majority of Belgian warm-blood mares (Veeckman and Odberg, 1978). However, playing recordings of stallion vocalization alone is not useful in detecting estrus in mares when a stallion is not nearby (McCall, 1991). Manual stimulation of the cervix and vagina during artificial insemination may facilitate uterine contractions and increase passive sperm transport (Campbell and England, 2004). However, this procedure has not been found to have any effect on conception rate (Valle et al., 1998).

Silent estrus

Mares may have follicular development and ovulate without showing any signs of behavioral estrus. Social factors, such as inhibition of proceptive behavior by subordinate mares in the presence of dominant mares, may be relevant, but they have not been empirically studied. Mares also show individual preferences for particular stallions and, conversely, non-preference for or avoidance of other stallions (Pickerel et al., 1993). Therefore, if a mare is evaluated only by exposure to one or two stallions, she may not show behavioral estrus because of a lack of attraction to those particular stallions. In one study in which cycling mares were able to freely interact with, or avoid, a stallion in a paddock with them, one in six showed silent estrus (Asa et al., 1979).

Sexual behavior in nonovulatory mares

During the winter months the mare's hypothalamic–pituitary axis becomes nonfunctional. GnRH secretion approaches zero, folliculogenesis ceases, and the ovary becomes nonfunctional (Sharp and Davis, 1993). Mares are unusual among ungulates in that they may exhibit estrous behavior during the winter, when they are anovulatory. Ovariectomized mares will also exhibit periods of estrous behavior (Asa et al., 1980a; Ginther, 1974). There is qualitative and quantitative individual variation in the estrous behavior. While some mares only exhibit mild estrous behavior, such as by occasionally approaching the stallion, others will exhibit the complete repertoire of estrous behavior, including standing for copulation.

Physiologically, this estrous behavior is probably due to hormonal stimulation of nonovarian origin. The adrenal cortex secretes androgens, estrogens, and progestins, which might influence the expression of sexual behavior (Nett, 1993). While much smaller quantities are secreted by the adrenal cortex than by the ovaries, the mare is likely more sensitive to small quantities of hormones than are other ungulates (Nishikawa, 1959). This possibility is supported by the fact that when ovariectomized mares are given dexamethasone (15 mg IM b.i. d.), which suppresses ACTH and therefore the production of adrenal steroids, they discontinue exhibiting estrous behavior. If they are given dexamethasone and estradiol, they continue to exhibit estrous behavior (Asa et al., 1980b).

From the ethological perspective of behavioral phylogeny, the development of this unusual behavior is probably significant for the maintenance of long term relationships between the mares and stallion of a family band. In most other ungulate species, the males and females come together only during the breeding seasons and separate during the non-breeding season. Family bands of horses remain together all year, and the stallion contributes to the defense of the mares and foals from predators. Sexual activity between the mares and stallion during the months when the mares are anovulatory probably facilitates the maintenance of this social organization.

Sexual behavior of pregnant mares

Five to ten percent of pregnant mares exhibit estrous behavior. Therefore, the display of sexual receptivity does not provide certain confirmation that a mare has not conceived (Asa et al., 1983; Satoh and Hosh, 1933; Tomasgard and Benjaminsen, 1975). The physiological cause of this phenomenon is not fully understood.

AN ECONOMIC MODEL DEMONSTRATING THE LONG-TERM COST BENEFITS OF INCORPORATING FERTILITY CONTROL INTO WILD HORSE (*EQUUS CABALLUS*) MANAGEMENT PROGRAMS ON PUBLIC LANDS IN THE UNITED STATES

Charles W. de Seve, Ph.D., and Stephanie L. Boyles Griffin, M.S.

Abstract: In recent years, the Bureau of Land Management's (BLM) Wild Horse and Burro Management program costs have increased dramatically due to a rise in the number of animals removed from public lands coupled with significantly decreased adoption rates. To assist with development and implementation of effective, cost-containing management programs, a robust economic model to project the costs and optimize outcomes of various management scenarios was created. For example, preliminary demonstration model runs show that by gradually replacing "removal-only" programs with contraception-and-removal programs on one hypothetical Herd Management Area (HMA), the BLM could save about US$8 million over 12 years while maintaining an area target population of 874 horses. Because the BLM estimates that more than 38,000 wild horses roam on 179 HMAs in the United States, the use of this economic model could result in a cost-savings of tens of millions of dollars if applied broadly across all HMAs.

Key words: Bureau of Land Management, economic model, *Equus caballus*, fertility control, porcine zona pellucida, wild horses.

BRIEF COMMUNICATION

The Wild Free-Roaming Horses and Burros Act of 1971 (Public Law 92–195)[13], as amended, directs the Bureau of Land Management (BLM) to manage wild horse herds by setting appropriate management levels (AMLs). AMLs are estimates of the optimum number of wild horses which results in a "thriving natural ecologic balance and avoids deterioration of the range" for each Herd Management Area (HMA). As of February 2012, the BLM estimates that approximately 37,300 wild horses and burros (31,500 horses and 5,800 burros) exist on 179 HMAs that comprise 31.6 million acres of public lands, of which 26.9 million are under BLM management.[10]

Herds can grow at an average rate of 20% annually.[2,3,4] When herd populations exceed established AMLs, the BLM conducts roundups to remove excess animals from HMAs, and roundups occur every 3–5 yr to ensure BLM complies with the requirements of the amended act. Removed animals are transported to long-term government holding pastures in the Midwest where they are cared for in perpetuity or, to a lesser extent each year, adopted by private individuals.

From 1971 to 2012, the BLM has removed over 300,000 wild horses and burros from the range and adopted out more than 230,000 animals.[10,12] However, in recent years the number of animals removed from the range and placed in long-term holding has far exceeded the number adopted or sold; adoption demand has fallen in response to the U.S. economic recession and other factors. According to the BLM's data reports for 2000 through 2012, over 121,000 animals were removed from the range while only 62,000 were adopted or sold. In Fiscal Year (FY) 2012, 66% fewer animals (i.e., 2,598) were adopted compared to FY 2002 when the BLM adopted out 7,746 animals.[10]

The remaining 46,500 animals have been placed in government holding facilities and, as a result, off-the-range wild horse and burro management costs have increased dramatically.[10] In FY 2012 alone, the cost of holding and caring for these animals exceeded $43 million—59% of the $72.4 million in total annual expenditures for the entire wild horse and burro management program.[10]

BLM is committed to caring for these animals, but the costs associated with their care will continue to increase because mortality rates in captivity are low, the average life span of wild horse and burros in captivity is approximately 30 yr, and every year the agency continues to remove more animals from the range and place them in additional holding facilities. This situation will

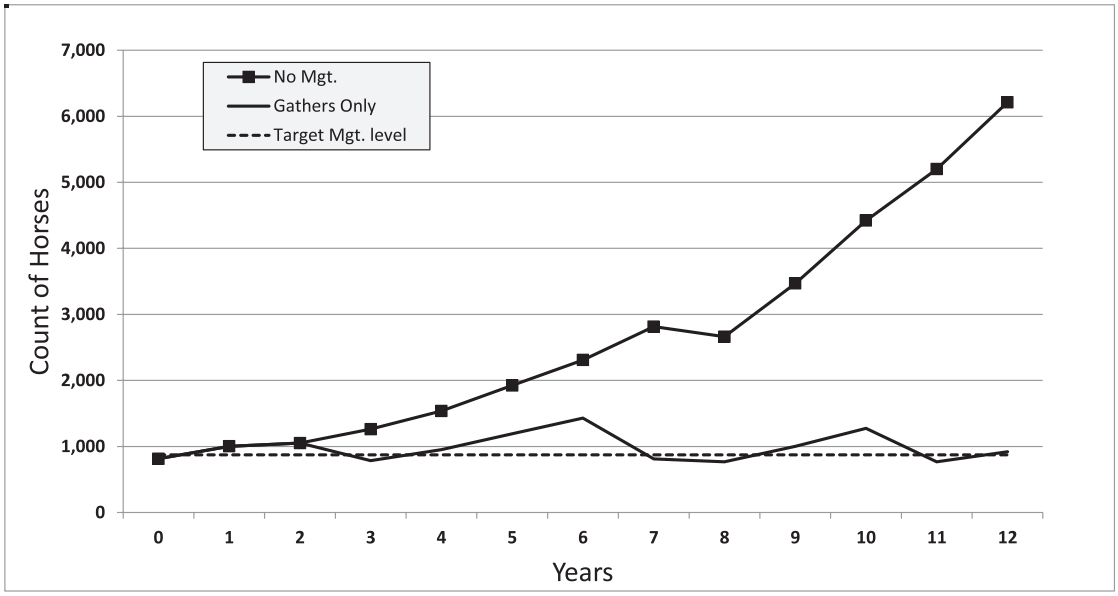
From American Economics Group, Inc., 6512 Lakeview Drive, Falls Church, Virginia 22041, USA (de Seve); and from The Humane Society of the United States, 700 Professional Drive, Gaithersburg, Maryland 20879, USA (Boyles Griffin). Correspondence should be directed to Ms. Boyles Griffin (sboyles@humanesociety.org).

result in exponentially increasing holding costs that will continue to rise as holding facilities become scarce and operators increase their prices, a trend now evident. Unless the agency develops and implements long-term management strategies to reduce the number of removals by reducing population growth rates on-the-range, the current removal-only approach seems doomed by inevitable budget constraints off-the-range.

Fertility control is a viable alternative to the current wild horse management regime. In early 2012, the Environmental Protection Agency (EPA) registered the first contraceptive vaccine for wild horses commonly known as porcine zona pellucida (PZP) and registered under the brand name ZonaStat-H.[11] Fertility control techniques and immunocontraception vaccines have been shown to be safe, humane, reversible,[8] and capable of stabilizing and reducing wild horse populations over time, either when used alone or when combined with other wild horse population growth suppression methods.[5,6,9] A United States Geological Survey (USGS) economic study[1] also demonstrated that reducing wild horse population growth rates through the combined use of fertility control drugs and sex ratio adjustments may reduce the need and frequency of removals which, in turn, could lead to long-term reductions in off-the-range management costs. This study estimated that fertility control on-the-range could reduce total wild horse and burro management costs by 14%, saving $6.1 million per year. The question is how to implement a humane and efficient cost-saving management plan.

Currently the BLM uses WinEquus, a stochastic wild horse population model, to evaluate possible management actions and select preferred alternatives, but the model does not calculate any costs associated with various management options.[7] The model cannot optimize management options, compare the combined removal and holding costs of alternative management plans, loop through multiple ranges to help build an efficient overall strategy, or simulate multi-year planning.

To assist the BLM in developing and implementing a long-term plan to maintain healthy wild horse and burro herd populations, a robust economic model to project the costs and outcomes of various management regimes was created which can be used by the agency to plan effective, cost-beneficial programs. The management system is designed to simulate range populations and alternative BLM management interventions and costs in either a single HMA or over multiple HMAs. It employs not only simulation methods but also optimization. Thus, it can help make sound management decisions under uncertainty, including allocating resources and reducing costs. The modeling incorporates stochastic simulations, conventional optimization, and stochastic optimization. There are four sub-models in the overall model framework: The Dynamic Population Simulation Model, The Economic Costing Model, The Management Intervention and Optimization Model, and The Population and Range Database System.



Recognizing the sparse data currently available for wild horse populations, the database system incorporates techniques for simulating missing data. It also guides the user to track range management results and enter additional data as the years pass, helping to initiate sound data collection procedures on the range and from contractors hired to conduct gathers. As with range data, missing cost items can be approximated or simulated using appropriate BLM assumptions.

BLM could use the model to decide on the optimum number and locations of round-ups, age–sex gather targets, fertility control elements, and remove:release ratios in order to allocate a fixed total budget, thus selecting the "best" limited set of gathers, or allocate to minimize cost in a single year or over multiple years to reach annual or overall population targets. The model might also optimize to control costs by suggesting adjustments to consider to HMA target populations or AMLs.

To demonstrate, using a hypothetical HMA with a target population of 874 animals, initial model runs over a 12-yr period demonstrate that the "no management" alternative, meaning no round-ups, removals, or contraception (or any combination thereof), is incapable of maintaining the target population and would lead to an exponential population growth rate that is not desirable or sustainable, as the population would rise from under 874 to over 6,000 in 12 yr (Fig. 1a, b). A model run of a typical "removal-only" management regime, where animals are removed from the HMA at years 3, 7, and 11, shows that such a scenario is capable of maintaining a population at or near the target population level (Fig. 1a.) but at a cost of over $13 million over 12 yr (Table 1).

A lower cost approach uses a contraception-and-removal management program where during a gather some animals are removed, selected by age and sex, but a high proportion of the mare population is treated with fertility control drugs and released. Population projections for years 3,

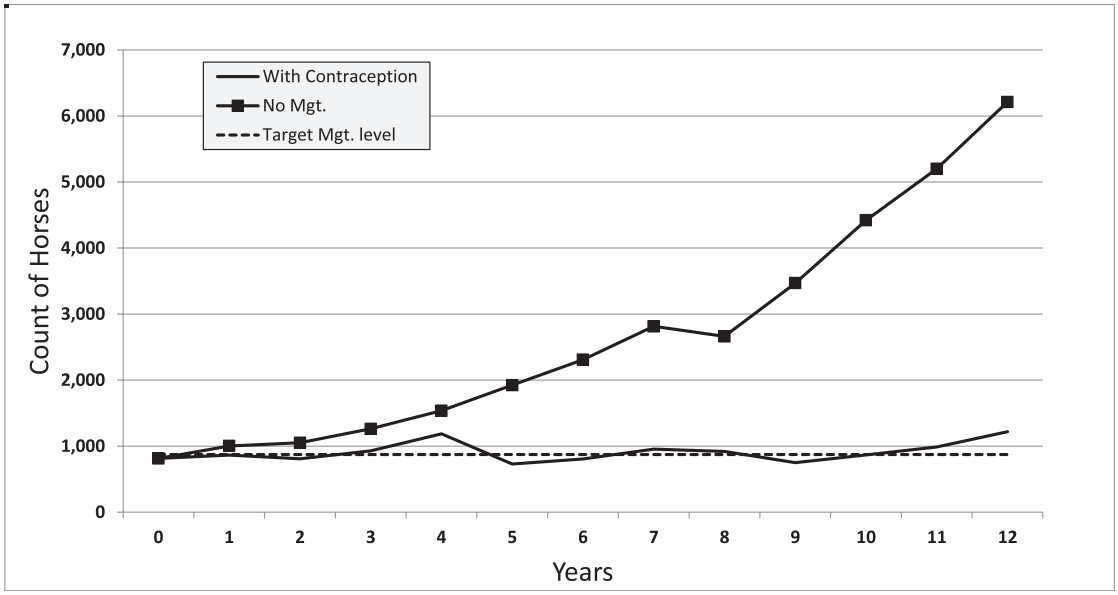

Figure 1. Example economic model output for a hypothetical Herd Management Area (HMA) with a target management population of 874 animals. The model simulates the difference in population growth rates over a 12-yr period when no management is conducted on the HMA versus (**a**) removal-only and (**b**) contraception-and-removals at years 3, 7, and 11.

7, and 11 show that such a management scheme will both maintain the target population level (Fig. 1b.) and reduce management costs by approximately $8 million over 12 yr—or $5.9 million present value compared to the "removal only" scenario (Table 1). Note that even a suboptimal effectiveness of PZP can achieve substantial population control and cost savings.

The model is flexible and, while these demonstration runs are based on realistic working assumptions provided by experts in the field, virtually all inputs can be adjusted to see the

Table I. Example of economic model output results of 12-yr contraception-and-removals versus removals-only scenarios.

	Contraception and removals	Removals only	Change (%)
Total horses to holding over 12 yr	798	1,790	−55.4
Average range pop. over 12 yr	910	982	−7.3
AML[a]	874	874	
Average difference from AML (%)	4.1	12.4	
Total gather and treatment costs	$2,435,523	$2,634,579	−7.6
Total holding costs	$5,560,426	$10,694,712	−48.0
Total cost (sum of years)	$7,995,949	$13,329,290	−40.0
Total cost (present value)	$5,852,135	$9,314,090	−37.2

[a] AML = appropriate management levels.

impact of other conditions, to test the limits of the model, the risks of other outcomes, or to use other assumptions. The examples here describe the population in an individual HMA while the gold-standard model would be a simultaneous collection of model runs for multiple, or all, HMAs in order to calculate the full population impact and the total cost to the agency's budget.

BLM estimates that there are approximately 38,000 wild horses and burros roaming on 179 HMAs located on public rangelands in 10 Western states. If about $8 million could be saved by implementing the proposed management scheme at one HMA over 12 yr, it stands to reason that such an approach could result in a cost-savings of tens of millions of dollars, if applied across all HMAs, recognizing the size differences among ranges.

Given current budget constraints imposed on federal and state wildlife and land management agencies, the hybrid population and economic model describe here could be used to develop and support the implementation of cost-effective and long-term wildlife and land management programs. It is clear to us that BLM and other agencies should invest more resources into both modeling and population growth suppression methods.

The Varying Role of the Male in Feral Horses

R. H. Denniston
Department of Zoology and Physiology, University of Wyoming, Laramie

Abstract

For the past four years a study has been conducted on the Red Desert of Wyoming concerning the role of males in multi-male bands and multi-band herds. During a colt's life he is barely recognized as playing a male's role. From the age of two-three, his role begins to emerge, at which time he usually joins a bachelor group or becomes a loner. At the age of three-four, the male associates with a mixed-sex band without constant status. With age comes a decrease in dominant status. In contrast to other equid systems, the multi-male organization could possibly represent an R strategy, whereas the multi-band herd organizational scheme must be emergent and represent a new strategy for large numbers of equids.

Introduction

The ungulate traditionally shows a sexual dimorphism in behavior. The male shows much more agonism, intra- and interspecifically. His prototype might be the bull elk or ram bighorn sheep, where a large amount of the rut is spent in sexual combat. In both, threat, ritualization, dominance-subordination, and submission play well recognized roles. The dominant male is a harem master, rounding up, defending, and doing most of the breeding with his group of females--a male chauvinist par excellence.

So it has seemed to be with equids, and four years ago when we started to work with feral horses this is what we looked for (Denniston and Miller, 1978; Miller and Denniston, 1979). To some extent it is what we found, but two sorts of exceptions appeared: multi-male bands and multi-band herds. Multi-male bands may represent a trade-off by a dominant male for band defense by subordinate male band members. Multi-band herds are an exception because they may include or have attached to them single males or bachelor groups. Such herds are groups of bands with a common home range and common movement patterns, organized into a social structure with considerable mutual recognition and compatibility.

Agonism and Dominance

Male-male conflict occurs in many situations. Some typical encounters are presented in Table I. Most often the instigator is a band male or a satellite male of a multi-male band. More rarely it may be the male of a small band; and occasionally, under crowded conditions, it may be a dominant female. The resource competed for is often related to band integrity: a female or a foal. It shifts from such resources to water, in the latter part of the summer. The recipient is most often an interloping male, either a bachelor or one from another band. The whole

array of agonistic behaviors described by Feist and McCullough (1975) may be shown in male-male conflicts. If the recipient is other than an adult male, the herding posture is most often used.

It is possibly equally significant that, under apparently provocative conditions, conflict and agonistic behavior do not appear. In the case of the band male who mounted a band female three times and then allowed a male from a different band to breed her, no conflict resulted. These bands were part of the same herd and were familiar with each other. This is also the case with bands which pass through each other while grazing without conflict. One band passed through another in which a foal had been born within the hour. No agonism was shown.

Development of the Male Role

I would like to examine the ontogeny of this male role in both exceptional situations--the multi-male band and the multi-band herd--and then speculate briefly on possible evolutionary significance.

During the first two years of a colt's life, his role is hardly distinguishable as a male. He may attempt to mount his mother or a sib. His sister may be mounted by mature or immature males as a two- or three-year-old.

As a two- or three-year-old and rarely as a yearling, the colt's role begins to emerge. He will probably leave his family band and either become a loner or join a bachelor group.

1. If he remains with his parental band, his presence is largely ignored by the mature stallion(s). He certainly is not driven off.
2. If he becomes a loner, he may associate temporarily with other males of like or older age or he may attempt to associate with an established band.
3. If he joins a bachelor group, the association may last up to two and one-half years. A bachelor group which acquires a mare may be quite lasting, but should be classified as a mixed band. Intra-group agonism is frequent but much of it seems somewhat playful. The dominant male in a bachelor group may act in many ways like a harem master, herding his bunch and responding to challenges from males from mixed-sex bands, to whom he is almost always subordinate.
4. If a lone male attempts to associate with a well established band, he will be challenged, chased, and driven off repeatedly by the mature male(s). Often the bachelor persists in his attempts, trailing the band at some distance, grazing close to them and watering with or immediately after them. A two-year-old palomino first started his attempts at association with a band early last fall. He is still not completely accepted, but now is most active in driving off intruding males and often waters with the band (c.f. Welsh, 1973).
5. A lone male may acquire a single mare, perhaps with foal, and so start the nucleus of a band. Groups commonly encountered include: a male-female pair; such a pair with a foal; a pair with a foal and a yearling; even a pair with a foal, a yearling, and a two-year-old.

However a three- to five-year-old male comes to be associated with a mixed sex band: as a member of a bachelor group which acquires females; as a finally accepted interloper; or possibly as one who grows up in and remains with his family band, his status does not remain constant. He will be increasingly active in defending the band and in breeding. He

will utilize the scarce water supply with the band. As the mares of his band come on heat, he may share them with little friction from other band stallions, either during the same day or doing all the breeding for two or three days and then none for a similar period. He will be increasingly recognized by other band stallions in the herd. Almost imperceptibly he may gain a dominant position in his own band and in relation to other bands.

Just as gradually, he will lose his dominant status. If the other stallions in his band are much younger, the band may start losing mares and their foals. The band may break up completely and the previously dominant stallion become a loner, sometimes tolerated briefly by other bands in the herd.

Adaptiveness of the Male Role

Such a system does several things for the overall population: (1) it insures that most breeding is usually done by the most rugged males; (2) at the same time it is usually only distantly related females with whom they breed; (3) a given female may be bred by a variety of males -- all with a high degree of fitness. The efficacy of this system is demonstrated by the thriftiness, generally good configuration, variety of coloration of the horse population on the Red Desert of Wyoming.

Our findings as to how a male may acquire a band are similar to Welsh's. His Sable Island ponies were also exposed to rigorous winters when bands mingled. He reported no multi-male bands or multi-band herds. Keiper in 1976 reported some multi-male bands. What he describes as co-dominance in bands of young horses is like our shifting dominance in mixed bands.

Both Tyler's (1972) New Forest ponies and Imanishi's (1950) Toimisaki horses had the adult males culled from the group, leading to a very low male/female ratio and little male-male competition.

These horses do not fit either Klingel's (1969, 1974, 1979) harem category nor his territorial male type. In the Pleistocene, horses showed a great morphological radiation. Is it possible that we now have an equally great behavioral radiation?

Why is this system different from other equid systems? Klingel lists only two types: harems and territorial males (Klingel, 1969, 1974, 1979). Feral animals tend to revert toward the wild condition. Possibly Red Desert horses are only partly reverted toward a harem system. The multi-male organization may represent an R strategy in an expanding population. The relatively low foal loss reported by Miss Lee Boyd (Boyd, 1979) would be characteristic of R strategy. The super-band herd organization must be emergent and represent a new anti-agonistic strategy for large numbers of equids in contact with each other. In the somewhat parallel situation of zebra, different strategies have evolved.

Article

Evaluation of post-operative pain after active desufflation at completion of laparoscopy in mares undergoing ovariectomy

Ian F. Devick, Britta S. Leise, Sangeeta Rao, Dean A. Hendrickson

Abstract — The cause of transient post-operative pain in a subset of horses undergoing laparoscopy is unclear. The objective of this study was to evaluate if residual pneumoperitoneum is associated with transient post-operative pain in mares undergoing ovariectomy. Thirty-eight mares undergoing routine standing laparoscopic ovariectomy were randomly allocated into 2 groups. At the completion of laparoscopy, either the abdominal cavity was actively desufflated or the cannulas were opened to achieve ambient pressure before incisional closure. Assessments were performed for 18 hours after surgery using a validated visceral/somatic pain scale for horses. Overall, pain was minimal in both groups (median score 2/39) post-surgery. Active desufflation of the pneumoperitoneum at the completion of laparoscopy approached statistical significance (P = 0.07) in decreasing pain at 12 hours after laparoscopy. However, effects of active desuffation were not significant throughout the monitored 18-hour post-surgery period. We conclude that the decision to actively desufflate at the completion of laparoscopy should be based on surgeon's preference.

Résumé — Évaluation de la douleur postopératoire après un désoufflement actif à l'achèvement d'une laparoscopie chez les juments subissant une ovariectomie. La cause d'une douleur postopératoire transitoire dans un sous-groupe de chevaux subissant une laparoscopie est indéterminée. Cette étude avait pour objectif d'évaluer si le pneumopéritoine résiduel est associé à de la douleur postopératoire chez les juments subissant une ovariectomie. Trente-huit juments subissant une ovariectomie laparascopique debout de routine ont été réparties au hasard dans deux groupes. À l'achèvement de la laparoscopie, soit la cavité abdominale a été activement désoufflée ou les canules ont été ouvertes pour obtenir une pression ambiante avant la fermeture de l'incision. Des évaluations ont été réalisées pendant 18 heures après la chirurgie en utilisant une échelle de douleur viscérale/somatique validée pour les chevaux. Dans l'ensemble, la douleur a été minimale dans les deux groupes (note médiane de 2/39) après la chirurgie. La désoufflement actif du pneumopéritoine à l'achèvement de la laparoscopie s'approchait de l'importance statistique (valeur de P = 0,07) en réduisant la douleur à 12 heures après la laparoscopie. Cependant, les effets du désoufflement actif n'étaient pas significatifs pendant la période de surveillance 18 heures après la chirurgie. La décision de désouffler activement à l'achèvement de la laparoscopie est toujours sujette à la préférence du chirurgien.

(Traduit par Isabelle Vallières)

Can Vet J 2018;59:261–266

Introduction

Standing laparoscopic ovariectomy is performed in mares for behavior modification, removal of ovarian tumors, preparation of "jump" mares for breeding operations, prevention of pregnancy, and for elimination of estrus-related abdominal discomfort (1–4). Laparoscopic ovariectomy has several advantages compared with other surgical approaches and includes superior visual observation, tension-free hemostasis, observation of the ovarian pedicle for hemorrhage during the procedure, reduced surgical morbidity due to the minimally invasive nature of the procedure, and shortened hospitalization (3–8). Additionally, when laparoscopy is performed in a standing sedated mare, the complications associated with general anesthesia are eliminated (9).

Peritoneal insufflation during laparoscopic surgery improves visual observation and creates working space (10). Carbon

dioxide is commonly used for insufflation because it can be used safely with electrosurgery, has a high diffusion coefficient which may reduce the risk of gas embolism, and is inexpensive (11–14). Pneumoperitoneum appears to be well-tolerated in healthy standing horses undergoing laparoscopy with few adverse cardiopulmonary, plasma chemistry variables, and hematology effects (15). However, it has been reported that horses can display signs of mild discomfort during a laparoscopic procedure at insufflation pressure of 15 mmHg or greater (15,16). Peritoneal insufflation and laparoscopic surgery result in a mild inflammatory response within the peritoneal cavity and a significant acute increase in peritoneal fluid total protein and nucleated cell count (3,15). The cause of the inflammatory response and post-operative discomfort has been suggested to be a result of carbonic acid formation from the carbon dioxide in contact with the peritoneal fluid (13,16).

Potential complications associated with laparoscopic surgery can be grouped as complications related to laparoscopy and those related to the specific procedure being conducted (12). In equine laparoscopic surgery, complications have been well-documented and include intestinal, splenic, or vascular puncture, retroperitoneal insufflation, and inadequate procedural hemostasis (17,18). Septic peritonitis, adhesions, ileus, and incisional complications can also occur (3). Subcutaneous emphysema can develop after surgery and is a result of the carbon dioxide escaping from the pneumoperitoneum through the incision and emanating subcutaneously (18). After peritoneal insufflation, the presence of the pneumoperitoneum remains for 24 h (19) or even a few days after surgery in humans (20). When the pneumoperitoneum is actively aspirated at the completion of laparoscopic surgery in humans, there is a decrease in post-operative pain (19). However, there are no reports on active peritoneal desufflation at the completion of equine laparoscopy and its effect on post-operative pain. Allowing carbon dioxide to escape at the completion of laparoscopic surgery has been reported as advantageous in reduction of development of subcutaneous emphysema in the horse (16). It has been suggested that actively desufflating the pneumoperitoneum at the end of the laparoscopic procedure would further reduce the incidence of post-operative subcutaneous emphysema (18). It has been reported that 18% to 20% of horses undergoing standing laparoscopic ovariectomy show signs of abdominal discomfort after surgery (17,21).

The objective of this study was to compare post-operative pain following active desufflation of carbon dioxide or no active desufflation at the completion of laparoscopic ovariectomies in mares.

Materials and methods

Cases and presurgical management

Mares admitted to Colorado State University Veterinary Teaching Hospital for a unilateral or bilateral ovariectomy between March 2015 and September 2016 and hospitalized for at least 18 h after surgery were included in this study. The study was approved by the Colorado State University Institutional Animal Care and Use Committee. Written client consent was obtained before participation in the study and clients received a financial incentive for enrollment in the study. Prior to initiation of the study, an online random list generator was used to create an order of group assignment for each mare to either the active desufflation or non-active desufflation (control) group. The author responsible for post-operative pain score assessment was blinded to the group assignment and the active or non-active desufflation procedure. Pre-operative vital parameters were recorded, and blood was collected for determination of packed cell volume and total protein in all mares. Feed was withheld for 12 h prior to surgery and mares were given access to water until the time of surgery.

Surgical procedure

An IV catheter was placed in the left or right jugular vein and the mare positioned in standing stocks. Presurgical antibiotic (penicillin G potassium; Pfizerpen, Pfizer, New York, New York, USA), 22 000 IU/kg body weight (BW), IV, and a nonsteroidal anti-inflammatory drug (flunixin meglumine; Prevail, VetOne, Boise, Idaho, USA), 1.1 mg/kg BW, IV, were administered approximately 30 min before the start of surgery. Sedation was initially achieved with detomidine hydrochloride (Dormosedan; Zoetis, Kalamazo, Michigan, USA), 0.01 mg/kg BW, IV, and butorphanol tartrate (Torbugesic; Zoetis), 0.01 mg/kg BW, IV. A level plane of sedation was maintained throughout the procedure by a continuous infusion of detomidine hydrochloride (20 mg) and butorphanol tartrate (10 mg) in 1 L 0.9% sodium chloride (Hospira, Lake Forest, Illinois, USA) at a rate adjusted to the desired effect depending on the individual mare's behavior and stimulation at any given time throughout the procedure.

Depending on previous determination (from history and clinical examination of the patient) and whether a unilateral or bilateral ovariectomy was to be performed, either one or both paralumbar fossae were clipped with wide margins, then aseptically prepared, and draped in a routine manner. Mepivacaine hydrochloride (Carbocaine-V; Zoetis), 0.01 to 0.05 mL/kg BW per site was injected subcutaneously and intramuscularly at 3 portal sites in one or both paralumbar fossae for local anesthesia. The middle portal site was at the level of the ventral aspect of the tuber coxae and halfway between the cranial aspect of the tuber coxae and the last rib. The dorsal portal was 4 to 5 cm dorsal and 4 to 5 cm cranial to the middle portal. The ventral portal was 5 to 6 cm ventral to the middle portal. A 1-cm incision was made through skin, subcutaneous tissue, and external abdominal oblique fascia at the middle portal site in the left paralumbar fossa (or right paralumbar fossa in the case of a right-sided unilateral ovariectomy). A laparoscopic cannula and blunt obturator (10 mm diameter, 20 cm long; Surgical Direct, DeLand, Florida, USA) were inserted into the abdomen at an angle perpendicular to the skin. A 30° forward viewing laparoscope (10 mm diameter, 56 cm long; Karl Storz Veterinary Endoscopy, Goleta, California, USA) was inserted into the cannula, confirming proper location in the peritoneal space. The peritoneal space was insufflated (Stryker 40L High-Performance Insufflator; Kalamazo, Michigan, USA) with carbon dioxide at a rate of 12 L/min and maintained at 10 to 12 mmHg throughout the procedure. Incisions were made in a similar fashion for the

remaining 2 instrument portals at the previously determined sites. Two additional cannulas were inserted into the abdominal cavity under direct visual observation and the laparoscope was transferred into the dorsal cannula for the remainder of the procedure. The left ovary in the case of bilateral ovariectomies or the ipsilateral ovary for unilateral ovariectomies was observed and mepivacaine hydrochloride (0.01 to 0.05 mL/kg BW) was injected into the mesovarium, mesosalpinx, and proper ligament of the ovary using a laparoscopic injection needle (5 mm diameter, 45 cm long, 19 gauge; Surgical Direct). The ovary was observed and grasped with acute claw laparoscopic grasping forceps (10 mm diameter, 45 cm long; Surgical Direct) through the ventral portal. A vessel-sealing device (LigaSure Atlas; Medtronic, Minneapolis, Minnesota, USA) was inserted through the middle portal and the jaws were applied to the cranial aspect of the mesovarium and proper ligament of the ovary. The device was then activated (setting 3 bars or 190 to 275 V) and once the tissue was sealed, it was transected using the integrated blade. This process was repeated across the mesovarium, proper ligament of the ovary, and the mesosalpinx, until the ovary was separated from the ovarian pedicle. For bilateral ovariectomies, once the ovary was transected, it was held by grasping forceps and remained in the left abdomen while a similar approach was carried out to the right ovary by approaching through the right paralumbar fossa. After transection of the ovary, the remaining ovarian pedicle(s) was assessed for hemorrhage and the ovaries were removed from their respective side of the abdomen in the case of unilateral ovariectomies. In cases of bilateral ovariectomy, the right ovary was passed to the left side of the abdomen using the acute claw graspers and sweeping the ovary over the bladder and under the uterus and small colon. The right ovary was then visualized and grasped with acute claw graspers from the left side of the abdomen. The 2 most ventral portal sites on the ipsilateral side for unilateral ovariectomies and the left side in cases of bilateral ovariectomies were connected by incising through the skin, subcutaneous tissue, and external abdominal oblique fascia. The muscle layers and peritoneum were separated bluntly with digital manipulation and the ovaries were then extracted through the incision with traction and manipulation. For the non-active desufflation group the external abdominal oblique muscle of the extended incision was closed with 0 polyglyconate (Maxon; Covidien, Mansfield, Massachusetts, USA) in a simple continuous pattern (10). The skin was sutured with 0 polypropylene (Surgipro; Covidien) with a simple continuous pattern for the extended incision and a cruciate pattern for the remaining portal incisions (10). For mares in the active desufflation group, the cannulas remained in the dorsal portal on each side and all other incisions were closed in the same fashion as described. The insufflation tubing was connected to suction and each side of the abdominal cavity was desufflated separately under laparoscopic visual observation until full peritoneal cavity collapse was achieved and no free gas was observed within the peritoneal cavity. The scope and cannula were then removed and the remaining portal incision(s) was/were routinely closed as described (10). The total surgery time and time of active desufflation, if performed, were recorded for each mare.

Post-operative management

After surgery the mares were monitored hourly while in the hospital. Complete physical examinations including evaluation of the incision sites for subcutaneous emphysema, swelling, heat, discharge, or pain on palpation were conducted every 6 h. Pain was assessed and scored every 6 h for the first 18 h after surgery using the composite pain scale described by Bussières et al (22).

The pain scale is a multifactorial rating scale with 13 assessment categories incorporating behavior, response to observer, and physiologic data. Pain is assessed with the patient in a box stall and each of the 13 categories is scored from 0 to 3 for a total pain scale range between 0 (no pain) and 39 (maximal pain) (22).

Patients received flunixin meglumine (1.1 mg/kg BW, IV) 12 h after surgery and then transitioned to a course of phenylbutazone (VetriBute; VetOne), 2.2 mg/kg BW, PO, q12h for 4 d. No post-operative antibiotics were administered.

Statistical analysis

Before initiation of the study, 30 mares were determined as the minimum number of mares to be included in the study for a power of 0.9. The association between active desufflation at the completion of standing laparoscopic ovariectomy and post-laparoscopic pain was evaluated using the Fisher's exact test separately for each time point (6, 12, and 18 h after surgery). The likelihood of post-laparoscopic pain was evaluated using logistic regression analysis to calculate odds ratios (OR) and 95% confidence limits (CI). Age, weight, and surgical time were evaluated for statistical difference between the 2 groups using a non-parametric Wilcoxon test and data were reported as the medians. A *P*-value of 0.05 was used to determine statistical significance and SAS v9.4 (SAS Institute, Cary, North Carolina, USA) was used for all data analysis.

Results

Cases

Thirty-nine mares were admitted to Colorado State University Teaching Hospital for a unilateral or bilateral ovariectomy between March 2015 and September 2016. One mare was excluded from the study group due to being discharged from the hospital shortly after surgery resulting in the inability for 18 h post-operative monitoring and pain score assessment. The remaining 38 mares fit the inclusion criteria and were included in the study for analysis. Breed was evenly distributed between the groups and was predominantly American Quarter Horse (n = 19), American Paint (n = 5), and Warmblood (n = 3) breeds with the remainder (n = 11) belonging to 8 different breed types. The median (range) in ages of the mares in the active and non-active desufflation groups were 11 y (range: 3 to 17 y) and 10 y (range: 3 to 24 y), respectively. The median (range) weights of the mares were 470 kg (range: 327 to 550 kg) and 490 kg (range: 390 to 650 kg), for the active desufflation and non-active desufflation groups, respectively. The median ages and weights were not significantly different between active desufflation and non-active desufflation groups. In 32/38 (84%) mares, a bilateral ovariectomy was performed and in the remaining 6/38 (16%) mares, a unilateral ovariectomy was performed (3 left-sided and 3 right-sided). Through randomization, 17/38 (45%)

Table 1. Distribution of no pain *versus* pain for the different post-operative time points of all mares.

Time after surgery	No pain score 0/39	Pain Score > 0/39	Odds ratio (95% Confidence interval)	*P*-value
6 h				
Active desufflation	4 (24%)	13 (76%)	1.30 (0.30 to 5.46)	0.73
Non-active desufflation	6 (29%)	15 (71%)		
12 h				
Active desufflation	7 (41%)	10 (59%)	0.24 (0.05 to 1.13)	0.07
Non-active desufflation	3 (14%)	18 (86%)		
18 h				
Active desufflation	3 (18%)	14 (82%)	0.49 (0.07 to 3.34)	0.47
Non-active desufflation	2 (10%)	19 (90%)		

Table 2. Distribution of no pain *versus* pain for bilateral ovariectomies.

Time after surgery	No pain score 0/39	Pain Score > 0/39	Odds ratio (95% Confidence interval)	*P*-value
6 h				
Active desufflation	4 (27%)	11 (73%)	0.85 (0.71 to 4.20)	0.84
Non-active desufflation	4 (24%)	13 (76%)		
12 h				
Active desufflation	7 (47%)	8 (53%)	0.24 (0.05 to 1.22)	0.09
Non-active desufflation	3 (18%)	14 (82%)		
18 h				
Active desufflation	3 (20%)	12 (80%)	0.25 (0.02 to 2.71)	0.25
Non-active desufflation	1 (6%)	16 (94%)		

of the mares were allocated to the active desufflation group and 21/38 (55%) to the non-active desufflation group. Of the unilateral ovariectomies performed, 2/6 (33%) were randomly allocated to the active desufflation group and 4/6 (67%) to the non-active desufflation group. Of the bilateral ovariectomies performed, 15/32 (47%) were randomly allocated to the active desufflation group and 17/32 (53%) to the non-active desufflation group.

Surgical procedure

The median (range) surgical times from first incision to complete closure of all flank incisions for the active desufflation group and non-active desufflation group were 55 min (range: 40 to 75 min) and 55 min (range: 35 to 85 min), respectively. The median (range) time for active desufflation when performed was 95 s (range: 40 to 300 s). In 1 mare (active desufflation group), the right circumflex iliac artery was lacerated while making the portal incisions. The artery was ligated and there were no resulting complications during surgery or during hospitalization.

Post-operative pain assessment

Patient pain was assessed and scored using a composite pain scale described by Bussières et al (22). The post-operative pain scores were mild with a median of 2/39 in each group. The likelihood of pain (score of 1 to 39) compared to no pain (score of 0) was evaluated. There were no statistically significant differences between the active desufflation and non-active desufflation groups at any of the post-operative time points (Table 1).

Unilateral and bilateral ovariectomies were then analyzed separately. The unilateral ovariectomy group (n = 6) was too small for meaningful statistics. The bilateral ovariectomy group (n = 32) showed a pattern similar to the overall study population. When the likelihood of pain (score of 1 to 39) compared to no pain (score of 0) was evaluated, there were no statistically significant differences between the active desufflation and non-active desufflation groups at any of the post-operative time points (Table 2).

Within the first 18 h after surgery, 7/17 (41%) and 11/21 (52%) mares had developed subcutaneous emphysema around the incisions for the active desufflation and non-active desufflation groups, respectively. There was 1 mare in the active desufflation group that experienced moderate discomfort and displayed signs of colic in the immediate post-operative period. The clinical signs resolved with medical therapy alone and the mare had no other complications after surgery. No other post-operative complications were observed within the defined study period of 18 h.

Discussion

Post-laparoscopic pain originates from 3 broad sources: the skin incisions and trocar sites in the abdominal wall, the pneumoperitoneum that is created, and the procedure itself (23,24). The stretching of the peritoneum that is caused by insufflation is thought to be one of the components of post-laparoscopic pain and may be exacerbated through secondary factors, such as peritoneal irritation and visceral hypoxia (23). Peritoneal irritation

Table 3. Pain scale median values and ranges for each post-operative time point.

Time after surgery	Pain score median (/39) All mares (n = 38)	Pain score median (/39) Bilateral ovariectomy (n = 32)	Pain score range (/39)
6 h			
Active desufflation	2	2	0–8
Non-active desufflation	2	2	0–4
12 h			
Active desufflation	2	1	0–5
Non-active desufflation	2	1	0–6
18 h Post-surgery			
Active desufflation	3	2	0–6
Non-active desufflation	2	3	0–6

may develop from carbonic acid formation as a result of the carbon dioxide in contact with the peritoneum which could result in post-operative discomfort (23,25). Visceral hypoxia can result from compression of the intra-abdominal pressure on the abdominal microvasculature (23). In human studies, the pneumoperitoneum can remain for 24 h (19) or even a few days after laparoscopy (20). There is an association between the volume of remaining post-laparoscopic pneumoperitoneum and the level of post-operative pain (26). Techniques previously used in humans to reduce the volume of the pneumoperitoneum include manual decompression of the abdominal wall to expel carbon dioxide through the trocar (25) or active aspiration at the completion of laparoscopic surgery to decrease post-operative pain (19).

More recently, low pressure pneumoperitoneum and intraperitoneal washout with saline at the end of the laparoscopic procedure have shown a reduction in post-operative pain and a superior outcome to low pressure alone in humans (23). In the standing equine patient, a complete saline washout at the end of a laparoscopic procedure could prove challenging to achieve due to the non-dependent nature of a gas and the mid-abdominal portal locations which would presumably result in gas remaining within the abdomen dorsal to the portal locations. If residual pneumoperitoneum is a component of post-laparoscopic pain and methods such as manual compression of the abdominal wall, active aspiration, or a saline washout improve post-operative pain in humans, then one would suspect that laparoscopic-guided active desufflation of the pneumoperitoneum would improve post-laparoscopic pain in horses.

Post-laparoscopic discomfort in horses has been reported (17,27), but is usually transient and resolves within 4 to 6 h after surgery (6,27). In this study the assessment of mare comfort was carried out over the first 18 h after surgery using a 39-point pain scale (22). The pain scale has been further validated for somatic and visceral pain in horses in a study by van Loon et al (28). Analysis of pain scores obtained in this subset of mares did not reveal a significant difference in post-operative pain between horses undergoing active abdominal desufflation or not. Throughout this study post-laparoscopic pain in mares was mild (Table 3). Due to the mild level of post-laparoscopic pain observed, the probability of pain (score of 1 to 39) compared to no pain (score of 0) was modeled (Table 1). The likelihood of pain did not reveal a statistically significant difference between the active desufflation and non-active desufflation groups at any of the post-operative time points. However, for the 12-hour post-operative time point, pain scores approached statistical significance (P = 0.07) with lower pain scores for the active desufflation compared to the non-active desufflated mares.

Other factors that may have contributed to post-operative pain that were not evaluated in this study include level and duration of anesthetic desensitization of the ovarian pedicle, length of the body wall incision created to extract the ovaries, and level of manipulation of the incision required to obtain successful ovarian extraction. Other limitations of this study include that multiple surgeons with different levels of laparoscopic experience were involved in the ovariectomies. As well, potentially a different pain scale assessment, such as a visual analogue scale, may have given different results. Although a power calculation was performed before the initiation of the study, the post-laparoscopic pain scores of the 38 mares were lower than anticipated and as a result a larger study population may have been necessary to show a significant difference between the 2 groups.

Lower pain in the active desufflated mares approached statistical significance, however, since a statistically significant difference was not achieved in this study, the cause of discomfort post-standing laparoscopic ovariectomy in a subset of mares still remains a question to be further investigated.

Subcutaneous emphysema surrounding the incision was observed after surgery and although fewer mares had emphysema (7/17; 41%) in the active desufflation group compared with the non-active desufflation group (11/21; 52%) there was no significant difference between groups. Pain was observed during peri-incisional palpation and was incorporated into the pain assessments. It is worth noting that in most cases in which pain was detected on palpation, it was located near the unilateral elongated incision used for ovary extraction. There was also 1 mare in the active desufflation group that experienced moderate discomfort and displayed signs of colic in the immediate post-operative period. The clinical signs resolved with medical therapy alone and the mare had no other complications post-surgery.

Results from this study demonstrate that pain assessed by a validated pain scoring system was very mild after laparoscopic ovariectomy. Active carbon dioxide desufflation of the pneumoperitoneum at the completion of standing laparoscopic ovariectomies in this group of mares approached statistical significance

(P = 0.07) towards decreasing post-laparoscopic pain at 12 h after laparoscopy. However, there were no statistically significant differences between the active desufflation and non-active desufflation groups at any post-operative time point. The lack of difference between the 2 groups could have resulted from the difficulty in detecting pain or from absence of moderate to severe pain observed in these patients. It is also possible that residual pneumoperitoneum is not a cause for post-operative pain in the horse as it is in humans. Therefore, the decision to actively desufflate or not at the end of laparoscopic surgery in horses to improve comfort should continue to be based on surgeon preference and experience.

Sexual and Aggressive Behaviour of Adult Male Marmosets (*Callithrix jacchus*) Castrated Neonatally, Prepubertally, or in Adulthood

A. F. DIXSON[1]

MRC Reproductive Biology Unit, Edinburgh, UK

Received 18 May 1992

DIXSON, A. F. *Sexual and aggressive behaviour of adult male marmosets (Callithrix jacchus) castrated neonatally, prepubertally, or in adulthood.* PHYSIOL BEHAV **54**(2) 301–307, 1993.—During early postnatal development, males of some primate species exhibit higher levels of plasma testosterone than females. The possible significance of this for behavioural development was examined in male marmosets castrated neonatally (NC), prepubertally (PC), or in adulthood (AC) and reared in their natal groups. Age-matched intact (AI) adult males served as controls. All males were removed from their natal groups as adults for pair testing with unfamiliar conspecific males and females. NC males did not mount, but were frequently aggressive during tests with females. NC males also elicited aggression from females but rarely from intact males. PC and AC males attempted copulation during the majority of tests with females; less aggression occurred but more so in tests with PC males than between females and AC males. Aggression between PC or AC males and intact males was much more frequent than when NC males met intacts in paired encounters. Results show that secretion of testicular hormones during infancy in male marmosets has important effects upon the development of sexual and aggressive behaviour. Castration in infancy has measurably different effects upon behavioural development than castration performed later in life (prepubertally or in adulthood).

Primates Behavioural development Testicular hormones Sex differences Marmoset

PRIMATES belonging to the South American family Callitrichidae (Marmosets and tamarins) are unusual among monkeys in that they normally produce twins. The twins are dizygotic and, during the presomite stages of foetal development, placental vascular anastomoses develop resulting in a shared blood supply throughout gestation. Haemopoietic chimaerism occurs in some species (4) but, despite this, there is no masculinization (freemartinism) of female foetuses which develop next a male cotwin (29). The role played by prenatal androgen secretion in masculinizing the neural substrates which control sexually dimorphic behavioural patterns in primates has been demonstrated in rhesus monkeys (14,16,22) and man (8,20). However, in both these species, elevated levels of plasma testosterone also occur in males during early postnatal life (13,23), and these may be implicated in behavioural and neuroendocrine development (18,24). Early postnatal increases in circulating testosterone have also been documented for one callitrichicd species, the common marmoset (1,5). Plasma testosterone is elevated in male marmosets until approximately 100 days of age, then declines before rising again at approximately 250 days, with the onset of puberty. Because of the unusual vascular arrangement that links twin foetuses in the Callitrichidae, it has been suggested that some aspects of neural sexual differentiation may be delayed until early postnatal development in these monkeys (1,26). Support for this hypothesis comes from the observation that early postnatal exposure to testosterone masculinizes some aspects of behaviour in female marmosets (1). Further, in a related species, the saddle-back tamarin (*Saguinus fuscicollis*), neonatal castration causes marked deficits in copulatory behaviour that are not reversible in adulthood by treatment with testosterone propionate (11,12). The purpose of the present study is to describe the effects of castration performed during three periods of life (neonatally, prepubertally, and adulthood), upon sexual and aggressive behaviour in male common marmosets. Behaviour of adult males that were castrated in infancy (between days 1–7) is compared to that shown by males castrated prepubertally (between days 140–180) or in adulthood (between 2.5–3.0 years) as well as to age-matched intact adult males, reared under similar conditions and observed during paired encounters with unfamiliar conspecifics.

METHOD

Animals and Husbandry Procedures

Seventy-eight marmosets were studied; eight males castrated neonatally, seven males castrated prepubertally, seven males castrated in adulthood, eight age-matched intact adult males, 24 nonage-matched sexually experienced adult males and 24 sexually experienced ovariectomized adult females. Females were

each implanted subcutaneously with two silastic capsules containing oestradiol 17β in order to stimulate proceptivity (6). All castrated males had been reared in their natal family groups until 2–3 years of age and then caged singly prior to behavioral testing between 3–4 years of age. The eight age-matched intact males were reared under the same conditions as the castrated males. None of the males in these four experimental groups was allowed physical contact with other marmosets, except for their parents and siblings in the family group. However, visual, olfactory, and auditory communication with other animals in the breeding colony was possible throughout development. Details of the diet have been described previously (25) as have the caging and management procedures (17).

Surgical Procedures

Bilateral castrations were performed on eight infant males (on days 1, 1, 2, 5, 6, 6, and 7 and 7, respectively), seven prepubertal males (aged between 140–180 days), and eight adults (aged 2.5–3.0 years). Operations were performed under aseptic conditions, using ketamine hydrochloride (Vetalar, Parke–Davis, Gwent, UK) and Saffan (Glaxovet, Middlesex, UK) for anaesthesia. A small incision was made in the scrotum or in the inguinal region (the testes are inguinal in position in younger animals), the spermatic cord was ligated using chromic catgut, and the testes removed. Incision sites were dusted with powdered antibiotic and closed with chromic catgut. Animals were returned to their family groups on the day of the operation and kept under observation during the weeks which followed. Postoperative recovery was uneventful and healing of the incision sites occurred rapidly in all cases.

Behaviour Tests

Each male in the four experimental groups (neonatal castrates (NC), prepubertal castrates (PC), adult castrates (AC), and age-matched intact adults (AI) was observed twice weekly during 10-min encounter tests with unfamiliar conspecifics of the same or opposite sex. Experimental males were tested under four conditions:

1. Resident in their home cages: female introduced.
2. Resident in home cage: male introduced.
3. Removed from home cage and introduced as an intruder into a female's cage.
4. Removed from home cage and introduced as intruder into a male's cage.

Each of the NC, PC, AC, and AI males was pair tested twice under each of the above conditions (1–4) and never met the same animal more than once. The experimental males were maintained in a separate room from the unfamiliar males and females used in encounter tests. A Latin square design was used to balance the order of testing conditions across subjects.

The following behavioural patterns were recorded during encounter tests: noncontact aggression (slit-eyed staring, arching and arch-ruffle displays, lunges, chases, and vocal threats), contact aggression (hitting, grabbing, or biting), submissive behaviour (squealing vocalizations, facial grimaces, and fleeing from an approaching conspecific), and sexual behaviour (proceptive tongue flicks, stares, and immobile displays, attempted mounts, mounts, penile erection, pelvic thrusting, ejaculation, refusal or initiation of male's mount attempts, or termination of mounts). Descriptions and definitions of behavioural patterns and testing procedures have been reported previously (6,17,28).

Tests were divided into 40 × 15-s intervals, and frequencies of noncontact aggression, contact aggression, and submissive behaviour were scored in terms of the number of intervals in which the various patterns occurred (Hansen frequencies) (3). The latency to first occurrence of biting attack was timed, and tests were terminated (promptly) if attacks persisted and injurious aggression seemed likely. Aggression was rapid in onset and severe in some tests (e.g., between NC or PC males and female partners) and it was not possible to record each individual agonistic display accurately. In many cases, frequencies of agonistic behaviour were, therefore, calculated as the percentage of 15-s intervals completed, in which the patterns had occurred. Aggressive dominance was scored if one partner consistently outranked the other in agonistic encounters. The various sexual patterns were recorded whenever they occurred and data are expressed as frequencies per test for these measurements.

Statistics

Statistical analyses were performed using overall mean values for each of the behavioural patterns, calculated for each animal Friedman analysis of variance was used to test for significant variation in behaviour between the four experimental groups (NC, PC, AC, and AI male groups). Paired comparisons between behaviour shown by NC males and each of the other three experimental groups were then made using the Mann–Whitney U-test (two tailed) (27).

RESULTS

Sexual Behaviour With Female Partners

Data on copulatory behaviour for the four experimental male groups are shown in Fig. 1. Neonatally castrated (NC) males did not attempt to mount females during pair tests. Prepubertally castrated (PC) males, by contrast, mounted females, displayed penile erections, and made pelvic thrusting movements. None of the PC males achieved intromission. Adult castrates (AC) mounted females and achieved intromission during some tests. However, intromission frequencies were lower in AC males (mean ± SEM, 0.61 ± 0.17 per test) than in tests involving intact adult (AI) males (1.12 ± 0.18; $U = 12$, $N_1 = 7$, $N_2 = 8$, $p < 0.05$). Only one AC male achieved ejaculation, whereas all AI males ejaculated (0.84 ± 0.11 per test; $U = 0.5$, $N_1 = 7$, $N_2 = 8$, $p < 0.001$). Both PC and AC males sustained penile erections and made pelvic thrusting movements. Failure to intromit was not, therefore, due simply to erectile problems, although in the case of PC males, the penis was markedly smaller during erection than in intact male subjects (Fig. 2).

Frequencies of precopulatory tongue-flicking behaviour (an invitational display used by both sexes in the marmoset) are shown in Fig. 3. Males in the PC, AC, and AI experimental groups all tongue flicked at females more frequently than did NC males. Females tongue flicked more frequently at intact male partners (mean ± SEM, 26.16 ± 8.02 per test) than at AC males (6.18 ± 2.79; $U = 14$, $N_1 = 8$, $N_2 = 7$, $p = 0.06$) or PC males (9.03 ± 3.42; $U = 15$, $N_1 = 8$, $N_2 = 7$, $p = 0.076$). Females rarely directed proceptive tongue flicks at NC males, however, the frequencies (1.22 ± 0.52 per test) being significantly less than for the other groups (Fig. 3).

Also shown in Fig. 3 are the percentages of males mount attempts or mounts that females refused or terminated. This provides a measurement of sexual receptivity in the female. Because NC males never attempted to mount females, it was not possible to calculate refusal or termination rats. Females were maximally receptive with intact adult males, refusing or terminating only 6.62 ± 4.72% of mounts. Adult castrates were refused or terminated more frequently (13.6 ± 6.10%) but the difference between the two groups of males is not statistically significant. The major effect upon female receptivity concerned

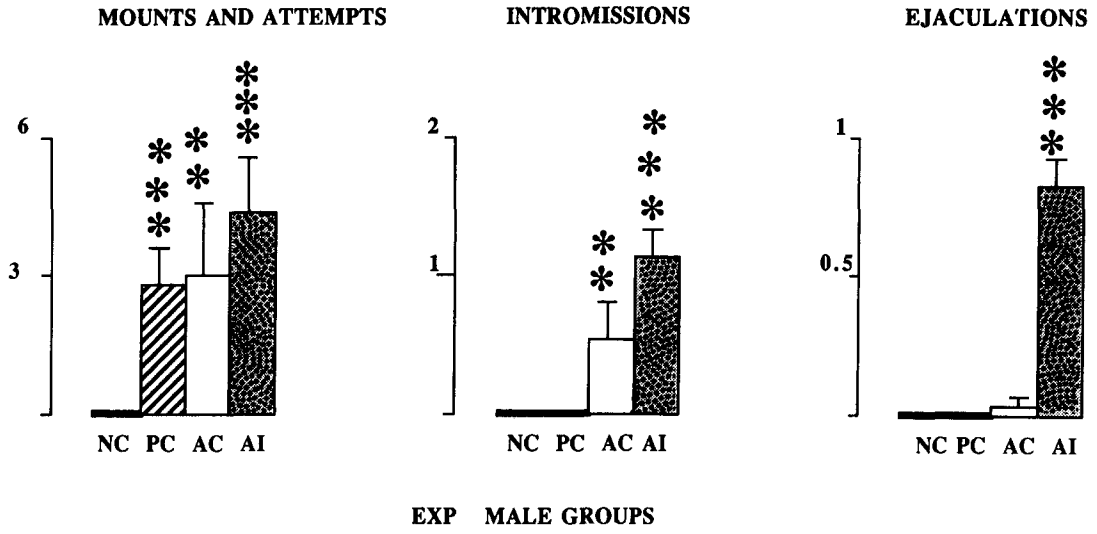

FIG. 1. Sexual behaviour by male marmosets in the four experimental groups during paired encounters with females. Data are individual means (+SEM) per test. Black bars = neonatally castrated males (NC); hatched bars = prepubertally castrated males (PC); open bars = adult castrates (Ac) and stippled bars = age-matched, intact, adult males (AI). Statistical comparisons are between NC males and those in each of the remaining groups. $^{**}p \leq 0.01$; $^{***}p \leq 0.001$ (Mann–Whitney *U*-test: two tailed).

tests with PC males. Mounts by PC male were refused or terminated, on average 60% of the time, significantly more so than those of adult castrates ($U = 0$, $N_1 = 7$ $N_2 = 7$, $p < 0.001$) or adult intact males ($U = 0.5$, $N_1 = 7$ $N_2 = 8$, $p < 0.001$). Many of the refusals or terminations by females occurred in response to repeated mounts and failures to intromit by their PC partners.

Sexual Behaviour With Male Partners

When males of the four experimental groups were pair tested with sexually experienced adult males, it was notable that the latter frequently attempted to mount males belonging to the three castrate groups (NC, PC, and AC groups) but only rarely behaved in this way towards AI partners (Fig. 4). Mount frequencies were highest with NC males, but did not differ statistically from those measured with either PC or AC males. Thus sexually experienced intact males attempted to mount, or mounted, NC males an average of 2.75 times per test; 88% of mounts were accompanied by penile erection and 65% by pelvic thrusting movements. Castrated males, by contrast, never attempted to mount sexually experienced intact males. Nor did the castrates behave in a proceptive or receptive manner during these tests. Thus, NC males rarely tongue flicked at intact males (mean ± SEM, 1.3 ± 0.7 per test), whereas intact males frequently directed this precopulatory display towards NC partners (13.7 ± 3.2 per test; $U = 7.5$ $N_1 = 8$, $N_2 = 8$, $p = 0.005$). The sexually experienced intact males initiated 96% of their mounts during encounters with NC males. The NC males were not proceptive by comparison with the other experimental groups and, because they refused or terminated 67 ± 16% of mounts by intact partners, there was little evidence of sexual receptivity (Fig. 4). Prepubertally castrated males refused or terminated 94% of mounting activity; AC males 93% and AI males 100%. Three of the NC males behaved passively and tolerated mounting by at least one of the four intact male partners. One NC male exhibited tongue flicking whilst mounted by an intact male. The behaviour observed appeared submissive rather than sexual and was in keeping with the virtual absence of aggression between NC and intact male partners (see the following paragraphs).

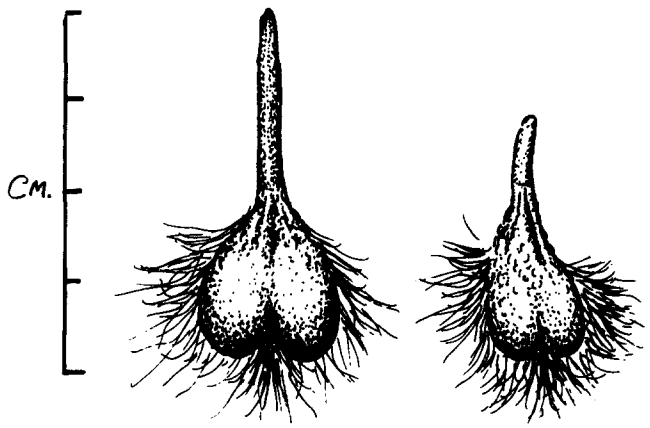

FIG. 2. External genitalia of adult male marmosets. Left: an intact male. Right: a male which was castrated prepubertally. Both males exhibit full penile erection. Fat deposits in the scrotum of the prepubertally castrated male give a false impression that small testes might be present.

Agonistic Behaviour With Female Partners

Encounters between NC males and females were characterized by much higher frequencies of mutual aggression than in tests with the other three male groups. It was necessary to terminate 66% of encounters between NC males and females in order to avoid possible injuries (Fig. 5A) due to frequent contact aggression by both sexes (Table 1). Each test was divided into 40 × 15-s time intervals; the average duration of tests between NC males and females was 19 ± 3 time intervals. Both sexes initiated aggression and fought vigorously, so that no clear-cut dominance–subordinance relationships were established for 75% of encounters (NC males were dominant in 6% and females in 19% of the tests). By contrast, no tests between females and AC or AI male partners were terminated; females never attacked males belonging to these experimental groups, and aggression

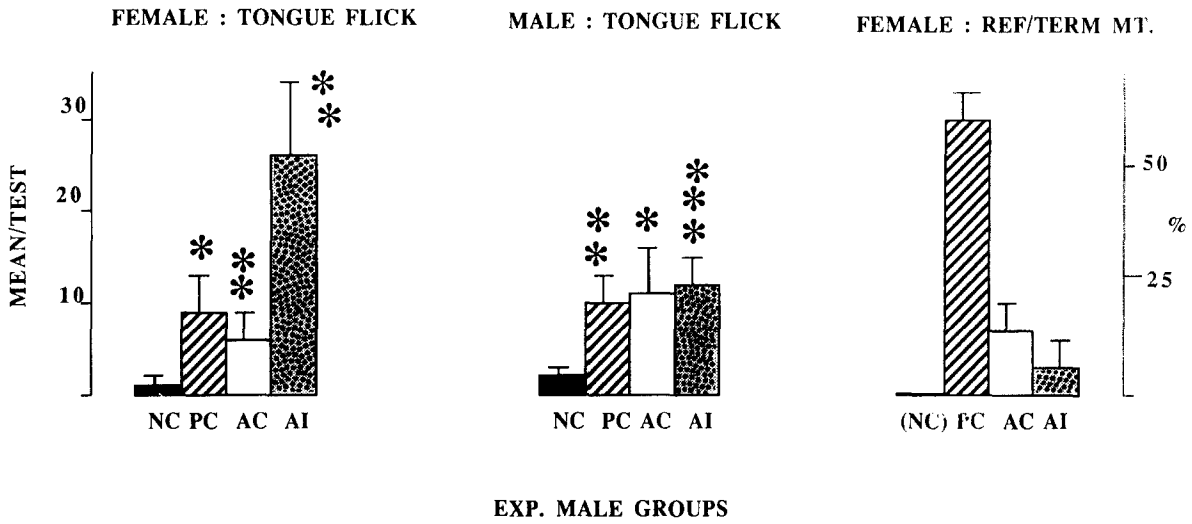

FIG. 3. Precopulatory tongue flicking displays by male and female marmosets and female's refusals or terminations of male's mounts during paired encounters. Data are individual means per test (+SEM) for precopulatory tongue flicking and mean percentages for female's refusals or terminations of male partner's mount attempts or mounts. Black bars = neonatally castrated males (NC); hatched bars = prepubertally castrated males (PC); open bars = adult castrates (AC) and stippled bars = age-matched, intact, adult males (AI). Statistical comparisons are between NC males and those in each of the remaining groups. $*p \leq 0.05$; $**p \leq 0.01$; $***p \leq 0.001$ (Mann–Whitney *U*-test: two tailed).

by the males occurred at very low frequencies (Fig. 5A; Table 1). Encounters between females and PC males did involve high frequencies of mutual aggression, although significantly less so than during tests between females and NC partners. Thirty-two percent of tests with PC males were terminated to avoid potential injuries to the animals. Examination of Table 1 indicates that females were more aggressive than PC males during these tests. Aggression often occurred in association with the females' refusals and terminations of males mounts and repeated failures to attain intromission. The PC males were very persistent in their attempts at copulation, however, and in some cases this led to attacks by females.

Agonistic Behaviour With Male Partners

Data on aggressive interactions between males in the four experimental groups and intact adult males during paired encounters are shown in Fig. 5B and Table 1. As expected, encounters between intact adult males resulted in frequent aggression and 58% of tests were terminated to avoid possible injuries. Tests between intact males and castrates (NC, PC, and AC males) resulted in less aggression, and this effect was most pronounced in the case of intact vs. NC male encounters. The NC males rarely behaved aggressively towards intact males, no tests were terminated, and attacks (by either male) occurred only during 9% of encounters. Encounters between intact males and PC males resulted in more frequent aggression, but in only one case was this statistically significant by comparison with data from NC—intact male tests (intact males contact aggression vs. PC males; $p = 0.05$, Table 1). Encounters between intact and AC males produced consistently higher frequencies of contact aggression than occurred during tests with NC males. Intact males also

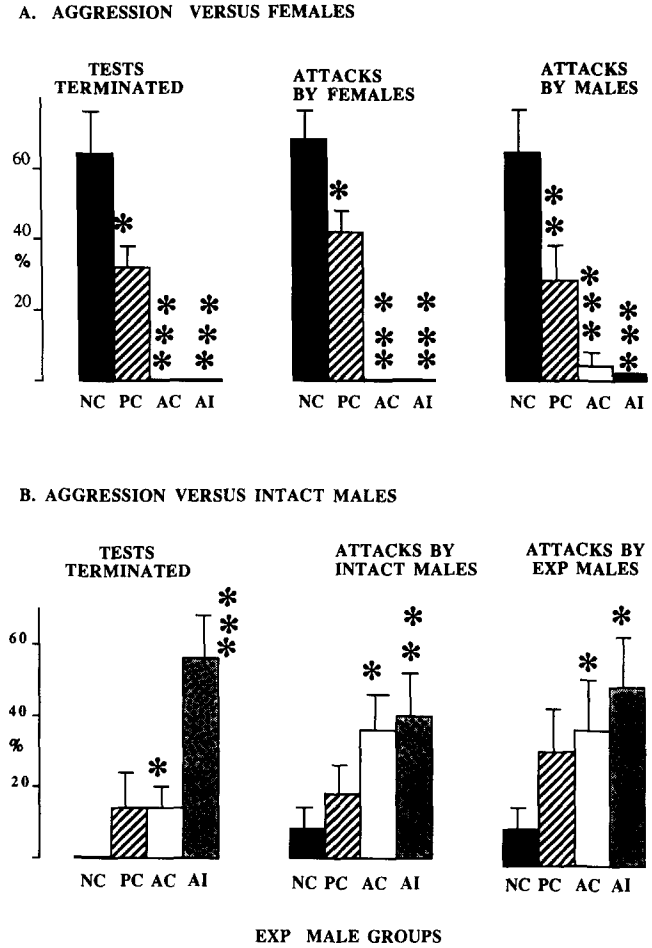

FIG. 5. Aggressive interactions between males in the four experimental groups A with female partners and B with intact male partners. Data are mean (+SEM) percentages per test. Black bars = neonatally castrated males (NC); hatched bars = prepubertally castrated males (PC); open bars = adult castrates (AC) and stippled bars = age-matched, intact, adult males (AI). Statistical comparisons are between NC males and those in each of the remaining groups. $*p \leq 0.05$; $**p \leq 0.01$; $***p \leq 0.001$ (Mann–Whitney *U*-test: two tailed).

directed more noncontact aggression towards AC partners than towards NC males ($p = 0.01$; Table 1).

DISCUSSION

The effects of castration during neonatal life in male marmosets differed from those produced by castrating males prepubertally or in adulthood. As adults, males that had been neonatally castrated (NC males) did not attempt to mount females during paired encounters. Prepubertally castrated (PC) males, by contrast, are sexually very active in adulthood, frequently mounting females and making pelvic thrusting movements with the penis erect. However, PC males lacked full phallic development, which probably explains the absence of intromissions during their mounts. Male marmosets that were castrated in adulthood, between 2-1/2–3 years of age, and tested with females 6–14 months after the operation were also very active in mounting their partners. Mount frequencies did not differ from those exhibited by PC males. However, the adult castrates succeeded in attaining intromission, although intromission frequencies were significantly less than those displayed by age-matched intact adult males. Only one adult castrate ejaculated during tests with female partners. It appears that adult male marmosets retain a high degree of sexual activity after castration even when they are relatively inexperienced at copulation. In their studies of castrated male rhesus monkeys, Michael and Wilson (19) observed film records of mating tests which "showed the penis bending on contact with the female's perineum." The AC marmosets observed in the current study maintained full erections, however, and made well-oriented mounts with vigorous pelvic thrusting movements. It seems likely that deficits in sensory feedback from the penis or in the central processing and responsiveness to such stimuli influenced intromission and ejaculation in these males (7).

The effects of neonatal castration upon copulatory behaviour in male marmosets parallel those reported by Epple et al. (11) in experiments on a related callitrichid species, the saddle-back tamarin (*Saguinus fuscicollis*). In that study, four males were castrated on day 2 of postnatal life. As adults, these NC male tamarins failed to mount females, whereas prepubertally castrated males did exhibit mounting behaviour.

As adults, NC male marmosets did not behave in a proceptive or receptive manner when paired with intact males. Intact males frequently directed precopulatory tongue-flicking displays at NC males and initiated mounts. The NC males rarely tongue flicked at intact partners, they initiated less than 4% of mount attempts made by the latter and refused or terminated 67% of their mounts. Although NC males tended to behave submissively towards intact males, they were not more receptive sexually than PC or AC males, tested under the same conditions. These results do not support the view that early postnatal secretion of testicular androgens is required for behavioural defeminization in male marmosets. However, no experiments comparing effects of androgen and oestrogen treatments to NC, PC, and AC marmosets have been reported. It remains unknown, for instance, whether oestrogen treatment of NC males might stimulate proceptive or receptive behaviour.

Effects of neonatal castration upon the development of aggressive behaviour were more pronounced than those which occurred in the PC or AC male groups. Encounters between NC males and females resulted in intense mutual aggression; 66% of these tests were terminated to avoid possible injuries to the animals. Aggression also occurred, although less frequently, during tests between females and PC male partners, but rarely during their encounters with AC or AI males. To this extent, the behaviour of NC males in particular was socially feminine, because pair tests between adult female marmosets also involve frequent mutual aggression (21). However, it is possible that nonbehavioural cues from NC males, and to a lesser extent PC males, might have affected the reactions shown by female conspecifics. Thus, early castration may have affected the development of cutaneous scent marking glands or urinary cues; both of which are of proven importance for social communication in Callitrichid primates (9,10). Likewise the infantile appearance of the external genitalia of NC and PC male marmosets might have influenced the behaviour of conspecifics. It is unknown whether visual cues play any role in sexual recognition in these monkeys. The remarkable lack of aggression shown by intact adult male marmosets towards NC males and their frequent attempts to copulate might also have resulted from the absence of those chemical and morphological changes which are stimulated by androgens during puberty. Further experiments are required to examine these questions.

The effects of neonatal castration in male marmosets upon aggressive behaviour differ from those reported by Epple et al. (11) for saddle-back tamarins. Neonatally castrated saddle-back tamarins rarely behaved aggressively when pair tested, in

TABLE 1

FREQUENCIES OF AGGRESSION BETWEEN MALES IN THE FOUR EXPERIMENTAL GROUPS AND PARTNERS DURING ENCOUNTER TESTS

Behavioural Measurement	Experimental Male Groups			
	NC	PC	AC	AI
A. Aggression Between Experimental Males and Females				
Non-contact aggression				
Experimental males' aggression towards females	48.1 ± 8.4	11.5 ± 3.3*	1.8 ± 0.8*	0 ± 0*
Females' aggression towards experimental males	49.2 ± 5.8	17.2 ± 3.7*	4.3 ± 2.5*	0.6 ± 0.3*
Contact aggression

adulthood, with females. However, pair tests involved familiar partners, rather than strange conspecifics as in the present experiment. Procedural differences, as well as interspecific variability may explain some of the differences in aggression observed in the two studies. An important point relates to the possible masking effects of aggression between NC male marmosets and females upon the expression of sexual behaviour during paired encounters. Females were pretreated with oestradiol 17β to maximise their proceptivity (6) yet they rarely tongue flicked at NC males. Females directed their proceptive tongue flicks more frequently towards PC or AC male partners and were most proceptive towards intact males. The relative absence of sexual initiating behaviour by females when tested with NC males, coupled with the intense aggression shown by both partners during the encounters, made it unlikely that males would display mounting behaviour. The possibility exists that the neural substrates that control mounting behaviour are organized by androgen primarily during foetal development in marmosets, as is the case in rhesus monkeys (15), but NC males fail to express the behaviour due to the negative effects of aggression. However, PC male marmosets also interacted aggressively with females, and yet they made persistent mounting attempts. Further, NC male tamarins failed to exhibit mounting behaviour in adulthood, even after treatment with testosterone propionate (11,12). Female common marmosets treated with testosterone during the first 50 days of postnatal life exhibited masculinization of behaviour (e.g., pursuit courtship and mounting) as adults (1). Taken together with the results of the present experiment on behavioural effects of castration neonatally, prepubertally, and in adulthood in the marmoset, these various studies indicate that testicular hormones secreted during early postnatal life play an important role in the development of sexual behaviour and aggression in callitrichid primates.

Behaviour of castrated animals

IAN FRASER DUNBAR, *Department of Psychology, University of California, Berkeley, USA*

Vet. Rec. (1975). **96.** *92-93*

THE main reason for castrating cats and dogs is to render them infertile. However, in clinical practice they are often castrated at the request of the owner, to hopefully reduce or abolish so-called "objectionable behaviour" such as mounting and onanism, urine scent marking, fighting and roaming. Often the veterinary surgeon is unsure of the outcome of the operation and the owner is disappointed when castration does not produce the required effect. In connection with a letter by J. Wharrier in your issue of July 27, 1974, concerning the "abnormal" mounting behaviour of castrated male dogs and the spraying behaviour of castrated tom cats, this note is an attempt to elucidate the behavioural sequelae of castration of dogs and cats, so that practising veterinary surgeons may be able to offer a fairly reliable prognosis regarding the effects of the operation.

For a long time it has been evident that testicular hormones contribute in some manner towards the male capacity for sexual arousal and performance. However, the relationships between androgens and mating behaviour are extremely complex and there appear to be many individual and species differences. In particular it has been shown that following the castration of some species of male mammals, various components of the copulatory pattern may persist for considerable lengths of time.

It has been proposed that with phylogenetic progression, the decline in mating behaviour following the castration of male mammals becomes more gradual and variable. This generalisation is reflected by a progressive emancipation of the males' sexual behaviour from dependence on testicular androgen. Furthermore, the extent to which male mating activity is dependent on testicular androgens is inversely proportional to the degree that the cerebral cortex is involved in the mediation of mating behaviour (Beach 1947, 1958). Accordingly, in rodents, the components of male mating behaviour begin to decline very soon after castration (Block and Davidson 1968), whereas male carnivores may retain the ability to copulate for a longer period. With monkeys, apes and man there is a very gradual decline in sexual behaviour and components of the copulatory pattern sometimes persist for a very long period following castration. Also, to some extent, this notion of 'phylogenetic progression' may be extended to scent marking and aggressive behaviour (Hart 1974b).

In dogs all elements of the mating pattern may survive for several years following castration (Hart 1968, Beach 1970). The main effects of castration after a period of six months are a slight decrease in the frequency of intromissions and a marked decrease in the duration of the copulatory lock or tie, presumably due to the failure to maintain full erection. There is, however, little effect on the mounting behaviour. If anything, immediately following castration there appears to be an initial increase in the incidence of mounting behaviour. Perhaps this is augmented by the decreased ability to achieve intromission yet the persistence on the part of the male to continually attempt to do so. There is usually no further decline in the mating ability for up to three to five years following the operation.

Adrenalectomised castrated dogs similarly continue to display the complete copulatory pattern, indicating that the retention of mating activity is not due to a compensatory increase in adrenal androgen (Beach 1970). Nevertheless, Beach has repeatedly demonstrated that the effects of castration are due to an androgen deficiency, since with replacement androgen therapy the mating activity is restored to preoperative levels.

In a study investigating the mating behaviour following the castration of sexually-experienced toms, there also appeared to be gross individual differences. For some toms the ability to achieve intromission persisted for several years and mounting behaviour continued indefinitely. In others intromission disappeared after only a few months, although mounting was still apparent many months thereafter. With some toms, however, there was a cessation of all mating activity shortly after castration (Rosenblatt and Aronson 1958a). The changes in mating behaviour were first evidenced by a decrease in the frequency of intromission and a prolongation of the mount and thrust response. The mounts became more prolonged and were often unsuccessful in achieving intromission, presumably since the ability to maintain a full erection was weakened. Eventually, only short mounts were apparent and these occured without the characteristic pelvic thrusting and treading responses. Gradually the mounting behaviour became infrequent and in some cases disappeared altogether. Overall, the toms retained the ability to achieve intromission for about three months, whereas mounting behaviour survived much longer and in some cases indefinitely.

The considerable individual variation in the effects of castration upon mating behaviour may be attributed to several factors: species differences, the degree of sexual experience prior to castration and the age at which the individual is castrated.

Dogs and cats seem to differ in the effects of sexual experience prior to castration. Compared with sexually-experienced toms, sexually inexperienced animals exhibit a lower frequency of mounting behaviour, and the ability to achieve intromission is considerably reduced and only

persists for a relatively short period following castratin (Rosenblatt and Aronson 1958a). However, with dgs, there is no evidence to suggest that sexually inexperiened castrates are in any way inferior to experienced castrates with regard to the many various components of appetitve and consumatory mating behaviour (Hart 1968). These data may reflect apparent species differences between cats and dogs or they may be the result of procedural differences between the separate experiments.

Compared with dogs castrated in adulthood, prepubrally castrated dogs show a much lower frequency of intmission, and the ejaculatory reflex and the ability o achieve a copulatory lock are markedly impaired. This may be related to insufficient development of the genial organs, in particular the bulbus glandis. The penes of prepuberally castrated animals are much smaller than those of dogs that have been castrated in adulthood. Nevertheles, prepuberally castrated dogs will mount an oestrous bith frequently and vigorously (LeBoeuf 1970). This is in contrast to prepuberally castrated male cats, which seldm exhibit mounting behaviour as adults (Rosenblatt nd Aronson 1958).

The castration of male dogs seems to have very lile effect on urinary scent marking behaviour apart from a generalised decrease in the frequency of urination (Hrt 1974a). Similarly, it has been reported that aggressie behaviours in male dogs are not readily reduced by castrtion (LeBouef 1970). These data, however, are in diret contrast to the effects of castration of adult toms. In a study to evaluate change in objectionable behaviours f male cats following castration in adulthood, it was estalished that there was a postoperative decline in fightig, roaming and urine spraying in 88 per cent, 94 per cent ad 88 per cent respectively. Moreover the greater proporton of these cases showed a rapid and prolonged decline within approximately two weeks following castration. This vas particularly so with the cases involving urine sprayng (Hart and Barret 1973). Often these behaviours declied at different rates in the same individual cat and furthrmore there was no apparent correlation between the ge of the cat at the time of castration and the subsequnt rate of decline of any behavioural pattern. Also it should be mentioned that a postcastrational decline in fightng and spraying in tom cats does not preclude the occasional display of these behaviours, perhaps in some cases precipitated by an environmental change.

Castrated animals behave very differently under est conditions than when unconfined, and one must be wry of direct extrapolation of experiment results to the domestic situation. For example, when a castrated dog is placed in a small pen in intentional proximity to an oestrous bitch, there is obviously a much greater likelihood that he will mate than casual observation of the free-ranging domestic situation might suggest. In summary, however, although there appear to be significant species differences between cats and dogs it would be fair to conclude that the major effect of castration of either species is reflected by an overall reduction in the frequency of intromissions sometimes followed by a decrease in mounting behaviour. Nevertheless, some individuals retain the ability to copulate for a substantial period of time. Castration is likely to have a more pronounced effect on the mating behaviour of male cats than on male dogs. Castration seems to have no reliable effect on either aggressive or urinary scent marking behaviour of dogs, whereas in male cats, castration usually proves to be quite effective in reducing urine spraying, fighting and roaming within a relatively short period.

Conferences, lectures, meetings

FEBRUARY

Radiological safety Introductory course for supporting staff not possessing professional qualifications, February 5 and 6. Details from Mr C. Lewis, Medway and Maidstone College of Technology, Horsted, Maidstone Road, Chatham, Kent ME5 9UQ.
Current diseases of poultry Course arranged by the Kesteven Agricultural College, Brant Broughton House, Brant Broughton, nr Lincoln, February 17 to 19. Details from Mr J. L. Odell, Kesteven Agricultural College, Caythorpe Court, Grantham, Lincs NG32 3EP.
Pigs: How far integration? Meat and Livestock Commission-*Farmers Weekly* conference, Cambridge, February 17 to 19.
Conference on experimental medicine and surgery in primates Jerusalem, Israel. February 24 to 27.
Industrial radiological protection Four-day residential course on general radiological protection and the sealed sources regulations, February 24 to 27. Details from Head, School of Science, Ipswich Civic College, Rope Walk, Ipswich.
Man as his own experimental animal Lecture by Professor P. Turner, at The Pharmaceutical Society's House, 17 Bloomsbury Square, London. February 27 at 7 pm.
Some diseases of fish, rabbits and mink One-day lecture course, Department of Clinical Veterinary Medicine, Madingley Road, Cambridge. February 28.

MARCH

Endangered deer British Deer Society symposium, Edward Lewis lecture theatre, Middlesex Hospital Medical School, Cleveland Street, London W1. March 1 at 11.30 am.
The Nutrition Society Details of programme from Dr J. D. Sutton, National Institute for Research in Dairying, Shinfield, Reading RG2 9AT. March 14.
European conference on equine nutrition Cambridge, March 18 to 21. Programme and registration forms from the Conference Secretary, 76 Kingswood Road, Tadworth, Surrey.
Association of Veterinary Anaesthetists of Great Britain and Ireland Spring meeting at University of Liverpool Veterinary Field Station, Leahurst, Neston, Wirral, Cheshire. March 25 and 26.

APRIL

Mastitis control International Dairy Federation Seminar, University of Reading. April 7 to 10.
History of veterinary medicine 12th International symposium, Rapperswil am Zürichsee (Switzerland). April 17 to 19.
Radiological safety Training course organised by the National Radiological Protection Board. Held in the evening, approximate duration two hours. At Bristol Polytechnic, April 10. Details from Mr D. T. Mullarkey, National Radiological Protection Board, Harwell, Didcot, Berks, OX11 0RQ.

MAY

European Society of Veterinary Surgery congress Copenhagen, Denmark. May 8 to 11. Subjects include: Abdominal surgery in cattle, orthopaedics, dental diseases of small animals, experimental surgery. Details from the Secretariat, ESVS, Institut for Kirurgi, Bülowsvej 13, 1870 Copenhagen V, Denmark.
Animal Models of Human Pathology VIth annual meeting of the French Society for Laboratory Animal Science, at the University of Paris-Val de Marne Medical School, 94000, Creteil. Details from Professor J. C. Friedman, Centre d'Etudes Biologiques I.F.M., BP 309, 27005 Evreux, France, May 31.

Efficacy of Dominant Male Sterilization to Reduce Reproduction in Feral Horses

Control of feral horse (*Equus caballus*) populations on federal lands in the western United States, since their protection by federal legislation in 1971, has been difficult and controversial. Constraints on management alternatives have been imposed by Congress and public interest groups (Wagner 1983, Boyles 1986). One management technique, advocated by Turner and Kirkpatrick (1986), is temporary sterilization of dominant males to reduce reproductive rates. Horses are polygynous, with dominant males maintaining a harem of females throughout the year (Berger 1986:129), so treating the dominant male might limit reproduction in many females. Kirkpatrick et al. (1982) treated 10 dominant males in Idaho with microencapsulated testosterone propionate. They reported reduced foal production for 1 year in 7 treated bands and suggested use of the technique to manage feral horse populations. But the effectiveness of the technique as a management tool has been questioned. Nelson (1978:64) and the National Research Council (1982) indicated that the technique is dependent on a stable harem structure and assumes that dominant males perform all breeding. Because of these conflicting opinions, the Bureau of Land Management (BLM), the primary agency responsible for managing feral horses, requested additional research on sterilizing dominant males. Our objective was to evaluate the efficacy of sterilizing dominant males to reduce foaling rates of feral horses for ≥ 2 years in Nevada and Oregon.

STUDY AREA AND METHODS

The Flanigan Herd Management Area (HMA) in northwestern Nevada and the Beaty Butte HMA in southeastern Oregon were chosen for study. The Flanigan HMA (66 km^2) primarily is mountainous with maximum relief of approximately 1,000 m. The Beaty Butte HMA (1,769 km^2) mainly consists of broad, flat plateaus with maximum relief of approximately 500 m. Both areas are managed by periodic removals of horses by the BLM. The most recent removals, before the study, occurred in September 1985 and November 1984 in the Flanigan and Beaty Butte areas, respectively. The BLM surveys conducted in the fall of 1985 resulted in counts of 320 horses (postremoval) in the Flanigan area and 167 horses in the Beaty Butte area.

Horses were trapped for the study between 5–10 December 1985 in the Flanigan area and 3–6 February 1986 in the Beaty Butte area. A helicopter was used to locate and herd individual bands into corral traps. Each horse was funneled into a squeeze chute, sex was determined, and age was estimated based on tooth eruption and wear (Am. Assoc. of Equine Practitioners 1981).

All horses ≥3 years old were fitted with numbered collars. We photographed each collared horse and recorded coat color plus face and leg markings to assist in identification throughout the study.

If >1 male was present in a band, we observed interactions among band members in the corrals until the dominant male could be identified. Dominance was indicated by outcomes of confrontations between adult males. We sterilized the dominant male in each group and fitted it with a numbered collar carrying a radiotransmitter. Vasectomy was chosen for sterilization because its effect was assured for >1 breeding season.

Males were immobilized with etorphine hydrochloride and xylazine hydrochloride using procedures described by Plotka et al. (1987). Following immobilization, the rear legs were secured with a rope, and the scrotal area was washed with Betadine solution. During surgery, diazepam (20–40 mg) was administered intravenously, as required, to reduce muscular rigidity and tremors (Plotka et al. 1987). A small (approx 3 cm) incision was made along the midline of the scrotum and the vas deferens was isolated by blunt dissection. Following ligation of the vas deferens with a 2-0 silk suture at 2 locations approximately 2 cm apart, a 1-cm segment was excised. The procedure then was repeated on the other side through the same incision. The incision was not sutured to allow drainage and minimize swelling. After intramuscular administration of 10.5×10^6 units of benzathine penicillin, immobilization was reversed with diprenorphine and yohimbine as described by Plotka et al. (1987). After all horses from a band had been processed, they were released as a group.

We attempted to locate each vasectomized male by aerial surveys from a helicopter 3–4 times annually between June and August 1986 and April–July 1987 and 1988. However, the April survey in Flanigan was omitted from the analysis because it occurred before the peak of foaling for that year. Baseline data collection by aerial survey began in spring 1986, before treatment could be effective (females were already pregnant for that season at the time of surgery). We searched each study area systematically, recording the number of adults and foals in each band. When collared horses were seen, we flew close enough to record collar numbers of marked animals in each band. By 1987, many collar numbers were unreadable, and vasectomized males sometimes had to be identified by radio frequency. If a vasectomized male was not observed during a survey, telemetry was used to try to locate the horse.

Approach by the observation helicopter frequently caused bands of horses to coalesce or split temporarily. When feasible, data were not recorded until large groups of horses split into smaller groups, presumably individual bands. Sometimes, however, we recorded numbers of adults and foals in the large groups. Thus, our data consisted of numbers of adults and foals in groups containing a male identified as vasectomized (treated groups) or groups without a male identified as vasectomized (untreated groups). Occasionally, foals from bands without treated males were recorded in groups with vasectomized males because intermingling of bands occurred during surveys.

We assumed that each aerial survey provided 1 independent sample of the foal/adult ratios in treated and untreated groups for a specific short time interval. We tested the efficacy of our sterilizations by contingency table analysis of number of adults and foals in treated and untreated groups of horses for each survey. We recognize that such an analysis likely underestimates efficacy of the treatment because foals from bands where the male was untreated occasionally joined treated groups as described above.

Data from aerial surveys were augmented by ground observations made during behavioral studies conducted from April through November 1987 (72 observation days) and in January plus May through August 1988 (39 observation days) in the Flanigan area. Observations in the Beaty Butte area (15 observation days) occurred in July and October 1987. When numbered collars were missing or unreadable, horses were positively identified using the descriptions and photographs taken at capture.

Data from ground observations were analyzed differently from aerial observations because ground surveys resulted in many observations of particular bands and few of others; thus, it was impossible to obtain a pool of observations reflecting foal/adult ratios for a specific short interval.

Vasectomized males were recaptured to replace damaged collars when needed. Horses were immobilized using darts containing etorphine and lyophilized xylazine following procedures described by Plotka et al. (1987).

RESULTS

In the Flanigan area, we captured 175 horses (77 male, 98 female) in 30 bands. In 25 bands with both males and females, 12 contained 1 adult male (≥3 yr old) and 13 had >1 adult male. Twenty males were vasectomized, radiocollared, and released with their band. One 17-year-old male died during handling, apparently from a complication with anesthesia, and the other adult male (8 yr old) in the band was vasectomized.

In the Beaty Butte area, we captured 148 horses (71 male, 77 female) in 25 bands. We collared horses from 19 distinct bands, including 2 bachelor bands and 2 harem bands from which the dominant male apparently had escaped. Among bands containing both males and females, 9 had 1 adult male, and 6 had >1 adult male. During 1 drive, the pilot de-

[a] Females were pregnant when males were treated in December 1985 and January 1986; hence, foaling in 1986 was unaffected by treatments.
[b] Number of treated males counted in the survey is in parentheses.
[c] The 21 April survey was conducted before the peak of foaling and is not included in annual total or analyses.

viated from the normal procedure of capturing individual bands when he consolidated 32 animals for capture. We held the horses overnight anticipating that the dominant males would isolate their bands from the others. They sorted into 6 groups from which 5 dominant males could be discerned; these 5 were vasectomized. Twenty dominant males were treated, but only 19 were released because 1 showed signs of radial nerve damage after surgery and was euthanized when no improvement in his condition was noted after 3 days in captivity.

Numbers of treated males seen in aerial surveys decreased each year (Table 1). This decrease was primarily attributed to collars lost or removed from treated males during the study. In the Flanigan area, 10 collars were retrieved from the ground before data collection in 1986. Three males were immobilized in January 1986 and 2 collars were replaced; 1 male died from injury during the recapture effort. Three additional collars were retrieved in 1987, and 2 in 1988 before data collection, and 2 collars were lost during the 1988 spring flights.

In Beaty Butte, 2 males were lost from the

This content downloaded from 129.82.52.33 on Thu, 24 Jul 2014 18:07:44 PM
All use subject to JSTOR Terms and Conditions

study before data collection in 1986; 1 collar was lost and 1 male died (cause of death was undetermined). Six collars were lost between surveys in 1986 and 1987, and 1 additional collar was lost between 1987 and surveys in 1988. Damaged collars were replaced on 8 horses in 1987 and 1988.

Examination of retrieved collars revealed numerous rips in the collar material and tooth marks on the transmitter container; 6 transmitters had been torn from the collars. This extensive collar loss and damage was attributed to fighting among harem males.

Data collection in 1986 allowed assessment of the effect of capturing and handling horses on foaling rates, improvement of flight procedures, and observer familiarity with the study areas. In 1986 foaling rates (foals/100 adults) in both study areas seemed higher among treated groups than untreated groups (Table 1). This result was expected because all treated males were dominant males in harem bands, but untreated groups, which usually consisted of uncaptured, thus unmarked, horses, contained both harem bands and bachelor bands. Five of 30 bands we captured in Flanigan and 2 of 19 bands in Beaty Butte were bachelor groups, and we avoided capture of bachelor groups in both study areas when feasible.

Foaling rates seemed reduced in treated groups in both Flanigan and Beaty Butte study areas in 1987 and 1988 (Table 1). Coalescing of groups of horses was more of a problem in the Beaty Butte area than in Flanigan. This mixing of groups in Beaty Butte was attributed to the flat terrain combined with few places where water was available; on each survey in Beaty Butte we encountered 30–75 horses near each of 2 wells. As the helicopter approached, the horses ran in 3–5 large groups that subsequently split into smaller groups as we searched for collars. In the Flanigan area, where water sources were dispersed, bands of horses tended to remain separated, and we encountered only 1 group of >30 horses in 3 years of surveys.

Our analyses of aerial surveys (Fig. 1) indicated that treated groups of horses had fewer foals than untreated groups in the Flanigan area in 1987; treatment effectiveness was marginal in 1988. In Beaty Butte, efficacy of treatments was less clear; 1 of 7 flights provided results with a difference ($P < 0.05$) in foaling rates between treated and untreated groups. Trends in results were apparent, however. Treatments seemed more effective in Flanigan than Beaty Butte and more effective in 1987 than 1988.

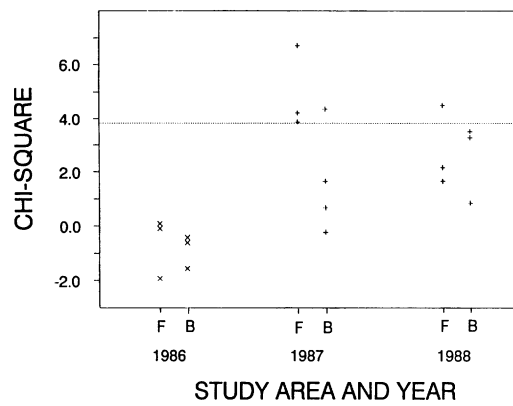

Fig. 1. Chi-square values of contingency tables comparing number of adults and foals in treated versus untreated groups of horses in the Flanigan, Nevada (F) and Beaty Butte, Oregon (B) study areas, 1986–1988. Females were pregnant when males were treated in December 1985 and January 1986; hence, foaling in 1986 was unaffected by treatments. Sign indicates the direction in which deviations occurred; positive indicates fewer foals in treated than untreated groups (positive treatment effect), and negative indicates more foals in treated than untreated groups. The dashed line shows the χ^2 value at which $P = 0.05$ with 1 df.

DISCUSSION

Although numbered collars with radiotransmitters attached have been used to identify and locate large numbers of female feral horses (Siniff et al. 1986, Eagle et al. 1992), their use for marking feral males seems to be of limited value. Berger (1986:134) noted that biting was a favored form of aggression between males, and the damage received by collars in our study indicated that radiocollars were a target of that biting. Therefore, we recommend alternative

All use subject to JSTOR Terms and Conditions

techniques, such as freeze brands or implantable radiotransmitters, to identify and locate feral males in future research.

Foaling rates in 1986 were unaffected by male sterilization because females already were pregnant when surgeries were performed. In both study areas, the proportion of foals in treated groups did not differ from that in untreated groups (Table 1, Fig. 1), and these were similar to foal/adult ratios in 3 other herds in the Great Basin Desert (Eagle et al. 1992). We concluded that despite the lack of sham-treated controls, the reduction of foaling rates in our study was caused by the treatment rather than stress during capture and handling procedures or disturbance during data collection.

There was a reduction in foaling within bands of horses when dominant males were sterilized, a conclusion consistent with that of Kirkpatrick et al. (1982); they selected bands with 1 adult male and found their treatment reduced foaling by about 80% for 1 year. We saw a reduction in foaling among treated groups in a herd area where approximately half of the bands captured contained >1 adult male, and the reduction in foaling among treated groups was noted for 2 years. We could not calculate the extent to which foal production was reduced.

Some foaling occurred in bands of horses with vasectomized dominant males, and ground observations provided insights into the apparent failure of our treatment to eliminate all foaling in bands with treated males. Band composition changed because of dispersal of juvenile horses of both sexes and acquisition of new females, possibly already pregnant, by dominant males. The most unstable band in our study contained 2 males (1 vasectomized) that alternated dominance every 2–3 months. Females sometimes left the band during exchanges of dominance between the 2 males. During 1988, foals were produced in 2 bands with treated dominant males. Both bands contained subordinate untreated males that had challenged for dominance and access to females. Although both vasectomized males remained dominant, the presence of foals in these bands suggested that subordinates succeeded in inseminating some of the females.

Although sterilization of dominant males may be an effective treatment to reduce foaling in a small sample of bands selected from a population, this treatment might not limit population growth. Enough animals must be treated so that foal production is reduced in the entire population (Garrott 1991). The success of male sterilization for limiting feral horse populations primarily depends on stable bands and the ability of the dominant male to prevent copulations by subordinate or bachelor males (Natl. Res. Counc. 1982). Although stable harem bands seem to be common (Kirkpatrick and Turner 1986), instability occurs in rapidly expanding populations (Berger 1986:77, 129) and when conditions are harsh (Miller 1981). Mean annual growth rate of 13 feral horse herds in the western United States was estimated to be about 20% (Eberhardt et al. 1982, Garrott et al. 1991), so many populations of horses may be rapidly expanding between periodic removals by the BLM.

Eberhardt et al. (1982) studied the Beaty Butte herd and estimated the instantaneous annual rate of increase from 1972–1977 as 0.20; they projected this rate from 1978–1980 and found it compatible with observations. Thus, the Beaty Butte herd is experiencing rapid growth and is subject to instability of bands. In their study of 5 feral horse herds (including Flanigan and Beaty Butte) in Nevada and Oregon, Bowling and Touchberry (1990) found that nearly one-third of 121 foals from 69 intact bands were sired by males that were unassociated with the band at the time of capture.

A further complication for male contraception has been suggested by Garrott and Siniff (1992). They demonstrated through modelling that in a polyestrous species with reproductive characteristics like those of feral horses, if the probability of breeding with a sterile male was significant (0.5–0.9 at each estrous period), the foaling dates for the population would be seasonally shifted. Obviously, this possibility should be considered if male contraception becomes part of management plans.

Ground observations in our study and findings by Bowling and Touchberry (1990) indicate that the bands in our study populations and others in the Great Basin are somewhat unstable and that breeding by subordinate or bachelor males occurs; thus, sterilization of dominant males, although efficacious in small samples, may be of limited use as a tool for population management. We therefore recommend that future research include studies in which both male-oriented (Kirkpatrick et al. 1982, this study) and female-oriented fertility control (Kirkpatrick et al. 1990, Eagle et al. 1992) are tested as tools for limiting growth of feral horse populations.

SUMMARY

We studied the efficacy of dominant male sterilization for reducing reproduction in feral horses on western rangelands by vasectomizing harem males in 20 bands of horses in each of 2 study areas. Reduction in foaling occurred for 2 years in groups of horses containing sterilized dominant males, thereby indicating the treatment was efficacious. However, the treatment may be unable to reduce foaling sufficiently to effect population control because females may move between bands and subordinate or bachelor males may breed.

Acknowledgments.—The authors wish to acknowledge the cooperation of BLM personnel in the Carson City, Nevada, and Lakeview, Oregon, district offices. C. J. Heaverne or R. Crowe skillfully piloted the helicopter for most counts. We also thank M. McBrair, J. Duffelmeyer, and K. Bildstein for assistance with ground observations. Comments by R. K. Swihart and 3 anonymous reviewers were most helpful. Funding for this project was provided by BLM contract USDI-AA852-CT5-29.

Abstract

Objective: To determine the temperature of a vessel sealer and divider device during unilateral paralumbar laparoscopic ovariectomy in standing, sedated mares.

Study Design: Prospective study.

Animals: Fifteen healthy research mares.

Methods: Healthy mares with normal ovarian palpation and ultrasonographic appearance were enrolled. Horses were restrained in standing stocks and sedated. A right or left paralumbar ovariectomy was performed with a laparoscopic portal and 2 instrument portals. Ovaries were excised with traumatic forceps and a blunt tip vessel sealer and divider. Temperatures of the vessel sealer and divider were recorded with a thermocouple device adhered to the tip of the instrument. Variables were reported as median and interquartile range (IQR).

Results: Surgical time was 30 minutes (IQR, 25-32) including use of the vessel sealer and the divider for 4.1 minutes (IQR, 3.2-5.8). The tip of the instrument reached temperatures of 77°C (IQR, 72-85) during activation and 64°C (IQR, 61-67) at end cycle. The median increase in end-cycle instrument tip temperature per activation cycle was 2°C (IQR, −1-6). All mares returned to their intended use.

Conclusion: Despite the instrument temperatures observed during unilateral laparoscopic ovariectomy, surgical complications were minimal. The clinical relevance of the increase in instrument tip temperature of the vessel sealer and divider is presently unclear, but surgeons should use the instrument with caution, especially in close proximity to viscera. The increase in temperature observed at the tip of the vessel sealer and divider during unilateral ovariectomy could be associated with morbidity. The clinical relevance of instrument tip heating during other procedures, such as adhesiolysis and intestinal resection, is unknown and should be evaluated.

1 | INTRODUCTION

Minimally invasive standing laparoscopy is a common technique used for performing ovariectomy in the mare.[1,2] The advent of energy devices for laparoscopic surgery has resulted in reduced blood loss and shorter operative times in both people and animals. Numerous reports describe the

The results of this study were presented in part at the 12th International Equine Colic Research Symposium; July 18th, 2017, Lexington, Kentucky.

advantages of vessel sealing devices, but disadvantages may be overlooked. Heating of the vessel sealer and divider instrument tip could increase surgical morbidity in surgical patients if the instrument inadvertently comes in contact with adjacent viscera.[3] Electrosurgery has been associated with inadvertent trauma to nearby tissues through the lateral spread of thermal energy.[4-6] Thermal injury, including denaturation of proteins and necrosis, can occur when tissues adjacent to surgical devices are heated at least 4°C. Thermal injury may have negative consequences, such as tissue dysfunction or perforation of vulnerable structures.[4,7] However, thermal heating during serial activation of the vessel sealer and divider instrument has not yet been investigated in the horse.

The present study sought to determine the temperature at the tip of the vessel sealer and divider when applied to unilateral paralumbar laparoscopic ovariectomy in the standing, sedated mare. We hypothesized that this temperature would increase beyond a safe threshold for visceral tissue during serial activation of the device.

2 | MATERIALS AND METHODS

Fifteen grade mares participating in a research project requiring unilateral laparoscopic ovariectomy were enrolled in a study protocol approved by the Colorado State University Institutional Animal Care and Use Committee (IACUC 15-5984A) in compliance with the US National Institutes of Health *Guide for the Care and Use of Laboratory Animals*, the Animal Welfare Act, and the Federation of Animal Science Societies *Guide for the Care and Use of Agricultural Animals in Research and Teaching*. Mare age was recorded.

All mares were stalled the evening prior to surgery, and food was withheld for approximately 12 hours prior to the procedure. Mares were restrained in standing stocks for surgical preparation. Procaine penicillin (22,000 IU/kg IM) and flunixin meglumine (1.1 mg/kg IV) were administered 30 minutes prior to surgery. A dose of detomidine hydrochloride (0.01 mg/kg IV) and a dose of butorphanol tartrate (0.01 mg/kg IV) were administered immediately prior to the surgical procedure.

2.1 | Surgical procedure

The left or right paralumbar fossa was clipped and aseptically prepared. Laparoscopic portal sites were each infiltrated with 5 mL of 2% mepivacaine hydrochloride local anesthetic. After routine draping, 3 portals were created as previously described.[1] For each portal site, a scalpel was used to create a 1 to 1.5-cm incision in the skin and external muscular fascia, after which a blunt obturator and an 11-mm diameter, 20-cm length laparoscopic cannula were inserted into the abdomen. The first portal was created midway between the tuber coxa and the last rib, at the level of the ventral aspect of the tuber coxa. Position within the abdomen was confirmed by using a 10-mm diameter, 30°, 57-cm length rigid laparoscopic telescope (Hopkins Telescope 62032BP; Karl Storz Veterinary Endoscopy-America, Goleta, California) prior to insufflation. Carbon dioxide was then insufflated at a rate of 12 L/min to a maximum pressure of 10 mmHg. The second and third portals were 5-10 cm craniodorsal and caudoventral to the first portal.

FIGURE 1 A thermocouple has been attached to the vessel sealer and divider instrument tip to allow temperature measurement of the instrument tip during the laparoscopic procedure. The wire connection between the thermocouple and microprocessor-based, digital thermometer is held to the instrument with a blue electric shrink-wrap sleeve

The laparoscopic telescope was moved to the craniodorsal portal to facilitate observation and instrument use during ovarian manipulation. When the ovary was visible, a laparoscopic needle (SD161919; Surgical Direct, Deland, Florida) was inserted through a portal, and 10-20 mL of mepivicaine hydrochloride was injected into the mesovarium through multiple injections and applied topically to the ovary and mesovarium. After the ovary was anesthetized, it was grasped with traumatic forceps and a 10-mm diameter, 37-cm length blunt tip vessel sealer and divider (LS1037 Ligasure; Covidien-Medtronic, Mansfield, Massachusetts) with an attached thermocouple connected to a microprocessor-based, digital thermometer with 7 Hz data recording (54IIB; Fluke Corporation, Everett, Washington), which was attached to an energy platform (Force Triad; Covidien-Medtronic) at the intermediate power setting, and was used to transect the mesovarium, mesosalpinx, and proper ligament of the ovary, avoiding contact with surrounding abdominal structures (Figure 1). The wire connection between the thermocouple and thermometer was held to the instrument with a blue electric shrink-wrap sleeve. Because of the resulting increased diameter, insertion of the vessel sealer and divider with attached thermocouple required removal of the laparoscopic cannula. Temperature readings were taken outside of the abdomen approximately 10 seconds after insertion into the

abdomen, upon initial clamping of soft tissues, immediately after each sealing cycle, and prior to removal of the instrument from the abdomen. The vessel sealer and divider device was removed from the abdomen after recording of the final temperature, without delay or other regard to tip temperature. Position of the thermocouple was observed during vessel sealing and dividing (Supporting Information Video). Vessel sealer and divider activation time and number of activations were recorded. The traumatic forceps remained attached to the amputated ovary in the abdomen, and the ovarian pedicle was observed to ensure adequate hemostasis had occurred.

Abdominal insufflation was discontinued, and positive abdominal pressure was released. The ovary was removed by enlarging the ventral incision. For incisions >4 cm, the external abdominal oblique muscle fascia was opposed with 2-0 polyester in a simple continuous pattern. Skin was closed with 2-0 nylon in a simple continuous (n = 7) or a continuous horizontal mattress (n = 8) pattern. Surgical time was recorded as the duration from the first incision to completion of incisional closure.

2.2 | Postoperative care

Postoperatively, mares received flunixin meglumine (1.1 mg/kg IV every 12 hours) for 5 days. Feed was gradually reintroduced, and monitoring consisted of twice daily examination including incisional inspection, behavior, appetite, urination, and defecation. Mares were confined to a stall until suture removal 10-14 days after surgery. After suture removal, horses were allowed small paddock turnout for an additional 2 weeks, prior to gradual return to routine exercise.

All continuous variables were reported as median and interquartile range (IQR). A Friedman test of multiple comparisons was used to identify changes in vessel sealer and divider tip temperature.

3 | RESULTS

Mare median age was 13 years (IQR, 10-14). Ovaries were removed unilaterally in all mares by using the described technique with no operative complications. Median surgical time was 30 minutes (IQR, 25-32), and median surgical time during which the vessel sealer and divider instrument was used was 4.1 minutes (IQR, 3.2-5.8). Median number of vessel sealer and divider activations was 12 (IQR, 10-12). Median temperature outside the abdomen prior to surgery was 23°C (IQR, 22-25). Median temperature inside the abdomen following initial insufflation was 32°C (IQR, 31-33). The thermocouple became dislodged from the instrument tip in 2 mares upon insertion into the abdomen and was located within the abdominal cavity approximately 1 cm from the instrument tip (n = 1) or along the instrument shaft and 2 cm

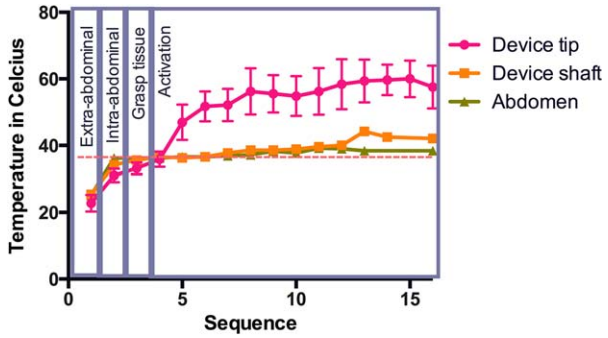

FIGURE 2 Temperature measurements (mean ± SD) recorded during unilateral laparoscopic ovariectomy performed with a vessel sealer and divider device

from the instrument tip (n = 1); therefore, data from these 2 mares were not included in instrument tip temperature calculations. Median temperature of the instrument tip after initial clamping of ovarian pedicle tissues was 34°C (IQR, 33-34). Sequential end-cycle temperature increases were observed with instrument activation. The vessel sealer and divider end-cycle tip temperature increased significantly from the preabdominal and postabdominal insertion temperature after the third instrument activation cycle. The vessel sealer and divider end-cycle tip temperature increased significantly from the initial soft tissue clamping temperature after the fifth instrument activation cycle. Median maximum instrument tip temperature during activation was 77°C (IQR, 72-85). Median end-cycle maximum instrument tip temperature was 64°C (IQR, 61-67). The median increase in end-cycle instrument tip temperature per activation cycle was 2°C (IQR, −1-6). After the initial activation of the vessel sealer and divider, instrument tip temperature did not return to preactivation values during the recording period in any of the mares. The ratio of the duration of instrument activation to the inactive interval was approximately 1:3, with a median activation time of 4.0 seconds (IQR, 4-5) and an inactive time of 10.5 seconds (IQR, 8-15) per activation. All temperature measurements are summarized in Figure 2.

The majority of mares had normal examination parameters postoperatively. One mare had mild colic that resolved after flunixin meglumine administration. Another mare developed serous incisional drainage and crusting postoperatively that resolved by the time of suture removal. No mares were prevented from returning to their intended activity due to complications resulting from ovariectomy.

4 | DISCUSSION

The main finding of our study is that end-cycle temperatures at the tip of the vessel sealer and divider increased with each sequential activation, reaching up to 77°C during activation, in mares undergoing unilateral ovariectomy. Temperature

increases in our study exceeded those described in a previous report, in which temperatures at the tip of a vessel sealer and divider reached 45.8°C during the activation cycle and were associated with tissue temperature increases exceeding 15°C for up to 20 seconds after activation.[3] Thermal tissue damage can occur when contact with surgical devices increases collateral tissue temperatures by 4°C or more. Inadvertent contact between the vessel sealer and divider and adjacent tissues during or following activation could, therefore, result in necrosis and other indicators of thermal damage in horses during ovariectomy.[4] Caution is also likely indicated to prevent surgeon injury during open or hand-assisted procedures.[8]

Endoscopic electrosurgical technology, specifically, electrothermal vessel sealing devices, have contributed to the rapid advancement of veterinary minimally invasive surgery. These devices have essentially eliminated the requirement for suture loops, intracorporeal suturing, or emasculation in many surgical procedures. Instead, these instruments allow hemostasis but remain easy to use and require fewer technical skills.[9-12] Although vessel sealing and dividing devices might be considered less technically challenging and a mainstay of equine minimally invasive procedures, including ovariectomy,[9,10] the present study suggests that their application may be associated with risks of iatrogenic tissue damage. The present study justifies caution when using a vessel sealer and divider during excision of the ovarian pedicle. Endoscopic control is required to check the location of adjacent viscera and to minimize the risk of lateral thermal energy spread and inadvertent contact between the instrument tip and tissues. Local erythema has been reported in the descending colon mesentery 3 days after ovarian excision with a harmonic scalpel, although gross changes were not noticed at the time of surgery and occurred in mares without detectable clinical effects.[13] Fibrosis of the descending colon mesentery has also been observed 3 weeks after ovariectomy in horses that underwent operations with the same vessel sealing and dividing device applied in the present report.[14] However, this instrument creates minimal collateral thermal spread, and its tip cools rapidly compared with other devices.[15] Activation of this device during equine ovariectomy in which the tip was in contact with the duodenum cranial to the ovarian pedicle for approximately 1 second has resulted in intraoperative blanching of the serosa and serosal fibrosis 3 weeks postoperatively, without associated clinical signs.[14] No complications directly related to the proximity of the electrosurgical devices were observed in the present study.

Multiple investigators have evaluated the safety of vessel sealing and dividing devices in close proximity to vital structures as well as the temperature of sealed tissues.[16,17] Previous articles describing clinical trials have reported device-related thermal injuries with vessel sealing and dividing devices, such as ureter injury, small bowel perforations, colonic perforations, and vascular injury.[18-21] Similar to the findings in the present study, Dunay et al[17] reported that the surface temperature at the sealing site of a vessel sealing and dividing device reached 69.25°C ± 0.98°C. Others report temperatures of the vessel sealer and divider reaching means of 88.9°C, 96.4°C, and 76°C during in vitro transection of porcine peritoneum, mesentery, and liver, respectively.[8] Mean maximum temperatures of 55.5°C have been reported 2 mm lateral to the vessel sealer and divider activation site during a single activation in vitro.[15] Furthermore, Chikamoto et al[16] evaluated thermal injury to the inferior vena cava after contact with a vessel sealing and dividing device during activation. Significant increases in temperature occurred within tissues as the activation duration increased from 5 to 15 seconds.[16] Muscular layers of the inferior vena cava sustained histological damage when placed in contact with the device for 10 seconds.[16] Activation time in the present study lasted approximately 5 seconds, with sequential increases in device tip temperatures observed over time. Investigators have previously reported that the vessel sealer and divider tip temperature exceeded 42°C for approximately 10-15 seconds after 15 seconds of application.[22] On the basis of these findings, care should be taken to avoid contact, especially during or immediately after activation and in applications requiring serial activation over several minutes, such as in the present study. Maintaining appropriate spacing between the device tip and adjacent organs can be especially challenging in the horse, depending on the amount of intestinal distention or relative migration of the viscera. Fasting horses prior to minimally invasive surgery is critical for maintaining safe distances between viscera and reducing the risk of accidental contact with the vessel sealer and divider.

Our study focused strictly on temperatures at the tip of the vessel sealer and divider during laparoscopic surgery in horses. Measuring tissue temperatures adjacent to the device would have determined collateral thermal variations relative to instrument tip temperature and improved the clinical relevance of our findings. Additional studies are warranted to determine the influence of bilateral ovariectomy or other common equine procedures, such as those requiring a longer duration of activation or additional activations. Real-time thermography could be considered to evaluate instrument and tissue temperatures and regional or collateral heating.[23] Furthermore, because thermal injury at the cell or tissue level is influenced by temperature and duration, evaluation of the duration of tissue and instrument temperature increases would further elucidate the risk of injury.[3,7] An ex vivo study measuring tissue temperatures at varying sites relative to the activation site of the vessel sealer and divider could further elucidate thermal spread and provide more information relative to the clinical application of this device. Finally, the time required for the instrument to return to preactivation

temperature and duration of thermal risk could have been determined if temperatures at the tip of the device had been monitored beyond final activation in the present study.

The present study emphasizes the importance of surgical technique and safety when using a vessel sealer and divider in minimally invasive surgery. In contrast to small animal and human surgery, equine tissues can be thicker and larger and may, therefore, accommodate longer periods of device activation before heat generation increases the risk of inadvertent thermal injury. In addition, the size of the equine abdomen provides adequate working space for the vessel sealer and divider, further reducing the risk of iatrogenic damage. The benefits of vessel sealing and dividing technology in minimally invasive surgery far outweigh the potential risks. Furthermore, lateral thermal injury can be mitigated by minimizing device activation times, increasing the activation interval, using the lowest effective device settings, and irrigating the region with cooled saline following device activation.[24,25] However, surgeons should be aware of the safety margin of these devices and understand that inadvertent contact between the device tip and surrounding tissue during or immediately following activation could result in thermal injury. Such damage could lead to surgical complications, especially in operations requiring multiple, sequential activations in close proximity to bowel or other viscera in sedated patients.[26] This study shows that unintentional contact between the tip of the vessel sealer and divider and abdominal structures is likely to result in thermal tissue damage. The present study highlights the importance of surgical safety, specifically the requirement to avoid contact with tissues and organs during or following activation of the vessel sealer and divider in equine laparoscopic surgery.

Dear Diplomates,

With the Annual SFT Meeting just around the corner on July 21 to 24 in Omaha, NE, I would like to note (again) that 2021 marks the 50th anniversary of the founding of the ACT as a Recognized Veterinary Specialty Organization, and as such, the occasion will be a featured component of the SFT meeting. A major highlight will be a keynote address by former ACT President, Dr. John Kastelic, in which he will share an historical overview of the first 50 years of the ACT. Dr. Kastelic's presentation will be given during the Plenary Session on Friday morning, July 23rd. Additional recognition events are slated for our annual ACT business meeting on Thursday, July 22nd, and a social reception later that same day (details tbd). Given the importance of the ACT milestone we will be celebrating in Omaha, I hope to see many of you there.

One group we certainly plan to acknowledge this summer are the Charter Diplomates of the ACT who are listed on the ACT website at https://www.theriogenology.org/page/History. Over the years, I have occasionally perused the list of Charter Diplomates, and each time I have done that I have been struck by the sheer eminence of those individuals (most of whom are now deceased). Not surprisingly, it's a "Who's Who" of Theriogenologists! Although I only had the pleasure of meeting a few of the Charter Diplomates, those I did meet made a lasting impression on me. And on that note, I would like to recount here a fond memory I have of sharing breakfast at an SFT meeting with ACT Charter Diplomate, Dr. Stephen J. Roberts of "Veterinary Obstetrics and Genital Diseases Theriogenology" (i.e., "big red book") fame. To set the stage, Dr. Roberts and I share our Alma Mater, Cornell University, so my knowledge of (more so knowing the Legend of) Dr. Roberts goes back to my undergraduate days at Cornell in the early 1980's. In addition to being a renowned clinical theriogenologist at Cornell (through his "retirement" in 1972, after which he practiced with his brother in Vermont for many more years), Dr. Roberts was an accomplished collegiate polo player having served as the Captain of the Cornell Polo Team, and then later the Team Coach during his time on the faculty. Collectively therefore, Dr. Roberts was a "larger than life" individual to me. Now back to the SFT meeting in San Antonio, TX in late November/early December of 2000 (in conjunction with the Annual AAEP meeting). One morning before the program started, I walked into the hotel restaurant to have breakfast, and who did I see sitting alone at a table, none other than Dr. Roberts! Now, I am not one to generally be particularly assertive, but I walked over to Dr. Roberts and introduced myself and asked if I could join him … and he graciously invited me to do exactly that! I can't say that I recall any of the details of our interaction at breakfast that day, but I have no doubt our conversation included some discussion of Cornell and his book. Given the fact that I am recounting what was likely no more than a 45-minute to one-hour interaction with Dr. Roberts that morning in San Antonio nearly 21 years ago, I hope you can sense the lasting effect it had on me. Quite simply, it's a memory I will cherish forever.

In closing, I hope that by sharing my recollection of a fairly brief encounter with Dr. Roberts, some of you will be prompted to reflect on similar experiences you have had with ACT Diplomates who have touched your lives in one manner or another. Doing so would seem to be a fitting way for each of us to begin getting into the celebratory spirit as we prepare to mark our 50th anniversary as a specialty college this summer in Omaha.

Sincerely,
Dirk Vanderwall
ACT President 2020-2021

Welcome New Diplomates!

Dr. Luis Henrique da Aguiar

Dr. Rory Gormley

Dr. Viviane Cristine Leite Gomes

Dr. Daniela Orellana Guerrero

Dr. Melissa Prell

Dr. Lacey Rosenberg

Dr. Agustin Javier Ruiz Olivieri

Dr. Julie Storme

Dr. Katie Withowski

Congratulations to the following candidates that passed the 2020 exam: Drs. James Barrett, Tessa Fiamengo, and Vanessa Peixoto de Souza.

Breakdown by Employment Type:

Academia	197
Government	9
Industry	27
Private Practice	169
Retired	43
Other	77

Breakdown by Primary Species:

Mixed	57
Bovine	124
Canine	17
Equine	176
Feline	2
Porcine	6
Small Animal	43
Small Ruminant	9
Wildlife	1
Other	87

The American College of Theriogenologists fondly remember the following members that have passed away since the 2020 spring newsletter.

Clarence John Bierschwal

Clarence John “Bush” Bierschwal, Jr., D.V.M., M.S. born 29 June 1923 in Carroll, Carroll County, Iowa to Ida Dankel Bierschwal and Clarence John Bierschwal. Bush was raised in Nevada, Iowa with his older sister, Virginia D. Bierschwal, who predeceased him 8 July 2012, in Springfield, Missouri.

Bush attended Iowa State University in Ames, Iowa briefly before World War II led him to San Diego as a Radioman in the Signal Battalion of the U.S. Marine Corps. Ultimately based in Hawaii, Bush fought in the Pacific Theater of the War (1942-45). He landed on Iwo Jima, but never talked about it. If asked he would just say he carried the radio. Bush was honorably discharged 28 September 1945, continuing his military service in the Army Reserves until he retired a Colonel, U.S. Army Veterinary Corp. (1950-1988). He received the Distinguished Service Medal, 3 Army Meritorious Service Medals and the Army Achievement Medal.

After the war, Bush returned to Iowa State where he met and married the love of his life, Lorette Beryl Nelson on 27 December 1948. Iowa State is where Bush received his doctorate in Veterinary Medicine in 1950. Bush and Beryl moved to Excelsior Springs where he first practiced. About 1952 they moved to Columbia, Missouri when Bush joined the faculty as a Professor of Veterinary Medicine and Surgery at the University of Missouri College of Veterinary Medicine. Columbia is where they raised their two daughters, Beverly B. Sherman D.V.M. (Paul) now of Springfield, Missouri and Betsy A. McQueary, D.D.S. of Rogersville, Missouri. Football Saturday at their home in Columbia was pure black and gold. In those days, all walked through campus to Faurot Field as the Autumn leaves fell, picking up the pace when Marching Mizzou was heard to play in the distance. Rain or shine, win or lose, Bush would not leave the game until the end.

Bush taught veterinary medicine at the University for 34 years (1952-1986). There he established research and clinical programs in his specialty, large animal reproduction (Charter Diplomate and former President of the American College of Theriogenologists). At MU he was twice awarded the Distinguished Teacher Award. He also received the Alumni Faculty Award, Distinguished Professor Award, Distinguished Faculty Award, Dr. David Bartlett Lecture Award and the Iowa State University Stange Award. His professional career took Bush and Beryl around the world, they loved to travel and dance. Bush loved his big band and swing music, Katy Trail, fishing, Jekyll, computers, photography, Missouri Tigers, Kansas City Chiefs, a great scotch and a fine cigar. He and his family spent a year in the Netherlands, (about 1968) on sabbatical while he taught and co-authored with Dr. C.H. W. de Bois the textbook “The Technique of Frenotomy in Large Animals”. It was in the Netherlands that Dr. de Bois introduced Bush to cycling. Bush was hooked on bicycling from then on. Veterinary students of his fondly recall making farm calls in a clinic truck with a bicycle tucked away in the back. After their farm calls were finished, Dr. Bierschwal would say “just let me off here” and then he bicycled the 30 miles or more back to the Vet School. They also report his classroom instruction was made more interesting because he loved to instruct using movies, he had made of actual procedures performed. Bush thoroughly enjoyed teaching, his students, his colleagues and photography, then along came computer digital photography. All along, he kept current, built his own computer, and could often be found late at night in his office editing film. Bush retired from the MU Vet School a Professor Emeritus. His portrait hangs in a place of honor at the Vet School to this day.

Truly, Bush and Beryl most enjoyed each other, family, and their many friends. Betsy has one son, Matt (Alex) of Ozark, and they have a young son James. Betsy has two daughters, Dr. Melissa Broaddus (J.T.) of Springfield (their son Sam) and Lindsey (Cody) of Charleston, South Carolina. Bev and Paul have two sons, Luke (Springfield) and Sam (Kansas City, engaged to Taryn Nash), and two daughters, Elise (Columbia) and Hayley (Iowa City). Bush leaves behind his cat, Tebow, now a new member of the Sherman household. All animals loved Bush, and he them.

Always active, always thoughtful of others, always positive, and always supportive, Bush taught us all many wonderful lessons, real life lessons including humility, hard work, responsibility and the importance of family and friends. Much loved, we miss him deeply but smile knowing Bush and Beryl are together again. Bush passed away Saturday, October 17, 2020 in Springfield.

Dr. Bierschwal was a founding member of the ACT.

C. H. W. de Bois

Prof. dr. C.H.W. (Cornelis Hendrik Willem) de Bois was born on 10 July 1927 and passed away on 23 January, 2021. He received his veterinary degree from the University of Utrecht and was a Professor of Veterinary Obstetrics and Gynaecology at the University of Utrecht, from 4 March 1964 to 1 January 1985. On 29 November 1965, he gave an inaugural lecture on “The development of instrumental and surgical obstetrics in horse and bovine” and he was co-author (1972) of the classic manual on fetotomy (Bierschwal CJ and de Bois CHW, "The Technique of Fetotomy in Large Animals”).

William Cates

The family of William F. Cates announces his passing on June 13, 2020 in Vancouver.

William Francis Cates was born to James Earl and Catherine Elizabeth (Simpkins) Cates on July 18, 1926 in Prior Lake Minnesota. He was the second child and oldest son in a family of seven children. As a child of the Depression, Bill learned to hunt and fish at an early age and these became life long passions. His parents farmed and worked a dairy operation in the town, and Bill helped with this as he grew. He attended elementary school in Prior Lake and finished his high school

in nearby Shakopee.

Bill was 15 years old when Pearl Harbour was attacked in December of 1941, and as soon as he finished high school in 1944, he enlisted in the U.S. Navy, serving as a Gunner's Mate on a minesweeper in the Pacific theater.

When the war was over and his enlistment done, Bill returned to Minnesota. He helped briefly with the family business, which by then had turned to home construction, and then began undergraduate work at St. John's University near St. Cloud. After earning a Bachelor of Science, he was accepted into the University of Minnesota's school of veterinary medicine, graduating with his DVM in 1954. This was the same year he married his sweetheart Ladonna Marie Scharf.

Bill worked a short time in the area while he and Donna started their family, but in 1955 they headed west to Mitchell, South Dakota, where he tried his hand at private veterinary practice. They were there a couple of years, and then returned to Minnesota, where he started on his PhD. He finished this in the early 1960s, working as an instructor at the U of M veterinary college at the same time.

All this time, the family was growing, and Bill and Donna now had five children to chase after. By the mid sixties, big changes were in store. The University of Saskatchewan was opening a veterinary college, the first in Western Canada. In 1965, Bill was offered a professorship there and the family moved to Saskatoon, where his youngest child was born, making it a family of six for Bill and Donna.

Bill enjoyed taking his family on weekend outings to places like Beaver Creek and the Forestry Farm. Sundays were special days that often involved a visit to the Victoria Ice Cream Shoppe and ended with the family gathered around TV to watch Walt Disney or Jacques Cousteau. His son Jim commented he knew Dad never played hooky from work because he always came home smelling like a cow pasture. When his children were young, it was common to see one or more of them in tow when Bill was called out to attend a sick animal.

Throughout their marriage Bill and Donna were inseparable. Their passion for dancing included several decades as members of The Happy Wanderers Square Dance Club. Bill was a quietly committed Catholic. When the family first moved to Saskatoon St Phillips Neri Church was still an unrealized vision and masses were held in a school gymnasium. Bill and Donna contributed towards building the church, supported the church's projects in South America and were among the first lay people to dispense communion.

Bill played a pivotal part in getting the Western College of Veterinary Medicine started. He taught at the U of S and worked his practice on the surrounding farms and ranches. His specialty was bovine theriogenology - herd medicine and reproduction. He was very active in research and much respected in his field, and worked at the college until he retired in 1994. He was professor emeritus for several years after that, but he and Donna enjoyed retirement and made a number of trips to Arizona and Texas, always trying to fit in a little bird watching wherever they went. They bought property at a lake north of Saskatoon, and enjoyed their time there as well.

He and Donna moved to Vancouver in 2010, where their daughter Kitty helped them out as they grew older. Bill suffered a stroke in 2011, and moved into a care home, and the family was glad that Donna was able to join him in the same home shortly thereafter.

Bill is predeceased by his beloved Donna (2015), and his siblings Jack, Anne Mae, Rosie, and Jim. He is survived his older sister and her husband (Kate and Duke Schrader), his sister in law (Pat Cates), his youngest brother and wife (Larry and Betty Cates), his six children (Steve, Cindy, Kitty, Jim, Barb, Michelle) and by his 4 grandchildren (Joel, Ryan, Zoë, and Connor).

Dr. Cates was a charter member of the ACT.

John Melancon

John Joseph Melancon, age 77 of St. Cloud passed away on Friday at the St. Cloud Hospital.

John was born September 12th, 1943 in St. Paul, MN to Joseph and Phyllis Melancon. He was known for his bright smile, generous spirit, and ability to easily make friends. He and wife Nancy visited many corners of the world making numerous friends along the way. When not travelling the globe, John enjoyed spending time with his adored children and grandchildren, playing bridge, fishing, and hunting. Always quick with a "Dad" joke, he relished time with family and friends playing parlor games, sitting by an open fire, or watching a movie with homemade popcorn.

While calling Stearns County home for more than 30 years, John grew up in the Highland Park neighborhood in St. Paul. He completed undergraduate studies at St. Thomas and went on to obtain a doctorate from the College of Veterinary Medicine at the University of Minnesota. John owned a veterinary clinic in Sauk Center for many years and then went on to work in veterinary pharmaceuticals. He retired from Merck/Merial in 2003.

He is survived by his wife, Nancy Gilbert; children, Maggie (Erin) Daugherty, Mike (Emily) Melancon, Toni Melancon, Jay (Mary) Melancon, Nathan Gilbert; siblings, Tom (Elizabeth Dichter) Melancon, Mary (Tom Spencer) Melancon, Jeanne (Bob) Dolan; and seven grandchildren.

He is preceded in death by his parents; and wife Carol.

Willis Parker

Dr. Willis G. Parker of Clayton, IN died peacefully on April 15, 2021 at Life's Journey Hospice of Avon. Willis, son of the late Roy and Doris (Kelly) Parker was born on June 10, 1936 in Greencastle, IN. Willis and his twin sister Willa Dean spent their early years growing up on the family farm near Coatesville. As a young boy he was active in both 4-H and FFA and graduated from Amo High School in 1954. He volunteered for the draft and served in the U.S. Army from 1954 to 1956.

Following his military service, Willis attended Purdue University where he earned his Bachelor of Science Degree in Agriculture in 1960. As an undergraduate student he resided in Rochdale Co-op House and participated in Purdue Reamer Club, Baptist Student Foundation, and Purdue Men's Varsity Glee Club. Upon graduation he married Linda Owens on August 14, 1960. They started their life together in West Lafayette, IN where Willis entered the Purdue University School of Veterinary Medicine. He received his Doctor of Veterinary Medicine Degree with the second graduating class in 1964. After graduation Willis and Linda, along with their son Eric, returned to their roots near Coatesville where Willis established a mixed veterinary practice. After the birth of their daughter Lisa, he made the decision to pursue his interest in animal reproduction and in 1965 accepted the position of staff veterinarian at American Breeders Service (ABS) located in DeForest, WI where he worked for 26 years. The family's primary residence was in Poynette, WI where Willis served several years on the Poynette Public Schools' Board of

Education.

Throughout his life, Willis was a humanitarian who was committed to his profession as well as service to others. He was a member of the American Veterinary Medical Association (AVMA) as well as the IVMA and WVMA, the American Association of Bovine Practitioners, the Society of Theriogenology, and the American College of Theriogenologists which he served as a diplomate and president from 1983-84. In 1990, Willis represented ABS on a trade mission to

Lithuania. This experience spurred his consulting and educational programing trips to the Baltic countries and to Ethiopia with Project Mercy. In addition, he served several weeks in the United Kingdom for the U.S. Department of Agriculture's Animal Disease Eradication Program. For his professional contributions, Willis was recognized by the WVMA as the 1991 Wisconsin Veterinarian of the Year and in 2000 was recognized by the IVMA as the Indiana Veterinarian of the Year. In addition, Willis was presented the Purdue University School of Veterinary Medicine's 2000 Distinguished Alumnus Award.

Willis's faith and values were an important aspect of his life. While a member of the Congregational United Church of Christ in Windsor, WI he served as moderator and on various church boards. During his several years of service on the Corporate Board for World Ministries of the United Church of Christ, he traveled to Sri Lanka on a mission trip. At the time of his death, he was a member of Hope United Presbyterian Church in Plainfield, IN where he served as an elder and contributed greatly to their mission projects.

Following his retirement in 1991, Willis and Linda returned home to Indiana where he established the Mill Creek Christmas Tree Farm on the family farm near Coatesville. He also continued his passion for historic preservation of agricultural implements, especially those related to the horse. He was a member of the Horse Brass Society of England and the Belgian Draft Horse Corporation of America. His interest in history included collecting postcards and he was a member of the Indianapolis Postcard Club. Willis also served his home county by helping to establish the White Lick Heritage Community Foundation, now the Hendricks County Community Foundation, and was a past president of its board of directors.

It is often said you can take the boy off the farm, but you cannot take the farm out of the boy. Willis often shared his love of the family farm with his granddaughters. He delighted in taking them there to share the joy of nature and his appreciation for agriculture.

In addition to his parents, Willis was preceded in death by his son Eric and nephew Christopher Yeager. He is survived by his wife Linda, his daughter Lisa Parker-Gummere and son-in-law Jeff Gummere, and granddaughters Erica and Anna. He is also survived by his sister Willa Dean Yeager, nephew Alan (Abby) Yeager, and great nephews Logan and Adam. In addition, he is survived by a large and beloved extended family.

From the President of the Theriogenology Foundation

Wow! What a year! I hope this finds all of you healthy. One year ago I was learning to negotiate curbside service, trying to understand what type of a/c filters would trap viruses, and figuring out which masks would not leave my ears raw. All this while dealing with an unexplainable increase in workload. It seems like January, 2020 was a very long time ago.

Along with learning how to practice in a pandemic, it didn't take much reflection to realize the other important aspects of life. Faith has always been a priority for me. Time with family became precious, particularly those family members that the pandemic made more difficult to see. The same goes for friends and our therio family. I am very excited to have an "in person" conference in Omaha this July. There are so many of you that I ache to see, and as great as zoom is, it is not the same.

The TF board has been busy during the last year. We have worked to continue providing benefits to students, with your help, to fund externships, research, student chapter events and speakers. The AKC/AKC CHF/TF residency program is still going strong. Although the Working Dog Project is not directly affiliated with TF, we are still supporting the important work that WDP is doing. And our newest project, the Nandi Scholars Program, is up and running. We will be presenting four scholarships to some incredible fourth year veterinary students in Omaha this year.

None of this would be possible without the hard work of many. Importantly, many of the individuals responsible for the success of these programs are not TF board members. When Dr. Jim Floyd, who heads up the Nandi Scholars Program, put together a team of applicant reviewers, I was pleased (but not surprised) at how quickly our SFT/ACT membership stepped up to the difficult task of reviewing the applications. A huge thanks to all who helped make this possible

We are able to continue to help so many thanks to the generosity of all of you. Thanks for your support. I hope that you will be able to attend the awards banquet this year in Omaha and get to meet our inaugural group of scholarship recipients.

Please stay well. Please don't hesitate to contact me if I can help you in any way. I'm looking forward to seeing everyone sans the computer screen.

Mike

Future Theriogenology Conference Dates

Sponsored by
The Society for Theriogenology
and
The American College of Theriogenologists

MAKE PLANS NOW TO JOIN US AT
THE FOLLOWING LOCATIONS:

2021
July 21-July 24
Omaha, Nebraska

2022
July 20-July 23
Bellevue, Washington

2023
July 19-July 22
Birmingham, Alabama

2021 Certifying Exam Committee Report

The ACT Certifying Exam Committee has been very active in the past year. Not only has the committee reviewed, updated, and set 2021 examination, there have been multiple efforts to update the examination process due to the electronic nature of our examination. Many thanks to the committee for their hard work and dedication to this committee: Brian Whitlock, Past-Chair; Julie Cecere, Chair; Ahmed Tibary, Vice-Chair; Kara Kolster, ACT Secretary; Jo Randall, Soon Hon Cheong and Jacobo Rodriguez. A summary of the committee's efforts, outside of examination preparation and review, are below:

1. A thorough question bank cleanup is underway. Each essay question in the bank was reviewed, assigned knowledge domain(s) and inventoried. Multiple choice questions will be reviewed over the next year. This is in an effort to maintain alignment with the current Job Task Analysis (JTA), which is the basis for the species and knowledge breakdown of the certifying examination as well as training skill sets. The JTA sets these parameters based on membership demographics and responses, so you as an ACT member are actively involved with the process. Please stay tuned for future requests of the ACT membership to submit new questions for use by the Examination Committee as well as an updated JTA survey, which is essential to creating a balanced and appropriate certifying examination for the ACT.
2. A completed movement towards a fully electronic examination has occurred. ExamSoft has been used as the examination platform since 2017. Due to COVID, the 2020 examination was administered remotely with live proctors. This electronic process was well received and this year we are adding the use of artificial intelligence (AI) proctor software. It is likely that the examination will follow the remote format moving forward with the use of AI proctoring software for ease of candidate and mentor travel as well as time zone and work constraints.
3. All forms related to the examination were revised to reflect the use of electronic software and AI proctors. This was essential to encapsulate this historic change for the ACT certifying examination process.
4. Dr. Réjean Lefebvre was selected as the new member of the Exam Committee, to replace Dr. Brian Whitlock. Dr. Lefebvre has accepted this nomination and will start his duties on the committee after the Annual Conference at the end of July 2021.

Dr. Brian Whitlock is finishing his term and will be leaving the committee this year. We are grateful for all his contributions to the committee, his friendship, and his stories. If you have not had the chance to sit around a dinner table with Brian I highly suggest it, you will not walk away the same person. All of us will miss him.

Lastly, the 2021 Certifying Examination will be administered July 13th and 14th electronically via Examsoft and AI proctor software. All successful candidates will be announced at the ACT Business meeting July 22 as well as new ACT members from 2020.

Sincerely,

Julie T. Cecere

ACT Certifying Examination Committee Chair

Thank you!

A huge thank you to the following individuals for all their efforts in planning the 2021 conference!

Annual Conference Program Chair
Dr. Ahmed Tibary

Equine Track Program Chair
Dr. Karen Wolfsdorf

Production Animal Track Program Chair
Dr. Juan Romano

Small Animal Track Program Chairs
Drs. Julie Cecere and Orsolya Balogh

Reproductive Pathology Symposium Chair
Dr. Christopher Premanandan

Zoological Species Theriogenlogy Symposium Chair
Dr. Anneke Moresco

Student Seminar Chair
Dr. Juan Samper

Silent Auction Chairs
Drs. Jim Floyd and Will Schultz

Live Auction Chair
Dr. Jim Floyd

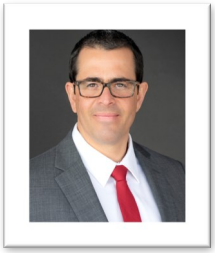
Theriogenologist of the Year
Dr. Gary Althouse

Dr. Gary Althouse received his BS degree from Sul Ross State University, his MS from Texas A&M University, and he completed a combined program leading to both DVM and PhD degrees at Iowa State University. Althouse became board certified with the American College of Theriogenologists in 1995. He joined the faculty at the School of Veterinary Medicine at the University of Pennsylvania (Penn Vet) in 2001. In 2011, he was named to the Marion Dilley and David George Jones Endowed Chair in Animal Reproduction. In 2019, Althouse was appointed Associate Dean of Sustainable Agriculture and Veterinary Practices. Additional leadership roles have included serving as president for both the Society for Theriogenology, and for the American College of Theriogenologists.

Althouse's efforts focus on global food supply and food security. He is the founder and director of Penn Vet's Reference Andrology Laboratory, which provides both critical research and clinical services in food animal production. He currently provides services to clientele throughout North America, with his current work having a direct impact on ~34% of the U.S. swine breeding herd. Globally, he provides veterinary consultation services in the remaining Americas, Europe, Asia, and Australia. Collectively, these experiences are woven into Dr. Althouse's teaching efforts in the areas of theriogenology and swine production medicine.

Althouse has been fortunate to have had many influential mentors over his career, including L. Evans, S. Hopkins, W. Hsu, M. Pineda and S. Seager. Over the past 27 years, he has enjoyed mentoring numerous talented veterinary and graduate students, faculty, post-doctoral fellows, interns and residents.

Nominees for officers and directors of the College-Vote Now!



The newly elected vice-president will assume the offices of president-elect and president in 2022 and 2023, respectively. Beginning in 2014, the decision was made by the ACT Board of Directors to initiate online voting. Please complete the ballot by June 15, 2021.

Vote and you could win!

Sign in to the ACT site, then click the link below or place the ballot link in your browser (**https://www.theriogenology.org/surveys/default.asp?id=1602791**). You will be allowed to vote one time only. Your vote is completely confidential. There will be a random drawing of the individuals who vote in the officer/board elections for a non-transferable prize of a complimentary Therio meeting registration within three years of the award.

Vote today for your chance to win!

Vice President nominees

Leonardo Brito

Dr. Brito, DVM, MSc, MVetSc, PhD is the Director of Global Quality Assurance at STgenetics and an associate editor of the journal Theriogenology. He became a diplomate of the ACT in 2004, served on the Certifying Examination Committee from 2009 to 2015, served on the ACT Executive Board as Treasurer from 2017 to 2020, and is currently serving on the newly created Standard Setting Committee. More details of education and professional experience can be found at https://www.linkedin.com/in/lbrito/.

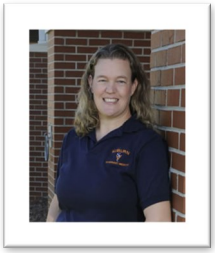
If given the opportunity to serve the ACT, Dr. Brito would focus on initiatives to promote the specialty and increase the College membership. Student marketing: promote the College to veterinary students by participating in national events as an exhibitor, providing speakers, and supporting other scholar activities. STF Student Chapters: promote organization of mentor network to exchange experiences and practices, support new mentors, and stimulate creation of new chapters; organize network of diplomates willing to support chapters through presentations and other instructional activities; promote cross-chapter student interactions; support industry lobbying efforts to secure financial support for student chapters. Residency training opportunities: support food-animal and equine industry lobbying efforts to secure financial support for residencies building on the successful AKC experience. Alternate Training Route: facilitate mentorship by organizing support network of prospective mentors, and sharing study plans and instructional materials; facilitate completion of clinical training requirements by organizing network of clinical trainers to include diverse geographical distribution and species representation; facilitate completion of scientific publication requirement by organizing network of specialists to provide expert advice on experimental design or case report planning, data analysis, manuscript writing, and peer-review process. Graduate Training Route: charge the credentialing committee with studying the re-institution of this training route in ways that would ensure minimal clinical competency and at the same time tap into the enormous benefits and diversity expert scientists would bring to the College.

Karen Wolfsdorf

Dr. Wolfsdorf obtained her DVM from the University of Florida, College of Veterinary Medicine in 1992. She completed an internship in equine field service at North Carolina State University and a Theriogenology residency at the University of Florida. Dr. Wolfsdorf became a Diplomate of the American College of Theriogenologists in 1995 then entered equine private practice as a specialist in reproduction first in Australia then at Hagyard Equine Medicinal Institute where she is presently a partner and specialist in reproduction and field care. Dr. Wolfsdorf served on several committees in SFT, AAEP and ISER. She served ACT as a board member and as a member of the training and credentialing committee. Dr. Wolfsdorf has authored several peer-reviewed articles and book chapters in the field of equine reproduction. She has contributed numerous presentations and proceedings at national and international conferences. She enjoys interaction with practitioners and veterinary students. She has lectured to several student chapters of the Society for Theriogenology.

Dr. Wolfsdorf is committed to advancement of the specialty of theriogenology in practice and veterinary education.

Board of Director nominees



C. Scott Bailey

I am C. Scott Bailey and I would be honored to serve as an executive board member. I graduated from Kansas State University in 2003 and pursued a theriogenology residency at the University of Florida 2005-2008, achieving diplomate status in 2008. I subsequently completed an MS at the University of Florida under the guidance of Dr. Macpherson and then moved to North Carolina to serve as a faculty member at NCSU from 2009-2019. I had a multi-species interest with clinical programs focused primarily on equine and canine reproduction and research projects that stretched across genera. In 2019, I left academic practice and moved to central KY to serve as resident veterinarian of Claiborne Farm, where I supervise the general and reproductive care of approximately 500 horses and continue to pursue clinical and collaborative research projects through NCSU and the University of Kentucky.

Like many members of our college, I have a broad interest in veterinary reproductive physiology and medicine, and varied clinical experience to match that. I have provided instruction to veterinary students at four different institutions and mentored both house officers and graduate students to successfully develop a career in theriogenology. I am passionate about the mission of fostering the development of clinician scientists who will aid our (collective) patients and clients, and further the knowledge in our field. I am also passionate about the need and opportunity for research arising from clinicians in private practice and hope to emulate some of the great members of our college who precede me in this endeavor. Our college has an ongoing important role to play, both through its mentorship of prospective members and through its outreach to veterinarians, students, breeders and owners. I very much look forward to participating in this important work.

Thank you once again for giving me the opportunity to run for the position of Executive Board member.

Aime Johnson

I entered private practice for 5 years following graduation from vet school (equine and mixed animal), but decided I wanted to specialize. I returned to "school" and completed my residency training at Texas A&M. This perspective allowed me to be a better specialist as I was able to gain experience in a large volume repro clinic, but also be in the world of general practice. I joined the faculty at Auburn University in 2007 and have enjoyed my career here. I was certainly strongest in equine after my residency, but due to clinical needs at Auburn, I have expanded to companion animal therio and am now comfortable in both. I am one of the few theriogenologists comfortable with feline reproduction. I became involved in Auburn's research cattery in 2008 when the fertility of the colony had declined to the point that they were unable to obtain animals for research. Since that time, I have learned through experience and now consult on catteries all over the US.

My research experience is concentrated in the horse and cat. Most notably, I have collaborated with several researchers using methods of non-surgical castration in small animals and estrus suppression in mares. Outside of theriogenology, I am also involved heavily with viral vectored gene therapy for degenerative neurologic disease in the cat as a model for a neurodegenerative, fatal disease in children. Through this research, clinical trials began last year and children with these diseases are showing improvement.

I look forward to serving my specialty though this board position. My children are older and I want to dedicate time to my fellow ACT diplomates. I admire those currently serving and have learned from their leadership. I can benefit the Board through my varied experiences from private practice and academia and from my experience in a variety of species. I am also the student theriogenology advisor at Auburn and hope to have a part in encouraging students to pursue theriogenology and board certification to the betterment of our specialty.

Honorary Member nominees

Jon Oatley

Jon M. Oatley, Ph.D. is the Director of the Center for Reproductive Biology and a full Professor in the School of Molecular Biosciences at Washington State University. Dr. Oatley received a Bachelor of Sciences degree in Animal Sciences from the University of Nevada-Reno, Master of Science and Doctor of Philosophy degrees from Washington State University, and was a postdoctoral fellow in the laboratory of Dr. Ralph Brinster at the University of Pennsylvania. Over the course of two decades, Dr. Oatley's research has focused on understanding the biology of germ cells which are the eternal cellular link between generations. Dr. Oatley's research also focuses on engineering the genetics of farm animals to develop more efficient avenues for feeding the expanding global human population. Dr. Oatley has authored more than 80 scientific research papers, book chapters, and news articles on the areas of germ cell biology and animal genetic engineering. As an independent investigator, his research program has been funded by multiple grants from the National Institutes of Health, the United States Department of Agriculture, and industry contracts.

Gary Warner

Dr. Warner grew up in north Louisiana in a family run cow/calf and stocker operation. His dad moved the family to Ferriday, Louisiana in 1965 where his dad operated an auction barn and continued in the cow/calf business and was also a procurer of replacement cows. Dr. Warner received a BS from the University of Louisiana at Monroe in 1977 and received his DVM degree from the Louisiana State University School of Veterinary Medicine in 1980. Immediately after graduation, Dr. Warner entered clinical practice as a mixed animal associate at Elgin Veterinary Hospital. After 2 years of employment, he became a partner and developed a primary interest in large animals and eventually, just beef cattle practice. Today, the practice is largely referral based, focusing primarily on lameness and reproductive problems in both the male and female. Dr. Warner has been actively involved with the Professional Bull Riders as a consultant and practitioner for many years, providing for animal welfare and the well-being of the animals involved in their sport. He sustains a very active presence within the industry.

Other practice interests involve the purebred and show cattle industries and servicing the needs of individual producers. He has been actively involved in the show steer industry in Texas, helping many children with their projects and even raising a few of his own. All three of his children grew up showing steers with many championships. Two of his children, Dr. Jenna Beyer and Dr. Kelly Warner, now practice veterinary medicine and the youngest, Jacob, is a 2nd year veterinary student at Texas A&M University College of Veterinary Medicine. Dr. Warner is a career-long member of AVMA, TVMA, (served as longtime member and chair of The Beef Practice Committee), AVC, AABP, PAC and the Society for Theriogenology, where he served a long tenue on the executive board culminating in becoming president of that organization in 2011-2012. Dr. Warner, along with his wife Terry, remain actively involved in the cattle industry at their ranch north of Elgin; producing show steers and high-quality replacement females. He continues to support the beef cattle production community and is always available to colleagues for consultation.

2021 Scientific Information/Abstract Committee Report

We want to thank all authors for their support and contributions to the scientific program of the 2021 Theriogenology Conference to be held in Omaha, Nebraska. We received 61 abstracts for consideration in the following categories: 19 Competitive Abstracts, 27 Non-competitive Abstracts, 14 Case Report Abstracts, and 1 Poster Abstract. Abstracts submitted to the Therio Conference are scored blindly by all members of the Scientific Committee. The eight competitive submissions with the highest scores were selected for oral presentations at the Dr. Jerry Rains Memorial Abstract Competition session. The next eight abstracts with the highest scores will be presented during the Opening Session on July 21, 2021. The remaining abstracts were assigned to their respective species-specific sessions: Equine - 8 abstracts; Mixed Species - 9 abstracts; Production Animal – 8 abstracts; Case Reports – 8 abstracts; and Posters – 12 abstracts. All abstracts will be included in the conference proceedings published in Clinical Theriogenology. The current members of the Scientific Abstract Committee are Drs. Candace Lyman (Chair), Julie Gard Schnuelle, Orsolya Balogh, Jennifer Roberts, and Julia Baldrighi. Drs. Gard Schnuelle and Roberts will end their terms in August 2021. Drs. Roberto Palomares (4-year term) and Jamie Stewart (2-year term) are the new members of the Abstract Committee. We would like to extend a warm invitation to everyone to attend the oral and poster sessions, interact with the authors and learn about their exciting work. We also ask you to actively participate in the Dr. Jerry Rains Memorial Abstract Competition session by asking questions to the presenters as answering your questions are also calculated in the final presentation score. We hope to see you in Omaha!

Sincerely,

Candace Lyman
Therio Conference Scientific Abstract Committee Chair

2021 Annual Conference Agenda

Wednesday, July 21

Opening Session Abstracts
Opening Session Reception
Reproductive Pathology Symposium (additional registration required)
Zoological Species Theriogenology Symposium (additional registration required)
Student Seminar: Critical Thinking in Practice: What does it look like?

Reproductive Pathology Symposium
(additional registration required)
8:00 am - 5:00 pm

Introduction
Christopher Premanandan, DVM, PhD, DACVP, DACT

General concepts in failure of pregnancy
Christopher Premanandan, DVM, PhD, DACVP, DACT

Equine/Camelid failure of pregnancy
Robert A. Foster, BVSc, PhD, MANZCVS, DACVP

Ruminant failure of pregnancy
Dalen Agnew, DVM, PhD, DACVP

Canine/Feline failure of pregnancy
Robert A. Foster, BVSc, PhD, MANZCVS, DACVP

Round table Q/A session
Drs. Agnew, Foster, and Premanandan

General concepts in perinatal mortality
Christopher Premanandan, DVM, PhD, DACVP, DACT

Ruminant perinatal mortality
Robert A. Foster, BVSc, PhD, MANZCVS, DACVP

Equine/Camelid perinatal mortality
Dalen Agnew, DVM, PhD, DACVP

Canine/Feline perinatal mortality
Drs. Agnew and Premanandan

Case based roundtable/discussion
Drs. Agnew, Foster, and Premanandan

Zoological Species Theriogenology Symposium
(additional registration required)
7:30 am - 4:30 pm

Welcome

Overview of traditional and novel approaches to amphibian reproduction in zoological institution
Jessi Krebs, OHDZA Curator of Reptiles and Amphibians

Birds-General husbandry as it pertains to reproduction
M. Scott Echols, DVM, DABVP (Avian Practice)

Birds- Common reproduction problems and diseases
M. Scott Echols, DVM, DABVP (Avian Practice)

Overcoming reproductive disorders in female greater one-horned rhinoceros (Rhinoceros unicornis) to improve artificial insemination and natural breeding success
Monica Stoops, MS, PhD Lead Scientist, Comparative Endocrinology OHDZA

Assisted reproductive technologies for endangered felids
Jason Herrick, PhD, Director of Reproductive Services

Zoo Clinical Challenge- Gorilla infertility
Anneke Moresco, DVM, PhD, Zoo Reproductive Specialist

Current understanding of elephant reproduction
Dennis Schmitt, DVM, PhD, DACT

Application of domestic dog theriogenology practice in wild canids
Bruce Christensen, DVM, MS, DACT

Avian reproductive tract diseases
M. Scott Echols, DVM, DABVP (Avian Practice)

Developing assisted reproduction for reptiles, what's next?
Sean Perry, DVM, PhD

Attendees will have the options of attending a seminar by Drs. Echols and Perry discussing "*Advanced topics in reptile and avian reproduction*" or traveling to the Henry Doorly Zoo and Aquarium for a behind the scenes tour.

Student Seminar
1:00 pm - 5:00 pm

Critical Thinking in Practice: What does it look like?
Juan Samper, DVM, PhD, DACT

Opening Session Abstracts

Luteinizing hormone receptor activation stimulates endothelial adhesion of neoplastic canine T-lymphocytes
Alexa Dietz

Suitability of non-cycling recipient mares for in vitro produced equine embryos
Charles Scoggin, DVM, MS, DACT

The temporal associations of B-mode, Power doppler, and ovarian steroid changes of the periovulatory follicle and corpus luteum during luteogenesis and luteolysis in jennies
Humberto Magalhaes, DVM, MSc

Cholesterol-loaded cyclodextrin improves cooling and fertility of donkey semen
Lorenzo Segabinazzi, DVM, MS

Characterization of reproductive parameters from Pennsylvania bull elk (Cervus canadensis)
Luisa Ramirez-Agamez,, DVM

Serum prostaglandin E metabolite (PGEM) in diestrus and pregnant mares
Mariana Diel de Amorim, DVM, DVSc, PhD, DACT

Expression and abundance of prostaglandins in the healthy and fibrotic mare endometrium
Michael Byron, MSc

Umbilical vein catheterization as an option for intravenous access in neonatal puppies
Soon Hon Cheong, DVM, PhD

Thursday, July 22

Bartlett Award and Address
Theriogenologist of the Year Award and Address
Dr. Jerry Rains Memorial Abstract Competition
sponsored by Merck Animal Health
SFT Business Meeting
ACT Business Meeting
Student Case Presentations
Student Research Presentations
Student/Mentor Reception
Opening Reception in the Exhibit Hall

Dr. Jerry Rains Memorial Abstract Competition
sponsored by Merck Animal Health

Comparison of nanoparticles and single-layer centrifugation for separation of dead from live stallion spermatozoa
Christian Bisiau, DVM

No adverse effect of air exposure on stallion sperm motility after 48 hours of cooled storage
Emily May, DVM

Epididymal sperm granulomas are associated with antisperm antibodies in frozen-thawed donkey semen
Giorgia Podico, DVM, MSc

Laser ablation of the equine oviductal papilla as a novel contraceptive technique
Grace Edwards

Clinical and physiological ultrasonography of normal and abnormal donkey pregnancies
Humberto Magalhaes, DVM, MSc

Comparing serum progesterone measurements by a point-of-care analyzer with a chemiluminescent immunoassay in breeding management of the bitch
Julia Zuercher

Mammary gland electrolytes and pH to detect impending parturition in jennies
Lucas Canuto, DVM, MSc

The effects of Kisspeptin-10 on equine chorionic girdle trophoblast cell in vitro migration
Viviane Gomes, DVM, DACT

Student Case and Research Presentations *sponsored by Bovine Services, LLC.*

Incidence of and factors affecting congenital defects in miniature Dachshunds
Colleen Kutzler

Electroejaculation and breeding soundness exam on a clouded leopard
Taylor Lashlee

Preputial prolapse and injury in a Brahman bull
Maryanna Hudson

Atypical mammary mass in an intact geriatric female Labrador retriever
Colleen Kutzler

Abnormal mobility in neonatal Labrador Retrievers
Jordan Farrell

Recurrent uterine torsion in an Arabian mare
Vaiva Palunas

Dystocia and diaphragmatic hernia in a Quarter Horse mare carrying twins
Vaiva Palunas

Vulvar discharge associated with exogenous estrogen exposure in a spayed Weimaraner bitch
Camille Ogdon

Phimosis and preputial abscessation with draining tract in an Angus bull
Rachael Doenges

The Future of Animal Reproduction

TF SILENT AUCTION 25.0

The passing along of boutique items from colleague-to-colleague through the silent auction has become a signature event of our annual conference. We are limiting the number of items to 25 again this year as it worked out well last year! Here are some suggestions for items:

*Educational items (text books, etc.)
*Arts and crafts
*Liquor/wine
*Sporting events
*Veterinary equipment

Once you decide on what your priceless creation or generous gift will be, please e-mail the attached form along with pictures of the item(s) by June 15th, 2021 to: jgfloydjr@gmail.com.

Get your donation into the spotlight by submitting early…….the final item list will be posted on the website by July 1 so the membership has a month to start saving their dollars to bid!

After 25 items have been selected, we will respectfully ask you to hold your gift until 2022!

No on-site donations can be accepted this year.

Thank you for your continued support of the Theriogenology Foundation Silent Auction!!!

We look forward to seeing you in Omaha!!

Click here for the Silent Auction Donation Form.

Awards Dinner and Story Night

This year's live auction will be held in conjunction with the Veterinary Story Night. Captivating stories will be paired with unique auction items. This year's event will feature stories by Dr. Isaac Bott, Dr. Kara Kolster, Dr. Andrew Lovelady, Dr. Cliff Shipley, and Mr. Jody Wade.

The 2021 Nandi Scholars will also be announced during the Awards Dinner.

Purchase your ticket at: therio.org.

Sealed bids for live and silent auction items are accepted until July 23. Items will be posted online and updated as submitted. Please complete the sealed form on the TF website at: http://www.theriofoundation.org/?page=sealedbidform.

Craft Beer Tasting Fundraiser for the Theriogenology Foundation

During the Opening Session Reception Wednesday evening, July 21 or during the Exhibit Hall Opening Reception, Thursday, July 22, attendees will have the chance to experience some locally brewed craft beer and help the Theriogenology Foundation at the same time. For $40 you will receive four samples of beer. Once you have sampled and chosen your favorite, you will get a full serving of that beer. Proceeds will benefit the Theriogenology Foundation. Tickets may be used at the event of your choice.

CHAPTER ELEVEN *Anatomy and Physiology of Reproduction in the Mare*

Traditionally, the mare has been regarded as having a low reproductive efficiency because many mares that had successful performance records were kept as broodmares without consideration of their existing reproductive problems. Reproduction in the mare is a complex process, and she is unique in several ways, including anatomical site of ovulation, follicular growth patterns, spontaneously prolonged corpora lutea, differentiation of fertile and nonfertile ova in the Fallopian tubes, and serum gonadotropin secretion (in pregnant mares). To be a successful horse breeder and to induce the difficult broodmare to conceive and foal, one must have a working knowledge of the anatomy of the reproductive tract and of the physiology of reproduction in the mare.

11.1 Reproductive Tract

The mare's reproductive tract is shown in Figure 11-1. The tract consists of 2 ovaries, 2 Fallopian tubes, uterus, cervix, vagina, clitoris, and vulva.

Ovaries

The ovaries function as endocrine and exocrine glands and are the essential organs of reproduction. As endocrine glands, they produce the estrogenic and progestational hormones whose functions are described in Chapter 12. As exocrine glands, they produce and release ova. The anatomical structure of the mare's ovaries has been described by Sisson and

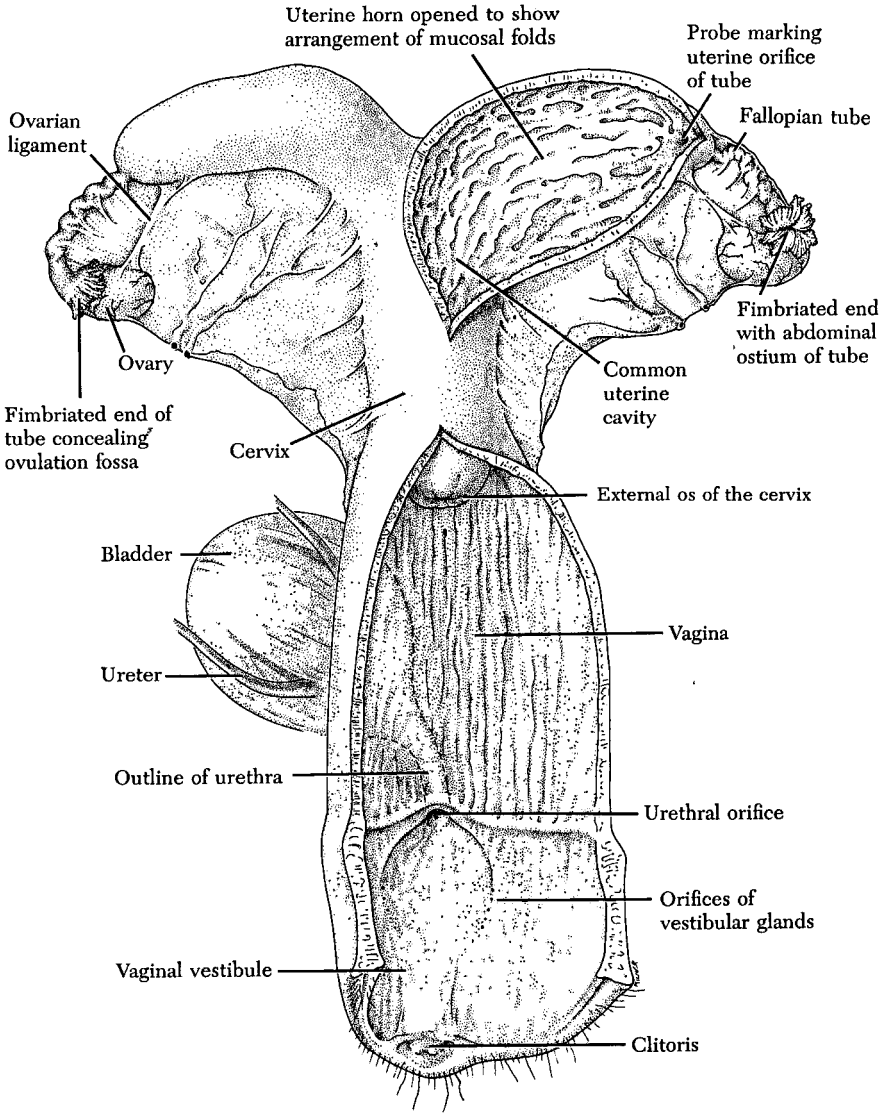

FIGURE 11-1
Reproductive organs of the mare (*posterior view*) showing vagina and right half of uterus opened. From Eckstein and Zuckerman. 1956.

Grossman (1953) as bean- or kidney-shaped because of the presence of a definite *ovulation fossa* (Figure 11-2). The size of the ovaries varies according to the age, breed, size, and reproductive state of the mare. In the mature mare, each ovary weighs approximately 50–75 g and is 6–7 cm long and 3–4 cm wide. Hammond and Wodzicki (1941) have reported that the mature ovary reaches maximum size at 3–4 years of age and then decreases in size. Although one ovary is frequently larger than the other,

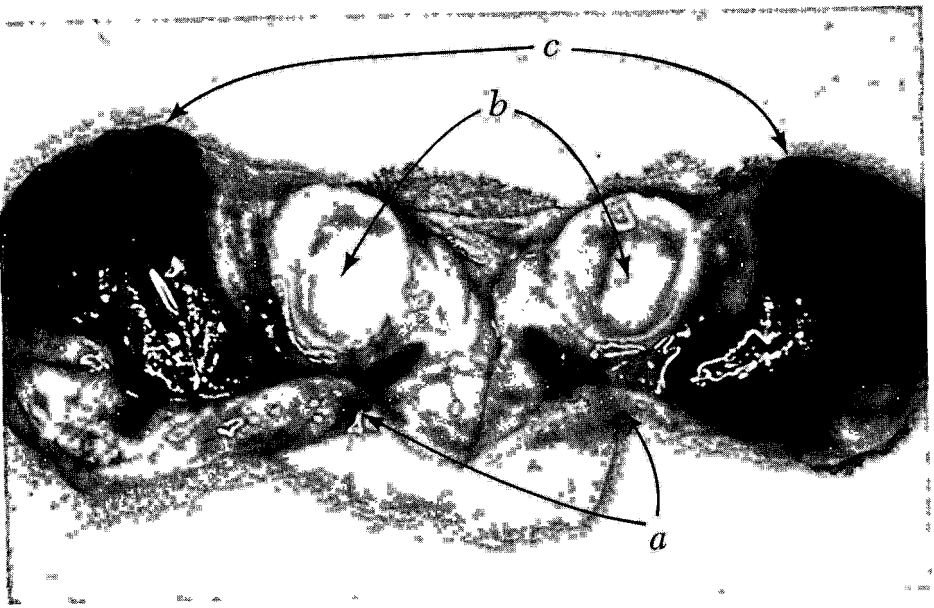

FIGURE 11-2
Cross section of a mare's ovary: *a*, ovulation fossa; *b*, Graafian follicles; *c*, corpus hemorraghicum. Photograph courtesy of John Hughes.

these researchers found that the average weights for each side from several mares were not significantly different. Nishikawa (1959) has studied a Japanese sample and reported that the ovaries of the jenny ass are similar in size and shape to those of the mare, whereas Berliner (1959) has observed that in the United States the ovaries of the jenny ass are larger than mare ovaries.

A *serous coat* that is part of the *peritoneum* covers the outer surface of the ovaries except at the *hilus*, where the blood vessels and nerves enter the ovaries, and at the ovulation fossa, which is covered by a layer of primitive germinal epithelium. The inside of the ovaries is composed of connective tissue and numerous follicles that are in varying stages of development during the breeding season. The *follicles* are not confined to a particular area or outer layer, as they are in other animals, but are distributed throughout the ovary.

The follicles are classified as being either primordial, growing, or Graafian. Primordial follicles consist of an *oocyte* surrounded by a flattened layer of cells known as the *zona pellucida*. As the primordial follicle starts to develop, it becomes surrounded by several layers of granulosa cells and is referred to as the growing follicle. The growing follicle continues to develop and forms the Graafian follicle. The Graafian follicle (Figure 11-3) is surrounded by the granulosa cells and by the *theca folliculi*, which has developed from the connective tissue surrounding the follicle. The theca folliculi differentiates into two layers called the *theca externa* and *theca interna*. The theca externa is a fibrous network

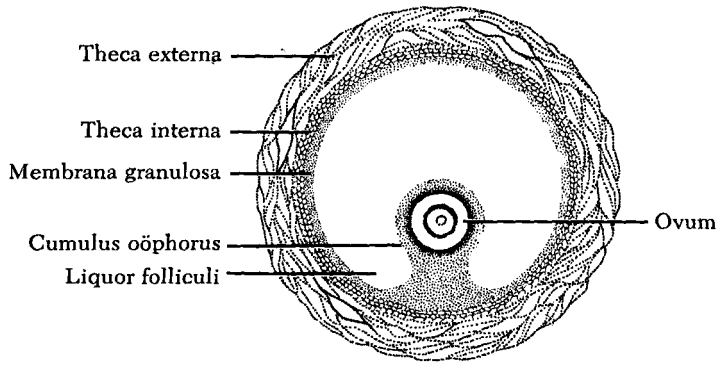

FIGURE 11-3
A Graafian follicle. Diagram courtesy of M. Morris.

that forms a supporting structure for the Graafian follicle. The theca interna, the inside layer of the theca folliculi, contains the vascular supply, and the cells that compose it are responsible for secreting the estrogenic hormones. The granulosa cells continue to increase in number. A cavity or antrum forms within the granulosa cells. At maturity, the cavity or antrum of the Graafian follicle is surrounded by the granulosa membrane and is filled with follicular fluid. Granulosa cells forming the *cumulus oöphorus* surround the ovum and form a stalk that projects the ovum toward the center of the antrum. As the follicle grows and develops, it migrates toward the ovulation fossa. Ovulation (rupture of the follicle) is spontaneous, and extrusion of the egg occurs in the ovulation fossa.

The development of the *corpus luteum* has been described in detail by Harrison (1946) and by many other investigators. Upon ovulation, the follicle walls collapse and fold inward. A blood clot forms in the cavity as a result of hemorrhage of the thecal capillaries (Figure 11-2). The granulosa cells undergo *lutealization,* and the theca interna cells invade the granulosa wall. The folds of the wall take on the appearance of *trabeculae,* which consist of theca externa cells and degenerating theca interna cells. The theca externa cells and degenerating theca interna cells invade the lutealizing granulosa cells. The trabeculae are extensively vascularized, and thecal capillaries exist between the luteal cells. By the sixth day, the whole corpus luteum is well vascularized, the theca cells are evenly distributed, the trabeculae are decreased in size and serve as a support for blood vessels, and the theca externa cells begin to pass inward. After approximately 14 days, the corpus luteum decreases in size, and its progestin-synthesizing capabilities decline quite rapidly if the mare is not pregnant.

Blood is supplied to the ovaries via the ovarian artery (Figure 11-4). The ovaries are supplied with an extensive arterial network that forms

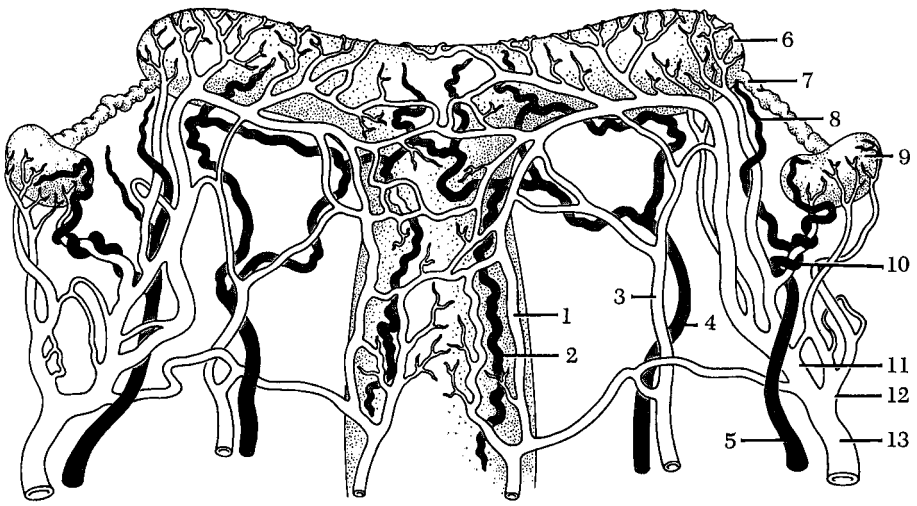

FIGURE 11-4
Composite diagram of dorsal view of arteries (*cross-marked*) and veins (*shaded*) of uterus and ovaries of the mare: (1) uterine branch of vaginal vein; (2) uterine branch of vaginal artery; (3) uterine vein; (4) uterine artery; (5) ovarian artery; (6) uterine horn; (7) uterine tube; (8) uterine branch of ovarian artery; (9) ovary; (10) ovarian branch of ovarian artery; (11) uterine branch of ovarian vein; (12) ovarian branch of ovarian vein; (13) ovarian vein. anastomoses with tributaries of the uterine branch of the ovarian artery. Several veins drain the ovaries and then unite to form the ovarian branch of the ovarian vein. The drainage is such that there is an extensive utero-ovarian plexus. The nerve supply is derived from the renal and aortic plexus of the sympathetic system.

Fallopian Tubes

The Fallopian tubes or oviducts conduct the ova from the ovary to the uterus and are the usual site of fertilization. They are approximately 30–70 mm long and 4–8 mm thick and have an inside tubal diameter of 2–3 mm. The end adjacent to the ovaries is expanded to form the *ampulla* and the *infundibulum,* which partially surrounds the ovary and directs the ova into the Fallopian tube. The edge of the infundibulum is split so as to form fingerlike projections, or fimbriae. The opening of the oviduct into the peritoneal cavity is called the *ostium abdominale,* and the uterine opening is called the *ostium uterinum.* Three layers of tissue compose the Fallopian tubes: tunica serosa, muscularis (longitudinal and circular), and mucosa.

Uterus

The uterus of the mare consists of a body and 2 horns. The horns, which are located in the abdominal cavity, are approximately 25 cm in length and cylindrical. The body of the uterus is located partly in the abdominal cavity and partly in the pelvic cavity. The body is approximately 18–20 cm long and 10 cm in diameter. The broad ligament of the uterus attaches it to the abdominal and pelvic walls.

Three coats of tissue similar to the ones forming the oviducts form the uterine wall. The serous coat is continuous with the broad ligament. The muscular coat consists of a muscularis longitudinalis, muscularis vascularis, and muscularis circularis. The muscularis longitudinalis and muscularis vascularis form one inseparable layer of muscle that can be separated from the muscularis circularis. The third layer of the uterus or mucosa is composed of a loose connective-tissue network (tunica propria), a deeper layer containing the long, tubular-shaped uterine glands, and the stratum epithelial.

Uterine blood supply is derived on both sides from 3 arteries: the uterine branch of the vaginal artery, the uterine artery, and the uterine branch of the ovarian artery. Three veins drain the uterus and correspond to the 3 arteries. Nerves derived from the uterine and pelvic plexus provide the nerve supply to the uterus.

Cervix

The cervix separates, anatomically and physiologically, the body of the uterus from the vagina. It is approximately 5–7.5 cm in length and consists of a powerful, well-developed muscular layer. Extensive folding of the muscle layer leaves no well-defined cervical canal. The mucosa of the cervix contains mucosal cells that secrete the mucus found in the vagina. The cervix protrudes into the vagina, forming a well-defined angle between the cervix and vagina known as the fornix.

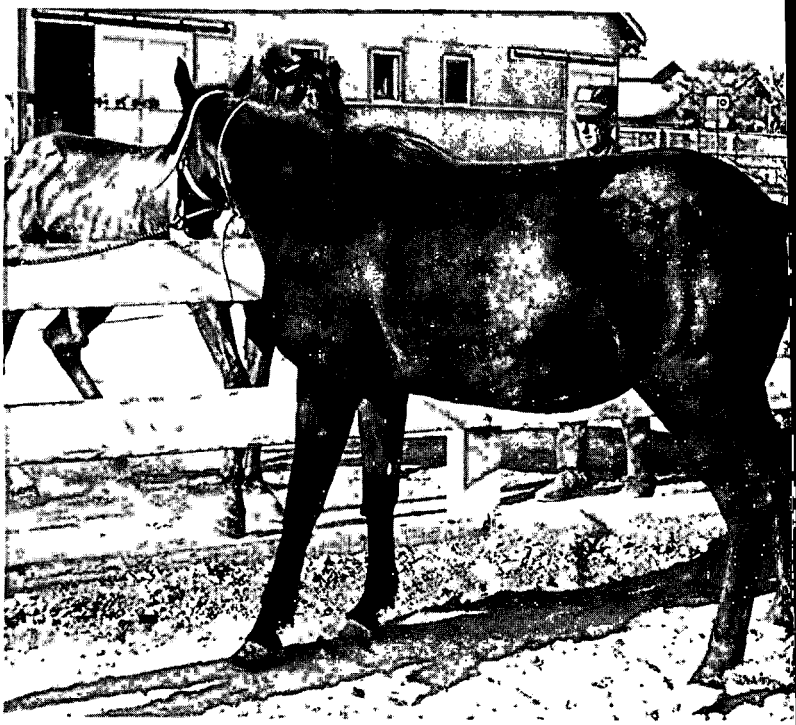
Vagina

The vagina extends from the cervix to the vulva. It is approximately 15–20 cm in length and 10–12 cm in diameter. The vagina is divided into the vagina proper and the vestibulum vaginae. The hymen separates the two parts and is just anterior to the area where the urethra enters the reproductive tract. The mucous coat contains no glands, is composed of a layer of loose connective tissue, and is covered with a stratified epithelium. Longitudinal and circular muscle fibers are surrounded by a *fibrous adventitia.*

Blood supply to the vagina is via the internal pudic arteries and drainage is via the internal pudic veins. The nerve supply is from the pelvic plexus of the sympathetic nervous system.

Vulva

The vulva is the terminal part of the reproductive tract. It is 10–12 cm in length and the external orifice is a vertical split approximately 12–15 cm long. The external urethral orifice is located 10–12 cm inside the vulva, and the glans clitoris is located approximately 5 cm within the vulva. The clitoris is the homologue of the male penis.



Mammary Gland

The udder is located in the inguinal region and is composed of 2 gland complexes. The 2 teats are broad and flat. Each teat is canalized by at least 2 streak canals that lead from separate teat cisterns. Each teat cistern is connected to a gland cistern that has a system of ducts leading into it from a secretory gland. The udder is served by the external pudendal artery and is drained by the external pudendal and subcutaneous abdominal veins. The nerve supply is derived from the inguinal nerve.

11.2 Physiology of Reproduction

Estrous Cycle

The average age of the filly at puberty is 12–15 months. Russian researchers have reported that crossbred Russian trotter mares reach sexual maturity at 10–11 months. Once puberty is reached, the filly begins to come into estrus (heat) in a rhythmic cycle. The estrous cycle is the interval from the onset of estrus until the onset of the next estrus. In the mare, it is commonly divided into 2 periods for practical purposes. The follicular phase or estrous period of the cycle is the period during which the mare shows behavioral signs of estrus, has rapid follicular growth, and finally ovulates. During the estrous period, the mare is interested in and is receptive to a stallion. Most mares in estrus display several characteristic behavioral signs when teased with a stallion (Figure 11-5). Initially, a mare may be agitated but will respond to the stallion and allow him to bite her on the neck and flank. Her stance is characterized by a raised tail without switching, hind legs spread apart, and pelvis flexed. The labia

a

b

FIGURE 11-5
Behavioral display of estrus (heat) by a mare: *a*, elevated tail, flexed pelvis, and acceptance of stallion; *b*, eversion of clitoris (winking).

of the vulva contracts and relaxes, and there is eversion of the clitoris, which is commonly referred to as "winking." Estrual winking, alone, should not be confused with winking after urination. Mares in estrus usually urinate quite frequently when teased.

Sexual receptivity is influenced by season. The behavioral signs of mares coming out of anestrus are rather variable, that is, some mares

have a normal estrous period whereas others are in and out of estrus for several days.

The behavioral signs of estrus in the jenny are quite different from those in the mare. Jennies will stand for the jackass with their hind legs spread apart. The head is lowered, the jaws display a chewing motion, and the labia repetitively contracts, exposing the clitoris. Jennies urinate frequently, and quite often a slimy mucus is discharged from the vagina.

In both the mare and jenny, the intensity of estrus manifestations increases from weak signs at the start of estrus to a peak at ovulation and then quickly declines to the diestrous state.

The diestrous period is the luteal phase of the cycle and begins with ovulation. During *diestrus,* the corpus luteum is formed and secretes progestins. The behavioral response of a diestrous mare to teasing with a stallion varies from a passive, noninterested attitude to complete resentment, often manifested by violent attempts to kick and bite the stallion.

The change from behavioral estrus to diestrus occurs quite rapidly after ovulation. Hughes *et al.* (1972b) have reported that approximately 50 percent of the mares they studied were in diestrus within 24 hours after ovulation and 80 percent were in diestrus within 48 hours. This finding emphasizes the close relationship between ovulation and the end of sexual receptivity. Occasionally, a mare will ovulate after she has ceased showing signs of estrus.

Estrous cycles of the mare are usually 21–23 days in length (Table 11-1). A wide range of estrous cycle lengths has been reported in the literature. Cycles vary from 7–175 days, but generally, approximately 50–60 percent of all mares have a cycle of 21, 22, or 23 days.

There are many causes of prolonged estrous cycles. Season of the year is the most common cause of irregularity. In California, the average estrous cycle length is shortest between April and October and longest between November and March. In South Africa, the average estrous cycle is shortest during the summer months of November through February and longest during the winter months of May to August. Winter *anestrus* (period of sexual inactivity) is responsible for the longer average length of time from one estrus to the next between November and March (Figure 11-6) (Hughes *et al.*, 1972b). During the winter months, ovulation often occurs without estrus. The estrous cycles can also be interrupted by spontaneous prolongation of the corpus luteum life-span (Figure 11-7). A spontaneously prolonged corpus luteum is a corpus luteum that continues to secrete enough progestins to maintain plasma levels above 3–5 ng/ml plasma, which suppresses signs of estrus. The spontaneous prolongation may be due to a failure of the uterus to produce or release the "luteolysin" required to lyse the corpus luteum at the proper stage of the cycle. An interruption of regular cyclicity may occur during very hot weather and was observed by Hughes *et al.* (1972a) in a 3-year study of a group of mares. Prolonged cycles are often merely a result of the stud

manager's failure to observe estrus. Another problem that is frequently encountered is that lactating mares that are extremely possessive of their foals may not show estrus.

The seasonal variability of the estrous cycle, excluding anestrus, seems mainly to be due to variability of the estrous period (Table 11-2). The normal length of estrus is usually 5–7 days, but from February to May (late winter and early spring in California), it is 7.6 days. The longest estrous periods are observed when mares are either going into or coming out of anestrus. Throughout the year, the diestrous period seems to average 14–16 days in length when anestrous periods are excluded.

Loy (1970) has classified mares into 3 groups according to seasonal variability. There is considerable overlapping of his classifications because of the variability of mares. In the first category is the polyestrous mare, which cycles regularly throughout the year even though she has seasonal variations that fall within the normal range. The second group includes the seasonally polyestrous mare, which has a definite breeding season and a definite anestrous period (Figure 11-6). The third classification is the seasonally polyestrous mare (Table 11-2), which has erratic reproductive patterns. "Silent heat," the failure to show behavioral signs of estrus, occurs infrequently in some mares, although other mares seldom show behavioral signs (Figure 11-8). Usually these mares ovulate and their plasma progestin profile is normal. Approximately 50 percent of mares ovulate at least once without estrus during a 2-year period. The opposite condition, estrus without ovulation, is less frequently observed—it occurred in approximately 3 percent of estrous periods during a 2-year period (Hughes *et al.*, 1972b). Nonovulatory estrus is usually observed immediately preceding the onset of winter anestrus. Split estrous periods, in which the mare is in estrus for a few days, out of estrus for a few days,

and then returns to estrus, are observed during approximately 5 percent of the cycles. Split estrous periods average 12 days in length.

Since most mares are seasonally polyestrus, periods of anestrus are observed in most mares that are observed for approximately 2 years. The winter anestrous period is usually 50–70 days in length but may be 4 or 5 months long. During the anestrous period, approximately 50 percent of mares ovulate at regular cyclic intervals. Other anestrous periods are accompanied by insignificant ovarian activity or the persistent presence of a corpus luteum. Even though anestrus is primarily a winter phenomenon, cyclic ovulation without estrus has been observed at other times of the year.

Diestrous ovulations without signs of estrus occur in most mares some time during a 2-year period (Figure 11-9, Table 11-1). The ovaries are the only part of the reproductive tract that is changed when ovulation occurs during diestrus. If the reproductive history of a mare is not known, the diestrous ovulation may be assumed to occur during a silent heat.

The mare is generally assumed to have one ovulation per estrous period; however, several follicles start to grow during each estrous cycle. Just before estrus, follicles destined to ovulate rapidly increase in size until they are to 35–60 mm long. When a group of Thoroughbred and Quarter Horse mares were observed at the University of California at Davis (Hughes *et al.*, 1972b), twin ovulations occurred approximately 21 percent of the time during a 2-year period (Figures 11-6 and 11-9 and

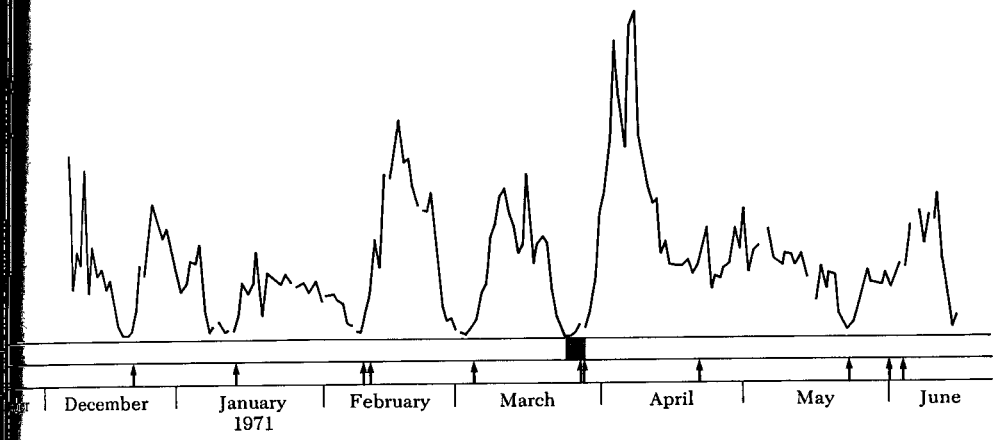

Table 11-3), and several other researchers have reported similar percentages. The percentage of twin conception is lower (1–5 percent). The percentage of live foals is 0.5–1.5 percent (Berliner, 1959). Some mares have a tendency to have multiple ovulations, and one mare had 25 twin ovulations in 24 months (Figure 11-9). Multiple ovulations do not appear to affect the duration of estrus, the length of the estrous cycle, or the level of plasma progestins (Table 11-1). A seasonal influence was indicated since few multiple ovulations were observed early in the breeding season (Table 11-4). Double ovulations are rare in pony mares.

Changes in the Reproductive Tract During the Estrous Cycle

The reproductive tract of the mare undergoes several characteristic changes during the estrous cycle. These changes are useful as a guide in determining the optimal time to breed a mare during estrus—especially mares with silent heats. The changes have been discussed by Warszawsky *et al.* (1972) and are summarized in Table 11-5.

During anestrus, the ovaries may be small and inactive, although some mares have considerable ovarian activity. As the mare comes out of anestrus, the ovaries begin to enlarge and soften as the follicles begin to develop. Although several follicles may start to increase in size, usu-

ally only 1 or 2 reach ovulatory size. The follicle destined to ovulate usually becomes quite prominent just before estrus and starts the rapid growth phase approximately 5 days before ovulation. Generally, maximum follicle size (40–50 mm) is reached the day before ovulation, but it may occur 3–4 days before ovulation. Some follicles soften just before ovulation, whereas others do not. Because of the variations in the occurrence and degree of softening, softening of the follicle cannot be used to predict ovulation accurately. Hughes *et al.* (1972b) observed that follicles that were 25–50 mm in size appeared in addition to the ovulatory follicle in 57.3 percent of the estrous periods of the 11 mares studied. These follicles may continue to increase in size before they regress. Smaller follicles may remain for a couple of cycles and then develop into the ovulatory follicle (Figure 11-10).

Definite changes occur in the cervix during the estrous cycle, and they are quite useful in predicting approaching ovulation. During diestrus, the cervix is covered by a small amount of sticky mucus. The quantity increases during estrus until a considerable amount of slimy mucus is present. During diestrus, the cervix is tightly constricted and pale pink in color. During estrus, the vascularity increases and the cervix becomes

FIGURE 11-10
Curves of growth of follicle and corpus luteum during the estrous cycle. From Hammond and Wodzicki. 1941.

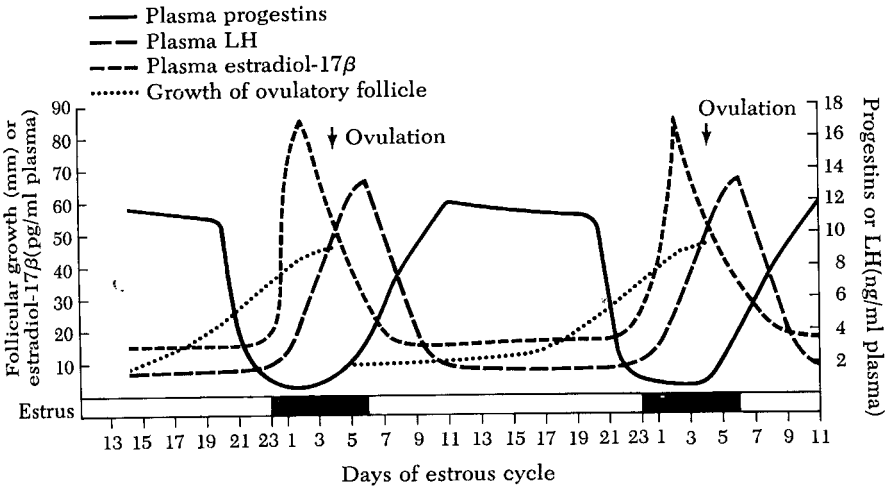

FIGURE 11-11
Endocrine patterns during the estrous cycle of a mare.

reddish in color. A complete relaxation occurs during estrus to the extent that the cervix may lie on the floor of the vagina. Palpation reveals the tactile sensitivity and muscular contractions of the estrual cervix.

The changes that occur in the vagina are more difficult to interpret than the cervical changes. The most obvious changes that occur in the vagina during estrus are an increase in vascularity resulting in a change from a pale to a rosy color and an increase in the size and number of secondary mucosal folds. The walls are dry and sticky during diestrus and become slimy during estrus as a result of changes in cervical mucus secretion.

Hughes *et al.* (1972b) have discussed the changes in uterine form that occur during the estrous cycle. From a practical standpoint, these changes vary in interpretation and their pattern is not sufficiently uniform to be useful in determining the optimal time to breed. The uterus has only slight muscle tone and is turgid during estrus; it may even be termed flaccid. During diestrus, an increase in tone and "tubularity" (contracted state that closely resembles a tube) is observed. However, during late diestrus, tone and tubularity may decrease.

During anestrus, the cervix and uterus lose muscle tone and usually become completely flaccid in most mares that have no follicular activity. In mares that have considerable ovarian activity, the uterus may have some muscle tone and the cervix may be firm and tightly constricted.

Endocrine Control

Endocrine control of the estrous cycle is not completely understood. Figure 11-11 is a generalized diagram of the sequence of events. The

hormones known to control the estrous cycle originate in the pituitary gland, the ovaries, and possibly the uterus.

The pituitary hormones are the *follicle stimulating hormone* (FSH) and the *luteinizing hormone* (LH). They are produced in the basophil cells of the medullary area of the anterior pituitary gland. FSH causes ovarian follicles to grow and to produce increasing amounts of estrogenic substances as they grow. FSH has been purified and its properties characterized by Braselton and McShan (1970) and by Nuti *et al.* (1972). It is a glycoprotein consisting of 74.9 percent protein, 9.3 percent hexose, 9.1 percent hexosamine, 4.7 percent sialic acid, and 1.3 percent fucose, and it has a molecular weight of approximately 33,200–47,900. The amino acid composition is characterized by high levels of cysteine (half-cystine), threonine, lysine, and aspartic and glutamic acids, and a low level of methionine. The NH_2-terminal amino acids are phenylalanine and aspartic acids, and the COOH-terminal residues are leucine and glutamic acid. The isoelectric point is pH 4.1.

The luteinizing hormone causes ovulation and initiates the formation of the corpus luteum. Equine LH has a number of LH components and an FSH component. Four LH components have isoelectric points at pH 7.5, 5.9, 6.6, and 7.3, and the FSH component isoelectric point is pH 4.8. The molecular weight is 44,500–63,800. LH concentration starts to increase in the plasma 2–3 days before ovulation, reaches a peak 1–2 days after ovulation, and declines to diestrus levels 6 days after ovulation (Geschwind *et al.*, 1975). FSH and LH work in a synergistic manner in the processes of follicular growth, maturation, and ovulation.

The ovarian hormones that control the estrous cycle are estrogens and progestins. Estradiol-17β is produced by the granulosa cells and by the theca interna of the Graafian follicles. The amount of estradiol-17β in the plasma begins to increase at the onset of estrus, reaches a peak 12–27 hours before ovulation, and declines to diestrus levels 5–8 days after ovulation (Figure 11-11). Because estrogen reaches a peak before LH peaks, it is possible that the estrogen surge may facilitate the ovulatory surge of LH. Within 24 hours after ovulation, the corpus luteum begins to secrete progestins. By the sixth day after ovulation, maximum levels of plasma progestins have been attained. The corpus luteum remains active for approximately 12–14 days, and then rapidly undergoes regression. The roles of the pituitary gland and the uterus in the maintenance and regression of the corpus luteum function are not fully understood. Injection of antibodies against FSH and LH during days 3–7 of diestrus causes a significant decrease in the weight of the corpus luteum, indicating that the mare's pituitary contains a substance that is necessary for maintenance of the corpus luteum. Evidence for a so-called uterine luteolysin has been provided by hysterectomy studies conducted by Stabenfeldt *et al.* (1974), in which functional corpora lutea were main-

tained for as long as 175 days postovulation after hysterectomy. It is believed that prostaglandin is the luteolysin.

The interval between the cessation of corpus luteum function and estrus is approximately 3 days. Estrus normally does not occur until the progestin concentration is less than 1 ng/ml in the plasma.

11.3 *Gestation*

Length of Gestation Period

Knowledge of the length of gestation and the ability to predict the mare's foaling date are important to the successful management of the pregnant mare. The average gestation period usually ranges from 335 to 340 days. There is considerable variation in the length of gestation, as evidenced by Paul's (1973) observations of Morgan Horses. The range was 300–385 days, the median was 342.5 days, the mean was 339.6 days.

Sex of the foal, month of conception, and the individual traits of the mare significantly affect the duration of pregnancy, although size of foal, sire of dam, age of sire, age of dam, and year apparently have no effect. Colts are usually carried 2–7 days longer than fillies, indicating that the sire does exert an influence on gestation length through the genotype. Season of the year seems to have an effect, in that the gestation length is shorter for foals born during warm weather. Mares on a high plane of nutrition foal approximately 4 days before mares on a low plane of nutrition. Therefore, the rate of development of the fetus could be affected by the nutritional plane of the mare. Fetal genotype has an effect; the gestation period of mares carrying a mule fetus (jack × mare) is approximately 10 days longer than the gestation period of the same mare when carrying a horse fetus.

The ovum migrates to the uterus 4–6 days after fertilization. Implantation does not occur for approximately 8 weeks. During the first 8 weeks of gestation, fetal fluid pressure holds the chorion (Figure 11-12) next to the uterine mucosa. By the tenth week, penetration of the uterine mucosa by the chorionic villi is quite extensive, and by 14 weeks the attachment is complete. The type of attachment is epitheliochorial, that is, the chorion of the fetus is in contact with the epithelium of the mare's uterus.

In the mare and donkey, the fetal placenta is formed by three membranes (Figure 11-12): chorion, allantois, and amnion. Villi, or fingerlike projections, are scattered over the surface of the chorion (outermost membrane), and for this reason the attachment is frequently said to be

Fetus of horse within the placenta. The chorion and allantois make up the chorioallantois, often called the chorion. From Frandson, R. D., ed. 1974. p. 388. Originally in Witchi. 1956. *Development of Vertebrates.* Philadelphia: W. B. Saunders.

"diffuse." The allantois (second membrane) lines the inside of the chorion and is fused with the amnion, thus forming the first water-bag or allantoic cavity. The allantoic cavity is continuous with the bladder by way of the urachus, which passes through the umbilical cord. The amnion is the innermost membrane and forms the second water-bag or amnionic cavity.

The umbilical arteries and veins are located in the connective tissue between the allantois and chorion. The umbilical arteries and their tributaries carry unoxygenated blood and waste products from the fetus to the mare. In general, the blood of the fetus does not mix with maternal blood. However, the two circulations are very close at the junction of the chorion and endometrium. At least 6 layers of tissue separate the maternal and fetal blood (Figure 11-13): fetal vein, stroma between fetal vein and cytotrophoblast, cytotrophoblast, uterine epithelium, uterine stroma, and maternal artery.

The mare has a peculiar specialization, in that *endometrial cups* begin to form on the thirty-sixth day of pregnancy opposite a transitory, though well-defined, circumferential thickening of the chorion called the allantochorionic girdle. Allen (1970a) has shown that the endometrial cups of the mare are composed of fetal cells and are not of maternal origin, as was thought previously. The endometrial cups are a discrete and densely packed mass of large, epithelioid, decidual-like cells, that develop before implantation. Upon development of the cups, a central depressed area

filled with coagulum is formed. The accumulation of coagulum, consisting of degenerate epithelial cells, erythrocytes, polymorphonuclear leucocytes, and pregnant mare's serum gonadotropin, causes a pouch to form in the allantochorion. The importance of the secretion of gonadotropins is discussed in the next section on hormonal changes that occur during pregnancy. Figure 11-14 illustrates the growth and development of the fetus.

Hormonal Changes that Occur during Pregnancy

Large quantities of pregnant mare's serum (gonadotropin), or PMSG, are present in the serum of mares between days 40 and 130 of gestation (Figure 11-15). The rate of secretion and/or absorption is sufficient by 35–40 days for it to be detected in the blood. Maximum levels are attained at 55–60 days, and the concentration declines until, after 130 days, it is undetectable in the blood. The amount of PMSG produced by the mare is related to the genotype of the fetus. Mares carrying a mule fetus (jack × mare) produce less PMSG than mares carrying a horse fetus. A jenny carrying a hinny fetus (stallion × jenny) produces more PMSG than the same jenny when carrying a donkey fetus.

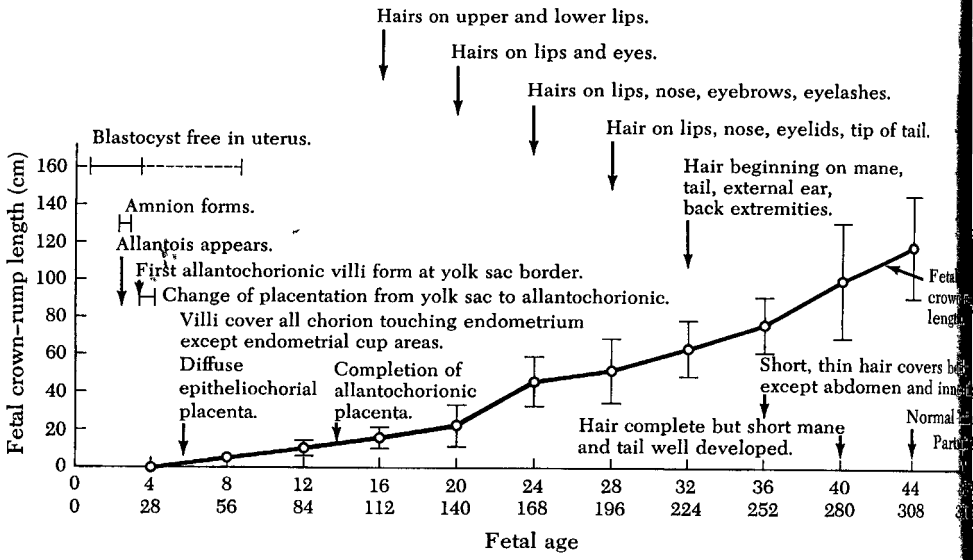

FIGURE 11-14
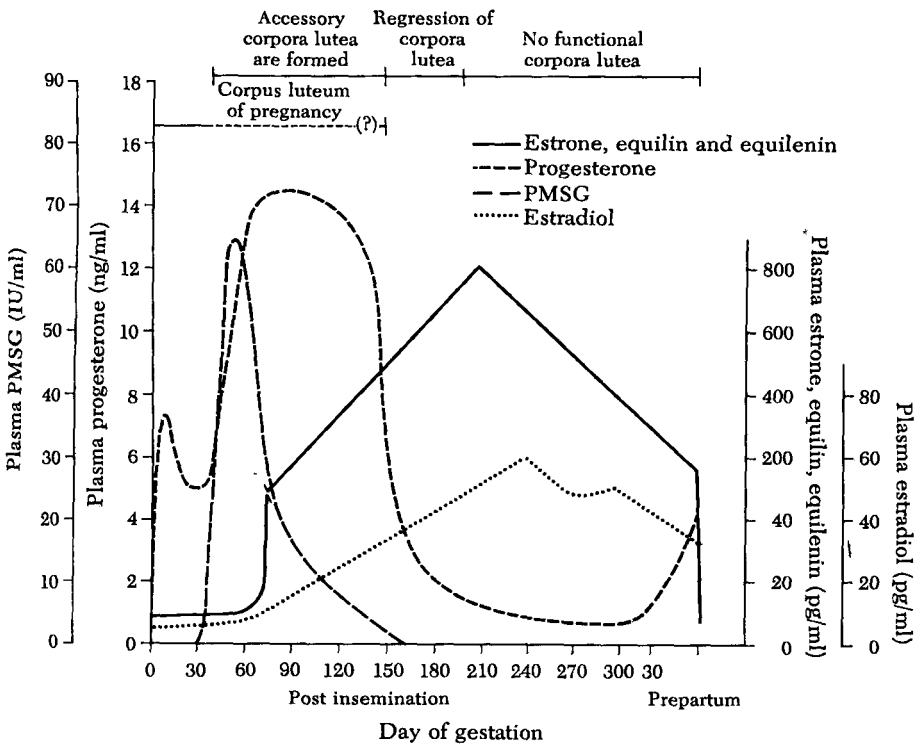
Fetal growth. From Bitteridge and Laing. 1970. p. 98.

PMSG is predominately follicle-stimulating in effect, but it also pos sesses a luteinizing fraction. The chemical characterization of PMSG ha been reviewed by Papkoff (1969). The molecular weight is approximatel 28,000. PMSG has a polypeptide content of 30–40 percent and a carbo hydrate content of 45 percent.

Nett *et al.* (1972) have shown that estrogen starts to increase at approx mately 45 days of gestation and increases at a rapid rate beginning at 8 days of gestation. Maximum levels are reached at 200–210 days, and the a gradual decline occurs. At parturition, a rapid decline occurs. Lovel *et al.* (1975) have observed that a rapid decline in progesterone level occurs on the day of parturition.

Ovarian activity, including formation and ovulation of many Graafia follicles and luteinization of follicles, reaches a maximum during the se ond and third month of pregnancy. It is during this period that accesso corpora lutea are formed and secrete progestins to maintain pregnanc Between 150 and 200 days, the corpora lutea undergo degeneration an no large follicles are present. By 200 days, the secretion of progesteron by the corpora lutea is insignificant since removal of the ovaries do not result in abortion.



There are several methods to diagnose pregnancy in the mare, althoug under normal conditions the first indication of pregnancy is failure to com into estrus 16–18 days after being bred. The most popular method is dia nosis by rectal palpation. This method has a decided advantage in that th result is immediately available. A skilled clinician can detect pregnanc in most mares at 25–30 days of gestation and be sure of accuracy after 3

days. After 45 days and until approximately 140 days, the detection of PMSG in the blood is a positive pregnancy diagnosis. Commercially prepared kits to test for PMSG are available to the horse owner who is without veterinary service. The detection of urinary estrogen by chemical means after 120 days of gestation is an accurate method. Fetal movements can often be observed in the mare's flank after the seventh month.

Foal Heat

A mare should come into "foal heat" between 1 and 12 days post-foaling. Even though a wide range of 1–50 days post-foaling has been observed, most mares are in estrus on the seventh to ninth day. The foal heat period may be as long as 12 days, but normally it is approximately 3 days in length.

Alliances and reproductive success in Camargue stallions

CLAUDIA FEH
Station biologique de la Tour du Valat, Camargue

(Received 2 September 1996; initial acceptance 5 December 1996; final acceptance 19 October 1998; MS. number: 5330R)

A study of a herd of Camargue horses, *Equus caballus*, showed that while the majority of high-ranking stallions held single-male harems, some sons of low-ranking mares, being low ranking themselves, formed alliances that could last a lifetime. The two stallions were each other's closest associate and preferential grooming partner. Alliances were based on coalitions in which either both partners confronted an intruder synchronously or the dominant of the pair tended the female(s) while the subordinate simultaneously displayed towards the rival. Alliance partners were of similar age but were not more closely related to each other than to other stallions in the herd. Long-term paternity data revealed that subordinates sired close to a quarter of the foals born into the alliance group, and significantly more foals than low-ranking stallions in the herd adopting a 'sneak'-mating strategy. The dominant appeared to benefit from the presence of his subordinate partner. Fights occurred all year round, and the subordinate stallion of each alliance pair fought outside competitors more than twice as often as the dominant. Forming short-term alliances before defending mares on their own may enhance long-term reproductive success for both partners. Other benefits to both partners include higher survivorship of their foals and increased access to proven reproductive mares. These results suggest that the relationship between alliance partners is based on mutualism, but several conditions for reciprocity seem to be fulfilled: the benefit to the dominant (assistance in fights), and the benefit to the subordinate (access to reproduction), are both costly to the other partner and delayed in time.

© *1999 The Association for the Study of Animal Behaviour*

Alliances are long-term cooperative coalitions (de Waal & Harcourt 1992), cooperation often being provided in the form of support during competitive encounters (e.g. van Hooff & van Schaik 1992). Alliances between males are generally rare in mammals (Clutton-Brock 1989). As low-ranking males are disadvantaged over access to resources or reproduction (Dunbar 1988), they may be able partly to compensate by forming alliances based on coalitions. The value of male alliances with regard to mating success has been reported in a variety of primates (Smuts 1987), but seldom in nonprimate species, where they have been observed only in lions, *Panthera leo* (Packer et al. 1991), wild dogs, *Lycaon pictus* (Moehlman 1986), hyaenas, *Crocuta crocuta* (Zabel et al. 1992), dolphins, *Tursiops* sp. (Connor et al. 1992), captive plains zebras, *Equus burchelli* (Schilder 1990) and feral horses, *Equus caballus* (Berger 1986). Only the study on lions was able to measure individual reproductive success. Packer et al.'s (1991) results indicate not only that male lions form coalitions, but also that paternity in coalitions of unrelated males is more evenly shared than in coalitions of related males. Therefore, whereas the immediate benefits of cooperative behaviour have been widely demonstrated (e.g. Smuts 1987), few studies have been able to show the effect of alliances on survival or reproduction (Harcourt & de Waal 1992) or to measure trade-offs between the partners.

Horses and plains zebras provide an unusual opportunity to investigate the effects of alliances on male reproductive success. Adults form small, long-term groups, usually consisting of one stallion, one to two mares and their offspring. As is typical for a species in which males have long tenure of a group, both sexes disperse from their natal family (Clutton-Brock 1989). Young mares usually join reproductive units directly (Monard & Duncan 1996), whereas young males first spend 1–2 years in a stallion group before forming their own family (this study). Apart from the typical one-male family, groups with more than one adult stallion have been reported by all authors who have studied free-living horses. Berger (1986) noted that 12% of the families that persisted longer than 7 months had two or more stallions, and Stevens (1990) reported that half of the 12 groups she watched for 2 years were multimale. With regard to these different types of groups in horse societies (one-male, multimale and all-male), the following mating strategies are observed in stallions: exclusive access to females in one-male families; shared reproduction in multimale

groups, including preferential male–female relationships in terms of proximity and exchanged interactions over several years (Feh 1987); and sneak matings by stallions living in all-male groups, these matings mainly occurring at night and without a social bond between partners (personal observation).

Individual reproductive success in Camargue stallions is positively correlated with their mother's rank and their adult rank, but not with their weight (Feh 1990). Stallions may therefore vary in 'quality' (e.g. rank), and the high-ranking individuals may be better able to hold groups on their own than others. The alternative for low-ranking individuals might be to team up in alliances in order to be able to defend females.

In this paper, I describe alliance behaviour based on coalitions between Camargue stallions living under semi-natural conditions. I then investigate the influence of genetic relatedness, rank and age on alliance formation and describe costs and benefits to the two partners with regard to fighting and reproductive success, based on paternity analyses. I finally examine mutual benefits to both alliance partners in terms of overall reproductive success, foal survival and access to specific females.

METHODS

Study Animals

The study herd started in 1974 with 14 horses of known genetic relatedness. They were released in a Camargue pasture of 300 ha composed of freshwater marshes, salt steppes and halophyte grassland. The number of horses peaked at 94 in 1981, with 11 family groups and one bachelor group. From 1980 on, horses were removed regularly to avoid overgrazing. No supplementary food or veterinary care was given. From 1979 on, all individuals were weighed twice a week. At the same time, blood samples were taken for paternity tests. All individuals were easily approached and identified and their exact dates of birth are known. From 1977 on, several family groups existed and from 1978, these family groups lived together in one herd. This meant that the horses were in sight of each other most of the time, so interactions between stallions were relatively frequent. This analysis considers 13 stallions, for which long-term reproductive success and social behaviour from birth to the respective ages of 11–14 years were known. These ages are beyond the peak of reproductive success in stallions (Berger 1986; Feh 1990).

Paternity, Relatedness and Foal Survival

Paternity exclusion tests were based on electrophoresis on a number of proteins at 28 loci (for further procedural details see Scott 1978). The combined reproductive success was calculated up to 11 years, when the paternity analyses stopped. A total of 154 foals were born to the groups under consideration; 10 foals were found dead shortly after birth (<48 h) and therefore were not analysed for paternity as the analyses needed fresh blood samples. As the adult sex ratio of the herd changed over the study years, stallions of different ages did not have the same opportunity for siring foals in each year. To standardize data for each stallion, I calculated the number of 'available' mares for each stallion at each age in the following way. Nearly all the mares had a foal every year and gestation lasts 11 months. The age at first breeding is taken as 2 for the mares and 4 for the stallions. The number of 'available' breeding mares was thus the ratio of the number of mares 2 or more years old divided by the number of stallions 4 or more years old. So the relative reproductive success of a stallion at a given age was the number of foals produced at that age divided by the number of available breeding mares the year before.

I calculated the relatedness of each pair of horses (e.g. H1 × K6) in the herd measured as the additive relationship (a) as follows:

$$a\text{H1} \times \text{K6} = 0.5(a\text{H1} \times \text{G3} + a\text{H1} \times \text{G4})$$

where G3 and G4 are, respectively, the mother and father of K6. For the full description of the method, see Evans et al. (1977).

For the comparison of foal survival between one-male and alliance families, I considered all 154 foals found shortly after birth (<48 h). Under such circumstances, identification of the mother, and therefore of the group into which the foal was born, was easy even for dead foals.

Assessment of Ranks

From 1976 to 1987, I established the dominance hierarchy in the field using observations of headthreats and bites, followed by a clear avoidance reaction by the recipient (Wells & von Goldschmidt-Rothschild 1979). Both focal animal and all-occurrences sampling were used. Observation hours varied from 564 to 1872 per stallion. Contexts were food, water or wind shelter. The horses were then ranked according to the classical method (Martin & Bateson 1993), where the individual that is never supplanted is at the top and the one that is always supplanted is at the bottom. As it was sometimes difficult to observe a resource-based hierarchy in the field, the herd was brought to a 1-ha enclosure where access to water could be controlled. Every 48 h, I stopped their otherwise free water supply for 24 h, so the horses were induced to show agonistic behaviour at a measurable rate (1.4 headthreats and 0.17 bites per horse in the first hour after having access to water). I repeated the experiment 10 times over a 3-week period in 1988 and 1989, and compared the results with data obtained in the field. There was no difference between the two data sets, and a stable linear dominance hierarchy could thus be determined among the stallions.

Relationships, Confrontations and Fights

Observation hours were evenly distributed over daylight hours in all seasons. The nearest horse to any other

horse of the herd was determined every 15 min. Single linkage cluster analysis based on these data was used to define groups and establish preferential individual relationships (Duncan 1992). For the same purpose, I used focal animal sampling, following each stallion for 60 min per day, 200 days per year from 1976 to 1980. I recorded 30 different types of interaction with the aid of a tape recorder and used them to calculate frequencies per h of 11 behavioural categories. A detailed description of observational methods is given in Feh (1987). For 2 years, the herd was observed for 48 h consecutively every 2 weeks in order to establish activity budgets. These observations also allowed sneak matings to be detected, although not quantitatively for all stallions. As all the families stayed close together during the study period and fights are conspicuous, I used all occurrence sampling to calculate the fighting frequency for each stallion. Fights in equids typically consist of rearings, attempts to bite or bites, and kicks with the fore or hind legs (Feist & McCullough, 1976; Berger 1986). Before the stallions start to fight, they usually go through a confrontation (Tschanz 1985; Berger 1986), where one stallion defecates on a dung pile while the other approaches. They then smell the dung together, and most often raise their heads rapidly while squealing. These actions are typically followed by kicks with the forelegs, and the dominant stallion of the pair then defecates over the dung while the subordinate leaves (Feh 1987). If the subordinate stallion is reluctant to leave, the confrontation usually ends in a fight.

Statistical Analysis

The statistical analysis is based on two categories of stallions. The first takes into account the stallions that adopted only one reproductive strategy during their life. They were treated as independent samples and compared with the Wilcoxon test (Siegel & Castellan 1988). For stallions that changed reproductive strategies during their life, I compared these using the Wilcoxon signed-ranks test or the permutation test for paired replicates (Siegel & Castellan 1988). For comparisons between alliance partners, these same pairwise tests were used.

RESULTS

Proportion, Duration and Stability of Two-male Groups

Detailed descriptions of the herd history, including group composition, genealogy and births are given in Duncan et al. (1984) and in Duncan (1992).

The majority of stallions first tried to monopolize mares on their own, but few succeeded at the first attempt. Stallions that failed to do so seem to have had two options: either they joined another stallion in a two-male group or they stayed in a bachelor group and tried to mate mares as 'sneaks'. Forming a two-male group with another stallion was a temporary situation for the majority of individuals but permanent for four out of 10 males that formed a two-male group.

Seven out of 13 stallions attempted to form a family on their own when 2–3 years old (corresponding to sexual maturity in males), whereas the other six joined an all-male group (Fig. 1). Half of the latter had been chased out of their original group by the dominant stallion. Attempts by young stallions to defend at least one mare against rivals never lasted for more than one breeding season (2 months), when they were forced by other stallions to abandon the mare(s) after numerous fights. The stallions then became integrated into a stallion group for up to 2 years. Only three males out of the 13 were subsequently successful in forming a one-male family group with a tenure length of up to 18 years. The other 10, on their own accord, formed a two-male group with a partner. Four of them stayed together over many years: one of these subsequently died while two stallions were still living in the same group after 16 years at the time of writing. Six left their partners after 2–3 years to form families on their own. Once they had succeeded, they never reverted to a two-male group until they died (9–17 years later) or were taken out of the herd (two stallions, 4 years after they formed a one-male group).

Anecdotal evidence suggests that from a certain age, the strategies adopted by stallions are fixed. In one case, I was able to test the stability of reproductive strategies in four 13-year-old stallions followed since birth. Each stallion had adopted a different strategy between the ages of 4 and 6 years. The dominant had gained control over three mares, the second-ranking stallion was a bachelor, and the third- and fourth-ranking stallions had formed a two-male group. The four stallions were separated from their mares and kept together on a different pasture for 2 months. They were then introduced to a group of six mares unknown to them. Initial fights (N=16 for all stallions) after the release lasted for 21 min in total. By the end of this period, the dominant stallion had monopolized three mares on his own, the second-ranking was a bachelor, and the two last-ranking stallions had teamed up in a two-male group and controlled the other three mares. The group composition remained stable over the next 3 months. Therefore, 7–9 years after initially forming their families with different mares, the stallions had adopted the same reproductive strategy and kept the same rank position. Three months later, when the stallions were reintegrated into the herd together with their old mares, there was again no change detectable in their strategies.

Relationship between Partners of Two-male Groups

Apart from the low-intensity agonistic interactions (bites and headthreats) maintaining the relative rank position seen in all pairs (Table 1), stallion partners in two-male groups were each other's closest associate. Proximity between the partners was maintained by the subordinate. Their relationship was further based on a high frequency of mutual groomings mainly initiated by the subordinate, smellings or body contacts as well as lightly agonistic rank displays that caused no physical harm (Tschanz 1985). The relationship with the mare(s)

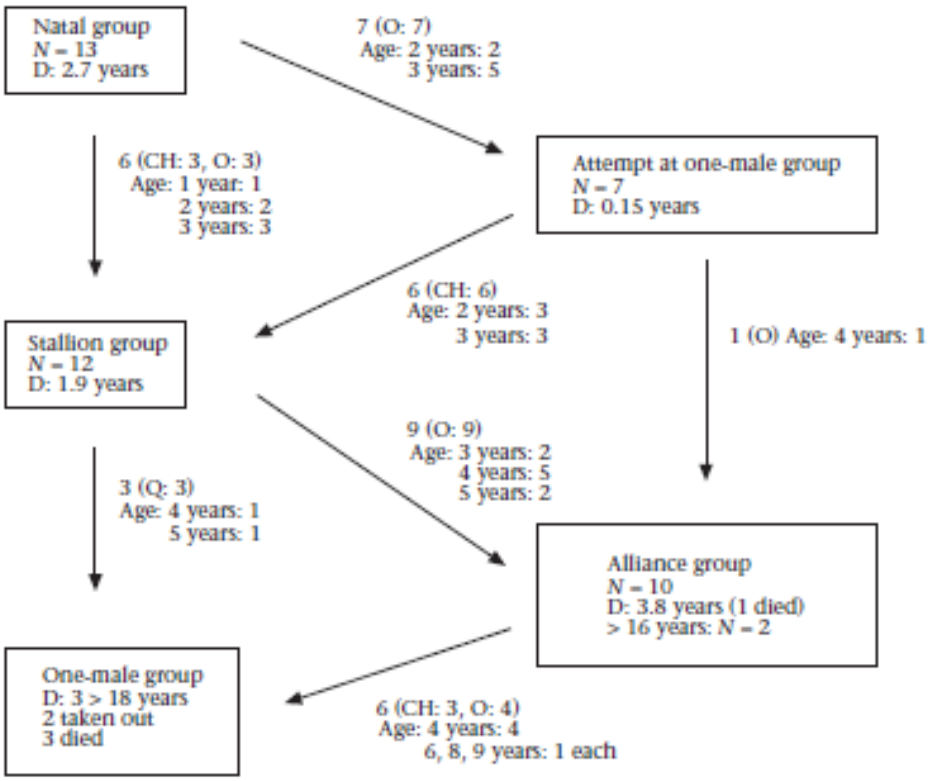

Figure 1. Succession of group changes showing alternative reproductive strategies adopted by the different stallions over their lifetime. D: mean duration of stay in the respective group. Age: respective age when the stallions changed groups or reproductive strategies. Of the 13 stallions studied, seven were still alive at the time of writing and in the herd. Four died and two were removed; all were more than 11 years old so were still included in the analysis. CH: number of stallions changing groups or reproductive strategies after being aggressively chased by a dominant stallion or subsequent to losing a fight. O: number of stallions changing groups or reproductive strategies on their own accord, that is, without being chased or attacked by other stallions.

differed between the dominant and the subordinate, the former being closer, engaging in more mutual grooming, and driving her (them) more often than the latter. The relationships of dominants and subordinates with both foals and yearlings of their group were similar, characterized by an exchange of mutual groomings, and submissive behaviour from the young horses towards the adults.

Alliance Behaviour Based on Coalitions

When an outside stallion approached the two-male group, the partners took one of two options. They either confronted their rival together, with aggression mostly initiated by the subordinate (20 times versus 4 times by the dominant; binomial test: N=24, P=0.002, two-tailed; in 10 cases initiator not determined), or the subordinate usually displayed to the rival stallion while the dominant drove away the mares (Fisher's exact test: P=0.001; Table 2).

Identity of Alliance Partners

Partners teaming up for alliances were low-ranking unrelated stallions of the same or similar age who had developed strong bonds during the time they lived together in a stallion group.

Of the individuals that formed alliances at some stage in their lives, seven out of 10 were part of the low-ranking half of the male dominance hierarchy (Table 3), and were sons of mares in the lower-ranking half of the female dominance hierarchy, whereas the three one-male family holders that never participated in alliances were sons of the higher-ranking mothers (Fisher's exact test: P=0.035) and were themselves in the high-ranking half of the dominance hierarchy (Fisher's exact test: P=0.02).

There was no consistent tendency for stallions to form alliances with close relatives. Thus, there was no significant difference between the genetic relatedness (additive relationship) of an alliance member with its partner and the relatedness of the same individual with any other stallion of the herd (paired t test: t_9=1.91, NS) or with another member of the same stallion group (Fig. 1) before the pair formed an alliance (paired t test: t_9=1.85, NS), although the mean additive relatedness between low-ranking mothers was higher ($\bar{X}$=0.239, N=4) than that between dominant mothers (0.083, N=3). It cannot therefore be concluded that close genetic relatedness was at the origin of alliances. Moreover, six pairs of maternal half-siblings (same mother, different fathers) from five different mothers knew each other well, having spent up to 2 years in the same group during their youth. None of these formed an alliance pair. The effect of paternal half-siblings could not be investigated. The fathers of six

Dom: dominant stallion in an alliance; Sub: subdominant stallion in an alliance. The mean frequencies of interactions per h for four pairs of alliance partners observed during 44 h each over 6 months are shown. Light agonistic: head threats and bites. Strong agonistic: attacks and chases. Interposition: one horse moves in between two interacting horses. The nearest neighbour data were recorded every 15 min at the same time as the interactions. The frequency indicates how many times the second of the 'partners' was seen closest to one of the alliance partners, e.g. 'Sub was closest to Dom 168 times'.

Table 2. Number of occurrences of display by one alliance partner to a rival while the other drives away their mare(s)

Actor	Display	Driving mare(s)	Total
Dominant alliance partner	2	33	35
Subordinate alliance partner	32	3	35
Total	34	36	70

See text for test. The total number of observation hours: 564 for each of the five alliance pairs.

of the stallions were absent from the herd, having sired their sons before the start of the study. The fathers of the other four were present, but the sons did not grow up in the same group as their fathers.

Stallions usually formed alliances with partners of the same age. Six stallions formed alliances with partners born in the same year, the difference in age for the other two pairs being 1 and 2 years, respectively. All but one of the pairs formed while they were together in a stallion group. Two such groups existed during the study, and all stallions forming alliances after leaving the stallion group had preferred social relationships with their future partner during their time together in this group. Future alliance partners were always the most frequent nearest neighbours and exchanged more interactions than with all other members of the herd (Wilcoxon signed-ranks test: $T=55$, $N=10$, $P=0.002$, two-tailed, for both nearest neighbours and interactions).

Benefit of Alliance to Subordinate Stallion

Subordinate alliance stallions had a higher relative reproductive success than sneaks (Table 3, Fig. 2). The sneak strategy was the least successful reproductive strategy (sneak strategy versus subordinate alliance strategy: permutation test for paired replicates: $N=5$, $P=0.02$, two-tailed; sneak strategy versus dominant alliance strategy: permutation test for paired replicates: $N=5$, $P=0.02$, two-tailed; sneak strategy versus one-male family holders: permutation test for paired replicates: $N=8$, $P=0.01$, two-tailed). Although in all of the five alliance pairs, dominants sired more foals than subordinates (permutation test for paired replicates: $N=5$, $P=0.02$, two-tailed) and dominants had a higher relative reproductive success than subordinates in individuals that never changed strategies (Wilcoxon test: $W_s=15$, $N_1=N_2=3$, $P=0.05$, one-tailed), stallions adopting a subordinate alliance strategy had a higher relative reproductive success than when remaining as sneaks (see tests above).

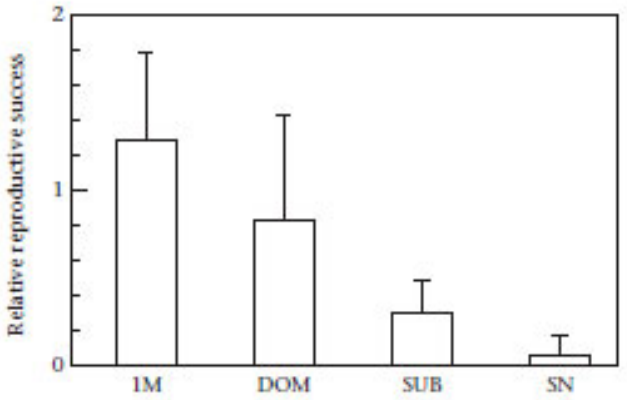

Figure 2. Relative reproductive success in relation to the four reproductive strategies (mean number of foals per year+SD). Data cover the stallions' relative reproductive success up to 11 years of age and correspond to the 10 years of analysis on fighting frequency. The data for this figure are pooled, but the statistical tests are based on independent samples or pairwise comparisons (see text). 1M: one-male family holders, $N=8$; DOM: dominant alliance stallions, $N=5$; SUB: subordinate alliance stallions, $N=5$; SN: sneaks (bachelors), $N=12$.

Cost of Alliance to Dominant Stallion

Apparently as a result of conceding foals to the subordinate, dominant stallions in alliances had a lower

*Mean±SE number of foals fathered per year from birth to 11 years, corrected for the number of available mares in the herd the year before.

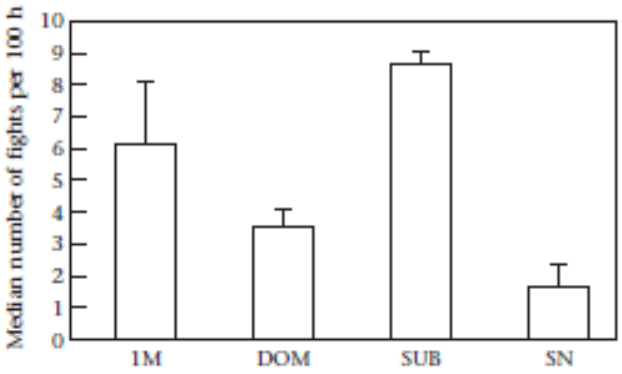

Figure 3. The stallions' fighting frequency with outside competitors in relation to the four reproductive strategies (number of fights per 100 h, median and interquartile range for all stallions). Data were collected from 1977 to 1986, at the same time as the paternity analyses. Observation hours for each stallion varied from 1240 to 1872, distributed over the 10 years. The data for the figure are pooled, but the statistical tests are based on pairwise comparisons (see text). 1M: one-male family holders, N=8; DOM: dominant alliance stallions, N=5; SUB: subordinate alliance stallions, N=5; SN: sneaks (bachelors), N=12.

relative reproductive success than males controlling mares on their own. Excluding individuals that changed strategies (Table 3, Fig. 2), stallions in one-male groups were more successful than dominant alliance stallions (Wilcoxon test: W_x=15, N_1=N_2=3, P=0.05, one-tailed). Stallions changing from alliances to one-male family holders improved their relative reproductive success (permutation test for paired replicates: N=5, P=0.02, two-tailed). As they changed strategies after the age of 4, fertility linked to age could not act as a confounding factor (Evans et al. 1977).

Cost of Alliance to Subordinate Stallion

Subordinate stallions took more risks and probably expended more energy because they fought more often than dominants and sneaks (Fig. 3). In all pairs, the fighting frequency of subordinate alliance stallions with other stallions of the herd was significantly higher than that of the dominants (permutation test for paired replicates: N=5, P=0.02, two-tailed). Comparisons between reproductive strategies show that subordinate stallions fought more often than sneaks (permutation test for paired replicates: N=5, P=0.02). There was no significant difference between the frequency of fights for the other categories.

Benefit of Alliance to Dominant Stallion

Dominant alliance stallions benefited from the presence of the subordinate because he assisted in fights against outside rivals. Excluding stallions that changed reproductive strategies, the total fighting frequency for both alliance stallions combined was significantly higher (Wilcoxon test: W_x=15, N_1=N_2=3, P=0.05, one-tailed) than the frequency for one-male strategists, probably because alliance stallions were lower ranking so had to defend their mares more often. The sample size was inadequate to test for tenure length and/or survival in order to see whether there was a long-term benefit to the dominant from the presence of his subordinate ally. Again, only anecdotal evidence suggests that this may be the case. At the time of writing, of the same four stallions tested for the stability of reproductive strategies, the bachelor stallion died 3 years ago, the one-male family holder now controls two mares whereas the two alliance partners share five mares between them.

Mutual Benefits to Alliance Partners

Short-term alliance partners, dominants and subordinates alike may have the same long-term reproductive success as one-male group holders that never formed alliances. The stallions that lived in alliances for 2–3 years only and later changed to form a one-male group did not have a lower overall reproductive success than stallions adopting a one-male strategy from the start: when comparing the combined reproductive success up to 11 years (Table 3), there was no significant difference between stallions that had never formed an alliance and those that were temporarily dominant (Wilcoxon test: W_x=8, N_1=N_2=3, P>0.90) or even temporarily subordinate in an alliance (Wilcoxon test: W_x=12, N_1=N_2=3, P=0.35) that had later changed to a one-male group strategy.

Stallions in alliances were more successful than those in one-male groups in rearing their foals to weaning. There was significantly less neonatal (0–1 week) mortality in foals born into alliance families than in foals born into one-male groups. Only one foal out of 31 (3.2%) died in a family with two stallions, whereas 27 out of 123 (22%) were found dead in families with only one male (Fisher's exact test: P=0.02). As the overall foal mortality in this herd was highest during the first week and close to zero thereafter (Duncan 1992), foals born into alliance groups had a higher chance of survival.

Alliance stallions had increased access to proven reproductive mares. All young females of breeding age leave their natal family to integrate into a reproductive unit (Monard & Duncan 1996). They therefore become 'available' to stallions outside their natal group. The majority of mares (72.5%, Monard & Duncan 1996) leave at puberty before having a foal (gestation length is 11 months), but some mares wait until shortly after the birth of their first foal before they change groups. When two allies start their group, or integrate a new female into their already existing group, they associate preferentially with mares with very young foals of less than 1 week of age. Nine (50%) out of 18 available mares with very young foals were acquired subsequent to fights by allied partners compared to only four (16%) out of 25 taken over by single males (chi-square test: χ^2_1=4.24, P<0.05).

DISCUSSION

In this herd of horses, low-ranking unrelated stallions of similar age formed alliances based on coalitions where

both partners participated in defending their mares against rivals. Why should some stallions engage in alliances at all? As Dunbar (1988) stated, low-ranking males in general are at a disadvantage with regard to access to females. Alliance stallions both gained substantial benefits from their cooperation. Some individuals seemed to engage in short-term alliances in order to enhance their long-term reproductive success so as to catch up, in the long term, with the most successful strategy, holding mares alone, but the mechanisms are unclear. Other stallions seemingly engaged in long-term alliances because this represented the best option or because they might have had an advantage in controlling more mares in the distant future, but only anecdotal evidence suggests the latter. Another benefit was higher foal survival in alliance groups than in one-male groups. Again, the reason is not entirely clear, but a number of newborn foals were wounded accidentally during fights between adults shortly after birth, although we never observed infanticide. The young foals during their first critical hours after birth may benefit from the protection of two stallions against harassment from other horses. The third advantage of alliances was increased access to proven reproductive females that already had a foal. Mares are usually on heat from 7 to 10 days after the birth of their foal. However, since the majority of young mares, most of them without foals, change groups when they are on heat anyway (Monard & Duncan 1996), this may well indicate that oestrus alone was not the key factor in the alliance stallions' preference for proven breeding mares. Ninety-five per cent of the mares from the herd had a foal every year (Duncan 1992), so it was not possible to investigate the long-term consequences for this preference of stallions in alliances.

In conclusion, the benefits for both alliance partners seem to be straightforward. Mutual benefits to male alliances have been widely reported in mammals, although nonprimate species are poorly represented (for a review, see Clutton-Brock 1989), and benefits are usually discussed in terms of access to resources or enhancement of the common rank position rather than direct measurements of the consequences for an individual or its offspring (Harcourt & de Waal 1992). Nevertheless, mutualism or its synonym by-product mutualism (Mesterton-Gibbons & Dugatkin 1997) is defined as 'cooperation regardless of the opponent's behaviour, cooperation being merely a by-product of following the best strategy' (West-Eberhard 1989). My results suggest that alliance stallions both benefit from their association and follow the best strategy for both of them but not without costs to each of the partners.

Two main conditions are required for a cooperative behaviour to be reciprocal, first that the initiator behaves altruistically, which implies at a cost to him, and second that his reward, costly to the recipient, is delayed in time (Axelrod & Hamilton 1981). Moreover, if reciprocal altruism exists not only to enhance inclusive fitness, it should be observed between unrelated individuals and not just between kin. This seems to be the case in stallions. In a herd with many groups and multiple reproductive males, there is a dilemma for any stallion controlling females when challenged by a rival. He has to keep the rival at bay while making sure his mare(s) are not approached by other males. Stallions overcome this difficulty by forming coalitions where two males support each other. They either confront the intruder(s) together or share the task: while the dominant of the pair drives away the mare(s), the subordinate engages in an encounter with the other stallion(s). This is consistent with Berger's (1986) data on three alliance pairs, where the subordinate on average fought three times more often than the dominant. Guarding the females is less risky than fighting, thus the subordinate has a higher cost.

During a fight both stallions rear up, kicking with their forelegs or trying to bite each other at the throat, neck or legs. The risks incurred during these fights are infected wounds or damage to the legs which may lead to severe limping and can incapacitate a stallion to the point of his not being able to follow his group and permanently losing it as a consequence (Berger 1986; this study). During Berger's 5-year study, he estimated that 3% of all stallions died as a result of fighting. In our herd, no stallion was killed or mortally wounded, but fights clearly are risky and costly in terms of an individual's fitness. Two stallions, a one-male family holder and a subordinate alliance stallion, had reverse melanism (their usually white coat-hair grew black on scars); at the age of 20 in May 1996, the first had 35 permanent scars whereas the second had 146. Besides the risks, fights and displays are energetically costly. I do not have data on direct energy expenditure stemming from the higher frequency of displays or fights for subordinates, but Berger (1986) calculated that one of his dominant alliance stallions spent 7.1 MJ/day less than the subordinate. In domestic horses, the basal rate (digestible energy without work) is 65 MJ/day (National Research Council 1978), so the difference is considerable.

In exchange for his investment in defending their mares, the subordinate stallion gains paternity. Alliance stallions of one family almost never lose sight of each other. Mating needs a minimum of 3 min if the mare is receptive. The position of the stallion during mating is unbalanced, and therefore makes it easy for another stallion to intervene and prevent it. For example, a one-male family holder immediately interferes when another stallion tries to make body contact with one of his mares. The benefit granted by the dominant alliance partner to the subordinate is thus a passive one.

Finally, fights are not immediately related to matings. Although fights are most frequent during the reproductive season, they occur all year round (Feh 1987), whereas the majority of mares are on heat for only a few days per year (Duncan 1992). The reward to the subordinate partner, siring foals, is therefore delayed in time.

These results suggest that the relationship between the two allies contains elements of reciprocity. Although I could not test the Prisoner's Dilemma model or any strategy such as 'Tit for Tat' experimentally, in one case I was able to observe a dominant alliance male punishing noncooperation by the subordinate. In the experiment on the stability of reproductive strategies (see above), the four stallions were filmed individually and continuously

after their release with the new mares. For the first 15 min, the subordinate alliance stallion tried to monopolize a mare on his own without participating in the defence of the dominant's mares against the other stallions. In the 16th minute, the dominant attacked the subordinate repeatedly, tearing out part of his lip. From that moment on, the subordinate cooperated in the defence of the mares. This may imply that in some situations, the dominant may coerce the subordinate into cooperation (Clutton-Brock & Parker 1995).

Authors mostly agree that reciprocal altruism between unrelated mammals is difficult to measure and examples are rare (Harcourt & de Waal 1992; Slater 1994). This study, like Packer et al's (1991) on lions, and Connor et al.'s (1992) on dolphins, shows the existence of male alliances in a nonprimate species, the alliance being based on coalitions against rivals with reproductive benefits to both partners.

Acknowledgments

All my thanks to S. Faraman for teaching me alliances in horses. The long-term study was initiated and supported by the Foundation Tour du Valat. I thank its president, Dr L. Hoffmann and director general, J.-P. Taris. Part of the analysis and writing up was done at LARG, Cambridge University. Many thanks to Professor T. Clutton-Brock and the whole team for stimulating discussions and corrections. Several persons were involved in the data collection, especially Ph. Malkas and J.-C. Gleize. Dr M. Scott from the Animal Health Trust in Newmarket performed all paternity analyses without charge to the project. Long-term financial aid was provided by the Basler Stiftung für Biologische Forschung and the Fondation Tour du Valat.

Behavior Patterns and Communication in Feral Horses

By JAMES D. FEIST[1]) and DALE R. MCCULLOUGH

With 15 figures

Received: 25 January 1975

Abstract

The social behavior of feral horses was studied in the western United States. Stable harem groups with a dominant stallion and bachelor ♂♂ groups occupied overlapping home ranges. Groups spacing, but not territoriality, was expressed. Harem group stability resulted from strong dominance by dominant stallions, and fidelity of group members. Eliminations of group members were usually marked by urine of the dominant stallion. ♂-♂ aggression involved spacing between harems and dominance in bachelor groups. Marking with feces was important in ♂-♂ interactions. Foaling occurred in May and early June, following the post-partum estrous. All breeding was done by harem stallions. Young were commonly nursed through yearling age. These horses showed social organizations similar to other feral horses and plains zebras.

Introduction

A study of the behavior and ecology of a population of feral horses (*Equus caballus*) was conducted on the Pryor Mountain Wild Horse Range between May 1 and November 1, 1970. The study area (Fig. 1) encompasses 13,598 ha of public land administrated by the Bureau of Land Management (BLM) on the Wyoming-Montana border approximately 16 km north of Lovell, Wyoming. Complete information on the composition and social structure of the population is given by FEIST (1971) and FEIST and MCCULLOUGH (1975). All 270 horses on the Range were individually identified. Many showed evidence of the Barb and Andalesian blood lines which were originally introduced to the American west by Spanish explorers in the 16th century. During the period of the study there was no human manipulation of the population, with the exception of completion of a Range boundary fence

[1]) JAMES DEAN FEIST, age 27, was killed on September 12, 1973 in the crash of a light plane while conducting a count of caribou in Yukon Territory and adjacent Alaska. This study was originally done for a master's degree (FEIST 1971) under the direction of the junior author who prepared this manuscript.

during the study which excluded 40 horses from the Range. Pryor Mount horses were in naturally occurring social groups, and can be considered have been a natural population at the time of the study. Subsequent to t study some horses have been removed from the range.

Methods

Travel on the Range was primarily by a half-ton truck on three main access roads. T usual procedure was to drive to an access point and work from there on foot. A saddle ho was used on the extreme western side of the Range where there were no roads. The horse w not used when behavior notes were being taken because of interactions between the sad horse and the wild horses.

When horses were first sighted, the color, sex, age, and other markings were record for each individual on prepared silhouettes. These were further documented with photograp Individuals were classified to age as foal (born that spring), yearling, immature (two or thr years old), and adult. In many cases it was difficult to distinguish immatures with certain since mature body size and length of mane and tail are usually attained at this age.

Locations of horses were recorded on a map with quarter-mile square grids. Each i dividual was given a name, and the name of the group usually was that of the domina stallion. Data on members of a social group were filed together. Each time the group was sight again date, location, and group changes were recorded.

Detailed quantitative notes were obtained by direct observation over extended perio of time. Frequency of behavioral interactions was recorded continuously and reported minute intervals. This usually consisted of watching one band at a time and noting the tim of occurrence of behavior events for all individuals in the band. Stereotyped behavior ac were described and photographed. Cloud cover, wind, and temperature were described in qualitative manner.

Charts on group cohesion were kept simultaneously with the quantitative notes. The charts were based on a determination every 15 min of estimated distances between (1 mares, (2) mares and their foals or yearlings, (3) mares and the dominant stallion, and (4) t group and the next closest group, if one was in sight. Extended periods also were spe observing water holes to obtain information on frequency of use and behavior at this resourc When it was possible to observe more than one group at once, sketch maps were kept t diagram the groups movements and their relative positions throughout that period of no taking. Behavior observations were aided by 16 × 50 binoculars. To avoid biases all of th quantitative notes were taken while the horses were unaware of the presence of the observe

In addition, six bands were habituated to presence of the observer in order to ga observations at close range. By approaching groups in a slow, calm, and relaxed manner, nev moving directly towards them or staring at them, these groups came to tolerate presenc within 8 to 30 m for extended periods of time. There was considerable variation in excitabilit of horse groups. All horses were excitable during strong winds, as previously reported fo elk (MCCULLOUGH 1969), white-tailed deer (NEWHOUSE 1973) and pronghorn antelope (KIT CHEN 1972). Similar excitability occurred during stormy weather.

Results and Discussion

Population Characteristics

To summarize, a total of 270 horses were censused on the Range by individual identification. They included 78 mature stallions, 79 mature mares 21 immature stallions, 17 immature mares, 11 yearling stallions, 19 yearlin mares, 19 colts and 16 fillies.

Horses were organized into 44 harem groups consisting of a dominan stallion, 1—3 mares, and their immature offspring, and 23 bachelor stallio groups. Mean size of harem groups was 5.0 and bachelor groups 1.8. Haren groups were quite stable, with most of the changes involving immature ♀♀. Considerable shifting occurred within bachelor stallion groups. Social orga- nization closely paralleled that reported for plains and mountain zebras by

KLINGEL (1964, 1965, 1967, 1968, 1969 b, 1969 c) and KLINGEL and KLINGEL (1968 a, 1968 b), for Sable Island ponies by BRUEMMER (1967) and for New Forest ponies by TYLER (1972).

Home Range and Spacing Between Groups

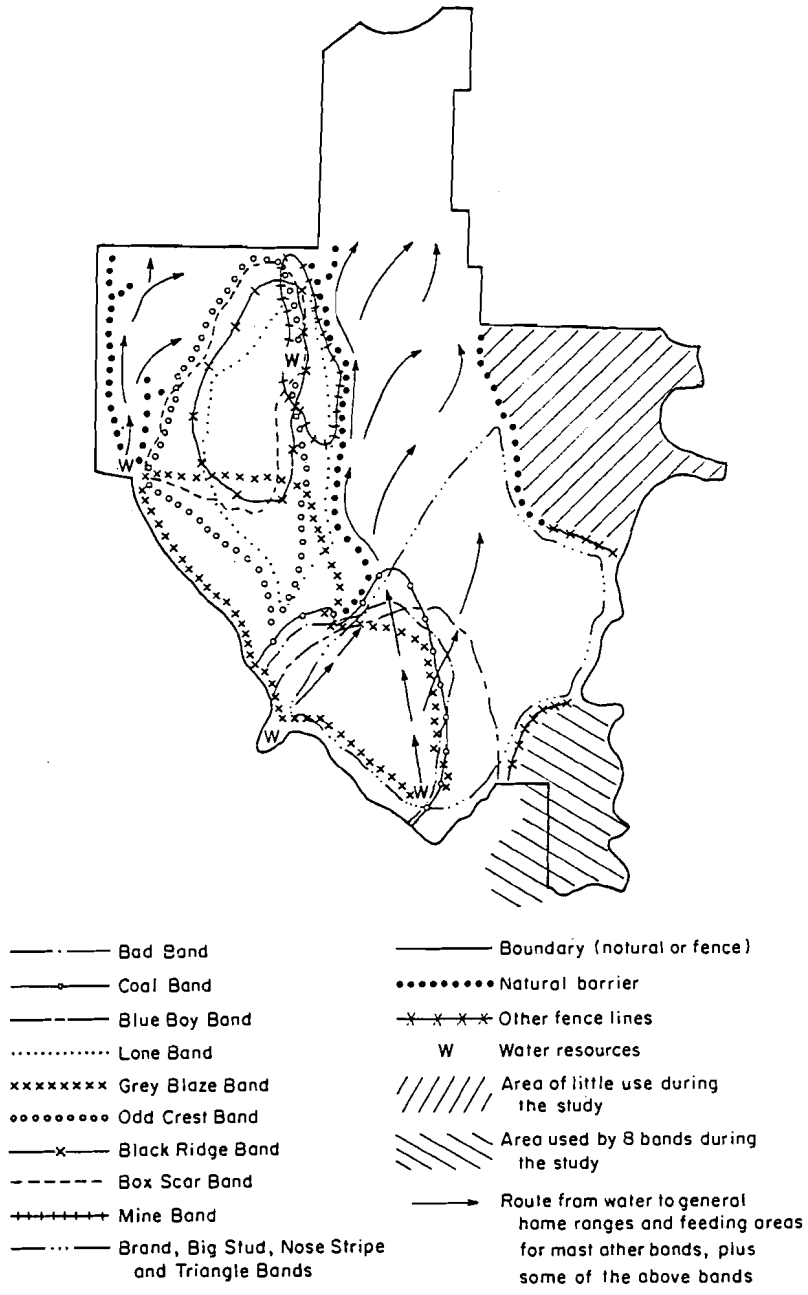
Groups of Pryor Mountain horses occupy home ranges in the sense of BURT (1943) as geographic areas in which most of the time is spent and life activities are carried out. The groups were quite predictable in the areas in which they could be found; each home range included a large feeding area and one or more watering sites. Territoriality, in which the geographic area is defended against other groups, has been reported by KLINGEL (1969 a, 1972) for Grevy's zebra and African asses, and by MOEHLMAN (1974) for some male feral asses in Death Valley, California. SCHLOETH (1958) interprets fecal pile behavior in horses as territorial marking. That the Pryor Mountain horses are not territorial is shown in Fig. 1 by the results of plotting the home ranges over the period of the study of 21 harem groups using the more accessible southern 54.8 % of the Range (7,451.7 ha). If the harems were territorial, one would expect to find a mosaic of areas with relatively well defined boundaries each used more or less exclusively by one group. The opposite situation holds. Only 10 % of the ground area was used exclusively by one harem, and this consisted of fragments on the edges of home ranges. The lowest overlap by other bands was one band overlapping 4; 4 bands overlapped with 5 others, 3 with 7 others, 12 with 8 others and one with 12 others.

Thus, considerable overlap of use of the area by harems occurred. In addition, bachelor groups shared the same areas, and most of the remainder of the harem groups crossed the area to reach water. These results are similar to those reported for New Forest ponies by TYLER (1972). Furthermore, no defence of boundaries or space-related dominance was observed.

Home ranges varied in size depending upon quantity and quality of food resources and closeness to water. Home ranges of the 21 harems plotted varied from 299.8 to 3,200.0 ha with a mean of 1,485.4 ha.

Much of the observing was done from high points from which several groups could be watched at the same time. Even though a number of groups used the same geographic area, minimum spacing between the groups was maintained, primarily through the activities of the dominant stallions. When bands came in contact the dominant stallions would approach each other, posture and threaten, and sometimes engage in a mild fight of pushing and kicking. In fact, maintenance of linear spacing of groups was the most common cause of observed stallion fights (37 out of 84; 44 %). After the encounter, the stallions returned to their respective harems and moved them apart, or maintained a distance of at least 90 m. Individual distance between members within a group was reduced when in close proximity to other groups.

Similar behavior was observed on trails and at water holes. Dominant stallions herded harems off the trail to allow bands coming from the other direction to pass without intermingling. Linear spacing was maintained between groups moving in the same direction. Horses whinnied when approaching water holes, and if a group was already present, the new arrivals would wait until they had left. As many as five harems were observed near a water hole at the same time, each waiting until others had left before moving in to drink. On only one occasion (on an extremely hot day) was a harem observed to move into water while another group was still there. This resulted in considerable tension and threatening, but no fights.



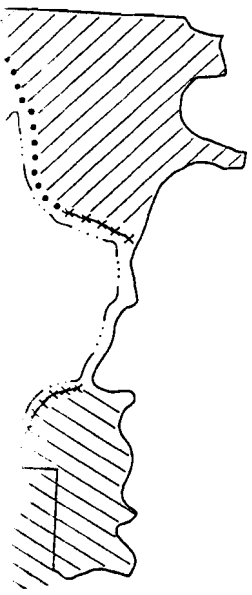


Fig. 1: Map of the Pryor Mountain Wild Horse Range showing home ranges of 21 harem bands. Note large overlap of home ranges

General Activity Patterns

Drinking

No consistent watering schedule was maintained by any group. The horses visited water holes from early morning until after dark. A few groups visited water holes at approximately the same time for several days, then

intained by any group. The ntil after dark. A few groups time for several days, then

anged times or, in some cases, even used another water hole. The constant shifts in feeding areas probably explain some of this variability. Although groups also visited water holes at night, watering at this time was much less frequent than in the daytime.

This is in marked contrast with the results of PELLEGRINI (1971) in Nevada where feral horses visited water holes at night. SOLMATIN (1964) has described watering behavior of Onagers *(Equus onager)*, observing that these animals appeared to visit the watering places at about 10 p.m., remaining for one to two hours. They also adhered to regular watering spots and routes to them. Perhaps the amount of human disturbance was an important factor in these instances. JOUBERT (1972) reported that undisturbed mountain zebras watered throughout the day while disturbed ones watered at night.

Generally, a group visited a water hole once a day. However, frequency was affected by weather conditions. Extreme heat caused some groups to drink twice a day and, on one occasion, caused five groups to stay close to a water hole (within 38 m) for more than two hours, which was much longer than usual. Rains that formed temporary water pools in the rocks, or snowfall, which made water available at the higher elevations, eliminated regular travel to water holes, as did cooler weather which reduced need.

Over most of the range, horses stayed within 5 or 6 km of water and generally visited regularly. However, there were shifts to one or two different water sources depending on feeding areas. Groups that usually fed on the higher elevations of Mystery Ridge had the longest distance (8 to 16 km).

This pattern will now be altered because of the construction of a water catchment basin on Mystery Ridge by the BLM. This new water supply will certainly make such long travels for water unnecessary, thus helping to distribute horses more evenly over the Range. A catchment basin in the northeast corner of the Range between the Mystery Ridge cliff and the Bighorn Canyon would have a similar beneficial effect there.

Groups approached water holes on a trail in single file with the dominant stallion or a mare leading. Groups returned to feeding areas in a similar fashion or grazed along the way. When a mare of the group was first to the water, she was often found to be lactating. Occasionally, such mares would even reach the water hole about 100 m ahead of the rest of the group and were often the last to finish drinking. At the Big Coulee water hole, which was a slow seep from a bank, lactating mares were observed to drink only from one of the clearer pools or directly from the seep. As each horse finished drinking, it would wait for the rest of the group to finish when all moved away together. An exception was the Triangle group, in which a mare and foal were observed to remain at the water hole a number of times for as long as 30 min after the rest of the group had left.

The time spent at water holes rarely exceeded 30 min, most groups taking between two and ten minutes to drink and begin leaving. MCKNIGHT (1958) and MOEHLMAN (1974) have reported that burros in the American southwest may remain at water holes for hours. MCKNIGHT also observed feral burros rolling and defecating in the water. Feral horses were observed rolling, but not eliminating in the water.

Feeding

Horses are primarily grazers, feeding with heads close to the ground, taking a few mouthfuls, then moving forward a step or two. Pawing with a front hoof occasionally was used to remove obstacles and facilitate feeding.

Each group grazed as a unit with individual distances of at least several m maintained between members. On rare occasions a group would be spread over a considerable distance while feeding. For example, Bucki, a mare in the Blue Boy harem was observed feeding out of sight and over 100 m from the band. At the approach of other horses, a group would usually stop feeding and gather behind the dominant stallion, as reported in domestic horses by ALTMANN (1951). Night observations revealed similar feeding habits.

Extensive studies of food habits of the horses were not conducted. Nevertheless, some general qualitative statements can be made. The most important and sought-after foods were grasses. However, grasses on the Range were extremely sparse, particularly in the low, semi-desert area, and the horses had to supplement their feed with other types of vegetation. These foods were generally of a coarser nature than the grasses, and in all cases their use was minimal compared to the use of the grasses. In the southeast corner of the Range and on the Tillett ranch in the same area, where water was abundant, horses used marsh grasses, reeds, and numerous forbs. On the rest of the range, which was dry, there were fewer species of forbs available to the horses. The most unusual use of a woody plant was the eating of the roots of winter fat (*Erotia lanata*). The tops of these plants are especially palatable (MCCULLOUGH 1969), but no known nutritional analysis has been done on the roots. Horses obtained roots by pawing the ground to remove the soil from around the tap root, which was either bitten off or pulled out of the ground and eaten. The tap-like roots of two species of milkvetch (*Astragalus kentrophyta* and *Astragalus gilviflorus*) were also eaten. These two plants formed compact, mat-like cushions at ground level but were pawed up and only the roots eaten.

Most grasses on the range were short grasses, which, along with consumption of roots, resulted in a considerable intake of grit. This produced excessive wear on the horses' teeth, as evidenced by jaws of animals found dead.

The new growth of a few woody plants was also observed to be eaten by the wild horses. These included saltbush (*Atriplex* spp.), greasewood (*Sarcobatus vermiculatus*), rabbitbrush (*Chrysothamnus* spp.), big sagebrush (*Artemisia tridentata*), and black sagebrush (*Artemisia nova*), and in rare cases and in minimal amounts, Utah juniper (*Juniperus osteosperma*) and mountain mahogany (*Cercocarpus* spp.).

When food becomes scarce horses may also supplement their diet by eating old feces. On August 14, observations were made of a mature, immature, and yearling ♀ eating old feces from a stallion fecal pile. Similar observations for the winter months were reported to us by LLOYD TILLETT. These observations do not agree with the statement of HAFEZ et al. (1962) that adult horses reject the feces of other horses, but that foals do consume fresh feces of adult horses. They state that this behavior ensures acquisition of the proper intestinal bacterial flora. This would not explain the eating of old feces which we observed, which seemed to be related to a shortage of quality natural forage.

On one occasion in the spring, a lone stallion was observed eating mud of a dark grey color from a nearly dried up water puddle. No similar observations were made at water holes. Horses may obtain minerals in this way. We have observed domestic horses eating mineral soils from a newly ploughed field in Canada, and such behavior is common among wild ungulates (COWAN and BRINK 1949).

Play

Activities such as running about alone or in groups, or chasing one another for no overt reason, were designated as "play". These activities involved much head tossing, sudden stops and starts, and kicking of the hind legs into the air. They were regularly indulged in by foals within a group and even between foals of different groups. The latter was tolerated by the dominant stallions if the foals returned to their groups after play. Foals were observed playing at all times of the day, but primarily in the early evening or when temperatures cooled. Other age classes exhibited similar activity only on rare occasions. This was always restricted to horses within a group and was not tolerated by the dominant stallion, who quickly attempted to end the activity.

HAFEZ et al. (1962) speculated that play functions to increase locomotive skills and to test social dominance of the young ♂♂. The first function of play seems obvious. The second function also seemed apparent, for larger and older foals clearly dominated the smaller ones by mounting behavior and threats. In one case, a foal forced another one to stand by biting and holding on to its mane. Short, mild, and sporadic fights — primarily by pushing — were seen occasionally while foals were playing. Play in New Forest ponies is discussed in detail by TYLER (1972).

Rolling

We observed 81 cases of rolling, 50 (61.7 %) of which were in dust and 31 (38.3 %) in mud and water. 26 of the 31 observations of rolling in mud and water involved mature stallions. A total of 62 (76.5 %) observations of rolling was of ♂♂ and 19 (23.6 %) were of ♀♀. Except for two, all of the ♀♀ were mature. No yearling or foal ♀♀ were observed to roll in dust or water; however, one male yearling and eight male foals were observed to roll. Mature ♂♂ were observed rolling in 47 (73.4 %) cases, as opposed to 17 (26.6 %) for mature ♀♀. Three of the 47 mature stallions observed rolling were stallions from bachelor groups.

6 cases of immature ♂♂ rolling were also recorded. Three observations were of an immature ♂ rolling at the same time with the dominant stallion of a harem group. These all occurred in the Crip group, in which Crip and J.S. rolled together. In the other three cases, the immature ♂♂ rolled alone but were always immediately followed by the dominant stallion of the harem rolling in the same place.

Places used for dusting were on exposed, fine soil which was free of large or sharp rocks. Some locations were found in which the horses had pawed at the ground to loosen the soil to create a dusting place. Pawing and apparent smelling usually preceded rolling. The dusting sites were found scattered throughout the range, but were particularly concentrated around the water holes. A dusting site was not exclusively used by any one horse or group, but was used by any horses who passed by. Sites for rolling in the mud and water were restricted to the watering holes. On occasion, horses would paw and splash water on their undersides after drinking, then occasionally roll in the water. On a few occasions, individuals were so covered with mud that they could be identified only because of the group they were with!

In some cases all or most of the members of a group rolled in succession, in the same dusting site. This was observed six times, and in each case the dominant stallion was the last to roll. If the group was moving across an area

with some members well in front of the stallion, and if a mare or mares rolled, the stallion would also roll in the same pit when he arrived. This may be related to dominance of the stallion over the group, as is also evidenced in the behavior of the stallions after the rolling of immature ♂♂. Three cases appeared to be clear indications of the stallion showing dominance over the immature. The other three incidents involved Crip and J.S. rolling together which may have indicated that Crip, with his abnormal front hoof, was losing his dominance in the group (which in fact, happened). 11 of the cases in which stallions rolled were related to some form of fight, challenge, or threat towards another stallion.

Rest and Sleep

Rest or sleep (Fig. 2) was observed in a number of situations. In some instances shade, offered by vegetation or vertical canyon walls, was sought for a resting place. At other times, high exposed knolls or hillsides were used to take advantage of wind during the heat of the day. Group members rested or slept in a tight group, or stood in small groups of one or two pairs. The common posture for resting was with ears out or forward, head lowered with the neck horizontal to the ground, eyes partially or fully closed, and the weight often taken off one of the hind legs. Foals rested either by lying down with the head up and legs partially folded under the body, or by stretching out with the body flat on the ground. Foals spent much time in these positions when young, but as the summer progressed the time spent lying down decreased. Yearlings spent less time in these positions than foals, but more than mature horses. Mature and immature horses only occasionally rested or slept lying down. These observations agree with those of JOUBERT (1972) on mountain zebras. No observations were made of the entire band lying down. The protective advantage is obvious. This agrees with HAFEZ et al. (1962), who note that such behavior is rare. KLINGEL (1967) also observed that during the rest period there is at least one member of the zebra band standing alert at all times. We saw only one case of the dominant stallion of a harem group resting by lying down. On this occasion, in the Crip group, the whole group except the "number two" stallion, an immature ♂, were found lying down at the same time.

Yawning often occurred at the end of sleep or rest activity. This was performed with the eyes usually closed, ears up, and the mouth held open in a "U" shape with the canine teeth exposed. Stretching followed a yawn, although there were instances when the acts occurred independently. Horses stretch either by extending one hind leg off the ground and to the rear and bending the back up and down, or by extending and raising the neck.

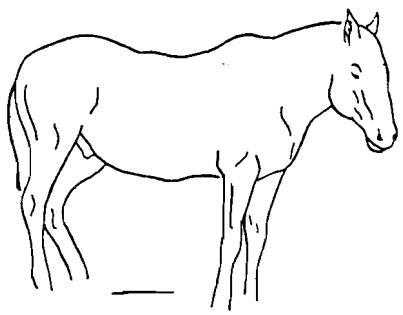

Fig. 2: Posture for rest or sleep

Communication and Social Behavior

Perceptions

Wild horses appeared to have good hearing. They were rarely alarmed by sound alone, but would usually have to see the source before a reaction such as escape behavior was elicited. Hearing was employed to detect and locate intruders and other groups, as well as in communication between individuals and groups.

Olfaction was important to the horses. As with hearing, we found that horses usually would have to see the source of the odor before taking action. On a number of occasions horses were observed using olfaction in a precautionary way. Big Coulee Spring was hidden so that a horse approaching it to drink would have to be within 30 m before it could see other horses at the water hole. Horses periodically tested the air by sniffing as they approached and as they drank. This precaution seemed to be an attempt to prevent one group from approaching too closely to another. Olfaction was also used in association with greeting between horses. They would approach and touch or almost touch nostrils, and smell each other. We also observed stallions periodically sniffing the air in what appeared to be attempts to locate harems which had become separated as they grazed. The most extensive use of olfaction occurred among stallions, particularly by those with harem groups. This occurred over urinations and defecations of mares, at fecal piles and dusting sites, and during encounters and fights.

The keenest sense of the horse, and the one that appeared to be most relied on for detection of intruders, was vision. The eyes of a horse are set at the side of the head, providing a wide field of view. The retina is non-elastic but is arranged on a slope or ramp, the bottom part being nearer to the lens (HAFEZ et al. 1962). With this arrangement, the grass on which the horse is grazing and distant objects are in focus at the same time. With the head up, slight movements of lowering or raising the head are used to focus. HAFEZ et al. also note that eyes of horses are adapted for nocturnal vision. Our nocturnal observations indicated that horses carry on normal activities at night.

Individual Recognition

The wild horses, especially those in the same group, seemed to have no difficulty in recognizing each other as individuals. An example of auditory recognition involved the Triangle harem. Goldylocks and her foal, Gold, would occasionally lag behind at a water hole. When they moved to rejoin the band, Goldylocks would often whinny or neigh. Hearing this, Triangle would stop the movements of the group to wait for the mare and foal, even though they were out of sight and over a quarter of a mile away. Numerous observations were made of mares and foals apparently recognizing each other by sound alone. KILEY (1972), TYLER (1972), and MOEHLMAN (1974) also noted that calls seemed to convey individual identification.

It was obvious that individual recognition occurred by sight. Harem stallions immediately recognized a strange member in the group and, similarly, singled out any of their harem who were temporarily in another group. The frequent smelling of other horses and excretions occurs with such regularity as to suggest individual recognition.

Vocalizations

Numerous observations were made of the louder vocalizations and the situations in which they occurred. Four definite vocalizations were identified: the "snort", the "whinny" or "neigh", the "nicker", and the "squeal". HAFEZ et al. (1962) described the snort as a danger signal, the whinny as a distress call, and the nicker as a sign of relief or close communication and courtship. WARING (1971) used recordings to distinguish seven sounds; squeal, nicker, whinny, groan, blow, snort, and snore. KILEY (1972) described and presented sonograms of six vocalizations: sigh, sigh-nicker, nicker, snort, whinny or neigh, squeal, and roar. She proposes that the vocalizations sigh, sigh-nicker, nicker, whinny, and long whinny, represent a series given in order of increasing excitement, with the snort being derived from the nicker, and the squeal and roar from the whinny.

In our analysis, we did not record the sigh as a separate vocalization, since much of our observing was done at a distance too great to hear this sound. The sigh-nicker is an intergrading vocalization (KILEY 1972) which we recorded as a nicker. Our observations of the nicker agree with those of HAFEZ et al. (1962), WARING (1971), TYLER (1972), and KILEY (1972) that it is given in close communication between horses primarily within the harem group. It is given most commonly in interaction between mothers and foals, and in courtship, and seems to be a close-range cohesion call. WARING (1971) and KILEY (1972) note that it is also directed towards a handler in domestic horses.

The whinny or neigh was used as a distress call by wild horses, but it was used in other situations as well. As a distress call, it was used primarily by mares and younger horses of both sexes. Foals out of sight of their mother or left behind in movements of a band would commonly neigh. A mare who was disturbed about the closeness of another mare to her foal neighed quite loudly, whereupon the stallion immediately moved in and separated the mares. A mare would whinny loudly and frequently for her lost foal.

Stallions used the neigh towards foals who had wandered to another group. In such cases, the foals always returned immediately to their group. The stallions Brand and Rye used neighing to achieve cohesion in their harems while trying to gain stray mares. When two of a group of three bachelor stallions left a water hole, the one remaining neighed. The two waited for him to catch up.

Neighing also was used by stallions in build-ups to fights. They would stand and stare at each other from a distance, occasionally calling back and forth. Mares from different groups once neighed back and forth, which led to a mild fight between the stallions. The neigh was also used occasionally when greeting another horse.

It seems that the whinny is a long-range communication call, which typically functions as a cohesion call, as reported by WARING (1971), KILEY (1972), and TYLER (1972). However, some of the observations of its use suggest it functions in the broader context of indicating location of distant horses which may, in fact, be a prelude to aggressive interactions rather than cohesion.

The use of the snort as a danger signal (HAFEZ et al. 1962; TYLER 1972; KILEY 1972; others) was evident from our study. WARING (1971) referred to this call as a blow, using snort to describe clearing of the nostrils. In our study, a snort was usually issued by the stallion of the group when an intruder was discovered. After the stallion snorted, the group came to the alert and watched the stallion for signals while they, too, studied the intruder. Only rarely did a

mare snort. If a mare discovered an intruder first, she would come to an alert posture; subsequently, the stallion would come to alert and snort. The call has the physical properties described by MARLER (1959) of carrying well, and being readily localized.

We frequently heard a vocalization, not described by HAFEZ et al. (1962), but which WARING (1971), KILEY (1972), and TYLER (1972) referred to as a squeal. KILEY (1972) described this call as a defensive greeting call, while WARING (1971) reported it in agonistic encounters. TYLER (1972) observed it to be used by mares in relation to stallions and in mare-mare fights. In our observations this call was used exclusively by stallions during fights. It was rarely issued when stallions were smelling noses and was commonly heard again in unison while smelling fecal piles after defecation by one or both. During the kicking and biting sequences of a fight, the squeal was again given at times, though not as consistently as in early stages of the fight. The roar, which KILEY (1972) reported as given by stallions in frustration or rejection by non-receptive mares was not heard in our study. Neither were several of the vocalizations reported by WARING (1971). However, the latter would be expected because of the distance at which we worked, and the gradation of sounds in the horse, which are subtle and difficult to distinguish by ear from a distance.

Alert, Alarm, and Flight Behavior

When a horse detected an intruder, it came to the alert posture (Fig. 3) and watched the intruder. The ears were flicked forward, then back, out, and forward to receive sound cues from other horses or the intruder. It quickly brought its weight evenly to all four feet and slightly raised its tail. While or after assuming this posture, it often gave a whinny to alert other horses. Even if it did not vocalize, its sudden shift to alert posture usually was sufficient to alert other horses.

If the group was disturbed greatly by the intruder, the stallion gave a snort and he and the rest of the group came to the alarm posture. This was similar to the alert posture except that it was a more exaggerated stance, with the head, neck, and tail higher. In alarm (Fig. 4), the stallion took a few quick steps toward the intruder to stare and, possibly, snort again. The group mem-

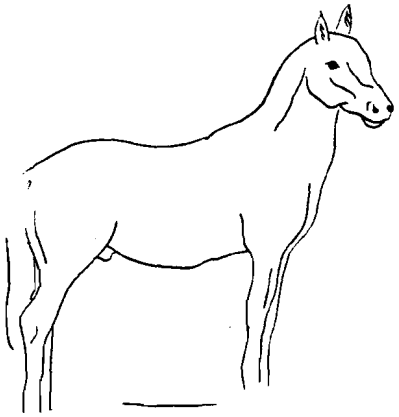

Fig. 3: Alert posture

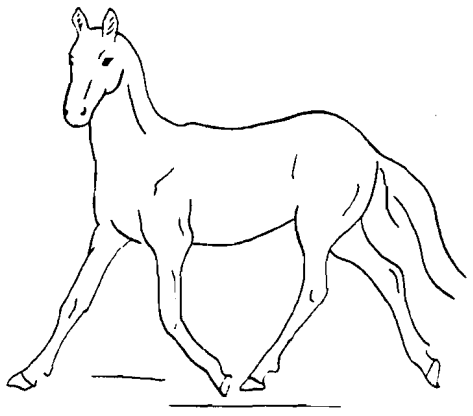

Fig. 4: Alarm and flight

bers bunched and moved to the rear of the stallion so that he was between the group and the intruder. During this interval, the horses often lifted their tails higher and defecated.

Members of the group other than the stallion often became excited about our presence, even whinnying to call the attention of the stallion. If the stallion was not excited by our presence or could not detect us, he remained calm, and the rest of the group would soon calm down as well. If a mare snorted, a rare occurrence, the stallion and other group members came to her side.

If flight behavior was elicited, the stallion turned and moved away from the intruder, and the group moved off with the stallion directing movement from the rear or, in some cases, from the front of the group. Sometimes the stallion moved the group by herding (Fig. 11).

Usually the group moved 50 to 100 m then stopped and watched the intruder again. The degree of alarm depended on the particular group, closeness of the intruder, and degree of surprise.

Aggressive Behavior

Threatening actions by both mares and stallions followed one of two general modes, each consisting of a progression of acts ranging from mild to serious. The first mode involved biting, and the progression from mild threat to serious threat included ears laid back, head swing (Fig. 5), mouth open, attempted bite, and bite. "Ears laid back" involved flattening the ears against the top of the neck with the head usually turned towards the threatened horse. The "head swing" consisted of the ears laid back plus the side swing of the neck and head toward the threatened horse. The "mouth open" consisted of the above described acts with the mouth being opened and the lips tightened in a manner that exposed the incisor teeth and, if present, the canines. The "attempt to bite" involved the above motions and was accompanied by aggressive forward movement, and finally, the infliction of the "bite" itself.

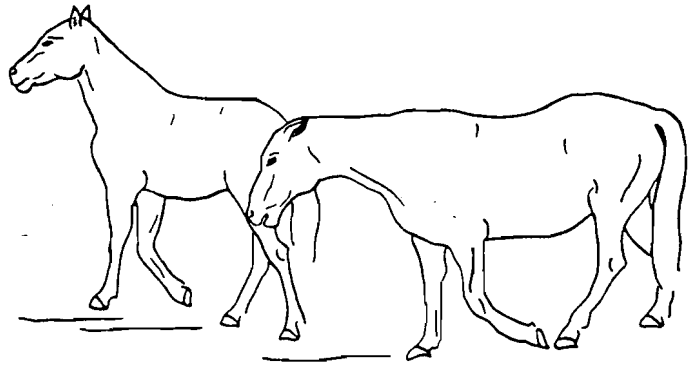

Fig. 5: Aggressive threat: "ears back, head swing" of the biting mode

In the second mode, kicking, the progression was turning the rear to another horse, threatening to kick with one hind leg (Fig. 6), kicking with one hind leg, and kicking with both hind legs (Fig. 12). In the "kick threat", a horse would raise one hind leg off the ground and pull it up under its body in readiness. To accomplish the "kick", the hind leg was struck out to the rear at the other horse. To "kick with both hind legs", it lifted them together and thrust them out to the rear, its weight and balance being taken up on the front legs.

Threat postures were used primarily in maintaining individual distance within the group. Threat was exhibited if another horse came within 1.5 m of one that would not tolerate close association at that moment. Mares also threatened other horses if they came too close to their foals. Threats were used at the water holes to gain drinking space, although for the most part, group members were tolerant of each other in this circumstance. Mares not in heat employed threat postures toward stallions who came too close in attempts to smell and tend them.

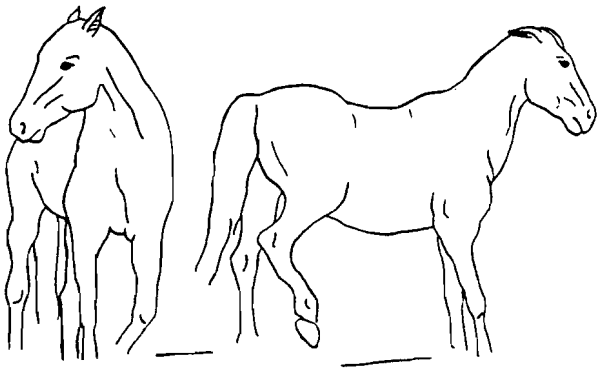

Fig. 6: Aggressive threat: "hind-foot kick" of the kicking mode

As noted below, we were unable to determine a dominance or a rank order expressed through threat displays among the mares of a group. In one situation one mare might threaten another; in a similar situation at another time, the roles would be reversed. Rarely was more than one threatening act used. If a mare threatened another, the threatened mare usually moved away a few steps, ending the encounter.

Threats were commonly employed by mares, perhaps because they were on much the same level of dominance in the group. The use of threats by stallions was considerably less frequent because of their strong dominance, but threats used were more forceful than those of mares. Also, stallions were commonly outside the cluster of the group which resulted in fewer interactions with other group members.

Several threats were used exclusively by stallions: the forefoot kick, herding, and the direct run. A description of "herding" behavior is found in the section under that title. The "forefoot-kick" was commonly used in fights between two stallions and was accomplished by striking forward with a front leg and hoof. The "direct run" was used to move an individual in a group or non-band members away. It involved running directly at a horse with ears laid back and head and neck low, but with no obvious use of the herding posture.

Submissive Behavior

The most common expression of submission was simply moving away. For example, a mare who came too close to a foal was threatened by its mother, and reacted by turning and moving away. Or if a mare was approached by a stallion in courtship and she was not receptive, she threatened the stallion. His response usually was to move off.

The second kind of submissive behavior was not induced by a threat. It involved interactions between the dominant stallions and young ♂♂ in the harem. No ♀ was observed showing this behavior. This act, which we called "teeth-clapping", consisted of the immature ♂ approaching the stallion from

the side or front with his neck and head stretched out, reaching up toward the stallion's head (Fig. 7). The ears of the submissive horse were pointed outwards, the mouth was open with the lips pulled back to expose the incisor teeth, and the lower jaw was moved up and down. TYLER (1972) has referred to this act as "snapping", a term we believe has aggressive overtones. We prefer to use the more descriptive term, "teeth-clapping", for this clearly submissive act.

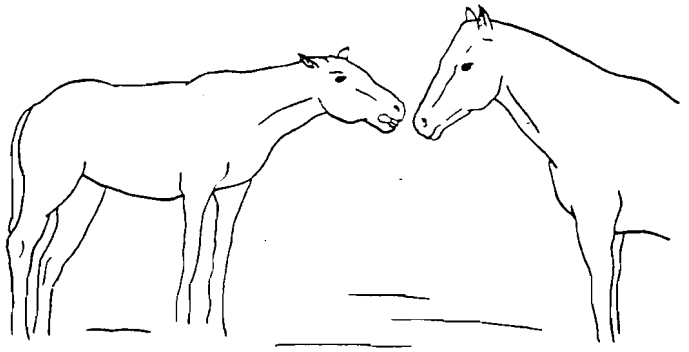

Fig. 7: Teeth-clapping by an immature ♂ towards the dominant stallion of the harem

6 harem bands contained an immature ♂, and we observed 21 instances of teeth-clapping in a variety of situations. Four cases followed fights between dominant stallions of different harems. After the fight, when the stallions returned to their harems the immature ♂ showed this submissive behavior. Two cases occurred in the Crip band on different occasions. J.S., the immature ♂, left the band to fight with another stallion and retrieve a mare and a foal. J.S. apparently was performing the role of a dominant stallion although submissive to Crip, whose mobility was impaired. Upon his return, J.S. teeth-clapped to Crip. 8 observations of teeth-clapping were made after encounters between the dominant stallion and one of the mares. For example, if the stallion were tending a mare and the mare rejected his advances by a threat, the immature ♂ would then approach the dominant stallion in this submissive posture. In another example, in the Sheik harem, Number-Two, the immature, performed teeth-clapping to Sheik after he returned from tending a mare. This was accompanied by an unusual response from Sheik, who reached out and bit onto the skin on the shoulder of Number-Two. They remained fixed in this position with ears laid back for about a minute. Ordinarily, the stallion simply stood and received the submissive posturing of the immature ♂.

Another interesting encounter arose when Sheik retrieved an immature ♀ that had wandered into the Buckskin harem. Following the retrieval, Number-Two approached Sheik in the submissive posture and then a yearling ♂ of the group also exhibited teeth-clapping. Two observations of teeth-clapping were recorded in the Del harem, both given by the immature ♂, Grey Streak. The first occurred after Del threatened Grey Streak, who had been attempting to groom him. This was the only case observed of a threat to an immature inducing teeth-clapping. The second instance occurred when Del rejoined the harem after becoming separated during feeding. He was met with a display of teeth-clapping by Grey Streak.

Two observations of colts giving teeth-clapping were recorded. In one case, Tone Foal of the Del harem walked over to the Buckskin harem and gave

the submissive posture to Short Tail, a yearling ♀. This was the only time the act was observed being given to a ♀. This may have been confusion because of the age of the animal. The other case of repeated occurrence of teeth-clapping by a colt was on the day that Cabin Black, formerly a lone stallion, gained the mare Box and her colt, Little Blaze, from Crip. The stallion spent two days trying to get Box to stand to be mounted. During these intensive encounters, occurring at a frequency of two to four per hour, Little Blaze remained close to his mother, stretching his neck out and teeth-clapping at Cabin Black.

The submissive action by teeth-clapping is believed by ZEEB (1959) to be an expression of ritualized grooming. Mutual grooming, as noted in the section below, can be an appeasement expression or it can be used for mutual social contact. However, in only 5 of the 90 cases of mutual grooming was a dominant stallion observed grooming with an immature ♂. One case followed immediately after a threat by the stallion to the immature ♂. The teeth-clapping and its approach, which is similar to that for grooming, may be a ritualization of a non-aggressive mutual act which allows young ♂♂ to express their subordinate rank, thereby avoiding aggression from clearly stronger animals.

Mutual Grooming

Mutual grooming was common in the daily activities among wild horses. It began with one or both individuals approaching head on. The ears were held forward or out, rather than laid back which indicates threat. The two horses often smelled each others' noses and/or necks before grooming. Mutual grooming began on the side of the neck, withers, and base of the mane, then progressed down the back to the rump and, in some cases, the base of the tail (Fig. 8). While this progression was most common, occasionally grooming was exclusive to the neck or the rump. Horses were also observed to groom along one side, then switch positions and groom along the opposite side. Grooming was accomplished by pulling the lips back slightly and using the incisor teeth. If one stopped grooming, the other also stopped. Only in rare cases was grooming not a mutual effort. The time span for grooming ranged from a few s to 10 min. In 90 observed cases of grooming, 90% lasted less than 3 min, and 10% lasted between 4 and 10 min.

The functional benefit of mutual grooming is the care of the coat and skin in areas difficult for the individual to reach. Self-grooming was accomplished by scratching with a hind hoof or by rubbing against trees and bushes. However, as noted by TYLER (1972), the close contact provided by mutual grooming may also strengthen the bonds between the group mem-

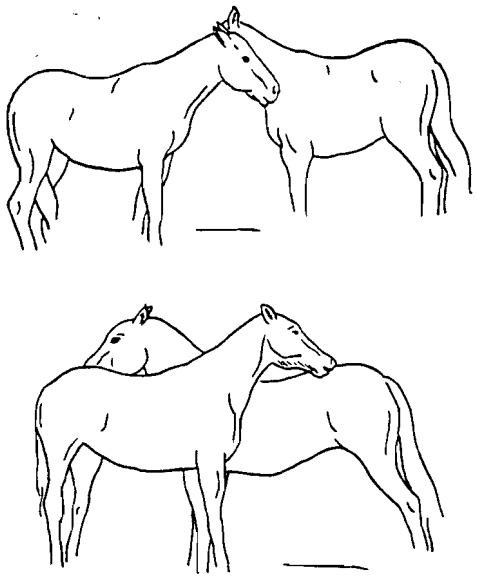

Fig. 8: Mutual grooming of the neck (above) and rump (below)

bers. Appeasement was an obvious reason for grooming in some instances, indicating the relationship of grooming to submissive teeth-clapping behavior or ritualized grooming. Most cases of unilateral grooming were by immature animals following threats by adults.

Mutual grooming occurred only between members of the same group. All combinations of group members were observed grooming, except dominant stallions and foals. In two cases a stallion groomed a mare for short periods during pre-copulatory activity. This was also reported by KLINGEL (1969b) for plains zebras; however, zebra stallions seem to groom more extensively in this situation than do feral horses.

Mutual grooming may also function as a subtle greeting or social contact, although this was not clear since the band members were in close formation almost constantly. The only form of greeting that we were able to identify in horses was naso-nasal contact. ZEEB (1959) notes that specific facial expressions are used by zebras but not horses for greeting and "sexual desire". Like ZEEB, we did not find these expressions in the horses. However, TYLER (1972) reported a greeting expression in New Forest ponies.

Urination and Defecation

Both ♂♂ and ♀♀ assumed stereotyped postures during elimination. Dominant stallions exhibited greater posturing in these acts than did younger ♂♂ or ♀♀. They also commonly smelled their own excrement. ♂♂ and ♀♀ defecated with the tail lifted to some degree, and moved the tail from side to side after defecation. Stallions usually lifted their tails higher when elaborately posturing and defecating on a stallion feces pile or on a mare elimination.

♂♂ urinated with the penis in the sheath and often extended it for a short time after urination. In wild horses, there was particular importance attached to the scent marking function of excretory products. This was most clearly manifested in the behavior of stallions towards eliminations of harem members and that of rival ♂♂. In harem groups, the covering of eliminations of harem members (particularly adult mares) by the dominant stallion, with their own eliminations was an apparent expression of possession or association. In conflicts between rival ♂♂, or within the bachelor groups, order of elimination was strongly linked to dominance.

Table 1: Eliminatory response of harem stallions to eliminations of harem group members

Elimination of harem group member	No. observed	Eliminatory response of harem stallions					
		No elimin.		Defecate		Urinate	
		No.	%	No.	%	No.	%
Defecation by							
Adult ♀	76	46	60.5	4	5.3	26	34.2
Immature both sexes	5	3	60.0	0	0.0	2	40.0
Yearling both sexes	7	7	100.0	0	0.0	0	0.0
Foal both sexes	17	17	100.0	0	0.0	0	0.0
Urination by							
Adult ♀	77	38	49.4	2	2.6	37	48.0
Immature both sexes	6	5	83.3	0	0.0	1	16.7
Yearling both sexes	6	3	50.0	0	0.0	3	50.0
Foal both sexes	12	11	91.7	0	0.0	1	8.3

The relationship of elimination by dominant stallions to that of harem group members, as recorded in the quantitative notes, is given in Table 1. Commonly a stallion detecting the urination or defecation of a harem band member would approach, smell it, step over it, urinate or defecate on it, and then turn and smell again (Fig. 9). Urination, particularly, was performed from an exaggerated stance as compared to simple elimination. The hind legs were extended farther to the rear, the tail lifted higher than normal, and the urine was released in a short but strong spurt.

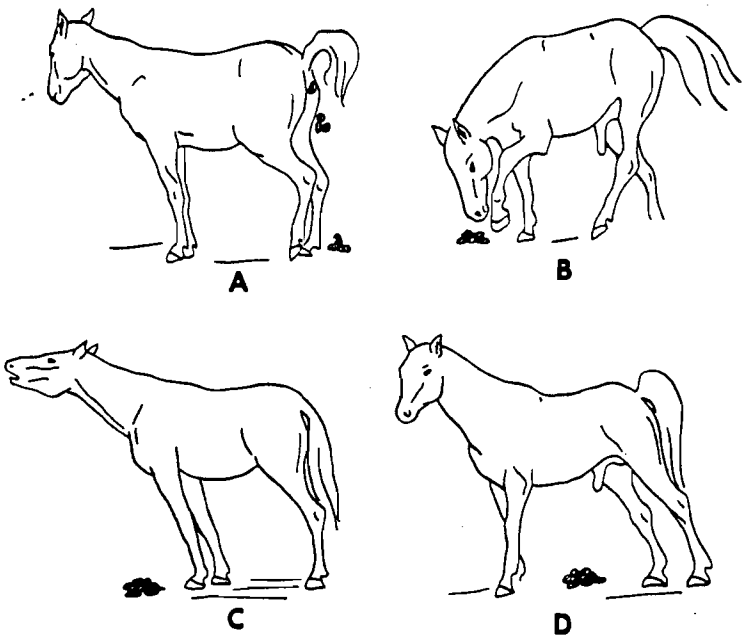

Fig. 9: Behavior of harem stallion in relation to defecation and urination of mares. A. Mare defecating. B. Stallion approaches, smells, and steps over the fecal pile. C. Stallion flehmens following smell. D. Stallion urinates on the mare's feces

Stallions did not always respond to harem members' elimination. From Table 1 it can be seen that stallions responded to 39.5 % of defecations and 50.6 % of urinations of adult mares. Response to eliminations of younger horses was much less frequent. The eliminations of both sexes of younger horses were combined because of small sample size, low sexual connotation to the stallion, and because all stallion responses were urination rather than defecation. This would suggest that in this situation, marking was related to possession or association rather than male dominance as discussed further below.

Failure by a dominant stallion to eliminate on the elimination of harem members sometimes can be explained by his failure to detect them. However, at least three defecations by adult mares were definitely detected by the stallion who smelled and "flehmened", but did not eliminate. Although elimination on harem member elimination occurred throughout the study, it was more frequent during the breeding season, and postures of the stallion were more exaggerated at that time. The sexual connotation of this behavior is further suggested by its being directed mainly towards adult ♀♀ in the harem groups.

KLINGEL (1969 b) also reported that plains zebra stallions sometimes failed to eliminate on eliminations of harem members.

The predominate response of the stallion to harem group elimination was urination (Table 1). Of the 76 follow-ups, 70 (92.1%) were by urination.

Mares were never observed to respond to the excrement of other horses. However, on 5 occasions male foals were observed to apparently smell and then urinate on the urination of a mare, and in two additional cases they smelled the urine of the mare and then flehmened. One of these observations occurred when a mare urinated, followed in succession by the smelling and urinating on it by Divide Legs (a male foal), Grey Streak (an immature ♂), and finally by Del (the dominant stallion). The response of foals and immatures to a mare's excretion was probably an early expression of male sexual behavior.

Dominant stallions eliminated on top of the eliminations of subordinate ♂♂. This order was strictly adhered to in bachelor groups. Usually such adherence to a dominance rank order was true among ♂♂ in harem groups, but exceptions were observed. The clearest example of a dominance order was observed in the Prostitute band, which contained one mare and 6 ♂♂. If the mare or a lower ranking ♂ defecated, the rest or part of the group would follow in order of dominance. Also, in a case where Del chased off the immature, Half Face, Del deliberately approached and urinated on the defecation that Half Face left before he ran. However, in other instances observed in the Del band the immature ♂ defecated on the defecation of a mare without any following action by the dominant stallion. In the Crip band, a mare urination was followed by those of J.S. (an immature), of Crip, and then of Ag (an immature). Other observations clearly set the rank order for these three ♂♂ to be Crip, J.S., then Ag.

Eliminations by stallions not related to elimination of a harem group member are summarized in Table 2. It is apparent that most elimination by stallions, whether urination or defecation, was somehow related to other horses. Of 186 total defecations recorded in the quantitative notes, only 8 (4.3%) occurred without apparent external stimulus, while of 107 urinations, 12 (11.2%) were without external stimulus.

Table 2: Eliminations by stallions in contexts other than response to elimination by harem group members

Situation	Defecation		Urination	
	No.	%	No.	%
No apparent external stimulus	8	4.5	12	32.4
During courtship or tending	5	2.8	7	18.9
On fecal pile in normal movements	69	38.3	2	5.4
On fecal pile during fight	96	53.3	16	43.3
On fecal pile during escape	2	1.1	0	0.0
	180	100.0	37	100.0

While most interactions of stallions with ♀♀ involved urination, those between ♂♂ mostly involved defecation, primarily at fecal piles. Of the total 186 defecations by stallions recorded, 167 (89.8%) occurred at fecal piles. For urinations, 18 out of 107 occurred at fecal piles (16.8%).

Most behavior at fecal piles occurred either among harem stallions or bachelor groups as they passed in normal movements, or during aggressive interactions between stallions. In two cases, piles were used by stallions as they

passed during escape. Numerous other instances of horses of both sexes defecating prior to flight were observed in response to the observer, but these were not included in the tables because the quantitative notes were taken only on horses unaware of the observer. Defecation seemed to be typically associated with alarm, and stallions stopped momentarily at fecal piles to defecate during mild alarm.

Nearly all use of fecal piles was by adult stallions. One observation was made of a yearling ♂ defecating on a pile, and another of a male foal, which was responded to by the harem stallion. Stallions showed typical eliminative behavior when passing by a fecal pile, either alone or with their harems (Fig. 10). They would smell, occasionally paw at the pile with a front hoof, defecate and occasionally urinate. No other stallion need be near to induce the use of the pile.

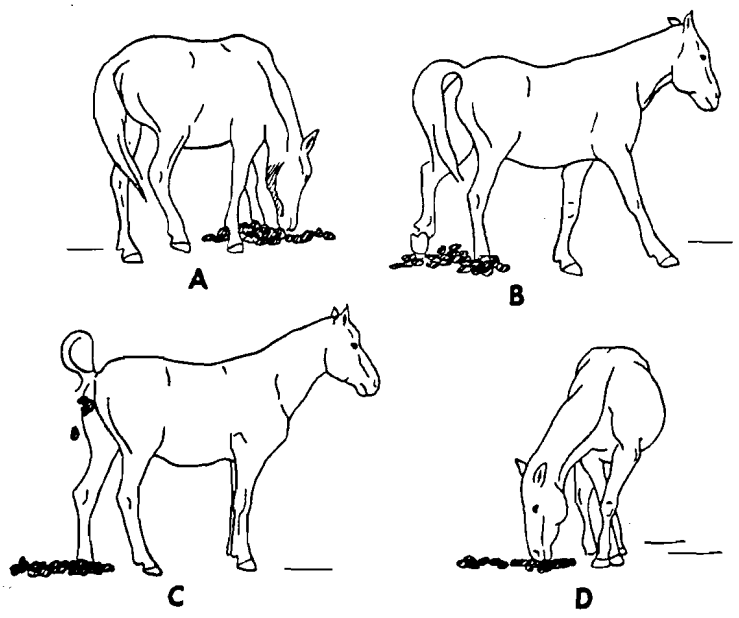

Fig. 10: Behavior of stallion at fecal piles. A. Stallion smells the pile. B. He steps over the pile. C. Defecation. D. Smelling of his own feces by the stallion

Fecal piles were also used in encounters between stallions, ranging from a mild challenge with only a direct stare to more serious fights. If one harem came close to another, the stallions commonly would come out a few m from their harems, stand and stare, smell the fecal pile, defecate, turn again, and lower the head to their own defecation. After this, the two would usually return to their harems and continue their previous activity. In more serious encounters, the two stallions would come together at a pile and proceed through a series of aggressive acts. Usually, before or during the encounter, the two stallions would smell the pile together, defecate in turn or together on it, smell the pile again, and then continue into the fight or separate and end the encounter. Within a bachelor group, this behavior was also observed in mild or "mock" fights. Even in serious fights, which included kicking and biting, often the stallions would stop to perform acts over the fecal piles. The amount of feces dropped by a stallion in any one elimination, or on a fecal pile, ap-

peared to be controlled, as reported by EBHARDT (1954). Stallions were observed to defecate up to three times in succession during a fight.

At the end of the study, a survey was taken of fecal piles in five different areas of the Range. One hundred and 20 fecal piles were examined. Of these, 69 (57.5%) were currently in use and 51 (42.5%) were old piles not in use that year. 54 piles (45%) were on or immediately beside a trail and 66 (55%) were away from trails. The greatest density of fecal piles was found on the trails near the water holes which received the most frequent and consistent use. A number of the piles comprised a series of from two to seven in a row, all touching or within several feet of each other. Piles made up of such series were counted as one. Only one of the piles in a series would be currently in use; the others extended in a row from the most recent pile to the oldest. Some of the recent piles reached a height of over one foot, while in many cases the older piles were so weathered that they had almost disappeared. It was obvious that as one pile became old or had been used for some time the stallions would begin a new one beside it. We estimated that a single pile or one in a series was used for one to three years.

The area covered by the piles ranged from about 3 × 3 for a single pile to 6 feet by 25 feet for a series of connected piles. Of the 120 piles examined, 70 (58.3%) were single piles, 16 (13.3%) two, 17 (14.2%) three, 8 (6.7%) four, 3 (2.5%) five, 5 (4.2%) six, and 1 (.8%) was seven piles in a series.

SCHLOETH (1958) suggested that fecal piles and pawing behavior by horses act as markers for territories, and PELLEGRINI (1971) believed fecal piles had a similar function in feral horses in Nevada. However, he presented no direct observations to support this view. Our evidence, as discussed in the section on home range, is that territoriality does not exist in the Pryor Mountain horses. No specific piles belonged exclusively to any one stallion, nor was any area around the pile defended. However, KLINGEL (1969a) found that Grevy's zebra stallions do maintain territories which are marked by fecal piles; this was also found in the wild ass in Africa (KLINGEL 1972) and some feral ass ♂♂ in Death Valley, California (MOEHLMAN 1974). Plains and mountain zebra stallions were found to defecate on fecal piles (KLINGEL 1967, 1968) but, like horses, were not territorial. According to KLINGEL (1972) the wild ass and Grevy's zebra are not as highly evolved as the other equids. He hypothesizes that territoriality is the older form of social living and that territorial marking is now lost by most *Equus*, but the fecal behavior continues as a "vestigial pattern" inherited from territorial ancestors.

Certainly much more investigation is needed before adequate discussion of the present function of marking behavior by non-territorial *Equus* on ♀ eliminations and stallion fecal piles can be provided. But based upon our observations of feral horses we do not agree with KLINGEL that this behavior is simply vestigial. We propose that fecal deposit behavior (and urine marking as well) has immediate visual and olfactory importance in terms of dominance relationships and associations. We further suggest that chemical information in such deposits persists over time, and serves as a rich source of information on dominance relationships, associations, estrous state, time of passing etc. which can be detected by other horses. In this sense, we view scent marking by horses as analogous to writing in human society, a communication mode by which stimuli can persist over time, and can be perceived long after the initial action was completed.

Flehmen

Flehmen, sometimes referred to as lip-curl or grimace (Fig. 9), is a common behavioral act in ungulates (ESTES 1972). Only the ♂♂ among the wild horses were observed to use this act, which was performed by curling the upper lip upwards and slightly compressing it from the sides and shortening the distance between the nostrils. The mouth was closed but the teeth exposed, and at the same time the head and neck were pointed upwards and generally off to one side of the body, with the ears pointing outwards. Flehmen is induced by olfactory stimuli since the ♂♂ appeared to smell something before exhibiting the flehmen. The 55 situations in which flehmen was observed can be broken down into 7 major categories: 1) smelling a mare's vulva in association with tending or copulation (8); 2) smelling a mare's urine (17); 3) smelling a mare's defecation (4); 4) smelling a fecal pile (7); 5) smelling a fecal pile in relation to a fight (2); 6) smelling his own urine (5); 7) smelling the ground, stimulus not established (12). If a series of flehmens occurred over the same stimulus, it was counted as one. For example, in one case, after smelling a mare's urine, a stallion flehmened 8 times. This was recorded as one.

Harem stallions, bachelor stallions, and a few immature ♂♂ in harems were all observed to flehmen. No yearling ♂♂ were observed to flehmen, but two cases of male foals were recorded. In one, the foal smelled the rear of a mare, not his mother, and flehmened three times. In the other, a foal smelled the urine of his mother and then flehmened.

The use of the flehmen was in evidence throughout the six-month study, but more frequently in the early part of the breeding season. Presumably mares at this time provide more olfactory stimuli to the ♂♂. However, as noted by many workers on ungulate behavior, it is shown in a number of other contexts as well. In at least a third of the cases we observed where the stimulus was identified, it was shown by stallions in relation to themselves or other stallions. Furthermore, TYLER (1972) has observed flehmen in female ponies as well.

Leadership and Herding Behavior

Leadership can be expressed either by the taking of initiative by one animal with the others following, or by the active driving or herding of the group by a stallion.

Leadership by initiative was recorded in 159 cases during movements from place to place, and going to and from water. Of these 106 (66.7 %) were led by the stallion and 53 by a mare. Of the 53 cases in which a mare assumed leadership, 7 were in response to the closeness of other harems, and 9 were due to unnatural disturbances. In these 16 cases, the stallion herded the group, directing its movements. Thus, in only 23.3 % of the observed cases was the mare solely responsible for leadership.

EBHARDT (1954) reported that stallions were the common leaders in Icelandic pony bands. TYLER (1972) found adult mares to be the leaders in New Forest ponies. However, her results may be biased by the few stallions present. With the plains zebra, KLINGEL (1964, 1967) found the oldest zebra mares to be the apparent leaders in group movements, but with the stallion still the dominant animal. KLINGEL (1968) reported that in mountain and Hartmann zebras, the stallion leads to water but the dominant mare leads when leaving water. The same situation was observed occasionally in the wild horses. We were unable to determine a hierarchy among the mares of a group with regard

to position in movements. However, observed leaders were usually older mares or mares with foals or yearlings.

Herding or driving behavior (Fig. 11) consisted of first assuming a threatening posture. The ears were laid back and the neck and head stretched out.

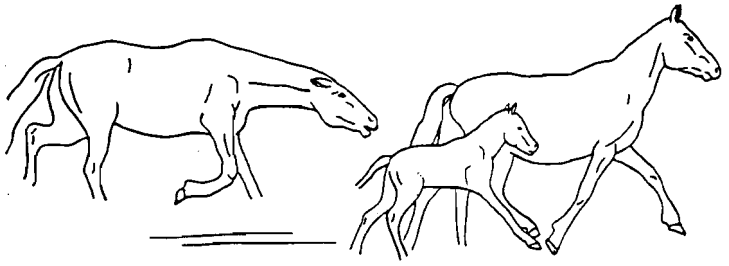

Fig. 11: A harem stallion (left) herding a mare and foal

The strength of this signal was determined by how low the head and neck was, how vigorously the position was assumed, and how fast the stallion moved toward the other horses. If a stallion laid his ears back and stretched his head and neck horizontally but merely walked toward the horses, the group responded with the same speed of action. If the stallion laid his ears back, snapped his head down so that his chin almost touched the ground, and ran towards the horses, they responded rapidly. Often the stallion's head would move from side to side, producing a snake-like motion. The intensity of herding depended on the particular situation that evoked it and the differing temperament of individual stallions. Some stallions exercised close control over harems while others were more lax.

The quantitative observations included 130 instances of herding behavior. In 55 (42 %), the stallion herded his harem away from another group or stallion. Herding by a stallion to indicate direction of movement, to retrieve members, or to reduce spread of the harem, accounted for 39 (30 %) of the instances. The herding of a member of another harem away from the stallion's own harem was observed 15 (12 %) times. 6 (4 %) times a stallion herded in the attempt to gather a mare, usually a stray, into his own harem. Finally, 15 (12 %) observations were made of a stallion herding a mare within a harem in an attempt to copulate.

On rare occasions an immature or secondary ♂ in a harem group exhibited herding behavior, usually simultaneously with the dominant stallion and at a position between the stallion and the rest of the group.

Both initiative leadership and herding behavior in the harem show that the stallions are the principal leaders and they direct most of the movements of the groups. Leadership by stallions, in conjunction with fidelity of mares to the group, results in a high degree of harem stability.

Dominance Hierarchy

A dominance hierarchy was present in the bachelor ♂♂. The largest bachelor group had 8 members. The dominant stallion herded the group as if they were a harem and met with, challenged, and fought with the stallions of other groups. Often this band split into two or three groups with the same stallions dominant in each. Smaller, more stable bachelor groups showed similar hierarchies. Dominance was expressed by threat gestures, herding, mild fights

within the group, and fights with stallions of other bachelor groups or harems. Age was a definite factor in the hierarchies, with younger, smaller stallions being lower while larger, older stallions were dominant.

During the study, three stallions from bachelor groups each gained a mare, and each of the three was the dominant ♂ of his bachelor group before the change. When a bachelor group approached a harem, it was always the dominant ♂ of the bachelor group that met and interacted with the stallion of the harem. The role of the hierarchy in fecal pile behavior has already been discussed. In cases where only one ♂ from the bachelor group defecated on the fecal pile, it was always the dominant ♂.

In bachelor groups, behavior analogous to the marking of mare elimination by the harem stallion was observed occasionally. For example, in the Forest group, when the youngest member urinated, he was followed by the second in rank on the same spot, and lastly by the oldest and dominant ♂, Forest. In the Prostitute band, when the mare defecated or urinated, the ♂♂, in a rank order from lowest to highest, defecated or urinated on the spot. In all cases, the dominant ♂, Blacki, was the final one to defecate. The hierarchy was also clearly expressed in this band by threats always being directed toward stallions lower in rank. The number 1 and 2 stallions, Blacki and Black One respectively, gave evidence of their rank by occasional mild fights which Blacki always won. Often both would herd the rest of the group at the same time. Black One would always be second from the rear, and Blacki at the rear, with a harem stallion.

No consistent dominance hierarchy was observed among individual mares of a harem. In some situations, a mare dominated another in protecting individual space, defending a foal, or establishing position at a watering site or in the resting group. However, the relationship depended upon the circumstances, and reversals were frequent. Further study might reveal that some particular mares do dominate others consistently enough to establish a rank order. Our observations indicated that female hierarchies are poorly developed, and strong dominance of the stallion over the harem overshadows the expression of a female hierarchy.

Dominance hierarchies have been reported for horses by other authors. ZIMEK (1944) and MONTGOMERY (1957) reported them in domestic horses, HJARDT (1954) for Icelandic ponies and TYLER (1972) for New Forest ponies. KLINGEL (1967, 1968) reports that plains, mountain, and Hartmann zebra bands exhibit a dominance hierarchy among the mares that is most clearly expressed by a rank order within the family unit when moving to water. That order was characterized by the most dominant mare in front, followed by her youngest then second youngest offspring, followed by the next most dominant mare, etc. The stallion, although often at the rear of the band, was dominant over all the other band members. It is interesting to note that KLINGEL found no dominance hierarchy in the adults of bachelor groups of zebras.

Stallion Encounters and Fights

Fights between harem stallions, lone bachelors, and bachelor stallions were observed throughout the study. 82 encounters between stallions were recorded. The largest number (37) resulted from nearness of other groups. Typically, these occurred when groups of bachelor stallions came too close to other groups while feeding or moving about the Range. Stallions would approach each other, and an aggressive encounter would follow. Such encounters help to maintain linear spacing between groups as previously discussed. Twelve

fights were the result of attempts by a harem stallion to gain a mare from another harem. Four fights were the result of attempts by stallions to regain mares that had been separated from the harem. In only one case was the mare not recovered as a result of the fight, and that involved a crippled harem stallion who lost mares to two bachelor stallions.

One fight was a unique case. It was a complicated encounter of undetermined cause, which involved 5 harem stallions and two immature ♂♂. All of the harem stallions fought each other in earnest, but the encounter between the two immatures was decidedly milder.

The first part of a stallion fight involved posturing by one or both stallions. Usually one or both would stand and stare at the other in a mild, alert posture, and occasionally paw the ground with a front hoof. In some cases,

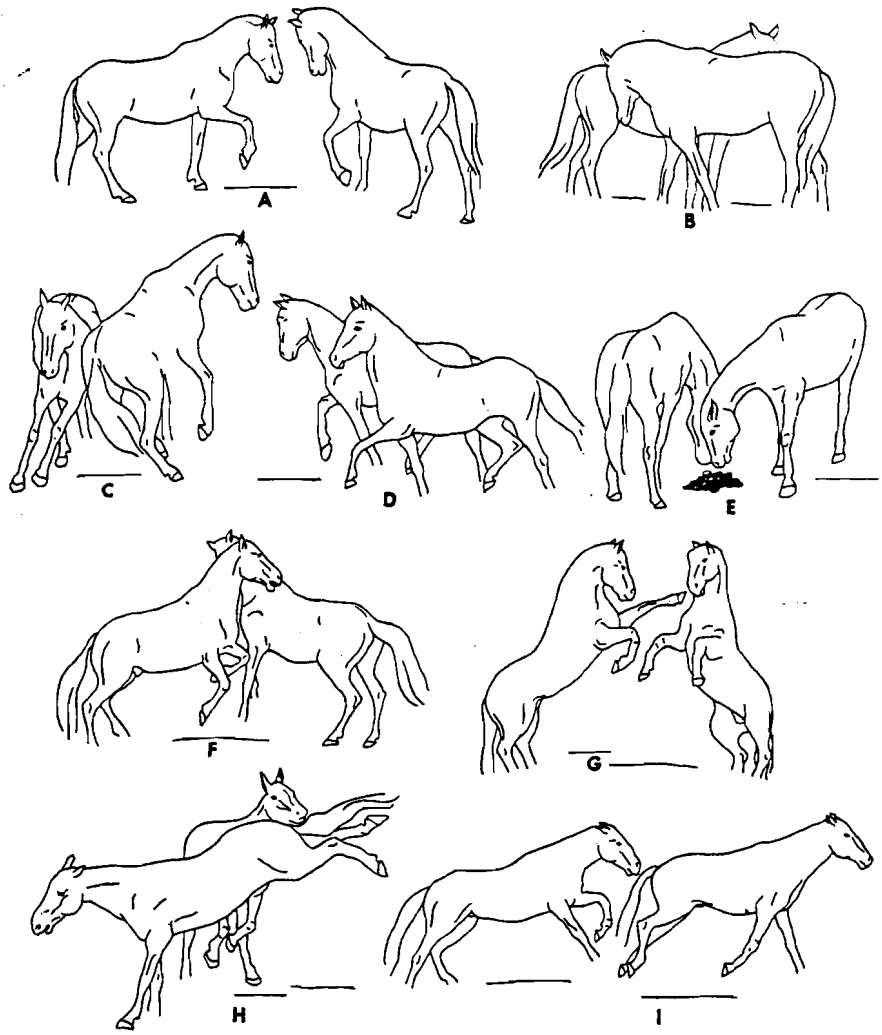

Fig. 12: Typical sequence of acts in an aggressive encounter between dominant stallions. A. Approach and smell noses, B. Smelling flanks. C. Pushing and threatening a hindfoot kick. D. Parallel prance. E. Smelling fecal pile together. F. Shoulder-pushing and biting. G. Rearing and front-foot kicking. H. Hind-foot kicking. I. Defeated stallion chased by the winner (left)

one or both would then walk to a nearby fecal pile and smell, sometimes paw at it, defecate on the pile, and turn and smell it again. Several times during the study the observer became the object of these challenges when close to habituated harems. These challenges were declined.

If the confrontation continued, the next step was an approach to one another by walking, trotting, or prancing with exaggerated movements. The head was held high with ears forward and the neck tightly arched, with occasional head tosses and with the tail lifted to some degree. The front legs were lifted high, often striking forward in a threatening manner. A parallel prance was usually observed in the initial stages as well as during intervals in the rest of the fight.

In all fights except the most serious ones, the two stallions came together and investigated each other. A typical series of acts is illustrated in Fig. 12. First they stood facing one another with their foreheads touching, or almost so, or with their heads side by side but still facing in opposite directions. In this position, and with heads high, necks arched, and ears forward, the stallions appeared to smell each other's nostrils and breath. Often at this point, a squeal would be emitted by one or both stallions. This sound would be heard again at intervals throughout the fight. Often the squeal was accompanied by a front-foot kick usually only striking the ground. Further smelling would then proceed, and this was accomplished by each stallion moving along the side of the other so as to smell the neck, withers, flank, genitals, rump, and occasionally, the tail of the other. In smelling necks, each stallion would turn his head and neck toward the other so that it appeared like two hooks caught together. The ears were held forward while smelling noses and necks, but were usually laid back when smelling the rear of the body. After these investigations were complete some fights involved pushing each other with shoulders, and head swings directed at the opponent's head and neck. Occasionally, a stallion would lay his neck over the other's neck and rear above the other in what appeared to be an attempt to force the opponent to the ground. However, the only time a stallion was observed to fall was when one was pushed over backwards while both were reared on their hind legs and striking with the forefeet.

In the most serious fights, initial posturing was sometimes omitted and the two stallions ran at each other, ears back and mouths open, engaging in immediate and active combat. Kicking and biting were the main actions that characterized the more serious fights. Kicking with the forefeet was used in a face-to-face confrontation, using one leg while standing or both while reared on the hind legs. Intense forefoot kicking exchanges usually were accompanied by biting. Scars on the sides, rumps, and necks of stallions attest to the effective delivery of bites.

Kicks with one or both hindfeet were used, although they were always in short and intermittent parts of the fight. Because hind-foot kicks are extremely powerful, the stallions made great efforts to avoid receiving such a kick, which gave many fights the appearance of consisting of active and passive phases. Broken jaws on skeletons recovered from the Range (3 out of 35) might well indicate the fate of a horse receiving a well-placed kick.

Behavior by both opponents at the same fecal pile often occurred during interludes between active fighting. The procedure was to smell, defecate, turn and smell again, either in unison or in turn. Great interest was shown in smelling the feces of the opponent. In serious fights we found no relationship between which stallion defecated first and which initiated the fight or won. However, in "mock fights" it was always the dominant stallion who defecated

last. This would be followed by resumption of active fighting, or an end to the confrontation, or to parallel prancing, again followed by a defecation sequence at the same or a nearby fecal pile.

Some encounters consisted of, or, in the case of fights, were terminated by, a chase. The stallions layed their ears back and, while running, the pursuer would attempt to bite the rump and tail of the escaping horse. In fights between harem stallions, it was seldom that a clear winner could be determined, except in the cases where one chased the other. Most fights ended in an apparent draw with both stallions simultaneously separating and returning to their respective groups.

The number of acts used in a fight, the order of their occurrence, the intensity of their use, and the general seriousness of a fight were all variable. Examples of some fights are illustrated in Table 3 where the numbers signify the acts used and the order of their occurrence. For example, a mild encounter may consist only of a simple stand-stare by one stallion, and a response of facing or moving away by the other. In a more serious encounter, the stand-stare, walk-together, smell noses, squeal, fore-foot kick, smell-defecate-smell, and head-swing may all be used. In a serious fight, the preliminary challenge and display may be omitted, and the two stallions may come together and begin biting, fore-foot kicking, and hind-foot kicking in a violent and determined manner.

The intensity of the acts was a measure of the seriousness of a fight which could be judged, for example, by how determined and aggressive the bites

Table 3: Sequence of acts in encounters and fights between dominant stallions

...e, how exaggerated the postures were, and how much of the fight consisted of biting and kicking as compared to displays. "Mock fights" between immature ♂♂ or bachelor stallions, for instance, lacked the exaggeration in posturing, and biting and kicking were executed with much less intensity, seeming to be more symbolic gestures (intention movements) than attempts to deliver injury.

The ear, head, and tail positions changed continually during fights. In the challenge or display stage the ears were forward, head high, neck arched, mouth closed, and tail up. In the active stage, acts such as kicking, biting at the neck and throat, and pushing and head swings were accompanied by the ears being laid back, mouth opened, and head stretched out toward the opponent. In the passive stage, the ears were held out or forward, mouth closed, and the neck or body swung away from the opponent.

While stallions were engaged in a fight, the mares, as a rule, seemed quite uninterested in the activity. They either continued feeding or grouped up and stood waiting for the stallion to return.

Smelling of the genitals was observed in mature stallion encounters, but it was more common between immature ♂♂. Both mature and immature stallions were observed licking another's penis. In all cases of smelling or licking the genitals, it was done by the lower in rank of the two, or both together.

In many respects, horses and zebras fight in a similar manner. However, according to KLINGEL and KLINGEL (1968 a) plains zebra fights involve a considerable amount of biting directed toward the legs, which they defend by dropping to their knees or haunches. This was observed only rarely in immature wild horses, while in serious fights bites were directed to the head, neck, and body. It also appeared that horses engaged in more forefoot kicking, especially while reared on their hind legs, than do zebras.

Reproductive Behavior

Breeding

Post-partum estrous and a constricted breeding season were shown by the horses (FEIST and MCCULLOUGH 1975). ♀♀ usually became sexually mature at three years, but two cases of two year olds successfully breeding were observed.

Stallions tended mares from May 1 to July 12, and often tried to copulate. However, only 8 successful copulations were observed in the study. All but one were performed by dominant stallions with mares of the harem.

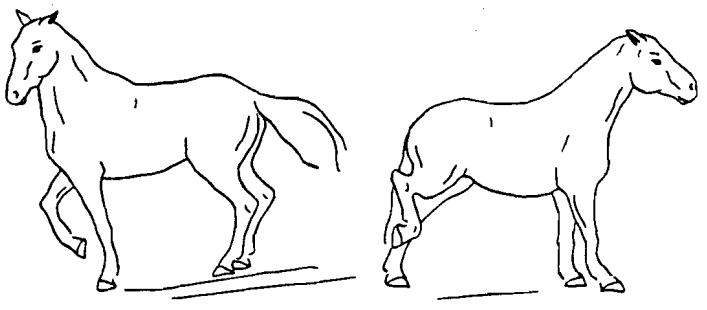

Fig. 13: Unreceptive mare (right) rejects sexual approach of stallion who then moves away. Mare lays back ears and kicks with hind-foot

During the breeding season heightened sexual activity by the stallion included more direct and frequent smelling of a mare's vulva, and increased displays over excrement of mares. As mares approached estrous, the stallion pressed them more persistently. Unreceptive mares rejected these advances by laying back their ears and moving away, or threatening, or delivering hind-foot kicks with one or both legs (Fig. 13).

Receptive mares indicated readiness for mounting by standing still and raising the tail (Fig. 14). This was followed by mounting with erect penis, intromission, and pelvic thrusts. Following ejaculation, the stallion dismounted and stood for a moment. He then smelled the ground beneath himself, flehmened, and urinated. This sequence often was repeated. A second copulation with the same mare sometimes occurred a few minutes later. Typically one or more mountings without erection of the penis preceded actual copulation. Nursing of a foal is commonly observed following mountings.

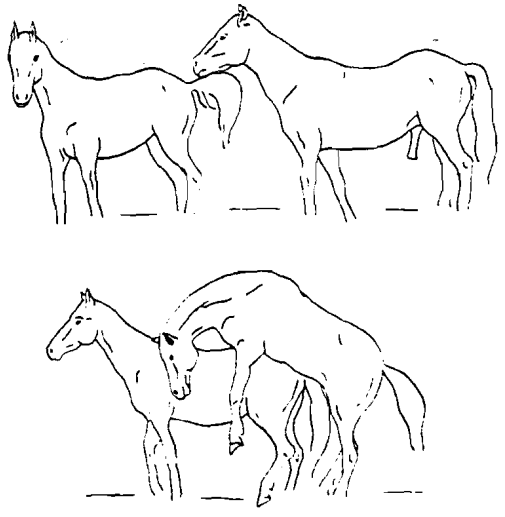

Fig. 14: Copulatory behavior. Above The mare (left) indicates receptivity by standing and raising the tail. The stallion approaches and smells. Below Mounting and intromission

On one occasion, another mare kicked at the copulating pair. ZEEB (1959) observed similar behavior in horses where older mares interfered with copulation of younger mares. KLINGEL (1968b) reported that in zebras, band members move into close contact with a mating pair in the harem.

ZEEB (1959) and TYLER (1972) reported mares in heat presenting themselves to a stallion. This situation seems characteristic of groups with unbalanced sex ratios with few stallions. It was observed once in the Sheik band, which contained the most mares. A mare in heat approached the stallion, and backed into him with her tail lifted. He drove her away with a strong threat. A half-hour later she returned and again presented. Copulation followed.

The lone instance of a copulation not involving the harem stallion involved an immature mare of the Sheik harem. She left the Sheik band to accept copulation with the dominant stallion from another harem group. Sheik stood passively watching through most of the sequence of events. During copulation he approached and drove the ♀ back to his harem, and then moved the harem away. KLINGEL (1969) reported that zebra mares approaching sexual maturity are abducted by rival stallions. This situation is not so clear in the horses, and young mares may voluntarily leave a harem band.

Many copulations and attempts to copulate occurred in situations of disturbance, such as an encounter between the harem stallion and another stallion, or our presence. This was true for 70 % of the observed breeding activity. It seems possible that some form of threat or stress to a stallion may influence

attempts to copulate. Such behavior would seem to have selective advantage since the stallion would attempt to maximize reproductive success before engaging in activities which involve risk of mortality, injury, and displacement by rival ♂♂.

Mounting is sometimes observed outside the normal breeding context. On four occasions male foals mounted other horses. One involved a male foal mounting a female foal. The others involved mature mares, in one case, the mother. A female yearling was observed mounting a mare. An immature ♂ attempted to mount a female yearling from another harem. The dominant stallion of that harem disrupted the encounter.

Twice ♂♂ were observed to establish or reinforce their dominance over subordinate ♂♂ by mounting them. One harem stallion, following rejection by a ♀, attempted mounting of an immature stallion in the harem. The penis was not extended. The other case involved a bachelor stallion mounting an immature ♂ who had momentarily moved away from the harem. The bachelor stallion mounted four times with an extended, but not erect, penis. This encounter also involved playful fighting, with nipping at the knees. This mode of fighting is common in zebras, but virtually absent in fighting in horses. Dominance apparently can be expressed in stallions by sexual patterns; and as previously observed, dominant stallions in bachelor stallion groups frequently treat the group as if it were a harem.

Extraneous Penis Extensions

We recorded 59 observations of ♂♂ with an extended penis in situations not connected with acts of copulation or urination. Of these, 31 included flexing of the penis after extension. The observations, which occurred at all times of the day, averaged 2 min in duration. Thirty-six stallions of harem groups, 6 immatures or secondary ♂♂ from harem groups, and 17 bachelor stallions (lone or in bands) were involved. No observations of male foals or yearlings were recorded except when all six ♂♂ of the Prostitute band (which included a yearling) were observed standing in a loose group, each with his penis extended.

The 59 cases were classified with respect to possible cause. Twelve were related to encounters with another stallion and occurred during the stand-stare, a common posture in the early stages of a fight. Only 10 cases were believed to have been caused by direct arousal from a mare or from smelling a mare's excretions. In the majority of the observations (37) we could not detect a clear external stimulus which induced behavior. In these cases, the ♂♂ were standing alone or a short distance from the harem, either quietly feeding or in a rest posture.

In some instances, extension might have been due to relaxation. However, in 31 of the 59 cases the penis was also rigid and flexed after extension, and 10 were accompanied by pelvic thrusts similar to those used in copulation. None of these extraneous penis extensions resulted in the obvious emission of urine or seminal fluid.

Mare-foal Relations

Foals were born from about mid-April to late June, with most births occurring in May and early June. No actual deliveries were observed, and it is our belief that mares usually seclude themselves from the harem prior to birth as reported by IMANISHI (1953), PELLEGRINI (1971), and TYLER (1972). We found the remains of two extremely small foals which may have been still-

born or died shortly after birth. Both were in sheltered clumps of juniper. However, the possibility of their being dragged there by scavengers cannot be ruled out.

The bond between mother and offspring was most apparent in the close association of the two. The foal remains at the mother's side in the band during all movements, and will get up from rest or sleep whenever there is movement. The ♀ is strongly protective of the foal, and issues a low whinnying if the foal becomes separated. She will threaten other horses which approach too closely to the foal. She positions herself between the foal and the intruder. Dominant stallions are also protective of the foal and will herd it with the band, and bring it back to the band if it becomes separated (FEIST and MCCULLOUGH 1975).

Dominant stallions also will separate band members if the mother is unable to maintain the distance of other horses from the foal. The mother gives a whinny in these cases and the stallion moves the other horse away. Such protectiveness is important since lost or orphaned foals are attacked by other horses.

Nursing

Nursing (Fig. 15) was usually initiated by the foal walking directly toward the mare, often crossing under her neck, and then moving along her side to the udder. Mares rejected these approaches only in 6.2 % of the cases. If she accepted, the mare would raise her head, stop eating, and stand still. As a foal began nursing, most mares would take a short step forward with their front legs, leaving the back ones stationary to facilitate nursing. At the end of nursing, foals began feeding on vegetation, stood or walked alongside the mare, or in most cases lay down a few yards away from the mare. If a yearling was nursing, it would commonly return to eating vegetation.

There were no observed cases of a foal or yearling nursing from a mare other than its own mother.

A total of 244 observations of nursing was recorded during the study (FEIST and MCCULLOUGH 1975). Of these, 222 were by foals, 21 were by yearlings, and one by an immature. For the six individual yearlings which nursed, it was not clear if the mare failed to produce a foal, or if the foal died shortly after birth. One ♀ nursed both a foal and yearling. The one case of an immature nursing involved a mare who dropped a foal which died soon after birth.

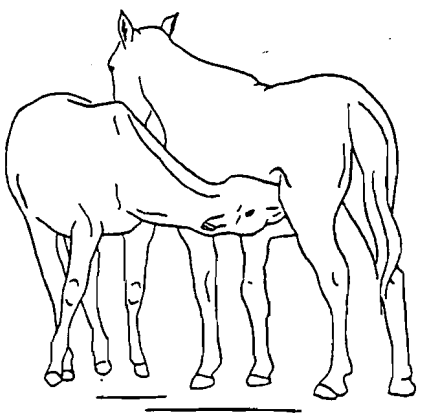

Fig. 15: Typical nursing posture, in this case by a yearling. The mare stands with hind-legs slightly extended

Nursing lasted from a few s to 2 min; the median time was about one and a half min. Foals nursed 1.85 times per h, while yearlings nursed (.97) times per h, or about one-half as often as foals. Length of nursing bouts was similar for foals and yearlings.

Termination of nursing was voluntary in 75.7 % of the observa-

tions, and involuntary in 24.3 % when the mare moved or there was interference by another horse.

The side of the mare from which foals or yearlings nursed was recorded in 230 cases; 110 were on the right side, 116 were on the left side and four nursings were from behind. The nursings from behind were all by the foal of a mare who was suckling both her yearling and foal. The yearling displaced the foal at nursing with no interference from the mare, and in these cases the foal usually moved to the rear position.

General Discussion

An impressive aspect of the social behavior of horses is the conservatism of social organization. The domestic horse has a long history of human-controlled artificial selection for characters having little or no bearing on survival in the wild, and for management in captivity which has not allowed expression of normal social structure. Despite this period of manipulation by man, once horses manage to escape and live in a wild or semi-wild state, the typical wild social organization emerges. This social organization is typical of what is known of the well-studied plains zebra, and apparently of the less-well-known remaining populations of *Equus caballus*. Reemergence of the pattern among feral horses is reported by IMANISHI (1953) in Japan, BRUEMMER (1967) on Sable Island off of Nova Scotia, TYLER (1972) in England, PELLEGRINI (1971) Nevada and FEIST and MCCULLOUGH (1975) in Wyoming-Montana. Although details are not available to us, we understand that similar results are being obtained on other feral populations. Certainly these feral populations represent a wide variation in genetic make-up, past history of handling in captivity, and length of time in the wild or semi-wild state. The constancy of social organization is remarkable, and deserving of closer study.

One of the most interesting differences between the results of our work and that of TYLER (1972) is the difference in behavior of ♀♀. In TYLER's population, ♂♂ were removed by man, and a population of mostly ♀♀ resulted. She observed many kinds of behavior, including vocalizations, being shown by ♀♀ which we observed only in ♂♂. In our population, dominant stallions are extremely dominant, and apparently they suppressed a number of behavior expressions in ♀♀. Nearly all alert-alarm behavior and aggressive behavior is expressed by ♂♂. Dominant ♂♂ quickly assume control if a ♀ first detects danger, and they intervene in mare-mare antagonisms and even play within the harem. They play a major role in keeping the group together. The dominant stallions are so successful in their control of the harem group that a remarkable homeostasis is achieved. We believe that this accounts for the very poorly developed social hierarchy among harem ♀♀ and the reduction of mare-mare aggression.

Evidence seems to be accumulating to suggest that in year-long harem groups dominant ♂♂ do not breed with their female offspring. Because harem groups persist for years, in most cases juvenile ♀♀ would be copulating with their own fathers. Why are rival zebra stallions able to abduct juvenile ♀♀, but not adult ♀♀? Why would a dominant stallion horse passively allow copulation of a young ♀ in his harem with a rival ♂? Why do vicuña dominant ♂♂ actively drive juvenile ♀♀ from the family group (FRANKLIN 1974)?

Surely the social system would collapse if rival ♂♂ were equally successful at abducting adult ♀♀. This would imply that fundamental to this phenomenon is the behavior of the dominant ♂. In vicuna, the dominant ♂ actively excludes juvenile ♀♀, while in horses it is more passive. One stallion allowed

copulation by a rival, and juvenile ♀♀ were responsible for most of the harem changes observed. The fact that rival zebras select juvenile ♀♀ to abduct suggests that such attempts are more successful than attempts at adult ♀♀, and ultimately that behavior of the dominant stallion must differ in the two cases.

For a polygynous ♂ to give up a potential mate implies that there is a substantial cost of such matings which either outweighs the benefits in cases of passive or active exclusion of juvenile ♀♀, or comes close enough in the case of abduction that the effort required of the dominant ♂ to retain the ♀ is not warranted.

The cost involved would seem to be the potentially deleterious effects of inbreeding. Clearly this question of fundamental evolutionary significance should be explored more completely.

Summary

A behavioral study of a population of feral horses in the western United States was conducted between 1 May and 1 November, 1970. Horses were organized into stable harem groups with a dominant stallion, and less-stable bachelor male groups. Home ranges of groups overlapped extensively, and territoriality was not present. Linear spacing between groups was maintained by interactions between dominant stallions. Daily activities involved mainly grazing, resting and moving to water during dry periods. Grasses were the major food, forbs and even roots were consumed on this poor range. During dry periods, water sites were visited once a day at any time of day, or less commonly, at night.

Stereotyped postures and modes of communication are described. Detailed quantitative notes were recorded at one min intervals on horses unaware of the observer. In addition, six groups were habituated to enable close-range observation. Harem group stability was maintained by strong dominance of the harem stallion and fidelity of group members. Elimination of mares was often marked by harem stallions, mainly with urine. Both mares and stallions rejected non-group horses. Most stallion fights and herding attempts involved keeping harems separated, with relatively few involving attempts at gaining additional mares. ♀♀ in harem groups showed poorly developed hierarchies. Immature ♂♂ were tolerated by the dominant ♂ because of their strongly submissive behavior. Leadership, as expressed by both herding and initiating movement, was most commonly shown by the dominant stallion.

Linear dominance hierarchies were present in bachelor male groups. The dominant ♂ behaved towards the group as if it were a harem. ♂-♂ interactions, both between harem stallions and between bachelor stallions involved prominant use of feces. Bachelor group hierarchies were clearly expressed at fecal piles where the lowest ranking ♂ defecated first, followed in order by the others, with the dominant animal last. All ♂♂ used the same fecal piles which were distributed widely over the range, but with concentrations along trails and by water holes.

Foaling was concentrated in May and early June with mares showing a post-partum estrous. All breeding was done by harem stallions. Mares were strongly protective of their foals, and dominant stallions showed protective behavior towards the foals of the harem. Nursing was initiated by the offspring and was seldom rejected. Yearlings were commonly nursed by mares if they failed to breed or lost the new foal early. One immature (2—3 years) nursed from a mare which had lost her new foal. Foals nursed 1.85 times/h

...d yearlings 0.97 times/h. Nursing bouts averaged about 1.5 min in length and did not differ between foals and yearlings. Termination was voluntary 76% of the time.

Equids show pronounced conservatism in social structure, with feral ponies and horses displaying organization similar to most zebras. Strong dominance of harem stallions apparently suppressed much behavior of ♀♀.

Zusammenfassung

Von Mai bis November 1970 wurden verschiedene Wildpferd-Gruppen in ... westlichen Vereinigten Staaten untersucht. Die Pferde lebten das ganze Jahr in stabilen Harems mit einem dominanten Hengst oder in weniger stabilen Gruppen aus jungen ♂♂. Weidegebiete überschnitten sich sehr stark, Territorien waren nicht feststellbar. Der Abstand zwischen Gruppen wurde vom dominanten Hengst gewahrt. Der Tageslauf umfaßte regelmäßig Grasen, Ruhen und bei Trockenheit Wanderungen zur Wasserstelle.

Wiederkehrende Verhaltens- und Verständigungsweisen werden beschrieben. Unbemerkt von den Pferden wurde das Verhalten in Minutenabständen protokolliert. Zusätzlich wurden sechs Gruppen daran gewöhnt, aus nächster Nähe beobachtet zu werden. Die Konstanz der Haremsgruppen wurde durch ...rke Dominanz des Hengstes und die Treue der Gruppenmitglieder gewahrt. ... Exkremente der Stuten wurden oft von den Haremshengs... mit Urin ...arkiert.

Sowohl Stuten als auch Hengste wiesen gruppenfremde Pferde ab. Kämpfe zwischen Hengsten und Zusammentreiben der Stuten dienten meist dazu, die Harems getrennt zu halten; selten ging es darum, zusätzliche Stuten zu bekommen.

Harems-♀♀ zeigten nur wenig entwickelte Rangordnungen. Halberwachsene Hengste wurden von den dominanten ♂♂ wegen ihrer starken Unterwürfigkeit geduldet. Führer, erkennbar am Hüteverhalten wie am Initiieren von Aktivitäten waren meist die dominanten Hengste. In den Junggesellen-...ppen bestand eine lineare Rangordnung. Das dominante ♂ behandelte die ...ppe wie seinen Harem. Bei Interaktionen zwischen Harems-Hengsten wie zwischen Junghengsten spielte Koten eine große Rolle. Die Rangordnung in Junghengst-Gruppen war beim Koten erkennbar: der Rangniedrigste kotete zuerst, die jeweils Ranghöheren folgten. Alle ♂♂ benutzten dieselben Kotplätze, die weitverstreut an Pfaden und Wasserstellen lagen.

Im Mai und Anfang Juni fohlten die Stuten, die sofort wieder rossig und dann ausschließlich vom Haremshengst gedeckt wurden. Die Stuten verteidigten ihre Fohlen sehr stark, und auch die dominanten Hengste zeigten Verteidigungsverhalten. Die Fohlen saugten von sich aus und wurden selten abgewiesen. Einjährige wurden gewöhnlich von Stuten gesäugt, die selbst keine oder ihre neugeborenen Fohlen verloren hatten. Fohlen tranken 1,85mal pro h, ein...hrige 0,97mal pro h, und zwar durchschnittlich 1,5 min lang. In 76% aller ...lle hörten die Tiere freiwillig zu trinken auf.

Pferde haben eine sehr ursprüngliche Sozialstruktur, die bei wilden Ponies und Pferden der bei den meisten Zebras ähnlich ist.

Acknowledgements

Financial support for this study was provided by the John P. Clark Scholarship Fund and the School of Natural Resources, The University of Michigan. We are indebted for aid

during the field work phase to Royce, Lloyd, and Bessie TILLETT, George LANGSTAFF, Dean BIBLES, D. OBERT, Bill, Ted, and Stephen FEIST. Assistance for translation of literature and preparation of the manuscript came from Marlene SIEBENHAAR, Claire ADLER, Doris HUMPHREY, and Carol FEIST. Carol FEIST did the preliminary drawings, and final drawings were done by Rebecca ANDERSON. John KADLEC reviewed early drafts of the manuscript, and the final draft was read by John BISSONETTE. Special thanks are due to Carol FEIST for her help in assembling materials for this manuscript in the difficult times following the death of her husband.

This paper is dedicated to the late John P. CLARK in warm remembrance of the experiences the three of us shared.

Abstract

Few controlled studies have been made of the possible mechanisms and physiological consequences of weight gain after cats have been neutered. In this study, six male and six female cats were gonadectomised and compared with five entire male and six entire female cats, before they were neutered and one and three months later. The neutered males gained significantly more weight (mean [SEM] per cent) than the entire males (30.2 [5·2] v 11·8 [2·3]) and the entire females gained 40·0 (7·3) v 16·1 (3·3) per cent, ($P<0·05$). The castrated males gained more weight as fat than the sexually intact males (22·0 [3·3] v 8·8 [4S] per cent, $P<0·05$). There was a significant increase ($P<0·05$) in daily food intake after neutering. Spayed females underwent a significant decrease in fasting metabolic rate (83·7 [5·5] v 67·2 [23] kcal/kg bodyweight$^{0·'75}$/day $P<0·05$). Gonadectomy had minimal effects on serum thyroid hormone concentrations, the resting or fasting metabolic rates in males, or on indices of glucose tolerance.

Optimal Control of Wild Horse Populations with Nonlethal Methods

Robert Fonner and Alok K. Bohara

ABSTRACT. *Effective management of wild horse populations has proven difficult for land managers. This paper develops and evaluates dynamic optimization models of wild horse management for three nonlethal population control methods: removals, fertility control, and a hybrid method combining removals and fertility control. Two state variables are included in the models to account for horses on the range and horses in off-range holding facilities. The optimization problems are solved and dynamic simulations are generated for each method. The results indicate that a strategic approach to nonlethal wild horse population control has the potential to significantly improve management efficiency.* (JEL Q28, Q57)

I. INTRODUCTION

Wildlife populations provide a variety of amenities to society, ranging from food and recreation to ecosystem regulation and existence values. Wildlife populations can also impose costs on society through interference with human activities, degradation of habitat, and spreading of disease. Species that both provide a valuable resource and impose societal costs are classified in the literature as multi-use species (e.g., Horan and Bulte 2004; Zivin, Hueth, and Zilberman 2000). Some multi-use species require active management to keep populations from imposing net societal costs. Striking a balance between the costs and benefits of multi-use species can involve active population management. Direct population control is commonly carried out through increased regulated hunting or trapping (Rondeau 2001). However, when multi-use species are endeared to the public, lethal population control methods may not be palatable from a societal perspective. In these cases, wildlife can be captured then relocated, or captured then held in captivity. A third alternative, fertility control, is an emerging nonlethal population control method that can be implemented without displacing animals from their range.

This study evaluates alternative nonlethal strategies for controlling wild horse populations in the American West—a multi-use species for which traditional population control methods are not a politically feasible option. Dynamic economic models of optimal wild horse management are developed for two nonlethal management methods: horse removals and fertility control. A third "hybrid" model is also developed to investigate the effectiveness of using removals and fertility control in tandem. The models account for how management decisions and horse biology influence the dynamics of horse populations on the range, and the population of horses in holding facilities. The objective functions incorporate the costs of on-range management, the costs of off-range holding, and the net benefits associated with wild horse populations. Model parameters are calibrated using published studies on wild horse population biology and Bureau of Land Management (BLM) expenditure data. The value of ongoing status quo management is also estimated, and policy simulations are generated for horse-removal, fertility-control, and hybrid management scenarios. Additional scenarios are developed to assess the sensitivity of model results to shorter time horizons and a cost minimization specification. The simulation results are then examined to glean insights for effectively managing wild horse populations.

This study fits within a growing body of literature examining the dynamics of multi-use species management. A key characteristic of these analyses is that the shadow price of multi-use species can be either positive or negative, which can lead to multiple potentially optimal equilibria (Rondeau 2001; Zivin, Hueth, and Zilberman 2000). Prior studies have investigated the dynamics of multi-use species management in the context of controlling beaver, deer, and wild pig populations (Huffaker, Bhat, and Lenhart 1992; Rondeau and Conrad 2003; Zivin, Hueth, and Zilberman 2000); wolf reintroductions (Rondeau 2001); and invasive species management with biological controls (Fenichel, Horan, and Bence 2010). This article contributes to the dynamic multispecies management literature an analysis of nonlethal population control using removals with off-site holding, and fertility-control methods.

II. BACKGROUND

Free-roaming horses are an enduring icon of the American West, but an effective and sustainable population management plan has eluded land managers for decades. Western wild horse populations are descendants of the domestic animals that were introduced by Spanish explorers in the early 1500s. Once introduced, the horse populations grew quickly, and by the year 1800 wild horses roamed in large herds from Texas to California (Dobie 1952).

Rapid settlement of the western United States and the subsequent development of western lands led to conflicts with wild horse populations in the 1800s and 1900s. During this time, wild horses were sought out and destroyed or captured for commercial slaughter to prevent their interference with grazing and agricultural activities (Phillips 2012). By 1971, the total U.S. wild horse population was reduced to approximately 9,500 a (Pitt 1984). Some wild horse advocates viewed wild horse management practices as inhumane, and by the mid-twentieth century these advocates had organized to lobby Congress for wild horse protections. The campaign garnered public interest and media coverage; and in 1959 Congress passed legislation to prohibit the use of aircraft or motorized vehicles to hunt horses and burros on public lands (Pitt 1984).

In 1971 Congress passed the Wild and Free-Roaming Horses and Burros Act, legislation that continues to guide the BLM's management of wild horse populations. The act banned private horse gathers and tasked the BLM with "protection, management and control of wild free-roaming horses and burros on public lands" (National Research Council [NRC] 2013). The bill's language guides the BLM to manage horses and burros at "the minimal feasible level" to "achieve and maintain a thriving natural ecological balance on the public lands" (NRC 2013). These directives must be balanced with the BLM's mandate to manage public lands for multiple uses. Without active control, horse populations can become a stress on grazing land (Pimentel, Zuniga, and Morrison 2005). To prevent rangeland degradation, the BLM actively gathers wild horses and removes them from the range with the goal of keeping populations within predetermined appropriate management level (AML) bounds. Adoptive homes are sought for removed horses, and unadopted animals are sent to long-term holding facilities. Current BLM policy does not support selling unwanted horses for slaughter.

In recent years, unwanted horses have been accumulating at holding facilities. During the 2015 fiscal year, 66% of the Wild Horse and Burro Program's (WHBP) $77.2 million budget was dedicated to maintaining captive horses (BLM 2016b). In 2000, by comparison, holding accounted for 46% the $19.8 million total program budget (Government Accountability Office 2008). Furthermore, Garrott and Oli (2013) estimated the total net present value (NPV) cost of caring for the horses currently in holding, if no more were added, at nearly $350 million. Under the existing management program, these authors estimate that the total 2013–2030 costs of maintaining unadopted horses in captivity would total $1.1 billion.

Facing an uncertain future, the BLM requested that the NRC scientifically evaluate the challenges facing the WHBP (NRC 2013). In their report, the council offered guidance for developing dynamic models that could assist the BLM with identifying cost-effective management options. Specifically, a need was

expressed for a model that evaluates the dynamics of on-range and off-range populations, and the costs and consequences of existing and alternative management regimes (NRC 2013).

The findings of the NRC report have not yet led to appreciable shifts in the BLM's wild horse management strategy. Meanwhile, horse populations remain above the AML in most areas, and over 45,000 horses are held in off-range facilities (BLM 2015c). The unsustainable nature of this situation recently garnered coverage by several major media outlets, heightening awareness of wild horse management issues (*The Economist* 2016; Phillips 2016). In September 2016, the citizen-led Wild Horse and Burro Advisory Board recommended euthanizing horses in holding after offering them for adoption. However, following public outcry from animal advocates, the BLM stated that it does not intend to change its policy against wild horse euthanization (Chokshi 2016). Here, we evaluate management alternatives using nonlethal strategies to inform future management actions under current BLM policy.

III. MODELS OF OPTIMAL WILD HORSE POPULATION CONTROL

This section presents dynamic models of optimal wild horse population control for two management methods: removing horses from the range and treating horses with a fertility-control vaccine. A hybrid management regime combining removals with fertility control is then developed. The optimal management policy under a given set of assumptions is to choose a sequence of annual population control efforts that maximizes the net benefits associated with wild horse populations over time.

Both removal and fertility-control methods require that horses be gathered on the range. With removal, gathered horses are transported to short-term facilities where adoptive homes are sought for the animals. Horses that go unadopted are shipped to long-term holding facilities. One of the most promising and practical fertility-control methods for wild horse populations is the long-lasting formulation of porcine zona pellucida vaccine (PZP-22), an imunocontraceptive that is administered through injection after horses are gathered. Treated horses are released back to the range, where the contraceptive remains about 85% effective after 22 months (NRC 2013).

The annual cycle of horse management in the optimization models coincides with the fiscal year. Management actions begin October 1 and continue through the end of February. Wild horse foaling (i.e., birthing) occurs from March 1 to June 30, and the BLM prohibits helicopter gathers during that period (BLM 2010). Net population benefits are assumed to accrue from July 1 through September 30.

Optimal Horse Removal

The NPV of a population of wild horses managed in perpetuity with removal methods is maximized where the chosen sequence of removals $\{Y_0,\ldots,Y_\infty\}$ solves the problem in [1].

$$\max_{\{Y_t\}} \sum_{t=0}^{\infty} \rho^t [B(X_t) - C^{\mathrm{g}}(Y_t) - C^{\mathrm{I}}(I_{t-1},X_{t-1},Y_t) - C^{\mathrm{TR}}(X_{t-1},Y_t) - C^{\mathrm{MISC}}(X_{t-1},Y_t) - CADPT\gamma_t - SC_t], \quad [1]$$

subject to

$$X_t - X_{t-1} = F(X_{t-1}) - Y_t\left[1 + \frac{F(X_{t-1})}{X_{t-1}}\right],$$

$$I_t - I_{t-1} = -I_{t-1}m_{\mathrm{I}} + Y_t\left[1 + \frac{F(X_{t-1})}{X_{t-1}}\right] - \gamma_t,$$

$$Y_t \le \min\{Y^{\max}, \delta X_{t-1}\} \forall t,$$

$$X_{-1} \text{ is given,}$$

$$I_{-1} \text{ is given,}$$

$$X_t^{\min} \ge AML \forall t,$$

$$SC_t = \begin{cases} 0 \text{ if } Y_t = 0 \\ SC \text{ if } Y_t > 0 \end{cases}.$$

Initial population X_{-1} is the population size when the first management cycle begins. The choice variable Y_t is the number of horses gathered during the first five months of period

t. In the absence of management, the horse population grows by $F(X_{t-1})$ during period t foaling. Under optimal removal management, the population transitions to size $(X_{t-1} - Y_t)$ after removals are implemented and then grows to size X_t before benefits are realized in the latter part of period t. Many of the female horses removed from the range are pregnant and give birth off-range rather than on-range. Thus the effective impact of removals on horse population growth is $Y_t[1 + F(X_{t-1})/X_{t-1}]$, where $F(X_{t-1})/X_{t-1}$ approximates the per capita growth increment for horses in a population of size X_{t-1}. This also implies that removing Y_t horses from the range results in $Y_t[1 + F(X_{t-1})/X_{t-1}]$ captive horse births during period t. Furthermore, the total cost of gathering horses, $C^{g}(Y_t)$, depends on the number of horses gathered. Initiating management actions at the beginning of a management period is associated with setup costs $SC_t = SC$.

The inventory of horses in long-term holding at the beginning of period t equals I_{t-1}. These horses are held in long-term facilities until the end of the period when a discrete mortality event occurs at rate m_{I}. The horse inventory in short-term holding during period t equals effective removals in that period, $Y_t[1 + F(X_{t-1})/X_{t-1}]$. Adoptions occur at the end of the period, and the remaining horses are shipped to long-term holding. The costs of off-range holding during time t are given by $C^{\mathrm{I}}(I_{t-1}, X_{t-1}, Y_t)$. The costs of shipping horses from short-term to long-term holding are $C^{\mathrm{TR}}(X_{t-1}, Y_t)$.

The parameter γ_t represents the horses adopted in period t, and γ is the annual state adoption demand. The first γ removed and captive-born horses are adopted and the rest go to long-term holding facilities. Thus, the number of horses adopted in period t equals $Y_t[1 + F(X_{t-1})/X_{t-1}]$ if effective removals (i.e., removed plus captive-born horses) are less than or equal to γ, and equals γ otherwise. The costs associated with administering an adoption are $CADPT$, and total adoption costs in period t equal $\gamma_t CADPT$. When removals plus captive births exceed adoption demand, adoption costs are a fixed cost of management. The miscellaneous costs related to compliance inspections, horse preparation, and additional holding are given by $C^{\mathrm{MISC}}(X_{t-1}, Y_t)$.

Wild horses are associated with economic values beyond the costs of population management. Wild horses provide recreation benefits for wildlife viewers and nonuse benefits for individuals who value knowing that wild horses roam free on the western range. Horse populations can also impose economic costs through displacement of wildlife species and domestic livestock, and through degradation of rangelands. The net economic benefits provided by a wild horse population of size X_t are given by the function $B(X_t)$. It is assumed that $B(X_t)$ is a strictly concave, single-peaked function that reaches its maximum where $X = \bar{X}$. Thus, the marginal benefits function $B_x > 0$ for $X \in [0, \bar{X})$ and $B_x < 0$ for $X \in (\bar{X}, \infty]$.

Several constraints are placed on the optimal horse management solution. During a given period, the horse population is smallest after removals occur but before foaling begins. The models specify that this minimum population level, $X_t^{\min}$, must be above the low-range AML set by the BLM. Wild horse managers may be constrained by the number and proportion of animals that can be gathered in a given year (NRC 2013). Constraint parameter δ is the maximum proportion of the population that can be gathered in a single period. Gathers are also constrained in the model by the maximum total number of horses that can be gathered in a single period, $Y^{\max}$. Finally, the discount factor ρ reflects time preference and is bound between 0 and 1 (inclusive).

Optimal Fertility Control

The optimal fertility-control program is a sequence of fertility treatment choices that maximizes the following problem:

$$\max_{\{Y_t\}} \sum_{t=0,2,4,\ldots}^{\infty} \rho^t \left[B(X_t) + \rho B(X_{t+1}) - C^{\mathrm{g}}(Y_t) - C^{\mathrm{fc}}(Y_t, HMA) - C^{\mathrm{I}}(I_{t-1}) - SC_t \right], \quad [2]$$

subject to

$$X_{t+2} - X_t = F_{t+1}(X_t, Y_t) + F_{t+2}(X_{t+1}, Y_t),$$
$$I_{t+1} - I_{t-1} = I_t(1 - m_{\mathrm{I}}) - I_{t-1},$$
$$Y_t \le \min\{Y^{\max}, \delta \tilde{X}_t\},$$
$$X_{-1} \text{ is given},$$
$$I_{-1} \text{ is given},$$
$$\tilde{X}_t \ge AML \forall t,$$
$$SC_t = \begin{cases} 0 \text{ if } Y_t = 0 \\ SC \text{ if } Y_t > 0 \end{cases}.$$

As in the removals model, the horse population is of size X_{-1} when fertility-control management commences, and Y_t horses are gathered during the first five months of period t. All gathered horses are released back to the range after the mares (i.e., female horses) are treated with contraceptives. Gathers are assumed to occur once every two periods to coincide with the approximate effectiveness duration of PZP-22.

Fertility-control treatments prevent conception but do not interfere with the development of horses in utero (Kirkpatrick and Turner 2003). Thus, fertility treatments applied in period t begin to impact population growth in period $t+1$. Because of this delayed impact, the population grows to size $X_0 = F(X_{-1}) + X_{-1}$ by the beginning of the second period regardless of the initial level of fertility-control effort. The fertility-control formulation considered in this model is effective for two periods, so the treatments applied in period t impact population growth in periods $t+1$ and $t+2$. Fertility-control treatments directly impact the population growth rate. The population growth increments impacted by fertility control undertaken in period t are given by $F_{t+1}(X_t, Y_t)$ and $F_{t+2}(X_{t+1}, Y_t)$. There are no horse removals in the fertility-control optimization model. Thus, the initial horse inventory decays according to mortality rate m_{I} until there are no horses left in holding. The costs of horse holding are determined in the same manner as in the removals model, except that gathers and population size have no impact on holding costs and no are horses held in short-term holding.

Costs specific to fertility-control management (C^{fc}) are assumed to be a function of the number of horses gathered for treatment (Y_t) and the number of BLM herd management areas (*HMA*) where fertility control is undertaken. Gather constraints under fertility-control management mirror the constraints under removals, with one notable exception. The delayed effect of fertility control necessitates a more restrictive gather constraint to facilitate dynamic programming of the solution. The constraint $\tilde{X}_{t-1}$ is the lower bound of the previous period population.

Hybrid Management: Combining Removals and Fertility Control

Horse-removal and fertility-control methods have thus far been considered independently. Each of these approaches has advantages that could be leveraged in a population management regime utilizing both removals and fertility control. The following section discusses the strengths and weaknesses of removals and fertility control and proposes a hybrid management regime that combines both methods.

Compared to removals, fertility control is a more benign method of population management that better aligns with the BLM's mandate to manage horses at the "minimum feasible level." Fertility control may also represent a low-cost population control alternative as it does not require off-range management of horses. However, reducing or stabilizing horse populations with fertility control alone requires that a large share of the population be frequently gathered and treated (NRC 2013).

Removal management directly decreases the base from which a population grows and prevents removed pregnant females from giving birth on the range. Furthermore, removals have an immediate impact on the population compared to the delayed effect of fertility control. These characteristics make removal management a more effective means of reducing horse populations in terms of population reduction per unit of gathering effort. Management with removals also has drawbacks. It requires costly long-term management of off-range horses and is a more intensive management alternative compared to fertility control.

Because removals and fertility each have respective strengths and weaknesses, a management alternative that allows for both removals and fertility control may be preferred to management under a single method. Specifically, a "hybrid" management program could allow for population reductions while reducing the number of horse removals required to maintain populations at a desirable level. Hybrid management may also reduce the intensity of population management subject to maintaining ecological balance on the range.

The NRC's report describes a possible hybrid management scenario (NRC 2013). Following this description, the hybrid scenario is specified to involve several years of intensive removals to reduce the population, followed by a management regime that incorporates fertility control. Specifically, hybrid management involves z consecutive years of removals at the $Y_t = \min\{Y^{\max}, \delta\tilde{X}_t\}$ level until the population is within the AML range. Following the initial reduction phase, horses are managed on a two-year gather cycle with a fixed number of removals and optimally chosen fertility-control effort. The hybrid management model is presented in the Appendix. The number of horses removed at the beginning of each management cycle, q, is the minimum removal effort that maintains a population below carrying capacity in the long term under optimally chosen fertility control.

IV. MODEL CALIBRATION

The objective of this article is to inform wild horse management through development and evaluation of dynamic bioeconomic models. Because the form of the defined optimization problems makes derivation of analytical solutions impractical,[1] we proceed by exploring the problems empirically and develop policy insights through dynamic simulations. This section specifies functional forms, parameters, and assumptions for the optimal horse management models.

[1] These characteristics include having objective functions that are nonmonotone in X, nonlinear transition functions for X and I, and multiple state variables.

Separate models were developed for Nevada and Oregon based on data availability. Thus, all of the herds within in a state were modeled as a single meta-population. This treatment is appropriate given the significant migration that can occur between herds (e.g., see BLM 2015b), but it also imposes no migration between states and equal density dependence (i.e., X/K) across herds.

The biological parameters specified for the models are based primarily on studies of the Beatys Butte herd in eastern Oregon. Due to data limitations, the models do not incorporate burro-specific cost or population biology parameters. Monetary costs and benefits in the models are inflation-adjusted to 2015 dollars. The discount factor (ρ) reflects a 4% discount rate in the base model. The functional forms and associated parameter values specified for the models are summarized in Table 1.

Wild Horse Population Biology

Eberhardt and Breiwick (2012) examined growth data from four wild horse populations, including one in the western United States. They found that the populations grew according to a theta logistic growth function, with the parameter controlling the inflection point equal to two, as shown in equation [3]. The carrying capacity (K) is the maximum population that can be sustained by an environment given available resources, and the intrinsic rate of growth (r) is equal to $b - m$, the birth rate minus the mortality rate.

$$F(X_{t-1}) = X_{t-1} r\left[1 - \left(\frac{X_{t-1}}{K}\right)^2\right]. \quad [3]$$

The theta logistic growth function exhibits properties that add intuition to the equation. The term $X_{t-1}r$ represents the intrinsic increment of growth of the population, and $X_{t-1}r(X_{t-1}/K)^2$ captures the density-dependent population effects. As carrying capacity K goes to infinity, the population is unconstrained by density effects, and population growth is equal to the intrinsic increment of growth. As the population approaches the carrying capacity, growth goes to zero.

For the Beatys Butte herd in eastern Oregon, Eberhardt and Breiwick (2012) estimated an intrinsic growth rate of 0.28 and a carrying capacity of 1,202 horses. The models developed in this study assume that in the absence of management, state horse populations grow according to equation [3] with $r = 0.28$. The states are also assumed to have the same carrying capacity to high-bound AML ratio as the Beatys Butte herd.

The models specify the initial population size based on the BLM's population estimates from March 1, 2016. Because the models require initial population estimates from the beginning of the fiscal year, the BLM population estimates are assumed to grow under model assumptions without management. In the optimization models, $X_{-1} = F(X_{\mathrm{BLM}}) + X_{\mathrm{BLM}}$, where X_{BLM} is the 2016 BLM estimate and X_{-1} is the population at the start of management.

Wild Horse Gather Costs

The annual cost of conducting horse gathers depends on the number of horses gathered. State-level gather expenditure data were obtained from the BLM for fiscal years 2009 through 2015 to parameterize this relationship. The gather expenditure data were escalated to the 2015 fiscal year and then merged with gather statistics from the WHBP website (BLM 2016a). Linear models regressing gather expenditures on the number of horses gathered were estimated for two candidate specifications: a linear specification to represent constant marginal gather costs, and a quadratic specification to represent increasing marginal costs. The quadratic specification provides a superior model fit for the Nevada data, and the linear specification provides a better fit for the Oregon data, as determined by the adjusted R^2 values of the regressions. The final Oregon and Nevada fitted regression lines explain 75% and 87% of the variation in annual gather costs, respectively, according to the final model R^2 values. The model constants are estimates of gather setup costs (SC), and the model coefficients are marginal gather cost estimates. Setting up gather operations is estimated to cost approximately $45,000 Nevada and $155,000 in Oregon. The marginal cost of gathers in Oregon is constant at $490 per horse. In Nevada, marginal gather costs are increasing. The cost of gathering the first horse is $345, and the marginal cost of gathering the 5,000th horse is $1,078. Other potential determinants of state-level gather costs were investigated by sequentially including additional covariates in the regressions described above. However, none of the candidate covariates improved model fit, according to the adjusted R^2, suggesting that gather costs are best predicted by the number of horses gathered without additional covariates.

The gather constraint parameters are specified as follows. The maximum number of horses that can be gathered in a given period ($Y^{\max}$) is set just under the maximum number gathered in a single fiscal year in Oregon ($Y^{\max} = 1{,}250$) from 2009 to 2015. In Nevada, where the current population is a greater share of the AML, the constraint is set to 140% of the maximum number gathered in a single fiscal year in Nevada from 2009 to 2015 ($Y^{\max} = 8{,}000$). Further, no more than half of the pregather population can be removed in a single period in either state ($\delta = 0.5$).

Off-range Horse Inventory

Horses removed from the range are transferred to short-term holding facilities where adoptive homes are sought for them. Horses that go unadopted are transported to long-term holding pastures to live out the rest of their lives. Thus, the inventory of horses in holding over time depends on the number of horses removed from the range, the number of captive-born horses, off-range horse mortality (assuming no reproduction), and the initial inventory of horses.

The models assume zero mortality for removed and captive born horses during the period they were gathered. Mortality for horses in long-term holding occurs as a discrete event at the end of each period. The rate of annual mortality for horses in holding (m_1) was specified as follows. First, inventory accrual was simulated over a 35-year period by looping over 1996–2015 removals and adoptions for Nevada and applying the gender-age-specific survival rates from Garrott and Oli (2013).

The simulations assumed that half of the horses removed were mares and that the age of removed horses is a Poisson process with $\lambda = 2$. The simulations yielded age distributions of horses in holding by gender. The mortality rate for horses in holding, $m_I = 0.095$, was then calculated as the overall annual mortality rate in the 36th year, given the age distributions derived in the simulations and the gender-age-specific survival rates. The initial holding inventories for Nevada and Oregon were approximated as the product of the total number of horses in holding as of September 2015 times the state's share of the total horse population, where $I_{-1}^{NV} = 24{,}335$ and $I_{-1}^{OR} = 2{,}707$.

Off-range Management Costs

Horses removed from the range are transported to short-term holding corrals where they remain until they are adopted or transported to long-term pastures. The models assume that adoptions occur as a discrete event just before the end of each period, and that all unadopted horses are transported to long-term holding facilities before the next period begins. The models also assume that future annual adoption demand remains constant at the 2010–2014 average and that long-term holding capacity is not limiting.

Gathers occur between October and February, and captive-born horses are foaled during the spring of the same period in which their mothers are gathered. To reflect this timing the models assume that I_{t-1} horses are held in long-term holding for the entirety of period t, removed horses are held in short-term holding for 290 days, and captive-born horses are held for 150 days of period t.

Off-range management costs were parameterized with WHBP adoption, horse holding, and expenditure data from the BLM. Per-horse adoption expenditures averaged $2,707 annually for fiscal years 2011–2015, and adopters of wild horses paid a $125 fee (BLM 2016b). Annual adoption demand in Nevada and Oregon averaged 75 and 196 horses, respectively, from fiscal years 2010–2014 (i.e., $\gamma^{NV} = 75$; $\gamma^{OR} = 196$). During fiscal years 2011–2015, long-term holding expenditures averaged $1.52 per day and short-term holding expenditures averaged $5.37 per day.[2] The cost of shipping unadopted horses to long-term facilities is $3.29/mi/40 horses (Arneson, Beutler, and Hurst 2002). The typical distance from short-term facilities to long-term facilities is approximately 1,500 miles, roughly the distance from short-term holding facilities in Reno, Nevada, or Burns, Oregon, to long-term holding pastures the midwestern United States. Horses removed from the range are associated with miscellaneous costs related to compliance inspections, horse preparation, and additional holding. Total miscellaneous costs are $210 for adopted horses and $726 for unadopted horses (BLM 2014).

Fertility-Control Effectiveness and Duration

The relationship between horse population growth and fertility-control effort is specified next. Recall that Eberhardt and Breiwick (2012) estimated the intrinsic growth rate for the Beatys Butte herd at $r = 0.28$ without managment. Another study of the Beatys Butte herd (Eberhardt, Majorowicz, and Wilcox 1982) estimated the average annual survival rate at 0.926. Thus, the intrinsic rate of growth at Beatys butte equals 0.28 with no fertility control, and equals –0.074 when every female in the herd receives effective contraception. In reality, PZP-22 is not 100% effective at preventing horse pregnancy. Bartholow (2007) reports that PZP-22 was 94% effective in the first year after treatment and 82% effective in the second year for Nevada's Clan Alpine herd.

To maintain tractability, the optimal fertility-control model assumes an equal sex ratio in horse populations, homogeneity across gender-specific gather production, and no gender selectivity in gathers. These assumptions yield the simplifying condition that half of the horses gathered are treated with fertil-

[2] For each fiscal year from 2011 to 2015, the number of horses in holding (short and long) is calculated as the average of monthly holding inventories reported by the BLM. The per day holding cost is then calculated as the average number of horses in holding divided by the total (short and long) holding expenditures reported by the BLM for that fiscal year.

ity-control agents and the other half are returned to the range.

Contraceptive applications occur on a biannual cycle in the fertility-control model so that two foaling seasons occur between management actions. In the first mating period after fertility-control application, fertility-control effectiveness is $\pi_1 = 0.94$ and the intrinsic rate of growth is r_{t+1}. In the second mating period after management, fertility-control effectiveness is $\pi_2 = 0.82$ and the intrinsic rate of growth is r_{t+2}. A linear functional form is specified between the growth rate and the proportion of females treated with contraceptive. Combined with the previously defined parameters, a linear functional form yields equations [4] and [5].

$$r_{t+1}(X_t,Y_t) = r_0 - \pi_1 0.354\frac{Y_t}{X_t}, \quad [4]$$

$$r_{t+2}(X_{t+1},Y_t) = r_0 - \pi_2 0.354\frac{Y_t}{X_{t+1}}. \quad [5]$$

The transition of the horse stock over time is then given by the theta logistic population growth function in equation [3], where the intrinsic rate of growth is $r_{t+1}(X_t,Y_t)$ in the second foaling period after fertility-control management and $r_{t+2}(X_{t+1},Y_t)$ in the third foaling period after management.

Fertility-Control Costs

The costs of fertility-control management are parameterized as follows. The combined cost of obtaining contraceptives and administering them on the range is approximately $300 per application (Bartholow 2007). Fertility-control management requires additional population monitoring compared to management with removals. The cost of fertility-control monitoring (M) is approximately $7,000 per HMA per year (Bartholow 2007). There are 18 distinct HMAs on BLM lands in Oregon and 84 in Nevada. Because management is considered at the state level, the models assume all HMAs on BLM lands are monitored for the two years after a fertility control cycle is initiated. The second year of fertility monitoring is discounted, so that if fertility control is initiated in fiscal year t, then monitoring costs per HMA for that management cycle equal $M_t = M + \rho M$. If fertility control is not initiated, then no monitoring costs are incurred during that management cycle.

Horse Population Net Benefits

Wild horse populations are associated with significant societal benefits. On the other hand, large horse populations can impose costs on stakeholders through displacement of alternative land uses and degradation to range lands. Pimentel, Zuniga, and Morrison (2005) estimated that U.S. wild horse and burro populations cause $5 million in forage losses annually. Bastian et al. (1999) found that the marginal opportunity costs of additional horses on the range in excess of target population levels are well over $4,060 in in 2015 dollars. Wild horses also provide use and nonuse benefits to wild horse supporters. However, these benefits are challenging to measure because their value is not revealed through market transactions.

The function describing horse population net benefits, $B(X)$, represents the aggregation of all costs and benefits attributable to that population. The shape of $B(X)$ depends on the shape of the marginal benefits and marginal costs functions. Bastian et al. (1999) found that the marginal costs of adding horses to a population were increasing through the population size associated with the $4,060 figure mentioned above. Intuitively, adding horses to a small population under BLM management (i.e., management subject to an overall grazing limit) would displace less valuable wildlife and livestock resources compared to when the horse population is already large. Conversely, attempts in the economic literature to measure benefit functions for wildlife populations and habitats support decreasing marginal benefits, (e.g., Layton, Brown, and Plummer 1999; Rollins and Lyke 1998), particularly when the wildlife population is above its minimum viable population (e.g., Bandara and Tisdell 2005; Ojea and Loureiro 2009). Decreasing marginal costs and increasing marginal benefits imply that the total net benefits function for horse populations, $B(X)$, is a single-peaked function. This analysis fol-

lows Rondeau and Conrad (2003) in assuming that total net benefits can be represented by a Gompertz function where

$$B(X) = \begin{cases} 0 \text{ if } X = 0 \\ aX\ln\left(\frac{b}{X}\right) \text{ if } X > 0 \end{cases}. \quad [6]$$

The Gompertz function is a single-peaked function that satisfies the characteristics of net horse benefits specified previously (i.e., that $B_X > 0$ for $X \in [0,\bar{X})$ and $B_X < 0$ for $X \in (\bar{X},\infty]$). The high-bound AML is assumed to be the population level $\bar{X}$ that corresponds with the maximum of $B(X)$. The marginal opportunity cost of an additional wild horse at high population levels is approximately \$4,060 (Bastian et al. 1999), and the models assume that this is the marginal net benefit at carrying capacity. The resulting system of equations (i.e., $B_X(\bar{X}) = 0$ and $B_X(K) = -4{,}060$) was then solved for parameters a and b. In the Nevada model, parameters a and b are equal to 2,586 and 34,824, respectively. The resulting function implies that a state population of 10 horses in Nevada produces \$211,000 in annual net benefits, while a population at the high-range AML produces \$33.1 million in annual net benefits. At carrying capacity, the Nevada horse population yields net benefits of −\$90.8 million annually. In the Oregon model, parameter a equals 2,586, and parameter b equals 7,380.

V. RESULTS

This section presents simulations of the specified optimal management models and compares them to current management practices. A 50-year time horizon is used to compare the base scenarios, and sensitivity scenarios with shorter horizons are also explored. A long-term time horizon is appropriate for identifying optimal management strategies because horse removals conducted in the current period are associated with holding costs that extend decades into the future.

Solving the Dynamic Optimization Problem

The solution to the removals problem in [1] is identified by solving the associated Bellman equation in [7], subject to the previously defined constraints and the terminal condition $V(T+1,X_t) = 0$, where T is the finite time horizon.

$$\begin{aligned} V(t,X_{t-1},I_{t-1}) = \max_{\{Y_t\}} \{ & \rho^t [B(X_t) - C^{\mathrm{g}}(Y_t) \\ & - C^{\mathrm{I}}(I_{t-1},X_{t-1},Y_t) - C^{\mathrm{TR}}(X_{t-1},Y_t) \\ & - C^{\mathrm{MISC}}(X_{t-1},Y_t) - CADPT\gamma_t - SC_t] \} \\ & + \rho^{t+1} V(t+1,X_t,I_t). \end{aligned} \quad [7]$$

The function $V(t,X,I)$ is the maximum achievable NPV benefits starting at time t with population level X and given action Y. All subsequent actions are assumed to be taken optimally, given the action taken in the current period. Bellman equations [8] and [9] are the equivalent for optimal fertility-control and hybrid population management, respectively.

$$\begin{aligned} V(t,X_t) = \max_{\{Y_t\}} \{ & B(X_t) + \rho B(X_{t+1}) - \mathrm{C}^{\mathrm{g}}(Y_t) \\ & - C^{\mathrm{fc}}(Y_t,HMA) - C^{\mathrm{I}}(I_{t-1}) - SC_t \} \\ & + \rho^{t+1} V(t+1,X_{t+1},I_t), \end{aligned} \quad [8]$$

$$\begin{aligned} V(t,X_t) = \max_{\{Y_t\}} \{ & \rho^t [B(X_t) + \rho B(X_{t+1}) - C^{\mathrm{g}}(Y_t+q) \\ & - C^{\mathrm{fc}}(Y_t) - C^{\mathrm{I}}(I_{t-1},\tilde{X}_t,q) - C^{\mathrm{TR}}(\tilde{X}_t,q) \\ & - C^{\mathrm{MISC}}(\tilde{X}_t,q) - 2CADPT\gamma - SC] \} \\ & + \rho^{t+1} V(t+1,X_{t+1},I_t). \end{aligned} \quad [9]$$

The Bellman equations were programmed in MATLAB (MathWorks 2015) and solved with a backward induction algorithm. The terminal period (T) was set to 65 years, so that realization of the terminal condition is not taken into account in the optimal management simulations. Robustness checks with longer-horizon models suggest that the solutions are stationary. The problems were discretized to limit their dimensionality and facilitate their solution via dynamic programming.[3]

The Nevada and Oregon scenarios were simulated with a 50-year planning horizon for

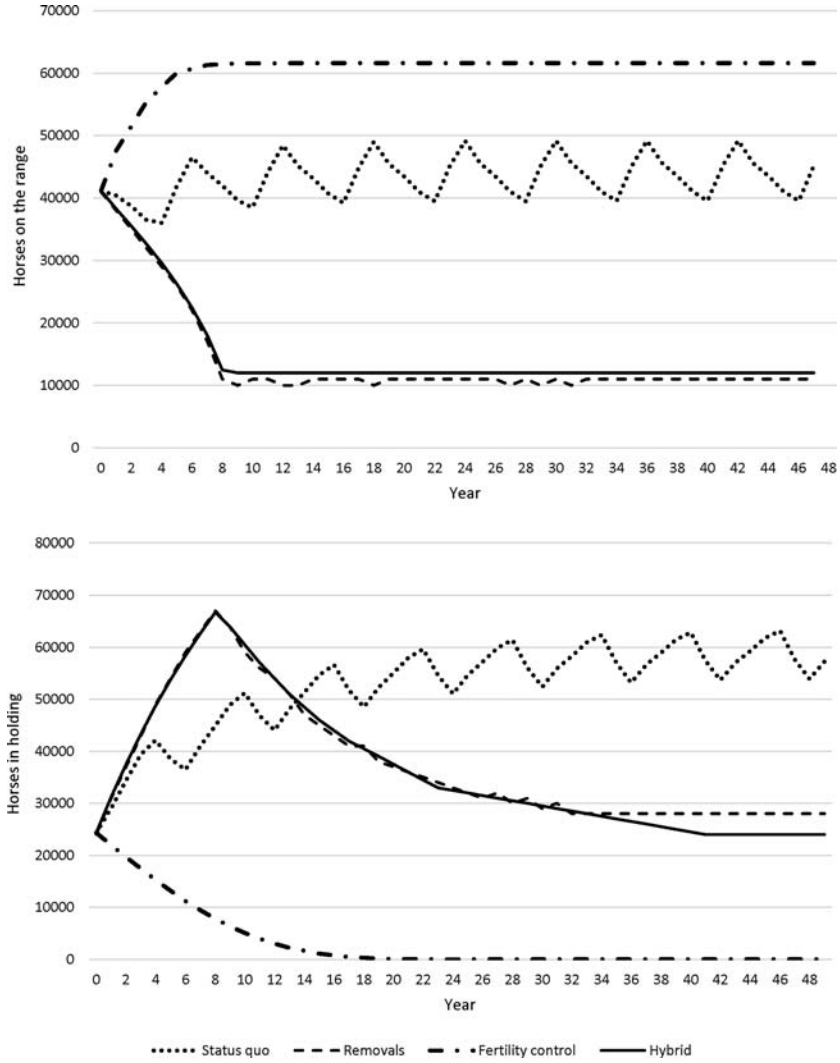
[3] Discretization involved grouping the horses into units and then rounding the state variables to the nearest unit before each value calculation. For removal and hybrid management, the Nevada and Oregon models grouped horses into 1,000-horse and 150-horse units, respectively. The fertility-control models grouped horses into 10-horse units.

both the horse-removal and fertility-control models. The steady-state solutions to the optimal removal and optimal fertility-control models are summarized for Nevada and Oregon in Table 2. The population and holding inventory paths for the optimal solutions and the status quo scenario are presented for Nevada and Oregon in Figure 1 and Figure 2, respectively.

Status Quo Management Scenario

Status quo horse management practices were simulated under model assumptions to provide a baseline for comparison. BLM horse population estimates from 2009 to 2014 and associated management actions from that period were evaluated to characterize current state-level management in Nevada and Oregon. Notably, the intensity of removal efforts varied substantially from year to year in both states. In Nevada, annual gathers ranged from 1.5% to 30.5% of the estimated prefoal population.[4] Annual Oregon gathers ranged from 0.0% to 54.0% of the prefoal population. The status quo management scenarios assume that future gather, removal, and fertility-control efforts reflect a state's recent management practices. Specifically, the scenarios follow a six-year management cycle based on the proportion of horses managed in the six-year period during fiscal years 2009–2014, subject to state gathers not exceeding $Y^{\max}$ or δX_{t-1}.

The periodic nature of removals in the status quo scenarios gives rise to oscillations in horse populations and holding inventories, as displayed in Figures 1 and 2. In terms of long-term trends, populations and inventories increase in the earlier periods before leveling off in the later periods. The cumulative NPV of status quo horse management over a 50-year time horizon is –$1.52 billion in Nevada and –$255 million in Oregon. The cumulative NPV program benefits over time for each scenario are presented in Figure 3, and the cumulative NPV management costs over time are presented in Figure 4.



[4] The status quo gather proportions were constructed with the March 1 BLM population estimate in the denominator and the horses gathered over the subsequent 12 months in the numerator.

TABLE 2
Optimal Steady-State Management Programs and Cumulative Optimal Program Benefits

Scenario	Pregather Population	Removals	Fertility Treatments	Total Gathers	Horses in Holding	Percent Gathered	Cumulative Net Benefits[a]	Change from Status Quo[a]

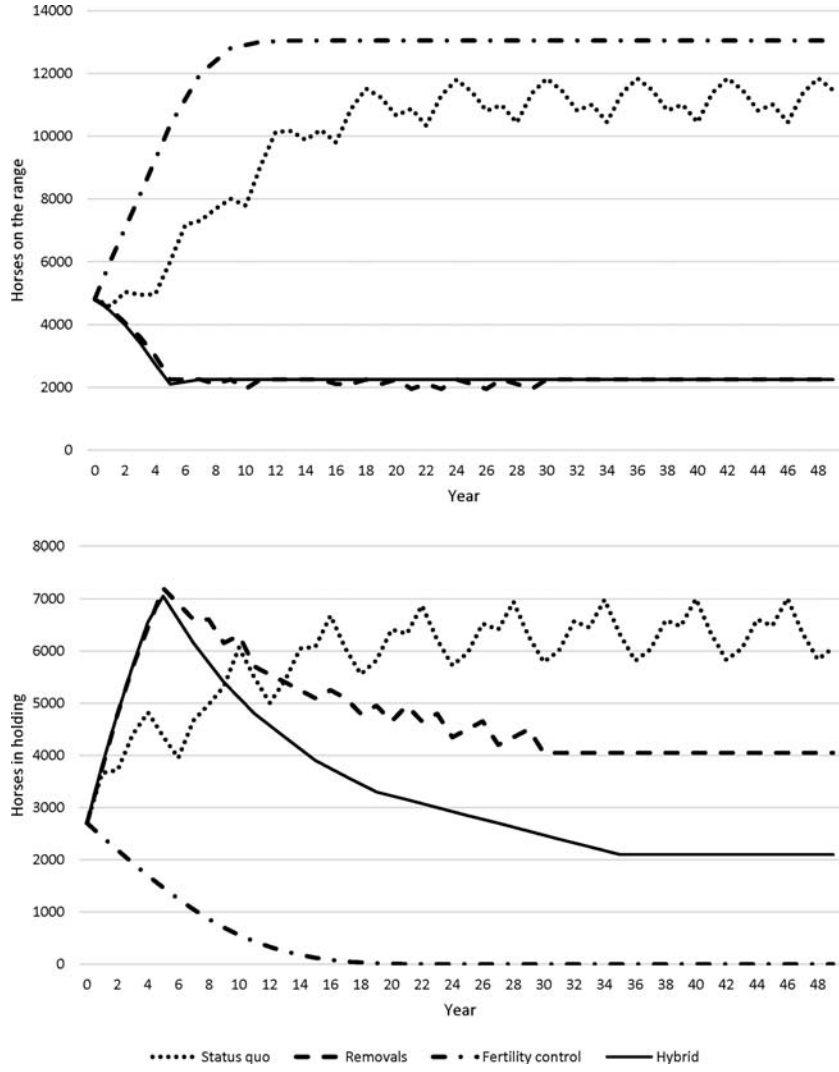
FIGURE 1
Population and Holding Inventory Paths for Nevada Simulations

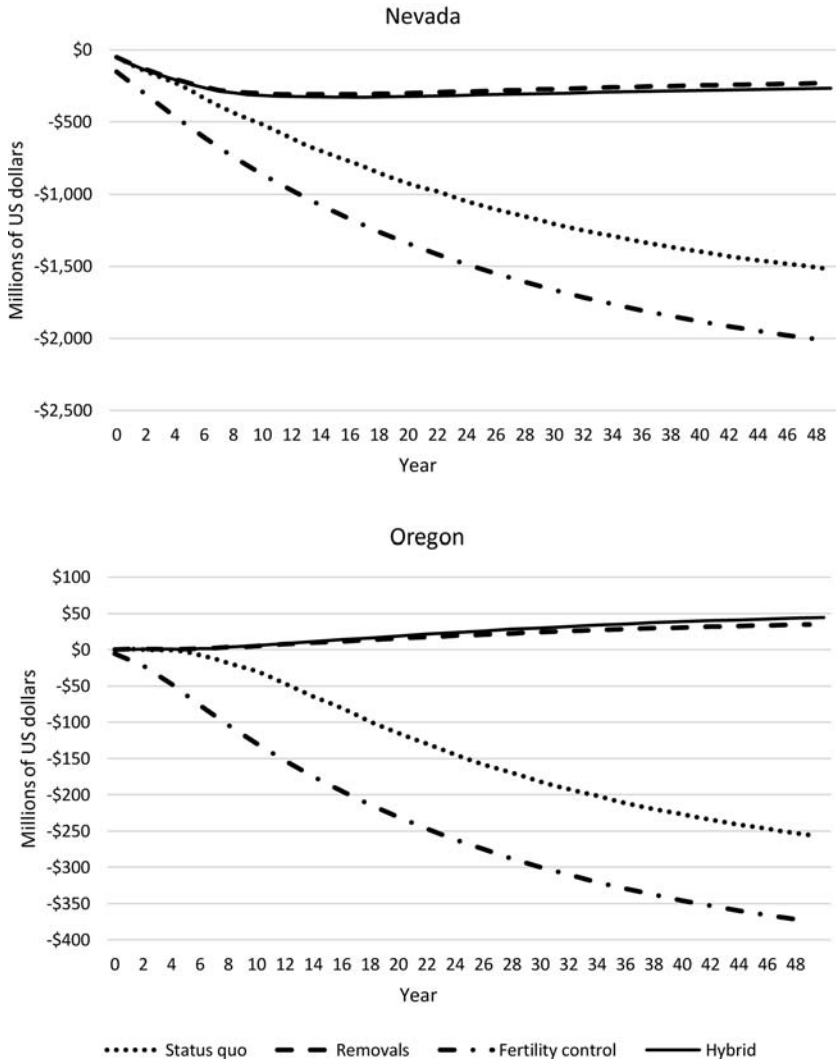


Management Simulations

Horse Removal

The Nevada and Oregon optimal removal scenarios involve an initial reduction of the population to a steady-state equilibrium. In Oregon, the optimal program involves five years of intensive removal effort at or near $Y^{\max}$. At steady-state equilibrium, 450 horses are removed from the range each year to maintain a population of 2,250 horses and a holding inventory of 4,050 horses. The 50-year cumulative NPV of the Oregon optimal removals program is –$34.7 million, a savings of $290.1 million compared to the status quo scenario. Similarly, the optimal removal program in Nevada involves intensive removals over the first eight years of management. Following the initial population reduction, a steady-state management regime commences where 2,000 horses are removed annually to maintain the population at 11,000 and the holding inventory at 28,000. The 50-year cumulative NPV of optimal removals in Nevada

FIGURE 2
Population and Holding Inventory Paths for Oregon Simulations



is –$230.1 million, a savings of $1.3 billion over that period compared to the status quo scenario.

As a check to the dynamic programming solutions, optimal steady-state values for removals, population size, and holding inventory were derived numerically using the discrete-time maximum principle (Canon, Cullum, and Polak 1970). While minor differences in the solutions occur due to rounding errors, the numerically derived steady-state values verify the dynamic programming solutions.[5]

The optimal management scenario results yield insights into the trade-offs involved in maximizing population benefits over time. The absolute gather constraint is binding while the populations are reduced in the initial

[5] The steady-state values derived using the maximum principle are as follows: $X_{SS}^{NV} = 10{,}141; I_{SS}^{NV} = 28{,}242; Y_{SS}^{NV} = 2{,}171; X_{SS}^{OR} = 2{,}175; I_{SS}^{OR} = 4{,}163; Y_{SS}^{OR} = 466$.

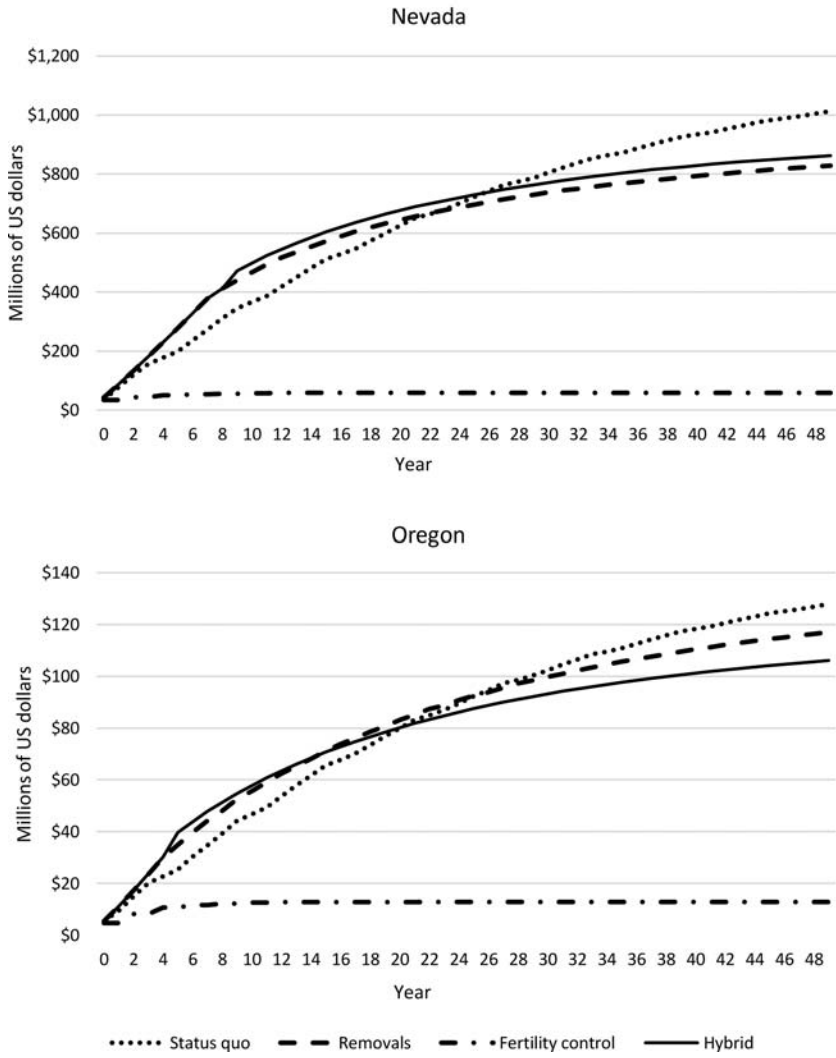


FIGURE 3
Cumulative Net Present Value Net Benefits of Management Programs

periods (i.e., $Y_t = Y^{\max}$). Whereas the removals optimization problem does not meet the sufficient conditions for bang-bang control defined by Spence and Starrett (1975),[6] the removal simulations suggest the optimal management path is indeed to approach a steady state as rapidly as possible. At the optimal steady state, neither the Oregon nor the Nevada optimal removals program is bound by the gather constraints imposed on the model (i.e., $Y^{SS} < \min\{Y^{\max}, \delta X^{SS}\}$). Thus, while the gather constraints regulate the speed with which the population is reduced to steady state, they do not constrain management in optimal steady-state equilibrium.

[6] The Nevada removal model specifies nonlinear gather costs in Y. Both state removal models specify setup costs and stock-dependent variable costs that violate the sufficient conditions of quasi-concavity and separability, respectively.

FIGURE 4
Cumulative Net Present Value of Wild Horse Management Costs

The management costs incurred over a single fiscal year in the optimal removals steady state are higher for the larger Nevada population ($22.4 million) than they are for the smaller Oregon population ($4.3 million). Likewise, in steady state, the larger Nevada population yields higher annual net benefits ($32.8 million) than the Oregon population ($6.9 million). The annual value of net program benefits from optimal removals in steady state is $10.3 million in Nevada and $2.6 million in Oregon.

Horse Fertility Control

The NRC report suggested that fertility control alone cannot address the challenges associated with managing western wild horses. The optimal fertility-control scenarios support this sentiment. The optimal fertility-control management program is to undertake fertility control in early management cycles and then to undertake no management once the population grows toward its carrying capacity. In Oregon, the optimal fertility-control

TABLE 3
Optimal Two-Year Management Cycles at the Steady State (Millions of U.S. Dollars)

Difference	− 2.7%	− 23.8%	31.4%

[a] Includes costs of off-range holding. For discounting purposes, $t = 0$ in the first year of the optimal management cycle, and $t = 1$ in the second year.

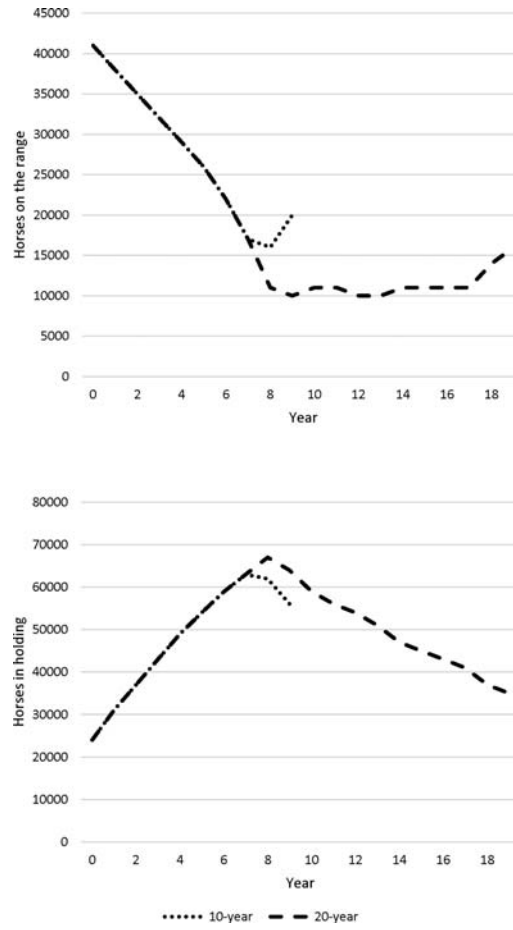
program is to treat around 600 females for the first three cycles and then cease fertility control in all subsequent periods. The optimal fertility-control program in Nevada is to treat 3,940 females in the first period and then undertake no further management actions. Without management, the horse populations grow to their carrying capacity (K) and remain at that level for the duration of the management horizon. The inventory of horses in holding declines to zero deterministically in all of the fertility-control scenarios. Intuitively, it is impossible to reduce the population with fertility control alone given the model gather constraints. Thus, after slowing growth in the initial period(s), it is optimal to just let the populations grow to their carrying capacity instead of applying costly fertility control. Because horse populations are not effectively managed in the fertility-control scenarios, subsequent discussion focuses on the removal and hybrid methods.

Hybrid Management

Fertility-control alone is not a viable population management strategy. The hybrid management scenarios explore the efficacy of fertility control when applied in tandem with horse removals. The hybrid scenarios begin with intensive removals over successive years until the state population is brought within the AML range. Next, a program of fixed removals with optimally chosen fertility-control effort ensues on a two-year cycle. Fixed removals are undertaken at the lowest possible level subject to maintaining a stable population below carrying capacity in the long run. When implemented in concert with removals, fertility control helps stabilize the horse population by decreasing the intrinsic rate of growth. The Nevada hybrid scenario involves nine years of intensive removals followed by a steady-state gather program that stabilizes the population at 12,000. The steady-state program involves gathering 5,750 horses biannually, of which 3,750 are removed and 1,000 are treated with fertility-control agents. Adoptive homes are found for 150 of the removed horses and 3,600 go to long-term holding facilities. A steady-state inventory of 28,000 horses is maintained in holding facilities. The hybrid program in Oregon involves six years of removals followed by a biannual steady-state management program that maintains a pregather population of 2,250 horses. The program involves gathering 977 horses every other year, including 677 removals and 150 horses treated with fertility control. In Oregon, 392 of the removed horses are adopted and 285 are sent to long-term holding facilities. A holding inventory of 2,100 horses is maintained in the steady state.

The NPV costs and benefits of the optimal removal and hybrid management programs over a two-year cycle are presented in Table 3. The steady-state NPV management costs of a two-year hybrid management cycle in Nevada are $46.1 million, an increase of 4.8% compared to the NPV costs removals over the same time period. In Oregon, the NPV of steady-state hybrid management over a cycle is $6.4 million, which represents a 23% re-

duction compared to removals. In terms of program net benefits, a cycle of steady-state hybrid management yields NPV $18.0 million in Nevada and $6.7 million in Oregon. Compared to optimal removals in the steady state, hybrid management decreases two-year net program benefits by 11.3% in Nevada and increases net program benefits by 31.4% in Oregon. The superior performance of the Oregon hybrid scenario is related to Oregon's higher adoption demand, which facilitates a lower steady-state holding inventory.



Time-Horizon Sensitivities

A long-term time horizon is appropriate for capturing the economic impact of wild horse management decisions because removals in the current period result in holding costs for the life span of removed horses. In practice, however, land managers may base their management decisions on shorter time horizons, due to budgetary constraints, management uncertainties, or other factors. Additionally, the models assume that specified parameters remain constant over time, and setting a shorter time horizon makes this assumption more likely to hold. The Nevada removals models were solved under 10-year and 20-year time horizons (i.e., $T = 10$ and $T = 20$) to explore how shorter time horizons influence optimal management. The optimal population and holding inventory paths from these simulations are shown in Figure 5. The paths suggest that even when considered under a shorter time horizon, it is optimal to reduce the population rapidly in the early periods to avoid incurring costs (i.e., negative net population benefits) associated with a larger population. The population uptick at the end of the shortened time horizons occurs to satisfy the terminal condition.

Removals under Cost Minimization

Allowing horse populations to become self-limited can reduce population growth rates, and potentially reduce the number of horses removed and sent to holding compared to current management. On the other hand, larger populations grow from a bigger base and thus produce more horses annually for a given growth rate. If managers determine

FIGURE 5
Optimal Paths for Removal Management in Nevada under Alternate Time Horizon

horse populations should not exceed some maximum level, the question arises as to whether it is cost-effective to maintain self-limited populations just below the threshold, or if it is less costly to maintain smaller, but faster growing populations. To explore this question, the next section examines optimal horse removals under a cost minimization objective, where the net population benefits term is dropped from the objective function. Dropping $B(X)$ from [1] and imposing a maximum population constraint frames management decisions in terms of cost-effectiveness, where management costs are minimized subject to maintaining the horse population under some ceiling.

The cost-effectiveness scenarios were run for optimal removals management in Nevada. If the maximum population constraint is set above 50,000, or roughly 80% of carrying capacity, then it is cost-effective to actively manage a large population at the constraint. If the maximum population is set below this level, then it is cost-effective to manage a population of 11,000 horses, the optimal steady-state solution to the model in equation [1].

VI. DISCUSSION

Dynamic, benefit maximizing models of wild horse management were developed for three nonlethal population control methods using published research on wild horse population biology and expenditure data from the BLM. The optimal model solutions were compared to each other and to a scenario that represents status quo management. Finally, optimal removal models were simulated with shorter time horizons, and with a cost-minimization objective to assess the cost-effectiveness of maintaining populations under a specified level.

The model simulation results provide evidence of how to undertake state-level horse management to maximize benefits for stakeholders. Importantly, the results indicate that societally efficient management programs involve an initial reduction of state horse populations from their 2015 levels. This result is robust to the time-horizon specifications, and to the cost minimization specifications where the maximum population is set less than 80% of carrying capacity. The upshot here is that even in the face of costly removals and holding, efficient management involves reducing populations from current levels and maintaining them within their AML ranges. Moreover, the removal and hybrid management simulations suggest that with current technology nonlethal wild horse management requires maintaining off-range populations comparable to, or greater than, the on-range populations.

A second takeaway from the results is that, as defined, fertility control alone is not an effective method for managing horse populations. The reason is that nearly all of the mares must be effectively treated to reduce horse populations using fertility control only. Further, the gather constraints imposed by the model make reducing or stabilizing horse populations with fertility impossible. If all mares in the population could somehow be effectively treated in each period, fertility control has the potential to slowly reduce the population at the mortality rate. However, it is unlikely all mares could be treated, and even if they could, fertility control would not produce a significant population reduction over the short term.

While fertility control alone is not an effective population management strategy, the hybrid management results indicate that fertility control can reduce the total number of horses removed from the range while maintaining comparable management costs and net program benefits. At the optimal steady state, for example, there are 6% fewer horses removed over each two-year hybrid management cycle compared to optimal removals in Nevada, and 25% fewer in Oregon.

When framed in terms of cost minimization, the models yield the cost-effective solution for keeping populations under some specified maximum level. For removals in Nevada, it is cost-effective to reduce populations and maintain them at the base model steady state unless the population constraint is set above 50,000, or roughly 80% of carrying capacity. Thus, maintaining small populations that are not resource limited is less costly than managing large, resource-constrained populations unless the large populations are near the carrying capacity. Further, managing medium-sized populations is costly because many horses need to be removed to stabilize fast-growing populations that are not resource limited.

As shown in Figure 4, cumulative NPV management costs are higher in the optimal scenarios than in status quo management until at least the twentieth management year across scenarios. Thus, realizing the gains associated with optimal management requires enduring higher initial management costs in return for greater population benefits and lower management costs in the future. Furthermore, while the optimal scenarios involve intensive management in the initial periods, the status quo scenario is the most intensive manage-

ment method across the 50-year management horizon. In the Nevada status quo scenario, over 280,000 horses are taken to long-term holding facilities across the management horizon, compared to around 175,000 with optimal removals and 170,000 with hybrid management.

Overall, the simulation results show that significant economic gains can be realized with a more strategic approach to wild horse population management. Relative to the status quo scenario, the results indicate that implementing optimal removals or hybrid management would result in 50-year NPV program savings of $1.3 billion in Nevada. Undertaking optimal hybrid management would save $300 million compared to the status quo in Oregon. Realizing these savings, however, is a matter of incurring short-term costs to realize future benefits.

Separate models were developed for Nevada and Oregon, and comparison of the results across states yields additional management insights. Oregon contains almost 3 million HMA acres compared to 14 million in Nevada. Likewise, the Oregon models specify a smaller carrying capacity, AML, and initial population to carrying capacity ratio compared to the Nevada models. Adoption demand is greater in Oregon than in Nevada despite Oregon having a much smaller horse population. This allows Oregon to send a smaller proportion of removed horses to long-term holding. These state-specific management differences reflect the difficulties inherent in managing the large Nevada population of horses. Though the larger Nevada population yields nearly five times the population benefits at the optimal steady state, Oregon yields greater 50-year program benefits due to the high costs of managing the Nevada population.

Implementing the optimal management programs identified in this study would require allocating additional resources to the WHBP to fund intensive removals in the early periods and associated increases in the horse-holding inventory. The BLM currently has capacity for around 32,000 horses in long-term facilities. Implementing the optimal management programs would require temporarily increasing that capacity to around 70,000 to handle the Nevada population alone (Nevada's horse population represents roughly half of the overall wild horse population in the west.) Securing the resources to implement these programs would surely be challenging. However, the model results suggest that the investment would yield benefits that outweigh the costs.

While the models developed in this article represent a step toward understanding the economic consequences of alternative wild horse management regimes, they also have some notable limitations. First, the models do not capture potentially significant heterogeneity in biological and economic parameters across the state. More granular models may increase overall precision and provide guidance regarding how to best allocate management effort among state HMAs. Second, the models implicitly assume that specified economic and biological relationships remain constant across time. Aside from uncertain shifts in preferences or management costs, horse habitats are likely to change in the future due to climate change. In the Great Basin, where most of Oregon's and Nevada's wild horses reside, climate change is expected to increase overall precipitation, but also increase interannual precipitation variability. In summer, stream flows are expected to decline (Chambers 2008), which could have limiting impacts for wild horse populations. Beschta et al. (2013) suggest that reducing wild horse grazing is a prudent policy for mitigating the expected effects of climate change on western public range lands. Future research efforts could incorporate emerging climate science and related ecosystem impacts into horse management models. Despite its limitations, this article presents significant evidence that current wild horse management is inefficient, and that significant efficiency gains are possible if management actions are undertaken strategically.

APPENDIX: HYBRID POPULATION CONTROL

$$\max_{\{Y_t\}} \sum_{t=z+1,z+3,z+5,\ldots}^{\infty} \rho^t \big[B(X_t)+\rho B(X_{t+1}) - C^{g}(Y_t+q) - C^{fc}(Y_t,HMA) - C^{I}(I_{t-1},X_t,q) - C^{TR}(X_t,q) - C^{MISC}(X_t,q) - 2CADPT\gamma - SC\big], \quad [A1]$$

Effects of Ovariectomy and Season on Plasma Luteinizing Hormone in Mares

M. C. GARCIA, O. J. GINTHER

Endocrinology, Volume 98, Issue 4, 1 April 1976, Pages 958–962, https://doi.org/10.1210/endo-98-4-958
Published: 01 April 1976 **Article history** ▾

Six pony mares were ovariectomized (OVX) on day 16 of diestrus during June and July, 1972, to study short term changes in plasma luteinizing hormone (LH) concentrations. Plasma LH was higher ($P < .05$) 3 days after OVX (1.76 ng/ml) than the day after OVX (1.01 ng/ml), and a gradual increase occurred over the first 2 weeks. Elevated plasma LH concentrations similar to mid-estrus levels were present from the 2nd to 11th week post-OVX.

In another experiment, the same 6 OVX mares were bled once a month from February, 1973, to January, 1974, to study long-term changes in plasma LH in relation to the anestrous (November-April) and breeding seasons (May-October). Mean monthly plasma LH concentrations in OVX mares during all months of the anestrous season were lower ($P < .05$) than mean monthly plasma LH during the months of June-September of the breeding season. During the transition from anestrous to breeding seasons (April, May) and breeding to anestrous seasons (October, November), mean plasma LH concentrations were not significantly different between April and May (1.39 us 1.84 ng/ml) and between October and November (3.02 vs 2.56 ng/ml), but April and May levels were lower ($P < .05$) than October and November levels. Mean monthly plasma LH levels in OVX mares during the anestrous season were similar to those in intact mares during the anestrous season and at mid-diestrus during the breeding season. Mean monthly plasma LH levels in OVX mares during the breeding season were similar to plasma LH levels at mid-estrus in intact mares.

These data indicate the presence of inhibitory (most likely progesterone) and stimulatory (most likely estrogen) influences from the ovary which modulate the endogenous LH pattern in mares during the breeding season. (*Endocrinology***98**: 958, 1976)

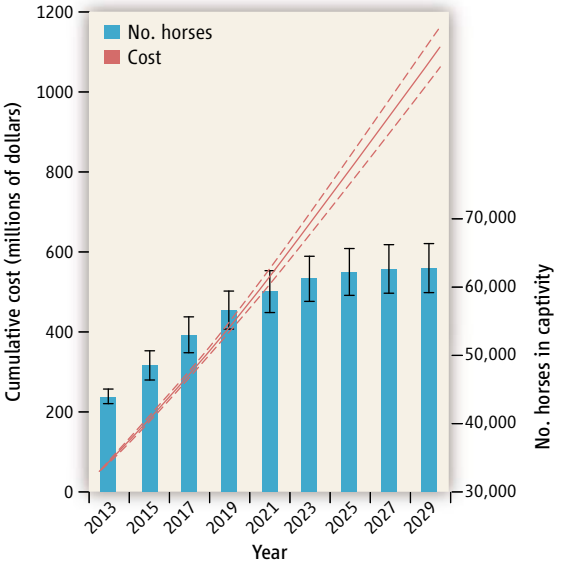
CONSERVATION

A Critical Crossroad for BLM's Wild Horse Program



Captive wild horses will cost the United States over $1 billion by 2030 unless management approaches change

Robert A. Garrott,[1]* and Madan K. Oli[2]

Although horses evolved in North America, they went extinct 10 to 12 thousand years before the present. Spanish conquistadors returned domestic horses to the continent in the mid-1500s, and since then, domestic horses have escaped captivity and also were purposefully released onto western rangelands where they thrive today. Most free-roaming horse populations are managed primarily by the Bureau of Land Management (BLM) of the U.S. Department of the Interior (*1*).

In 1971, the Wild Free-Roaming Horses and Burros Act (*2*) was passed, which establishes public ownership of free-roaming horses and instructs federal agencies to "protect and manage" horses as "an integral part of the natural system of the public lands." The act mandates that BLM and other federal agencies monitor horse numbers, determine appropriate population levels, and remove excess horses from public lands "to preserve and maintain a thriving natural ecological balance." However, at present, tens of thousands of horses are not living the life of "wild mustangs" as Congress intended in passing the Wild and Free-Roaming Horses and Burros Act; instead, they have reverted back to the status of captive, domestic livestock, and the cost of the captive horse program is increasingly unsustainable.

The BLM currently reports ~33,000 free-roaming horses in the western United States. The WHB Program has 179 designated Herd Management Areas, with population objectives for each, and an aggregate maximum goal of 23,622 horses (*3*). Since its inception, the WHB Program has been embroiled in controversy over appropriate population goals, management activities, and the accuracy of its estimates of population size and growth rates (*4*–*7*). The BLM monitors numbers using aerial surveys and captures and removes horses from rangelands when horse numbers exceed target population size. As of 2012, BLM has removed >195,000 horses from public lands under this program (*3*). The act requires BLM to place removed horses into "private maintenance and care for which … an adoption demand exists," with unadoptable, old, and excess animals, beyond the adoption demand, either sold or "destroyed in the most humane manner possible" (*2*). The number of horses BLM removes from public lands routinely exceeds adoption demand (*8*). However, because of pressure from horse advocates, administrative directives and congressional appropriation bills prohibit killing healthy horses (*9*); therefore, BLM is left with large numbers of captive horses that must be maintained indefinitely.

Projections of U.S. captive wild horses and costs (with 95% confidence intervals). (see SM for more details).

These policies have led to a complex and costly system for maintaining captive horses. Horses removed from public lands are processed in short-term holding facilities similar to cattle feed lots and held for several months or more. Many mature females are pregnant when captured and foal in the facilities, which adds to the captive population. Most adult males are castrated. Horses can be adopted from the short-term holding facilities, and some are removed through deaths, sales, or release back onto public lands. Excess animals are eventually transferred to private pastures, primarily in the Midwest, that are contracted as long-term holding facilities. Although small numbers are sold, horses typically remain in these facilities until they die of natural causes. Currently, the ~45,000 horses in captivity exceeded the estimated 33,000 free-ranging horses on public rangelands (*3*).

In a recently released National Research Council (NRC) report (*7*), a committee of 14 scientists concluded that, left unmanaged, horse numbers on public lands would triple every 6 to 8 years until food and water became limited. Under these conditions, horses would be in poor health, reproduction would be suppressed, and deaths from starvation and dehydration would become common, with mass mortality events possible during periods of drought. High horse populations and limited resources would also degrade rangelands, which would affect all native species and public uses of these lands. Thus, although the NRC committee concluded that BLM must actively manage wild horse populations, it asserts that continuing "business as usual" will impede effective management of wild horses on public lands and recommends management changes to put the WHB Program on a more sustainable course (*7*).

Although the NRC report focused on scientific issues, a major impetus for changing the WHB Program is the escalating costs of maintaining increasing numbers of horses in captivity. The WHB Program budget grew from $19.8 million in 2000 (*10*) to $74.9 million in 2012 (*3*). More than 60% of the 2012 budget was used to maintain captive horses, 11% expended to capture and remove animals from public lands, and 10% for adoption programs (*3*). To inform the policy debate, we extend the implications of the NRC report to provide a projection of the captive horse population and associated costs if current policies and management approaches continue.

*Corresponding author. rgarrott@montana.edu

The Consequences of Business as Usual

We used records of the sex and age of 165,459 horses removed from public lands and placed in captive facilities between 1990 and 2011 to develop demographic projections and associated costs (see the chart) (Fig. 1) [see supplementary materials (SM) for details]. We made two basic assumptions. First, we projected the life span of 33,946 unadoptable horses currently in long-term holding facilities. Under this scenario, BLM will accrue 366,846 horse-years of maintenance costs over a 30-year period before all animals currently in captivity die. Given that $45.9 million was budgeted to maintain 42,835 horses in captivity during 2011 (*10*), annual per-horse maintenance costs would be ~$1074. Thus, the 30-year cost of maintaining horses currently in long-term holding facilities would be ~$394 million ($449 million with 2% annual inflation).

Second, we assumed the current management program would continue, with a mean of 9412 horses in short-term holding facilities and 3803 horses transferred annually to long-term holding facilities. Expenses would be ~$1.1 billion between 2013 and 2030, and annual costs thereafter would be $67 million. Although some citizens may support such expenditures, these projections reinforce assertions (*7*, *8*) that BLM's current approach to managing horse numbers is not sustainable.

A Way Forward

Over 30 years of research on contraceptive agents for feral horses have resulted in the development of effective vaccines that prevent pregnancy in both captive and free-ranging mares for 1 to 3 years (*7*). Experimental application of these vaccines has contributed to the control of a small horse population on an Atlantic Coast barrier island, and limited experiments on western horse herds have also produced encouraging results. The Environmental Protection Agency recently sanctioned two contraceptive vaccines, which enables their routine use for horse population management on western rangelands (*7*). The average life-expectancy of horses entering long-term holding facilities is about 15 years (see SM). Therefore, every horse that does not enter long-term holding facilities would save, because of contraceptive application, $16,110 in maintenance cost (or savings of $1 million for every 62 horses), not considering the modest cost of contraceptive application.

Uncertainties exist when attempting to deliver vaccines to large numbers of horses. Although concerns have been raised regarding behavioral, physiological, and demographic consequences of contraceptive vaccines, none of these concerns preclude their use for managing rapidly increasing populations (*7*). The level of reduction in population growth that can be realistically attained for western horse herds through application of contraceptive vaccines remains unclear. Large-scale management experiments, perhaps within an adaptive management framework, would help address some of this uncertainty (*11*).

We estimate that the typical 15 to 20% annual population increase of western horse herds (*7*) could be halved by means of contraceptive vaccines. If a gather-and-removal effort reduced the western horse population to the BLM's goal of 23,622 horses and aggressive contraception treatment was initiated, then BLM need only remove 2000 to 3000 horses annually to maintain its goal. The number of horses annually removed would then more closely match adoption demand and that would minimize or eliminate the need for long-term maintenance of unadopted animals.

Although broad-scale use of contraceptives can help reduce the number of horses that BLM must remove to control populations, it is not a panacea. Current contraceptive vaccines are most effective when hand-injected, and remote delivery of vaccines via dart is impractical for most free-ranging horse populations (*7*). Accordingly, vaccine delivery will require continuing, and perhaps increasing, the frequency of horse captures. It may also take a decade of experiment and refinement of treatment regimens and contraceptive methods to scale-up management to include the entire population of horses on western rangelands. Furthermore, most populations already exceed management objectives, and population modeling efforts indicate that current contraceptives can only reduce, not stabilize or reverse, population growth. Thus, even with the changes suggested by the NRC report, BLM must continue removing horses from public lands for the foreseeable future.

It is up to society to decide how they want their government to manage wild horses, how many wild horses should be accommodated on public lands, what should be done with excess horses, and how much they are willing to spend. The debate has gone on for many decades; however, we are at a critical juncture. BLM recently announced that because of funding constraints and lack of additional capacity for maintaining captive animals, it will substantially reduce scheduled removals of horses from public lands this year. This decision has been made despite worsening drought conditions that are causing severe shortages of forage and water for horses, wildlife, and livestock (*12*). Terminating or reducing active management will lead to a rapid increase in the number of horses, further exacerbating resource limitations.

The current situation in Australia provides a sobering view of what might be in store for western rangelands in the United States if the current management dilemma is not resolved. The wild horse population in Australia is estimated to exceed 400,000 animals (*13*), and severe drought conditions in central Australia have reportedly forced government agencies to propose shooting 10,000 horses from helicopters to reduce animal suffering and environmental degradation (*14*). One can only hope that there is the political will to change current policy and place BLM's WHB Program on a more sustainable trajectory.

LIMITATIONS OF MALE-ORIENTED CONTRACEPTION FOR CONTROLLING FERAL HORSE POPULATIONS

ROBERT A. GARROTT, Department of Wildlife Ecology, University of Wisconsin, Madison, WI 53706
DONALD B. SINIFF, Department of Ecology, Evolution, and Behavior, University of Minnesota, Minneapolis, MN 55455

Abstract: We developed a computer program to simulate key features of feral horse (*Equus caballus*) population dynamics and breeding cycles because of the continuing controversy over male- versus female-oriented contraceptive approaches to population management. We used the program to investigate the potential efficacy of male-oriented contraception as a population management tool, and to explore the impacts of such programs on the normal seasonal foaling pattern. The treatment strategies we tested included sterilizing only dominant harem stallions and sterilizing males without regard to their social status. Sterilizing only dominant harem stallions resulted in relatively modest reductions in population growth. Substantial reproduction may occur even when 100% of the dominant harem stallions are sterilized if other males perform as little as 10% of the breeding. The long breeding season allows mares to cycle 6–10 times if not successfully bred and provides many opportunities for mares to breed with males outside the harem. Adequate suppression of population growth may be attained only if a large proportion of all males in the population, regardless of their social status, could be sterilized. Both treatment strategies resulted in the disruption of the normal seasonal foaling pattern. The foaling season became less synchronized and more skewed toward summer and autumn as the proportion of sterile males in the population increased.

J. WILDL. MANAGE. 56(3):456–464

During the last 15 years there has been considerable interest in controlling feral horse populations in the western United States by inhibiting reproduction with contraceptive devices. From the outset of contraceptive research on feral horses, there has been controversy over whether male- or female-oriented contraceptive approaches were most practical for population management (Natl. Res. Counc. 1982, Turner and Kirkpatrick 1986*a*). Two studies in which dominant harem stallions were sterilized (Turner and Kirkpatrick 1982, 1986*a*; T. C. Eagle et al. unpubl. data) suggested a decrease in foal production, indicating that male-oriented contraception may have promise as a management tool.

We became concerned that applying male-oriented contraception may cause some undesirable changes in the seasonal reproductive patterns of feral horses. Horses have a 340–350 day gestation period and undergo a post-foaling heat approximately 5–15 days after parturition (Ginther 1979). These characteristics essentially lock mares into a relatively fixed yearly reproductive cycle, dictating that if a mare conceives during the post-foal heat she will produce consecutive foals at essentially the same time each year. Horses are polyestrous (Ginther 1979); therefore, if a portion of the males in a population are rendered infertile by some contraceptive technique, the mares bred by these males will cycle and become receptive again. If in-

fertile males continue to breed the mare, she will continue cycling until late summer or autumn when ovarian activity ceases (Turner and Kirkpatrick 1986*b*, Plotka et al. 1989). We hypothesized that if mares cycle throughout the breeding season, there are enough opportunities to breed and conceive even if the probability of mating with a fertile male is small. Each time a mare cycles, she drifts further from the spring breeding season, and the foal will be born later in the season if she is successfully bred. Once out of the normal seasonal breeding and foaling cycle, the yearly cycle of gestation and post-foal heats could make it difficult for the mare to regain seasonal synchrony.

We constructed a computer program that incorporated key features of feral horse population dynamics and breeding cycles. The program then was used to perform simulations to investigate the potential efficacy of male-oriented contraception as a population management tool, and to explore the impacts of such programs on the normal seasonal foaling pattern.

We thank the Bureau of Land Management (BLM) employees in Nevada for access to their data files. T. C. Eagle, E. D. Plotka, T. M. Pojar, and J. R. Tester reviewed early drafts of the manuscript, and L. L. Eberhardt provided advice during program development. Funding for this project was provided by BLM contract USDI-AA852-CT5-29.

METHODS

Defining the Foaling Season

We obtained information on the normal foaling season of feral horses from records of horses removed from BLM lands in Nevada between 1979 and 1987. Of the 33,521 horses captured during this time, 5,993 animals were judged to be foals (Garrott 1991*a*). The age of 4,678 of the foals was estimated to the nearest month based on the eruption patterns of incisors (Am. Assoc. Equine Practitioners 1981). The birth month of these foals was estimated by back dating to develop a histogram of the seasonal foaling pattern. Most foals are born between April and July; however, foaling may occur throughout the year (Fig. 1). Because the criteria used to estimate the ages of foals was not precise and aging errors undoubtedly occurred, the histogram derived from these data must be considered an approximation of the true foaling distribution. However, because our derived foaling distribution (Fig. 1) approximates observations from field studies (Feist and McCullough 1975, Boyd 1979, Keiper 1979, Berger 1986, Kirkpatrick and Turner 1986), we assume it adequately represents the seasonal foaling pattern. Because mares enter estrus soon after foaling (Ginther 1979), we also assume these data represent the normal seasonal breeding pattern. We fit a cosine curve to the foaling data (Fig. 1), emulating the asymmetry in order to create a frequency distribution that could be used in the model to randomly assign each mare a foaling date. The limited reproduction occurring between November and February (3%) was ignored.

Development of the Simulation Program

The simulation model was comprised of 2 principal components, a population model and an annual breeding cycle model for individual mares. The population model, constructed only for females, utilized age-specific fecundity and survival schedules to simulate population growth. Mares were assigned to 1 of 26 age classes ranging from zero (foal) to 25 years old. The number of females in each age class and age-specific fecundity and survival schedules were user-defined. A series of feral horse survivorship and fecundity schedules were formulated by Garrott et al. (1991*b*) using models presented by Eberhardt (1985). We used the F2 fecundity schedule, which was derived from reproductive data compiled for 1,144 mares captured immediately after the foaling season in Nevada (Garrott et al. 1991*a*). The S1 survivorship schedule (Garrott et al. 1991*b*) was used because it represents the only age-specific survival data available for a feral horse population, and was developed from 11 years of data collected on animals in the Pryor Mountain herd in Montana (Garrott and Taylor 1990). The survivorship schedule was converted according to Caughley (1977) to obtain the annual age-specific survival rates required for the population model.

We determined the stable age distribution for these 2 schedules by projecting an arbitrary initial population forward 10 years using a Leslie matrix type model (Leslie 1945). The stable age distribution was used to calculate the number of mares in each age class for an initial population of 1,000 animals. No density-dependent

mechanisms were incorporated into the model, creating a population growing geometrically at a rate of approximately 21% annually. Many feral horse herds throughout the western United States have grown at annual rates of 15–27% (Garrott et al. 1991*b*); thus, the demographic characteristics in this model reflect typical feral horse populations.

The social structure of feral horse populations has an important influence on breeding and, hence, the efficacy of any contraception program. The primary social unit is the harem group, which is composed of mares and their young from the previous 1–2 reproductive seasons, a dominant stallion, and an occasional subdominant male. All females are normally associated with a harem, with bachelor males forming loose aggregations (Feist and McCullough 1975, Miller 1979, Berger 1986). Although harem stallions attempt to maintain exclusive access to mares for breeding, some mares are bred by other males (Nelson 1978, Miller 1979, Bowling and Touchberry 1990). This social structure suggests 2 treatment strategies that could be used in a male-oriented contraception program: sterilization of only dominant harem stallions (Turner and Kirkpatrick 1982, 1986*a*; T. C. Eagle et al. unpubl. data) or sterilization of a proportion of all males regardless of their social rank. The degree of population control that can be attained by sterilizing males will be dependent upon which of these 2 strategies is employed, the proportion of males treated, the probability a mare will breed with her harem stallion, and the probability of mating with a treated male if the mare breeds outside the harem.

We constructed the model to allow the user to define whether sterilization would be applied to only harem stallions or to all males, the proportion of males that were treated, and the probability that a mare will breed with her harem stallion. We assumed that treatments were applied randomly and that all males in the population had equal access to mares breeding outside of the harem structure. Therefore, in simulations where a proportion of all males were sterilized, the probability of mating with a sterile male, if a mare bred outside the harem, was equal to the proportion of males sterilized. For simulations where only dominant harem stallions were sterilized, this probability was not only dependent on the proportion of harem stallions sterilized, but also on the proportion of males in the population that were dominant stallions. We assumed a population sex ratio of 82 males/100 females (Garrott 1991*c*) and that an average harem contained 4 mares (Berger 1986).

This content downloaded from 159.189.162.28 on Thu, 9 Oct 2014 16:35:11 PM
All use subject to JSTOR Terms and Conditions

A population of 1,000 mares, therefore, would contain 820 males, 250 of which were dominant stallions. Hence, 0.30 of the males (250/820) in the population would be dominant stallions, and the probability of mares mating with a sterilized male outside the harem can be calculated as 0.30 times the proportion of dominant stallions treated.

The breeding cycle component of the program traced individual mares through the annual reproductive cycle. When the initial population was read into the program, each mare was stochastically assigned a foaling date using the frequency distribution fitted to the Nevada foaling data (Fig. 1). At the start of the annual loop, the program stochastically determined if each mare survived to the beginning of the breeding season. If a mare survived, her age was incremented by 1 year, and a second random number was drawn to determine if she would attempt to breed. The survival and breeding determinations were made based on the mare's age and the age-specific survival and fecundity schedules. For mares attempting to breed, we used the user-defined probabilities previously discussed to determine stochastically if she bred with the dominant harem stallion or outside the harem, and whether her mate was sterile or fertile. If she mated with a sterile male, her foaling date was incremented by 21 days, the average estrous cycle (Ginther 1979), and additional random numbers were drawn to determine if her second mating was within or outside the harem and if her mate was sterile or fertile. This sequence continued until the mare was bred by a fertile male or cycled beyond October, at which time she was assumed to cease cycling and remained barren. If the mare was successfully bred, she was assumed to foal 1 year later. The sex of each foal produced was assigned stochastically, and all female foals were added to the mare population. A new foaling date was drawn from the foaling distribution for all mares that remained barren for a year. This feature of the program allowed any mare that had her annual reproductive cycle altered due to repeated mating with infertile males to reestablish a normal seasonal reproductive pattern.

We conducted each simulation for 10 years and performed 50 repetitions for each treatment. Demographic output included the number of mares in the population at the beginning of the year, the number of mares that died, the number of foals born, and the number of mares in the population at the end of the year. The growth rate of the population was determined using log-linear regression techniques (Eberhardt 1987). Reproductive output included the number of foals born in each month, the number of estrous cycles required for each mare to conceive, and the number of mares that failed to conceive because all matings were with infertile males.

We simulated management programs where only dominant harem stallions were sterilized and programs where males were sterilized regardless of their social rank. For each of these treatment strategies, 3 probabilities of mating with the harem stallion were simulated: 0.70, 0.80, and 0.90; and for each of these probabilities, 12 levels of sterilization were simulated: 0.00, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, 0.80, 0.90, 0.95, and 1.00. Since the model was stochastic, each simulation resulted in unique results; therefore, the results are presented as means of 50 simulations for each of the 72 combinations of treatment strategy, probability of mating with the harem stallion, and the proportion of males sterilized.

RESULTS

Effects of Sterile Males on Population Growth

Results of the simulations indicate that the effectiveness of male-oriented contraception techniques to suppress population growth increased with increasingly severe treatment levels and as the probability of mating with the harem stallion increased (Fig. 2). These trends were evident whether sterilizations were limited to only harem stallions or were applied to a sample of all males regardless of their social rank. The general effectiveness of the 2 treatment strategies, however, was dissimilar. Sterilizing only dominant harem stallions resulted in relatively modest reductions in population growth, while sterilizing a sample of all males in the population severely depressed population growth at the higher treatment levels.

Effects of Sterile Males on the Foaling Season

Our simulations indicated that the normal seasonal foaling pattern of feral horses would be disrupted by introducing substantial numbers of infertile males into the population. As the probability of mating with an infertile male increased, the foaling distribution became more

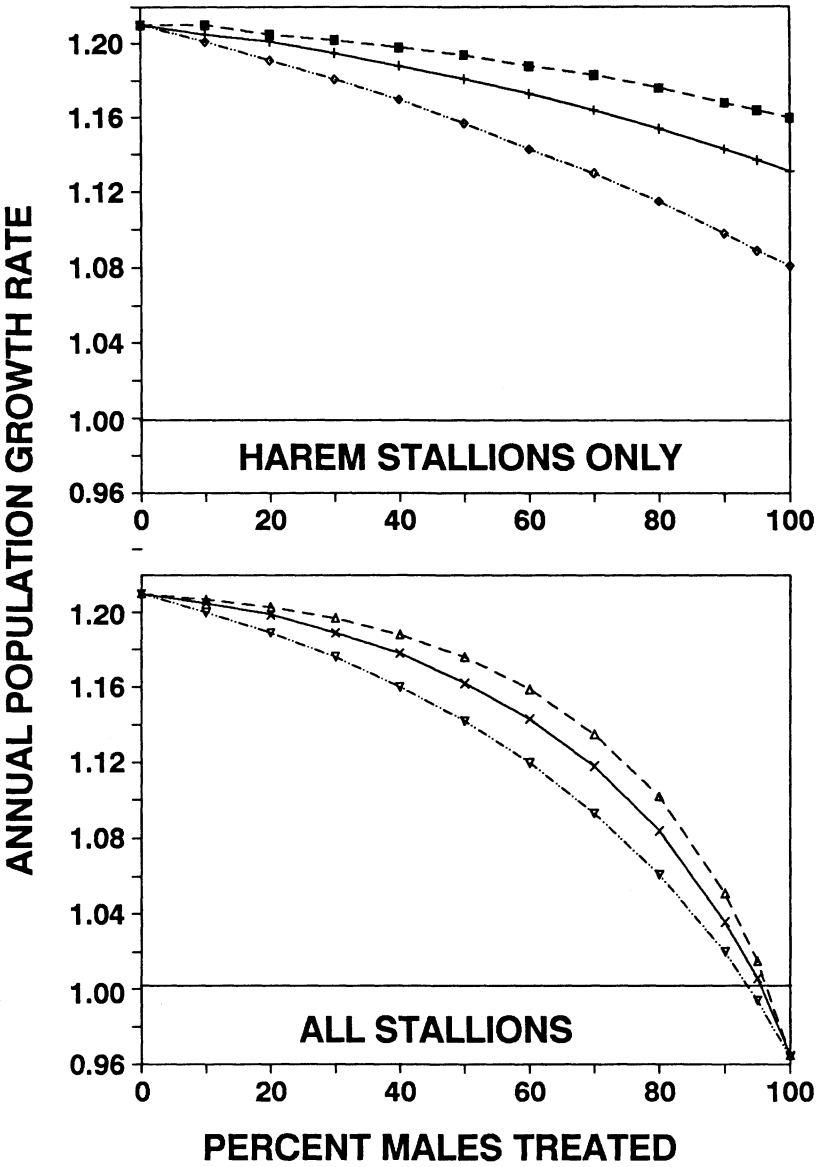

Fig. 2. Comparison of changes in the annual growth rate of a simulated feral horse population subjected to sterilization of dominant harem stallions, and sterilization of males without regard to their social status. Simulations performed assumed the probability of a mare mating with her harem stallion was 0.70 (dashed line), 0.80 (solid line), and 0.90 (dash-dotted line).

flattened and shifted increasingly toward late summer and autumn months (Fig. 3). This disruption was not gradual and occurred during the first foaling season after sterilized males participated in the breeding season. Once the shift in the foaling distribution occurred, it remained relatively unchanged throughout the 10-year simulation (Fig. 3).

Although the shift in foaling seasons was evident for both treatment strategies (sterilizing only dominant harem stallions and sterilizing males without regard to their social status), the magnitude of the shifts differed. In untreated populations, the seasonal foaling distribution used in the model dictated that approximately 8% of the foals were born late in the reproductive season, between August and October. Sterilizing males resulted in a nearly linear increase in the proportion of late-born foals in the simulations where only dominant harem stallions

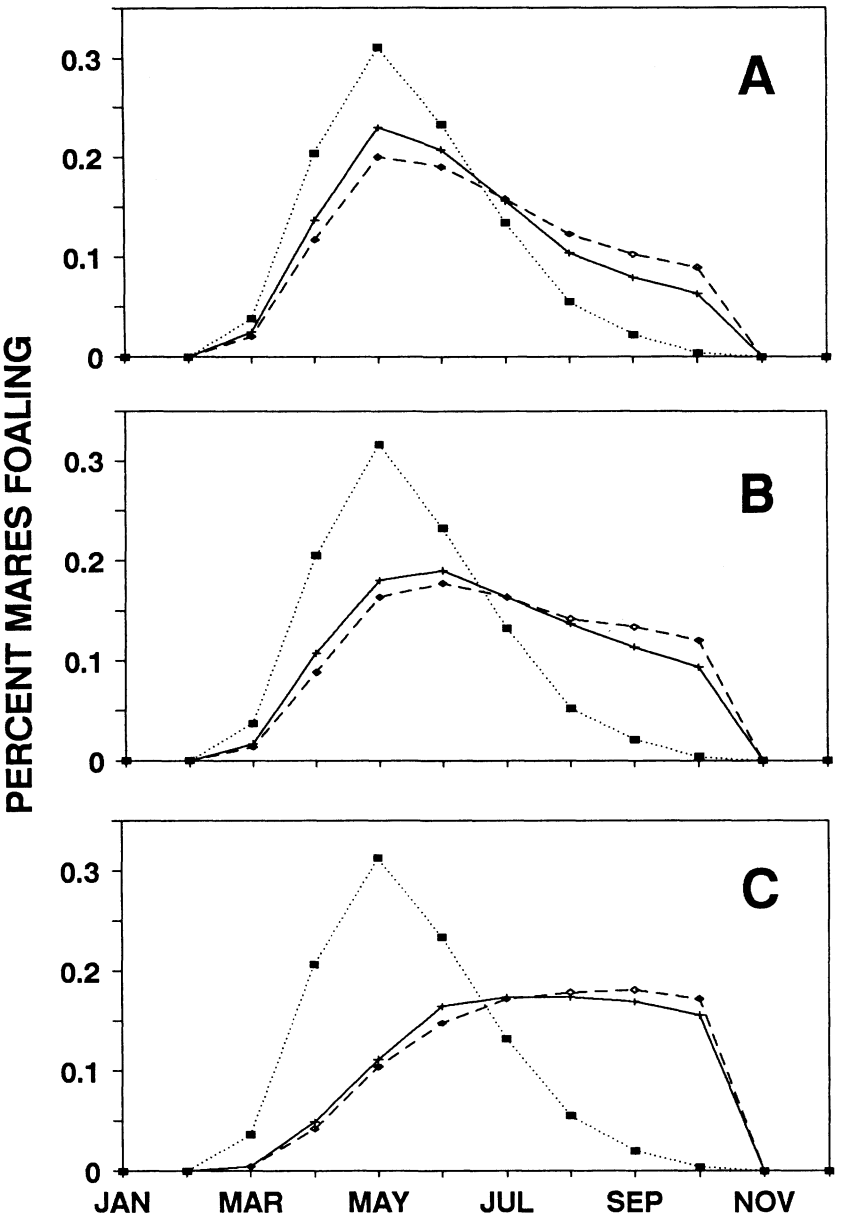

Fig. 3. Temporal changes in the seasonal foaling pattern of a simulated feral horse population when (A) 60%, (B) 80%, and (C) 100% of the dominant harem stallions were sterilized. Dotted lines represent normal foaling distribution at year 0, solid lines are distributions at year 2, and dashed lines are distributions at year 10. Simulations assumed that mares had a 90% probability of mating with their harem stallion during each period of receptivity.

were sterilized. When ≥80% of the stallions were sterilized, 40–50% of the foals were born during the August–October period (Fig. 4). The magnitude of the shift in the foaling season was not as pronounced for simulations where a sample of all males was sterilized. Under this treatment regime, the relationship between the proportion of males sterilized and the proportion of late-born foals was curvilinear with the most severe treatments resulting in 20–40% of the foals being born during the August–October period (Fig. 4).

DISCUSSION

The effectiveness of any male-oriented contraceptive program depends on each female

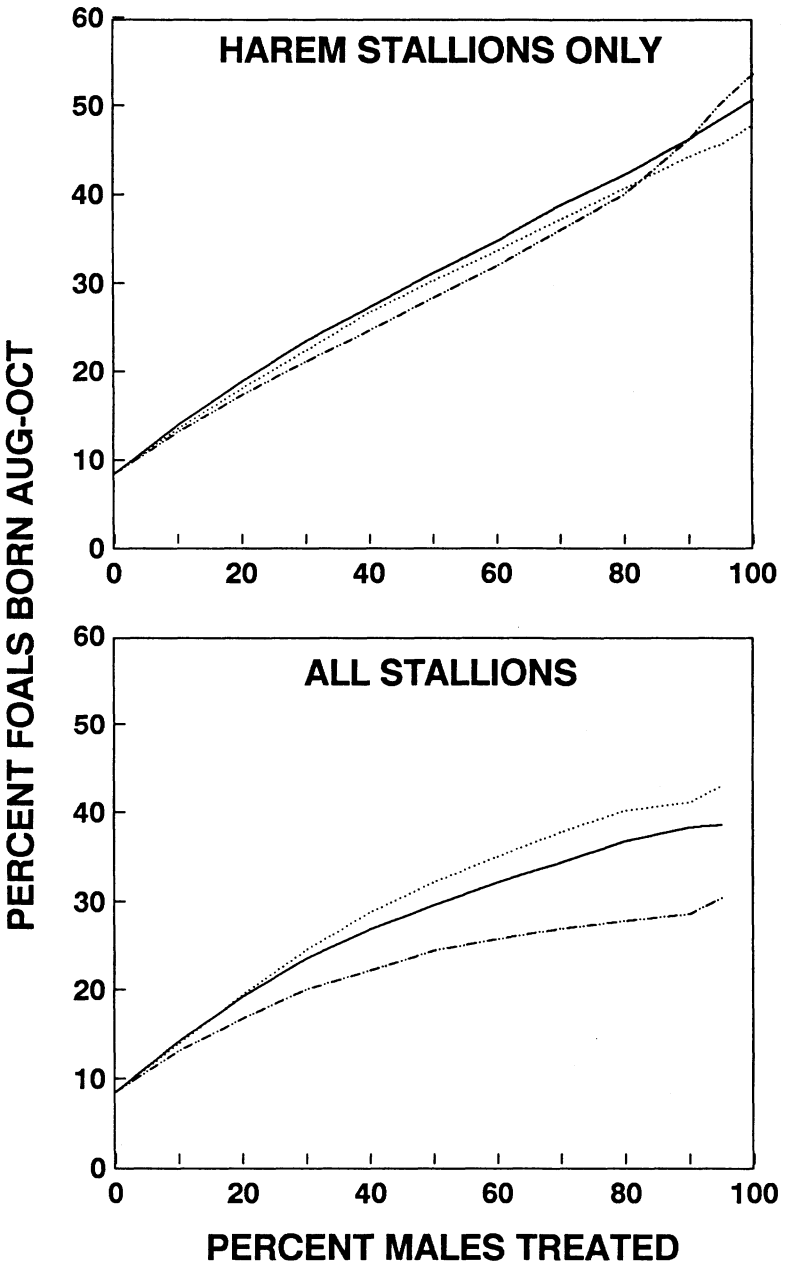

Fig. 4. Comparison of changes in the proportion of late-born (Aug–Oct) foals in a simulated feral horse population subjected to sterilization of dominant harem stallions, and sterilization of males without regard to social status. Simulations were performed assuming the probability of a mare mating with her harem stallion was 0.70 (dotted line), 0.80 (solid line), and 0.90 (dash-dotted line).

mating with an infertile male during all periods of receptivity throughout the March–October interval of cycling. The efficacy of sterilizing only dominant harem stallions, therefore, depends heavily on the ability of the stallions to maintain exclusive breeding access to their mares. Berger (1986) found that dominant harem stallions in the Granite Mountain herd in western Nevada performed nearly all copulations with their mares; hence, in some populations, such regimented breeding may exist. However, several other studies have provided

This content downloaded from 159.189.162.28 on Thu, 9 Oct 2014 16:35:11 PM
All use subject to JSTOR Terms and Conditions

evidence that not all mares in a harem are bred exclusively by the dominant stallion (Nelson 1978, Miller 1979, Bowling and Touchberry 1990).

Our simulation results indicate that significant reproduction may occur even when 100% of the dominant harem stallions are sterilized, if other males perform as little as 10% of the breeding. The long breeding season allows mares to cycle 6–10 times if not successfully bred and provides many opportunities for them to breed with males outside the harem. Our results indicate that a male-oriented contraceptive program will effectively suppress population growth only when a large proportion of all males are sterilized. A potential consequence of introducing substantial numbers of infertile males into the population, however, is disrupted normal seasonal foaling. This shift in the foaling season is caused by the repeated cycling of mares before mating with a fertile male. As the probability of mating with an infertile male increased, fewer mares conceived during their first estrous cycle and increasingly greater numbers of mares did not mate with a fertile male until cycling several times. Because each estrous cycle required 21 days to complete, every time a mare came into estrus and failed to mate with a fertile male, her potential conception date was delayed by 3 weeks, and her foal would be born 3 weeks later in the following summer. Such events were more common when only dominant harem stallions were sterilized because large numbers of fertile males were available for breeding (Fig. 4).

RESEARCH AND MANAGEMENT IMPLICATIONS

Male-oriented contraception is attractive because there is a perception that sterilizing dominant harem stallions, which represent a small proportion of any population, will result in inhibiting reproduction in a large proportion of the mares in the population. Such a concept seems to be more practical and economical than female-oriented contraception where a larger proportion of the population must be treated (Garrott 1991*b*). Some animal welfare groups also appear to favor male-oriented contraception because they believe the techniques may be less intrusive and require treating fewer animals, and therefore, more humane than female-oriented contraception. Although several studies have demonstrated that sterilizing dominant harem stallions can reduce foaling rates of individual harems (Turner and Kirkpatrick 1982, 1986*a*; T. C. Eagle et al. unpubl. data), results of our simulations suggest that such a treatment strategy would not be an effective population management tool. Adequate suppression of population growth may be attained only if a large proportion of all males in the population, regardless of their social status, could be sterilized.

The probable disruption of the seasonal foaling pattern is a potential obstacle to the application of male-oriented contraceptive techniques as a population management tool. Seasonal reproduction has evolved in most temperate animals presumably as a response to the predictable pattern of food abundance and scarcity caused by seasonal climatic changes. Shifting the foaling season toward the summer or autumn months would result in large numbers of relatively young foals entering the winter without adequate forage for themselves and the lactating dams, or adequate body reserves to endure long periods of nutritional stress. The consequences of such conditions would undoubtedly be higher mortality of foals during the winter. Although this would have the effect of reducing population growth, some would question the appropriateness of such a mechanism.

Our simulation program had many limitations and was extremely generalized. Its major weakness was the rigid and relatively simplistic way we modeled behavioral and social mechanisms. These mechanisms undoubtedly influence mating and reproduction in the real world and are much more complex and flexible than the mechanisms we built into the model. Despite these limitations, we think the general conclusions that can be drawn from this exercise are valid and, in many ways, intuitive when one considers some of the fundamental aspects of feral horse reproduction. Our results also may apply to other polyestrous large mammals that restrict their reproduction to specific seasons.

Review of Castration Complications: Strategies for Treatment in the Field

Liberty M. Getman, DVM, Diplomate ACVS

Castration is a commonly performed procedure, but it has a relatively high complication rate. Complications encountered can include post-operative swelling and edema, infection, hemorrhage, eventration, peritonitis, penile damage, and hydrocele. Prompt recognition of a complication and the institution of appropriate therapy are essential for the treatment of these complications. This report reviews treatments that can be performed in the field and indicates the cases that should be referred for more aggressive treatment. Author's address: Department of Clinical Studies, University of Pennsylvania, School of Veterinary Medicine, New Bolton Center, Kennett Square, Pennsylvania 19348; e-mail: libertyg@vet.upenn.edu. © 2009 AAEP.

1. Introduction

Castration is the most common surgical procedure performed by equine veterinarians in the field. Although the surgery is technically easy to perform, the complication rate associated with it is relatively high with 20–38% of horses experiencing a complication.[1,2] Additionally, equine castration complications are the most common cause of malpractice claims against veterinarians in North America.[3] Pre-operative identification of risk factors for the development of complications can ensure that proper measures are taken to reduce these risks. This can help eliminate some complications, but even with appropriate pre-operative evaluation and proper surgical technique, complications can still occur. Therefore, prompt recognition of complications and quick application of appropriate therapy are essential for the treatment of post-operative complications. This may include treatment that can be performed in the field or in some cases, treatment that is best performed at a referral center.

2. Post-Operative Swelling and Edema

Post-operative swelling and edema of the prepuce and scrotal area are the most common "complications" of equine castration, although some degree of swelling develops in almost every horse after castration. This generally peaks 3–4 days after surgery and resolves completely in 10–12 days. Swelling beyond this time or swelling associated with clinical signs such as a stiff gait or reluctance to move or urinate is abnormal (Fig. 1). This is often caused by failure to remove enough scrotal skin, failure to stretch the skin and SC tissue after castration, or inadequate exercise after castration, any of which allows the scrotal incision(s) to close prematurely and excess fluid to accumulate. Older horses are also reported to be more prone to developing excessive edema after castration than younger horses.[4]

Swelling beyond the initial post-operative period is also suggestive of an infectious process, which should be treated appropriately (see below) if suspected. Horses with swelling that is not suspected to be infectious in origin can be treated at the farm

NOTES

Fig. 1. Horse with excessive post-operative swelling and edema after castration.

by establishing drainage and administering non-steroidal anti-inflammatory drugs (NSAIDs). The horse is sedated, the area is aseptically prepared, and the incision is manually opened and stretched using sterile gloves. It is imperative that the owner follow this treatment up by instituting daily (or twice daily) exercise to prevent premature closure of the incision. If left untreated, excessive swelling can lead to the development of paraphimosis, surgical site infection, and dysuria.

3. Infection

Infection is the second most common complication after equine castration; 3–20% of horses are reported to experience this complication.[1,2] Clinical signs can occur anywhere from days to years after surgery, and they include fever, scrotal/preputial swelling, lameness, and incisional discharge. Use of ligatures around the spermatic cord has been associated with a higher risk of post-operative infection.[2,4] Different forms of post-castration infection exist. Champignon, or infection caused by *Streptococcus sp.*, is characterized by the presence of a purulent discharge from the spermatic cord stump surrounded by a mound of granulation tissue. This form was more common historically when non-sterile materials were used as ligatures. Scirrhous cord refers to chronic infection of the spermatic cord stump, typically with a *Staphylococcus sp.* In these cases, the scrotal incision heals, but the infected stump continues to enlarge and abscess; eventually, a draining tract develops. This may take months to years to become evident. The abscessed stump is palpable externally as a firm mound of tissue in the inguinal area (Fig. 2). In some cases, the abscesses can involve the entire spermatic cord stump through the inguinal ring and into the abdomen; in these horses, the abscessed stump can be palpated per rectum as a firm mass.

Any horse with a fever and scrotal/preputial swelling after castration should be treated as a post-castration infection until proven otherwise. Treatment in the field can be successful, especially if it is instituted early. This should consist of opening and stretching the incision using the aseptic technique as described above, lavage of the incision with sterile isotonic fluids (with or without dilute antiseptics), and administration of broad-spectrum antimicrobials. This treatment protocol has been found to be more effective than doing any of the above components alone.[1] The incision may need to be reopened periodically, and exercise should be instituted to prevent premature closure of the wound. NSAIDs should be used for analgesic and anti-inflammatory purposes. It is also advisable to obtain a deep sample from the incision for bacterial culture and sensitivity testing before the administration of antimicrobials to direct future therapy. This can be done after an aseptic preparation of the area around the incision by inserting a sterile cotton-tipped applicator deep into the incision while wearing sterile gloves and then placing it into culture media. Empirical broad-spectrum antimicrobial therapy can then be initiated pending these results. The most common isolate from post-cas-

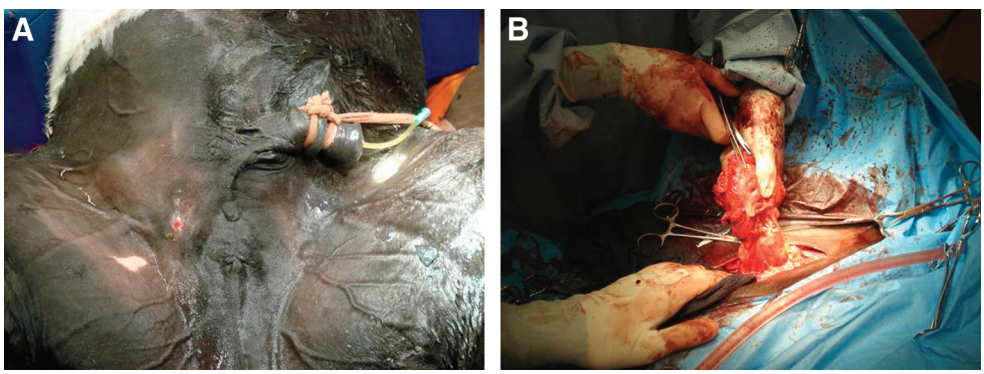

Fig. 2. (A) A pony with a chronic infection of the spermatic cord after castration ("scirrhous cord"). Note the swelling that is represented by a firm mass and the draining tract. (B) Infected spermatic cord stump resected at surgery.

tration infections is *Streptococcus zooepidemicus*, but other bacteria including *Staphylococcus sp.,* Enterobacteriaceae, and *Pseudomonas* are also isolated frequently. In our hospital, oral antimicrobials such as trimethoprim sulfamethoxazole, chloramphenicol, or doxycycline are often used initially with good results; however, if the horse is showing signs of systemic illness, it may be advisable to use broad-spectrum IV antimicrobials such as potassium penicillin or a cephalosporin in combination with an aminoglycoside for initial therapy.

Most infections will resolve with this therapy at the farm if treated early. For those that do not resolve or in cases where signs do not occur until months after the castration, then referral to a surgical center is warranted, because these cases will require surgical resection of the infected tissue for complete resolution. Other cases that warrant referral are those with systemic signs of sepsis or endotoxemia and those where infection with a *Clostridial sp.* is suspected. Although rare, tetanus and botulism can occur in unvaccinated horses, and wound infections with other *Clostridial sp*. can cause necrotizing cellulitis, myositis, and systemic endotoxemia. Infections with any *Clostridial sp.* can result in serious illness and death, and if suspected, these horses should be referred as soon as possible.

4. Hemorrhage

Some bleeding is usual for the first ~5 min after the emasculator is removed (or the horse stands up from anesthesia); however, hemorrhage in the form of a fast drip or a stream beyond 15 min is excessive and should be addressed.[4,5] The most common source of post-castration hemorrhage is the testicular artery; less commonly, the hemorrhage is from a scrotal vessel (branches of the external pudendal vessels) or a vessel within the cremaster muscle. Hemorrhage typically occurs because of improper application or function of the emasculators, including non-perpendicular placement of the emasculators on the spermatic cord, inclusion of scrotal skin within the emasculators, tension of the spermatic cord during emasculation, premature release of the emasculators, and use of emasculators that are too sharp.

Initial treatment can (and should) be performed in the field and is often successful in identifying and eliminating the source of hemorrhage. In the acute situation, the horse should be sedated if it is systemically stable, and the spermatic cord stump should be identified and inspected for the source of hemorrhage. This may require injection of local anesthetic into the stump. If the stump is found to be the source of the hemorrhage, then it should be emasculated again, and a transfixation ligature with large, absorbable suture material[a] should be placed proximal to the emasculator while it is in place for additional hemostasis after its removal. If the stump is retracted too far within the scrotal incision to be emasculated, then it can be grasped with crushing forceps, which are then left in place for 24–48 h. If the source of hemorrhage is determined to be a scrotal vessel, then the vessel should be clamped and ligated routinely. For hemorrhage originating from the cremaster muscle, emasculation and placement of a transfixation ligature should be performed. If the source of the hemorrhage cannot be identified, then the scrotal incision should be packed with sterile gauze packing and sutured closed. Adjunctive therapy with substances that decrease fibrinolysis, such as aminocaproic acid (100 mg/kg, IV), can also be used. Although packing the incision with gauze may provide adequate hemostasis in some cases, referral should be considered if the hemorrhage does not resolve quickly.

Referral should be considered in cases where the source of hemorrhage cannot be identified, substantial blood loss has already occurred before the examination, the horse is in hypovolemic shock, or intra-abdominal hemorrhage is suspected. Horses in hypovolemic shock will show clinical signs such as tachycardia, tachypnea, pale mucous membranes, dull mentation, weak pulses, cold extremities, and generalized weakness. It is important to remember that the PCV and total protein values in these horses are often normal initially, and decreases will not be evident for 6 h (total protein) or 12–24 h (PCV). If possible, these horses should be stabilized with IV fluid therapy before transport. Horses with intra-abdominal hemorrhage will show signs of hypovolemic shock, but they may also show signs of colic. The diagnosis can be quickly made by seeing swirling, hyperechoic abdominal fluid on ultrasonographic evaluation. These horses often require general anesthesia to identify and eliminate the source of hemorrhage. All horses with post-castration hemorrhage, regardless of if the source is quickly identified, are at an increased risk for the development of an infection at the surgical site because of the presence of the blood clot (and potentially suture material or gauze packing). Therefore, they should be treated with a course of broad-spectrum antimicrobial therapy.

5. Eventration

Eventration after castration is rare, occurring in only 0.2–2.6% of cases, but it is the complication that is most likely to be fatal. Therefore, referral is always recommended in cases where the intestine is involved.[2,4–7] Horses with omental eventration do not normally require referral. The omentum can be removed by ligation and transection or emasculation, and generally, there are no complications associated with its protrusion. However, it is advisable in these cases to perform a rectal exam to evaluate the size of the internal inguinal rings and ensure that there is no intestinal protrusion through the rings.

Intestinal eventration usually occurs within 4 h of castration, but there are reports of it occurring as

Fig. 3. (A) A yearling that developed small intestinal eventration 4 h after a routine closed castration. Because of the large amount of intestine eventrated, it was not possible to replace it into the scrotum. (B) Therefore, a hand towel was sutured to the skin to form a sling. (C) This was covered with a sheet for additional support during transport to the referral center.

late as 12 days after surgery.[4–7] Risk factors include breed (Standardbreds and Draft Horses are over-represented breeds, and anecdotally, Saddlebreds and Tennessee Walking Horses are also at increased risk), pre-existing inguinal hernias, presence of an inguinal hernia as a foal, and an internal inguinal ring that 2 or more fingers can fit into on rectal palpation. In these cases, it is recommended that a closed or modified open castration with a ligature placed around the cord be performed. A closed castration without a ligature will not decrease the risk of eventration, but the addition of a ligature has been shown to decrease the risk.

After intestinal eventration occurs, initial therapy is aimed at keeping the bowel safe from damage and further contamination and preparing the horse for transport to a referral center. The protruding portion of bowel should be cleaned of all gross contamination with sterile saline and then replaced into the scrotum, which is sutured closed or closed with several towel clamps. If this is not possible because of the amount of bowel that is prolapsed, then a moist towel or drape should be made into a sling and used to support the bowel during transport (Fig. 3). The horse should be given sedation (if systemically stable), broad-spectrum IV antimicrobials, and flunixin meglumine for analgesic and anti-endotoxic therapy. Survival rates after surgical treatment of intestinal eventration range from 36% to 87%, and the lowest survival rates are associated with an inguinal-only surgical approach, increased length of prolapsed bowel, and the need to perform a resection and anastomosis.[6,7]

6. Peritonitis

Septic peritonitis rarely occurs after castration; however, the vaginal and peritoneal cavities do communicate, and therefore, the potential for infection to spread from the spermatic cord to the abdomen does exist. Clinical signs of septic peritonitis include fever, depression, tachycardia, dehydration, colic, diarrhea, and anorexia. Abdominocentesis should be performed in horses displaying these signs, and the fluid should be submitted for cytological evaluation, bacterial culture, and sensitivity testing. However, it is important to note that nonseptic peritonitis occurs frequently in horses after castration and is not clinically significant, but it will cause the cell count in the abdominal fluid to be elevated; 10,000 cells/μl is common, and counts can reach as high as 100,000 cells/μl for up to 5 days after surgery without causing any clinical signs.[4,5] This is thought to be caused by the inflammation from the presence of blood in the abdominal cavity. Therefore, in horses with clinical signs of peritonitis, it may be more useful to evaluate the fluid cytologically for the presence of bacteria or degenerative neutrophils to make a definitive diagnosis rather than relying on absolute cell counts.

Horses with clinical signs of septic peritonitis should be referred for treatment if possible. This should include broad-spectrum IV antimicrobials (pending the results of culture and sensitivity testing of abdominal fluid), NSAIDs, and anti-endotoxic treatments such as polymixin B and hyperimmune plasma. In severe cases, the placement of an indwelling abdominal drain may be warranted to perform lavage 3–4 times daily. Alternatively, an

exploratory celiotomy can be performed for a more thorough lavage, and a drain can be placed at the time of surgery.

7. Penile Damage

Iatrogenic penile damage has been reported after castration and usually occurs when inexperienced veterinarians mistake the penile shaft for a testicle. This can obviously be avoided by having a sound knowledge of the anatomy of the area. If the penis is partially dissected from the surrounding soft tissue while searching for an inguinal or small testicle, then the resultant inflammation and trauma can lead to soft tissue swelling and paraphimosis. In these cases, cold hydrotherapy of the penis and scrotum to reduce the swelling is indicated, and the penis should be manually replaced into the prepuce and then held in place with a sling or purse string suture until the swelling subsides enough for the penis to retract normally. If the penis is inadvertently transected during the procedure, then the horse should be referred for immediate surgical repair or partial phallectomy.

8. Hydrocele

A hydrocele is an accumulation of sterile serous fluid within the vaginal cavity that usually occurs months to years after castration. It occurs more commonly after open castrations, and mules are predisposed to developing the condition. Clinically, these horses have a flocculent, non-painful scrotal swelling. Hydroceles generally do not require any treatment unless the owner requests that it be removed for cosmetic purposes or in rare cases, where the swelling is severe enough to cause lameness. Surgical removal under general anesthesia is the treatment of choice, because the swelling will recur after simple drainage alone.

9. Conclusions

Although castration complications are relatively common, most of these can be resolved quickly with prompt treatment at the farm. However, complications with acute, life-threatening potential, such as hemorrhage, eventration, and infection or peritonitis with systemic signs of endotoxemia, are true emergencies, and these horses should be considered candidates for referral. Horses with suspected penile damage should also be referred promptly. Other complications may require referral at a later stage if the horses do not respond to the initial therapy attempted at the farm. These include cases with significant or chronic infections and those with peritonitis. Most cases of post-operative swelling and edema can be managed at the farm.

THE WILD HORSE POPULATION OF STONE CABIN VALLEY, NEVADA: A PRELIMINARY REPORT

Nancy F. Green and Howard D. Green*

Introduction

In Summer 1975 and Spring and Summer 1976 we studied the wild horse population of Stone Cabin Valley, Nye County, Nevada. Stone Cabin Valley covers over 380,000 acres and, at the beginning of the study, supported one of the largest wild horse populations in Nevada. The primary objectives of our study were: 1) to determine the number of wild horses in the Valley and gather data on sex and age composition and recruitment; 2) to evaluate habitat utilization in relation to forage quantity and quality, including determination of home range size, movement patterns, and food habits, and 3) to study social organization and behavior. This report is a preliminary analysis of our data.

Acknowledgements: Support was provided by the American Horse Protection Association for Summer 1975; research in Summer 1976 was funded by Wild Horse Organized Assistance. We also would like to thank the personnel of the Tonopah Area Office of the Bureau of Land Management for their help and cooperation.

Methods

Data was collected June 15-September 25, 1975 and March 10-May 25, 1976. At monthly intervals in June, July, and August 1976 we returned to the Valley and spent 3 days collecting census and distribution data, and clipped forage samples for nutrient analysis.

A 110 mile census route on established roads was used during Summer 1975 to determine the number and distribution of wild horses in the Valley. Stops were made at regular intervals and, using 20 power spotting scopes, the surrounding area was scanned and all horses counted. The sex and age of individuals was recorded when possible. The distribution of horses was plotted on grid maps of the Valley, and the number of horses in each vegetation type was determined.

Data on sex and age ratios were gathered by making detailed descriptions of as many bands as possible. This was a difficult process as it usually was not possible to get within 300 meters of a band without causing flight. Distinguishing between immature (2-3 year old) and adult horses was especially difficult; therefore the immature age class data are included in the adult category in this report.

Detailed descriptions were made of the color and markings of each horse in a band. Each band was assigned a number and a band list index was developed to provide a rapid means of determining which bands had been described. Home ranges of several bands were determined by recording the date time, and location of the bands each time they were observed.

Samples of fresh fecal material were collected in various vegetation types during the study. Food habits data are being analyzed by the Composition Analysis Laboratory at Colorado State University, and results will be presented in a separate report (H. Green, in prep).

The "instantaneous" and "all-occurrences" methods (Altmann 1974) were used to collect over 500 hours of detailed notes on wild horse behavior.

Results and Discussion

Population Size

Census data for Summer 1975 range from a low of 538 horses seen on July 4, 1975 to a high of 786 counted on July 17, 1975. The average number of horses seen was 703. It is likely that we missed seeing horses that were lying down as they were very difficult to detect at distances greater than 500 meters, expecially if they were bedded in vegetation more than one meter high. Not all areas were equally visible from the census route due to the rolling topography in portions of the Valley. Thus our data are a minimum estimate of the horses present in the Valley.

*Graduate Students, School of Natural Resources, Humboldt State University, Arcata, California

Foaling

Most foals were born between mid-March and mid-June. In 1975 we found 12 foals per 100 adults. About 50% of the mares did not have yearlings or foals with them. Almost without exception, mares with young had either a yearling or a foal, but not both. We do not know if this is because they did not breed the previous Spring (an unlikely alternative), aborted during pregnancy, or lost foals at or soon after birth to various mortality factors. Mares with foals or nursing yearlings were thin even at the end of Summer when the other horses had gained weight. It would be difficult for these mares to successfully overwinter since Winter and early Spring forage is in short supply. Mares unable to meet the energy demands of pregnancy probably abort or give birth to weak foals susceptible to mortality factors.

In Spring and Summer of 1976 we found 10 yearlings per 100 adults, indicating that some mortality among foals does occur during Winter.

The foal crop in Spring 1976 was considerably higher than that in 1975; a Bureau of Land Management (BLM) aerial survey conducted in September 1976 found 18 foals per 100 adults (M. Hedrick, pers. com.). Our data indicates that given relatively high moisture and subsequent improvement in forage, mares may raise foals in successive years. That they do not successfully foal each year is most likely due to variations in weather and forage conditions. Similar findings have been reported for the Plains zebra (Klingel 1969a).

Sex and Age Ratios

Detailed descriptions of 61 bands (321 horses) were obtained by repeated observations of groups. Band size averaged 5.3 horses and ranged from 1 to 15. Of the 248 adults, 53% were females and 47% were males. The number and percent of horses in each category is given in Table 1.

Table 1. Number and percent of horses in each age category for 61 bands. Summer 1975.

	Adult Males	Adult Females	Yearlings	Foals	Total
Number	117	131	44	29	321
% of total	36.4	40.8	13.7	9.0	

In Summer and Fall 1975, BLM trapped and removed 209 horses; 54% were females and 47% were males, essentially identical to our findings.

Mortality

Incomplete skeletal remains of seven adult horses, 3 males and 4 females, were found in the Summer of 1975. Most of the skeletons obviously had been lying exposed for several years and an exact determination of the cause of death was not possible. The mandible of one male skull was cracked and it is possible that the horse had difficulty feeding and may have starved. A cracked mandible would most likely result from receiving a rear kick from another horse during a fight.

Mortality among immature and adult horses is most likely the result of poor nutrition, disease, old age, or injuries sustained during fighting. We observed numerous aggressive interactions between stallions, but most were highly ritualized and did not involve injury to either participant. However, some fights between stallions included biting and kicking, especially during the Spring of 1976 when mares were in breeding condition. It certainly is possible that blows sustained during such fights could result in broken bones or internal injuries sufficiently damaging to cause death.

In March of 1976 most of the horses, especially mares with nursing young, were very thin. Forage availability was limited in both quantity and quality during Winter. Pregnant mares and those nursing young have high energy requirements and failure to meet these energy demands undoubtedly is a source of mortality. A dead mare was found at a water hole on March 12, 1976. She was extremely thin, her ribs and hips protruded. In April we found a mare lying near a water hole, she was unable to stand. There was a small amount of dried blood on her hind legs. She was very thin and appeared to be in shock; she made no attempt to move when approached and did not respond to the approach of her foal. The foal, a filly, was judged to be about two weeks old. It was not possible to determine the cause of the mare's condition. She may have had trouble giving birth and finally became paralyzed, she may have been kicked and paralyzed by fighting males, or perhaps she was undernourished prior to having her foal and nursing was simply too great an energy drain on her. It was our judgment that she could not be saved. BLM personnel concurred in this judgment and the mare was shot. We took care of the foal for several days until she could be transported to the BLM corrals at Battle Mountain. Without our intervention the foal certainly would have died.

Four old solitary horses were observed and were obviously in poor health. Their movements were lethargic and they seemed unable to raise their heads. It is possible that these animals were unable to obtain sufficient forage

due to tooth wear. Most of the forage is covered with grit and is highly abrasive, and tooth wear in old horses may lead to starvation.

Most mortality seemed to occur among foals. We found carcasses of four foals. Three had sanded hooves, and one had no exterior signs that indicated cause of death. Several lame foals were observed who probably had sanded hooves. Sanding is a condition in which the sole of the foot cracks and sand and rocks collect in the hoof, causing lameness. Lame foals have difficulty staying with their bands and often lag behind by as much as 300 yards. On July 4, 1975 we found a filly lying by a water hole. There were no other horses in sight for at least three miles; she apparently was abandoned by her band. She had three sanded hooves and could barely stand or walk. We suspect that many sanded foals do not recover and, unable to keep up with their bands, are abandoned to die.

Another source of foal mortality involves problems during or shortly after birth. In April 1976 we found an abandoned colt which was not more than 48 hours old. He was extremely lethargic and constipated. Intestinal blockages are not uncommon among newborn domestic foals and can result in death if not treated. We immediately gave the colt water and transported him to our camp. We were able to correct the constipation problem and the colt eventually was adopted by people from the East Coast. It is difficult to determine how often intestinal blockages or similar problems occur, but they are clearly a mortality factor among foals.

A total estimate of foal mortality is difficult to derive since most carcasses are scavenged quickly by coyotes and birds. Also, we were limited to finding carcasses visible from the road or near our vegetation transects.

In summary we found the following sources of foal mortality: death of the mother when the foal was young and dependent on her milk, leading to subsequent death of the foal; lameness; and intestinal blockage or other internal problems during or soon after birth. All of these are natural mortality factors. High mortality among the newborn of most species is a common phenomenon (Caughley 1966).

Social Organization and Behavior

The social organization of wild horses is very similar to that of the closely related Plains zebra (Klingel 1969b). The basic unit of social organization is the harem band, usually composed of one adult male and one or more adult females with their offspring. Of the 53 harem bands described in detail in 1975, 24 (45%) contained more than one adult male (note that we have combined the immature and adult age classes so the actual percent of bands with more than one adult male is lower than what is indicated by our data). In the Spring of 1976 we obtained detailed descriptions of 67 harem bands, 36 (54%) of which contained more than one adult male. We found that in harem bands with more than one adult male, one stallion was consistently the harem master.

Several bachelor (all-male) bands were observed in 1975, ranging in size from one to four horses. Bachelor bands were composed of adults or adults and immatures, but never contained yearlings or foals. A few adult males were solitary.

The harem bands tended to be stable in composition in terms of adult members. We were able to re-locate many of the bands we saw in 1975 in the Spring of 1976 and most of them had not changed in number. Changes in band composition were usually the result of immature horses leaving their original band. We documented such changes for two distinctly marked young mares. Also, in late Summer 1975 we found that yearling females sometimes approached and fed with other harem bands, usually close to the other harem stallion; they returned to their own band after five to thirty minutes. Harem stallions did not attempt to prevent this type of movement by yearling females in the Summer, but did attempt to prevent it during the Spring breeding period by herding females of all ages back toward the harem if they strayed. Feist (1971) found that immature females accounted for most of the changes in band composition he observed in the Pryor Mountain wild horse population, and concluded that stallions may not attempt to breed or hold their own offspring in the band. Most shifts of immature females, observed by Feist, occurred during the breeding period.

Klingel (1969a) reported that shifts between bands of zebras were usually the result of immature females being abducted by other harem masters or bachelors during the breeding period. He found that stallions tried to prevent such abductions but usually failed, especially if several stallions simultaneously attempted to abduct a young female. Thus, the change by immature females from their original harem band to some other band seems to be a common pattern in equine species. One effect of this behavior is that inbreeding is probably not a problem, as has been suggested in some of the wild horse literature.

Immature males were present in some of the bachelor bands. No instances of immature males being chased from their original band by the harem master were observed. We have no data as to how or why young males leave their original harem. Their presence was generally tolerated by the harem stallion, who rarely interacted with young males. Foal, yearling, and occasionally immature males showed a submissive gesture called teeth-clapping when they were close to stallions. Teeth-clapping probably serves to acknowledge the dominance of the stallion and may prevent aggression of stallions toward young males in the band.

Changes in harem band composition can occur for several other reasons. If the harem stallion dies the mares and other harem members may be adopted by another stallion. We documented this for one band: a stallion who already had a mare and 2-year-old son adopted two mares and their foals. He was aggressive toward the 2-year-old male from the new group, who eventually left. Band composition also changed as a result of a single harem being split by two stallions (two observations). Bands also may change if the harem stallion is defeated and driven away by another harem master or a solitary male. The new stallion takes over the harem.

Wild horses spend a vast majority of their time (about 90%) either feeding or resting. Large aggregations of bands feeding in close proximity were seen during Summer 1975. The density of horses during these feeding aggregations was as high as 90 horses per square mile. There was little inter-band aggression during Summer months. In the 1976 Spring breeding period, however, we saw many more aggressive interactions between harem leaders, and inter-band spacing was much greater than it had been the previous summer.

A detailed analysis of the behavior of wild horses, with emphasis on stallions, will be published separately (N. Green, in prep.).

Home Range and Habitat Utilization

The home range of one band often overlaps the home ranges of several other bands. We saw no evidence of one band defending any particular area or excluding other bands from their home range, nor did we see any evidence that any one band had exclusive use of an area, i.e. we observed no form of territoriality. Figure 1 shows the home ranges of five bands in Spring and Summer 1976. The size of the home ranges is quite variable: that of Band 218 was only 4.2 square miles, while Band 96 had a home range of 30.2 square miles. It should be kept in mind that these are Spring and Summer home ranges and do not include possible seasonal movements. If any of these bands migrate seasonally their home ranges would be considerably larger.

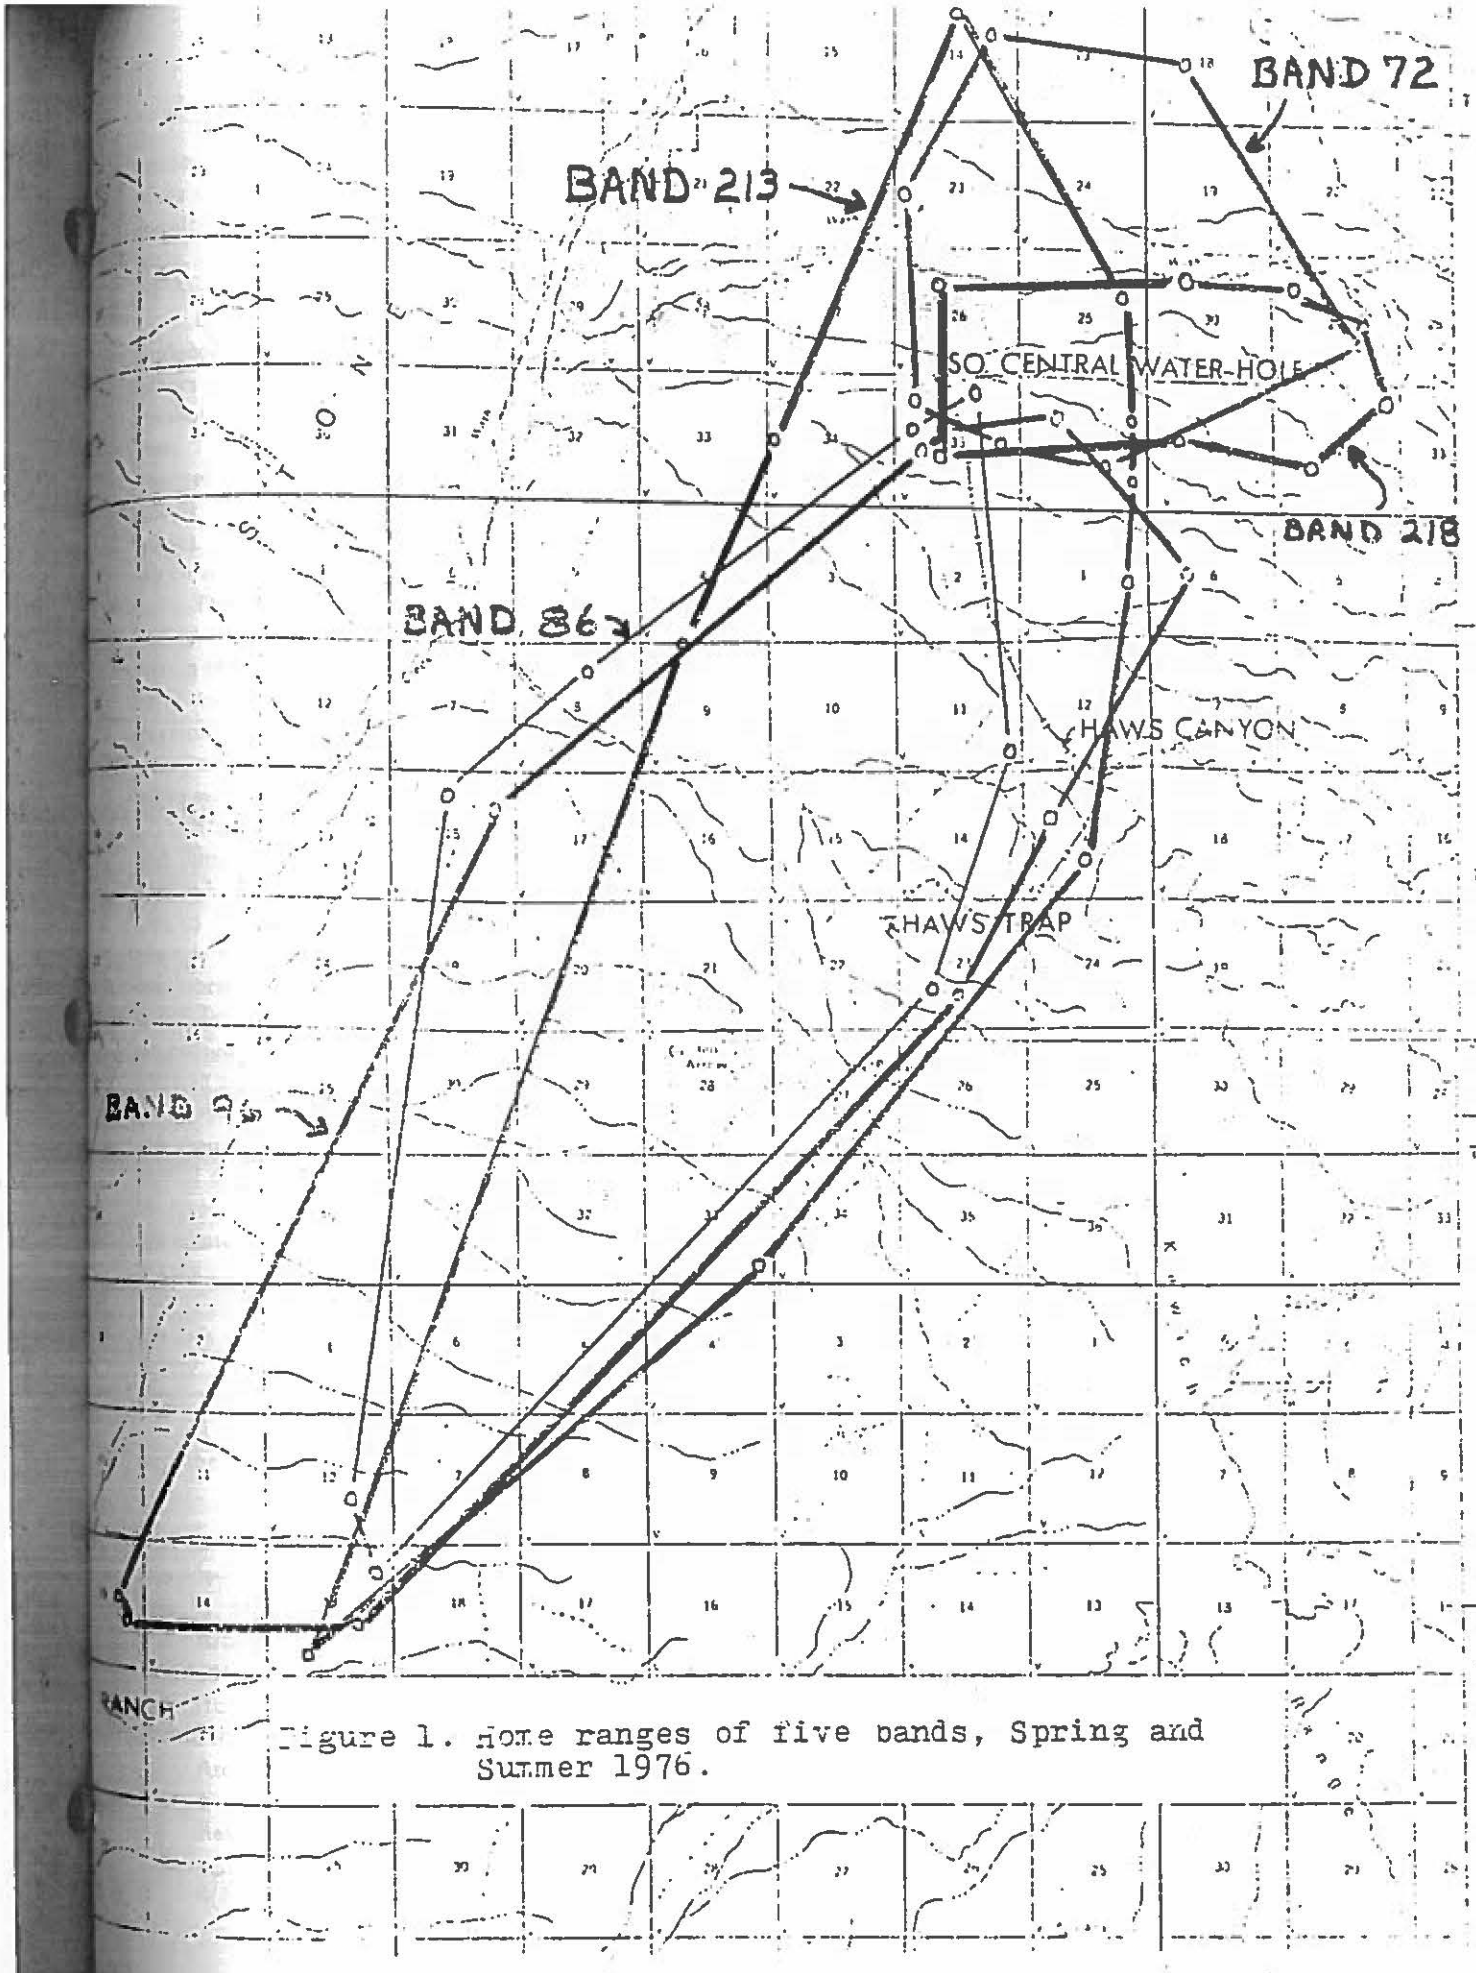
Most bands had a smaller area within their home range in which they spent most of their time; this is referred to as the maximum activity area. In the Southern part of the Valley (below Highway 6) each band's maximum activity area was located within three miles of a water source. Movements outside of the maximum activity areas were instigated for reasons which are not completely understood. The southern-most extensions of the home ranges of bands 86, 96 and 213 (Fig. 1) were the result of these bands moving out of their maximum activity areas in response to heavy rain or snowfall. On three occasions in Spring 1976 following several hours of rain or snow many of the bands which normally occupied the area around the South Central Water Hole, Haw's Canyon, and Haw's Trap moved to an area East of the Pond and Reed's Ranch (Figure 2). The area normally is grazed very little by horses even though forage is relatively abundant. Water is available at Reed's Ranch and the Pond on a seasonal basis, being turned off in Summer and Fall. It may be that this area is little used by horses, despite the good forage, because they have no way of determining when water will be available there. However, following heavy rain or snow large pools of water accumulate in shallow depressions. Many bands (as many as 150 horses) move South and feed in the area until the standing water dries up, at which time they return to their maximum activity areas.

In the North end of Stone Cabin Valley (North of Highway 6) the distribution patterns of horses are different. Several water sources are available all year (Fig. 2). However, most are located in areas of very poor forage (in some cases this seems to be due to over-grazing by cattle around waterholes), and the area of maximum concentration for most bands is located several miles from the water sources in an area of better forage. These bands travel up to 7 miles each day to water.

These data suggest that at least two environmental factors, water and forage availability, influence the distribution of horses.

In the southern part of the study area most horses stay in an area where both food and water are available (Figure 2) and move South to take advantage of better food sources when water becomes available in those areas. In the North end of the Valley where there are no locations with both ample forage and water, the maximum concentration of horses is found in areas of good forage and the horses travel longer distances to water.

Within the Valley there are three broad habitat areas: the valley floor, the foothills and mountains, and the mountain meadows. The valley floor, which covers a majority of the study site, is an area of relatively flat topography vegetated primarily by low brush species such as *Atriplex canescens* (four-wing saltbush), *A. confertifolia* (shadscale), *Tetradymia glabrata* (horse brush) and perennial grasses such as *Hilaria jamesii* (galleta grass) and *Oryzopsis hymenoides* (Indian rice grass). Surrounding the valley floor on three sides are foothills primarily vegetated by *Artemesia tridentata* (big sage) and *A. nova* (black sage); the foothills grade into the mountains where Pinyon and Juniper trees are dominant. At several locations in the mountain ranges there are meadows primarily vegetated by sedges and annual and perennial grasses.



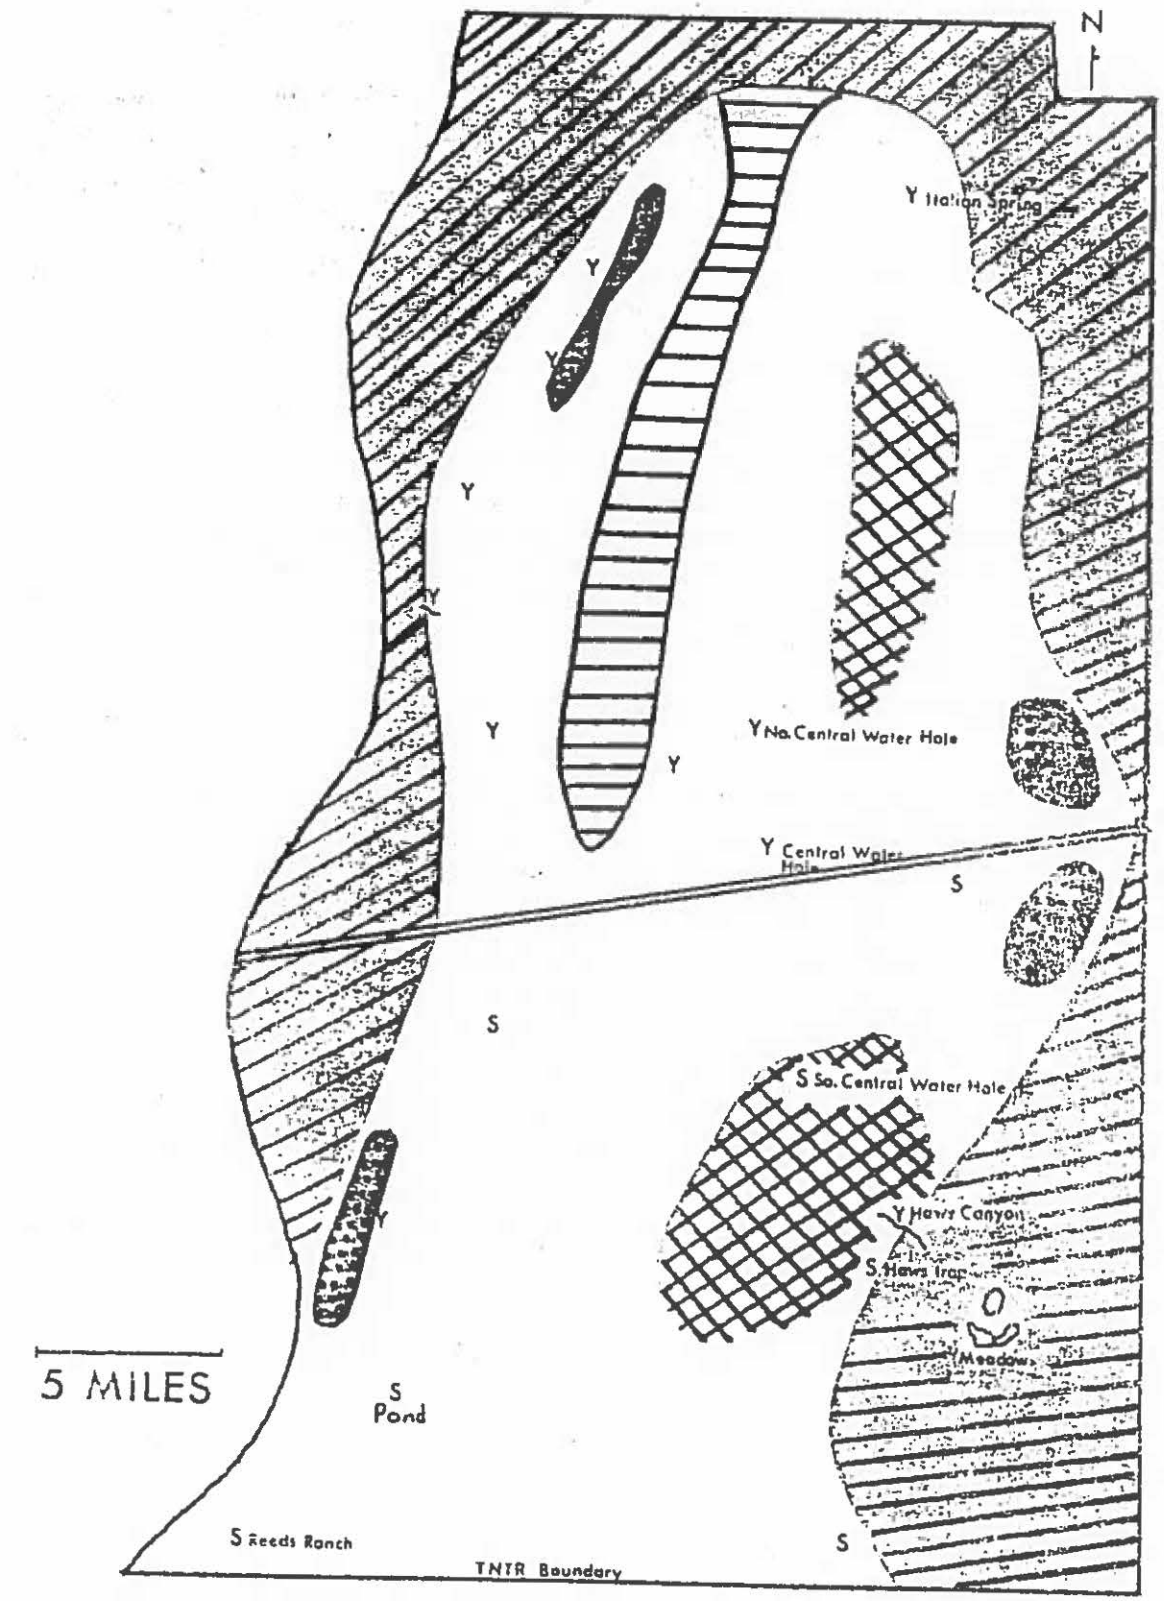


Figure 1. Home ranges of five bands, Spring and Summer 1976.

Figure 2. Habitat utilization by wild horses in Stone Cabin Valley. Summer 1975, Spring and Summer 1976.

Most of the horses inhabit the valley floor. Meadows have small populations of horses in Summer. The rest of the mountain areas are lightly populated by dispersed bands of horses. The bands occupying each of these broad habitat areas showed a remarkable fidelity to their area during the period of the study. Valley horses were not observed in meadow areas, and valley bands did not move into the mountain areas further than the first low foothills. Correspondingly, bands which occupied the meadow areas were not observed in the valley floor.

SEASONAL MOVEMENTS

Due to the short time span of this study few direct observations of seasonal movements were obtained. Indirect evidence of seasonal movements suggests that some North-South migration does take place. Ranchers in the Valley and others who have observed the horse population levels on a year-round basis agree that there are many fewer horses present in Winter than in Summer. On our first census in the Spring of 1976 (March 29) relatively few horses, 221, were seen. This low population level was still evident on the second census made on April 8, 1976 when only 204 horses were counted. As the season progressed more horses were counted on each census: April 19 - 334 horses; April 28 - 527 horses; May 8 - 446 horses; May 18 - 570 horses; June 18 - 315 horses; July 18 - 317 horses; and August 18 - 395 horses. (The decrease in the census numbers in June, July and August probably was due to the trapping operation which removed 205 horses from the Valley between May 20 and June 29, 1976.)

These census data indicate that at least some of the bands spend the Winter in places other than Stone Cabin Valley. Some of the bands with which we were familiar in the Summer of 1975 were not observed in the Valley until late in the Spring of 1976, after which they were observed frequently. Their sudden reappearance in the Valley indicates that they probably had returned to the Valley from some other location. Other bands which we had described the previous Summer were present in the Valley early in the Spring of 1976 and remained there at least through August, when our study terminated. These data indicate that some of the bands stay in the Valley year-round, while others make seasonal movements to other areas.

Stone Cabin Valley is bordered on the North, East and West by moderately high mountains vegetated by Pinyon and Juniper trees. The mountains appear to act as ecological barriers to horse movements. To the South the study area is bounded by the Tonopah Nuclear Test Range (TNTR). There are no fences or other barriers and the horses are free to move on and off the TNTR. Individuals who are allowed on the Test Range report that the horse population there is high during Winter. We made one trip South of the Test Range boundary in the Summer of 1975. There were few horses south of the Stone Cabin Valley-Test Range boundary. These data suggest that some of the horses which spend late Spring and Summer in the Valley may spend the Winter on the Test Range to the South. This is further supported by a series of observations made of Band 500 during Spring 1976. Band 500 spent the entire Summer of 1975 in a mountain meadow area in the Kawich Mountain Range, east of the Valley. During the entire Summer of 1975 we never observed these horses outside of the immediate meadow area. On April 29, 1976 we observed Band 500 in the main Valley area, 6 miles southwest of the meadow and 7.5 miles north of the Test Range border. For the next several days we observed the band slowly move further northeast, closer to the meadow. On May 10 the band was observed in the meadow, where they remained for the Summer. The meadow area was covered with snow for much of the Winter, forcing horses out until Spring. From our observations of the direction from which Band 500 returned to the meadow, it is likely that they were coming from the Test Range.

Seasonal movements are probably a response to both water and forage availability. It is our opinion that due to the lack of water and forage on the Test Range, many horses spend the Summer North of the TNTR, in Stone Cabin Valley. In winter, snow is sometimes available to eat and snowmelt water is available in natural catchments, thus eliminating lack of water as a hinderance to southern movement.

A detailed analysis of the distribution of horses in relation to the quantity and nutrient quality of forage will be published separately (H. Green, in prep.)

Nd:YAG Laser Photoablation of Endometrial Cysts: A Review of 55 Cases (2000–2001)

Richard L. Griffin, MS, DVM; and Scott D. Bennett, DVM

Videoendoscopic assisted laser photoablation of endometrial cysts is an effective method of cyst reduction. The group of mares in this review had been barren for at least one breeding season. Following laser treatment a high percentage of these mares conceived. Authors' address: Equine Services Surgical Hospital, P.O. Box 464, Simpsonville, KY 40067. © 2002 AAEP.

1. Introduction

Endometrial cysts have been previously described as originating from uterine glands or from lymphatic lacunae.[1–3] Glandular cysts have been described as being <10 mm in diameter, with a significance that is largely unknown.[4] Lymphatic cysts, however, are lymphatic lacunae that can be significantly larger than 10 mm in diameter. Ragon reported that these cysts could be found in the endometrium or myometrium. The cysts may appear as unilocular or multilocular, be round or elongated, and their presence is associated with both normal and chronically inflamed endometria.[5]

Ragon also stated the prevalence of glandular cysts is unknown, but regardless of the population of mares studied (fertile or subfertile), the incidence of lymphatic cysts increases with age.[5] In one study, 73.1% of mares over 14 yr of age had endometrial cysts.[6] In a study of mares acquired from a slaughter-house market, the mean age of mares with endometrial cysts was reported to be 13.4 yr of age.[7]

Uterine cysts are most commonly diagnosed by ultrasonography. Prior to the advent of trans-rectal ultrasound, postmortem examination was the most common method of diagnosis.[8] Recently hysteroscopy has become more common in equine practice. Hysteroscopy allows for a thorough visual inspection of the uterus and potential pathology, which other diagnostic procedures cannot provide. Hysteroscopy has been found to be a useful diagnostic technique, and has been used on a routine basis at Equine Services since 1977.[a]

The effect of uterine cysts on fertility has been debated. McKinnon et al suggested that the relationship between infertility and uterine cysts was axiomatic.[4] These authors also stated that later in pregnancy, contact between the cyst wall and yolk sac or allantois may prevent absorption of nutrients. Ragon noted in her review that the presence of uterine cysts has been associated with decreased conception rates, increased early embryonic death, and decreased foaling rates.[5] It has also been shown that endometrial cysts are closely associated with increasing age and biopsy scores.[7] This makes the specific effect of uterine cysts on infertility difficult to predict. The purpose of this study was to determine the conception rate in a group of previously barren mares, after photoablation of endometrial lymphatic cysts with Nd:YAG laser.

2. Materials and Methods

Records of fifty-five barren mares presented for photoablation of endometrial cysts during 2000 and 2001 were reviewed. Of the cases seen, three mares were evaluated twice. The mares were placed in stocks and sedated to effect with a combination of detomadine[b] (0.01–0.02 mg/kg, i.v.) or xylazine[c] (0.3–0.4 mg/kg, i.v.) and butorphanol[d] (0.01–0.02 mg/kg, i.v.). The rectum was emptied of manure, and the tail was wrapped and secured out of the working area. The perineal region was then thoroughly cleansed for aseptic procedure. The operator is gloved with a sterile sleeve. A one-meter videoendoscope[e] is cold sterilized[f] then rinsed and flushed with sterile saline and guided through the cervix into the uterine body. A sterile artificial insemination pipette is then placed alongside the videoendoscope into the uterine body. A sterilized hand-held bulb-type air pump is attached to the pipette and used to insufflate the uterus with room air. The cervix must be tightly closed during the procedure, or the uterus will not insufflate.

Once the uterus is insufflated and the endometrium in the uterine body can be clearly visualized, the endoscope is passed into both of the uterine horns. It is helpful to make a thorough inspection of the uterus and locate the cysts prior to photoablation. Other important structures that should be clearly visible include the corpus-cornual junction, both utero-tubal papillae, and the endoscopic appearance of sub-endometrial blood vessels. The endometrium should also be evaluated for the appearance of scarring or atrophy. Although this is a subjective assessment, we believe experience will allow the operator to provide a more accurate prognosis of fertility in the mare. Bracher et al. and Inoue et al. have clearly shown the usefulness of hysteroscopy for the evaluation and prediction of the reproductive ability of mares.[9,10]

After all cysts have been located, the laser fiber is passed through the biopsy port of the endoscope until 1–2 cm of the fiber is visible. An Nd:YAG laser system with a 4-m long, 800-μm diameter transmitting fiber is used.[g] The beam is passed through a fiber, with a 1-mm orb tip. Coaxial cooling is not used with this contact fiber. The laser output is set at 15 W. It is helpful to start at the tip of a horn and work in a posterior direction. The tip of the laser fiber is guided to a cyst and placed in contact with the central dome of the cyst and energy is applied. The cyst is photoablated until all lymphatic fluid has leaked out and the cyst is reduced in size. Once fluid empties, the remaining cystic tissue will collapse around the fiber and reduce back to the level of the endometrium as energy is applied. Energy may have to be applied to several points on a large cyst in order to accomplish this. If numerous lymphatic cysts are present, the uterus may have to be emptied of air and smoke, then re-insufflated in order to clearly visualize all cystic structures. When all cysts have been satisfactorily ablated, all air is emptied from the uterus. If uterine biopsy is to be done, it should be done following cyst reduction.

The perineal region can then be cleansed again and a Foley catheter is passed in order to lavage the uterus. The uterus is lavaged with 1 L of 7% hydrogen peroxide in sterile saline, followed by a 2% povidone iodine solution in sterile saline. It is felt that the hydrogen peroxide lavage helps to effectively remove debris resulting from the procedure. The follow-up povidone iodine solution is used as an anti-microbial lavage, to aid in prevention of possible infection secondary to the procedure. The recommended take-home instructions include lavage of the uterus twice more before breeding the mare.

3. Results

The 55 mares in this case review had been barren for at least one season. A total of 269 cysts were photoablated. Many cysts were multiloculated structures that were counted as one cyst. The mean age of this group of mares was 18.8 yr, with a median of 18 yr of age. The range was from 13, to a group of four mares, all 24 yr of age. The cysts were divided as to their location within the uterus. They were divided into four groups; those in the left horn, right horn, at the corpus-cornual junction and in the uterine body. In this group of mares, 21.6% of cysts were located in the left horn, 28.2% of cysts were in the right horn, 16.4% of cysts were at the corpus-cornual junction, and 33.8% of cysts were in the uterine body.

Follow-up of the 29 mares treated in the year 2000 was attempted. Of these mares, 25 were located for further information. Of the four lost to follow-up, one had died, and we were unable to contact the owners of the other three. Of the 25 available, 18 had conceived in either 2000 or 2001. These mares were bred an average of 2.3 cycles per conception. Mares that conceived had an average of six cysts. The group of mares that did not conceive had an average of five cysts.

Follow-up data on the mares treated during 2001 was obtained for 14 mares. Of this group, eight are known to have conceived. They were bred an average of 1.4 cycles per conception. Of the six that did not conceive, one was retired from breeding due to age, and another was diagnosed with a granulosa cell tumor. Mares that conceived had an average of 7 cysts, whereas those that did not had an average of 4 cysts.

4. Discussion

As has been previously stated lymphatic cysts have been associated with infertility in the mare. Tannus and Thun found that pregnancy rates at 14 d and 40 d were significantly lower in mares with cysts compared to mares without cysts.[6] Several different methods describing removal of endometrial cysts were previously reviewed. These include me-

chanical curettage, hypertonic saline infusions, aspiration, rupture with endoscopic biopsy instruments, electrocoagulation, and photoablation with laser.[4]

Blikslager et al. previously described a technique for photoablation of uterine cysts with Nd:YAG laser on a small group of mares, both *in vivo* and *in vitro*.[11] They used a coaxial cooled fiber, at much higher power than is described in this paper. *In vivo*, they performed the procedure in two stages. Initially they were placing the probe 1 cm from the cyst surface, blanching the entire cyst at 50 W. This was followed by membrane puncture at 100 W. We have not found this level of power to be necessary in order to adequately photoablate uterine cysts. Their *in vitro* study also described creating Grade 4 lesions by using high-energy densities. This is obviously undesirable in clinical cases.

Nd:YAG laser has been used for treatment of endometrial cysts at Equine Services since 1986.[a] We have found Nd:YAG laser to be an effective, affordable treatment for ablation of intrauterine cysts. Continued follow-up of mares, including the live foal rate of those that conceived following this procedure, would provide further valuable information regarding the usefulness of this procedure.

A dynamic simulation model for evaluating effects of removal and contraception on genetic variation and demography of Pryor Mountain wild horses

John E. Gross *

Natural Resource Ecology Laboratory, Colorado State University, Fort Collins, CO 80523-1499, USA

Received 6 January 2000; received in revised form 1 May 2000; accepted 5 May 2000

Abstract

I used an individual-based model to simulate population dynamics and changes in genetic variation of horses in the Pryor Mountain Wild Horse Range under a range of management strategies. Management strategies included population objectives of 90 to 180 horses and removal and/or contraception of animals of random, young, or old ages. Populations controlled only by removals fluctuated widely in size and generally exceeded objectives by >20%. Populations controlled by contraceptives remained within 3% of objective. Over a 200-year period, populations were very likely to lose alleles with an initial frequency of <3%, which included nearly 30% of alleles in the population. Allelic diversity was lost faster than population-level heterozygosity. Removal or contraceptive treatment of older animals hastened the loss of genetic variation compared to treatment of random-aged or young animals. Rate of loss of genetic variation was directly related to generation interval, and differences in loss of genetic variation were greater between treatments of old and young animals than between populations that differed in size by a factor of 2. These results apply to management of many long-lived species in harvested populations and they illustrate the importance of actions that modify age structure and generation interval. © 2000 Elsevier Science Ltd. 1. Introduction

About 150 horses inhabited the Pryor Mountain Wild Horse Range (PMWHR) in 1998, close to the estimated range carrying capacity (BLM, 1997). The small size of this population concerned those mandated to sustain a viable and healthy population, because genetic diversity rapidly disappears in small populations (Wright, 1931). The Pryor horse population has the reproductive potential to double in size every 4–5 years and attain a size that poses risks to habitats and to populations of mountain sheep and deer that also inhabit the PMWHR (Garrott and Taylor, 1990). Management of the Pryor horse population is illustrative of the general predicament faced by agencies with a mandate to control an isolated population characterized by high reproductive potential, long life span, and limited area of available habitat. In these situations, management plans must balance measures to minimize risk of long-term habitat degradation while maximizing long-term retention of genetic variation and the likelihood of population persistence. There are thus conflicting needs to minimize population size to control habitat degradation while maximizing population size to conserve genetic resources.

Feral horses in the United States are protected by the Wild Free-roaming Horse and Burro Act of 1971 and management of most feral horse populations falls under the jurisdiction of the Bureau of Land Management (BLM, 1997). Wild horse populations in the western United States have exhibited growth rates that frequently exceed 15% per year (Garrott et al., 1991a) and they can rapidly achieve population sizes that raise concerns about long-term habitat damage. A total of about 35,000 horses inhabit ranges on public lands in the western United States, but only 25% of the 186 wild

PII: S0006-3207(00)00078-1

horse populations under active management have a population objective of greater than 150 horses (BLM, 1997). The small size of these populations raised concerns about long-term maintenance of genetic variation and emphasized the need to identify methods to control population size while retaining genetic variation.

Wild horse populations have been controlled primarily through periodic gathers and removals. Programs were developed to place wild horses in private ownership, but this has proven to be exceedingly expensive (> $16 million in 1995; BLM, 1997) and it has become impossible to place all horses acquired by removal programs. As a result, there is great interest in the potential use of contraceptives to reduce fertility of horses and other overabundant species (Sturtevant, 1970; Hoffman and Wright, 1990; Garrott et al., 1991b; Holden, 1992; Eagle et al., 1992; Fayrer-Hosken et al., 1997). Use of contraceptives could provide opportunities for a variety of new management scenarios, including permanent infertility, delayed reproduction, or permitting mares to reproduce once and then preventing further breeding. Simulations of horses population dynamics have shown that a relatively high level of infertility would likely be needed to maintain a low growth rate in horse populations (Garrott, 1991), but no analyses have specifically considered the consequences of alternative management actions on long-term persistence of genetic variation in horses or similar mammals.

Management strategies to control growth rates of abundant populations by removal or contraception must focus on three decisions: How many animals should there be? What sex and age of animals are to be removed or made infertile? How often are animals removed or treated? The model described below was developed to address these questions by simulating removals only, contraceptives only, or a combination of removal and contraception. The model was specifically applied to the Pryor wild horse population to evaluate a set of realistic management alternatives. Results from the simulations lend insight to the consequences of management actions used or considered for control of overabundant species including bison, deer, elk, elephants, mountain goats, and some carnivores (Hoffman and Wright, 1990; Bradley, 1994; Fayrer-Hosken et al., 1997; Kirkpatrick et al., 1997). To preserve genetic variation, guidelines for managers almost always emphasize actions that increase overall population size or reduce reproductive variance. I offer analyses that clearly demonstrate the importance of age-related management actions and show that actions that increase (or decrease) generation time of long-lived species can have an effect equal to doubling population size. These results are important because it is frequently much easier to modify age structure than increase population size.

2. Method

I developed an individual-based population model to simulate the dynamics of the PMWHR horse population. The model operated on a yearly time step and it simulated the processes of breeding, recruitment, removal, contraception, natural mortality, and aging. Each individual in the population was explicitly represented and the sex, age, genetic constitution, number of mates, and reproductive status of all animals was followed from birth to death. Model outputs included sex and age of each individual in the population, number of mates (by age) of males and females, and the frequency of all alleles.

2.1. Model processes and parameter estimates

Wild horses on the PMWHR have high rates of survival and reproduction (Garrott and Taylor, 1990; Singer et al., 1998), consistent with observations of wild horse populations throughout the western United States (Berger, 1986; Garrott et al., 1991a). Estimates of fecundity and survival were derived from observations of the Pryor population, emphasizing data subsequent to management changes that occurred about 1990 (Garrott and Taylor, 1990; Singer et al., 1998). Horses in the PMWHR have been intensively studied since the 1980s and about 95% of all horses are individually known and repeatedly observed each year. Age-specific survival rates are thus known with a high degree of confidence up to about 15 years of age. Relatively few horses have lived longer than 15 years and these older horses make up a small proportion of the population. No density dependent regulation of survival or reproduction was included in the model because the horse population has been maintained at a size well below estimates of range carrying capacity and evidence for density dependence is lacking. Recent analyses found a significant correlation between growth rate and population size, but neither recruitment nor survival varied significantly with population size ($P > 0.10$; Singer et al., 1998).

Breeding was simulated by comparing a uniform random deviate to the probability of recruitment for each mare, and then selecting a mate. Age-specific breeding success of wild stallions was used to simulate paternity (Berger, 1986, p. 200). It is difficult to determine mating success in the field and tenuous to extrapolate results to another site. However, sensitivity analysis showed that model results were insensitive to age-specific breeding success, but were more sensitive to the probability that a male bred during its lifetime. Estimates of breeding success (Berger, 1986; Singer et al., 1998) show that that virtually all prime-aged stallions breed. The likelihood that a particular stallion mated with a female was determined by the number of breeding-age males in the

population and the age-specific probability of breeding. Every male in the population was assigned the appropriate age-specific probability of breeding (Table 1) and the cumulative breeding probabilities were placed in a vector with a length equal to the total number of breeding-age stallions. For each female that bred, a uniform random deviate between 0 and the sum of breeding probabilities was generated and compared to values in the vector. The male that corresponded to the value of the deviate was chosen as the mate for that female. All matings were independent. Factors that determined harem formation, size, and retention were too poorly known to include in the model, but harem interchange rates in the Pryor horse population are so high (Singer et al., 1998) that the age-specific algorithm was probably sufficient for this situation. If only harem-holding stallions mated, simulation results reported here will have overestimated retention of genetic variation.

After the parents of an offspring where determined, Mendelian inheritance was simulated by randomly selecting one allele from each parent at 10 independent loci. At the beginning of each set of simulations, individuals were assigned alleles in the frequency in which they occurred in the Pryor population (G. Cothran, pers. comm.). Each simulation began with a total of 41 alleles distributed over 10 loci; two to 13 different alleles occurred at each locus with an initial frequency of 0.0035 to 0.844.

2.2. Population objective, removal and contraception treatments

The current management plan for the PMWHR includes a population objective of 95 horses, excluding foals (BLM, 1992). A population objective, or appropriate management level (AML), is the optimum number of horses that remain after a removal event in order to maintain a "thriving ecological balance". Foals are usually excluded in determining the AML, and in this paper foals were always excluded from counts used to determine compliance with a population objective or to categorize a population size. Simulations included an AML of 90 horses, and increases in AML to 120, 150, and 180 horses. These objectives might be accommodated by supplemental feeding, acquisition of additional habitat, or other strategies. No specific means to attain a particular objective is implied.

Removals and/or contraceptive treatments of wild horses were simulated by applying rules based on current population size, post-treatment population objective, sex and age of animals to be treated, the minimum number of horses in each sex/age class that were to be unaffected by the treatment, and for removals, the length of time since a previous removal. To determine the annual control treatment, the population was first compared to size thresholds used to categorize the population as small, normal, or large. If the population size was less than or equal to the lower threshold, it was categorized as small. If the population size was greater than the lower threshold and less than or equal to the higher threshold, it was categorized as normal. If greater than the upper threshold it was considered large.

Population size could alter both the timing and magnitude of treatment. It is expensive to gather and remove wild horses and managers seek to minimize the frequency of these events (Boyles, 1986; BLM, 1997). The model therefore simulated a removal event only when the population size had grown to a sufficient size. Removals or contraceptive treatments always occurred when the population size was categorized as large, regardless of how long it had been since a previous treatment. Removals also occurred when the population size was categorized as normal and a threshold number of years had passed since the previous removal. This time threshold was set at 3 years for removal-only treatments and 5 years for removal-and-contraceptive treatments. For removal-only treatments, the threshold between a small and normal population size was set at 150% of the population objective and the threshold between a normal and large population size was set at 200% of the population objective. A removal never occurred when the population size was categorized as small.

Several variables determined which animals were removed from the population. The first variable was the

Table 1
Demographic parameters used to simulate wild horse dynamics

Males			Females		
Age	Survival	Probability of mating	Age	Survival	Probability of recruiting
1–4	0.98	0.00	1–2	0.98	0.00
5–6	0.98	0.10	3–4	0.98	0.50
7–8	0.98	0.26	5–16	0.98	0.60
9–16	0.98	0.64	17–22	0.75	0.47
17–19	0.75	0.50	23–24	0.50	0.47
20–22	0.62	0.25	25	0.00	0.00
23–24	0.50	0.25			
25	0.00	0.00			

population objective, which was the number of horses (excluding foals) remaining after a removal was completed. Removal treatments were categorized as young, old, or random for the age of horses emphasized in the treatment. Random animal treatments selected horses randomly with regard to sex or age until the population objective was reached. For old animal treatments, the oldest horses in the population were selected first, leaving a few males and females in each multi-year age class. Similarly, young treatments first removed the youngest animals, again leaving a few males and females in each multi-year age class. Males and females were removed to leave a slightly female-biased sex ratio, consistent with observations of other wild horse populations and prior BLM removals (Berger, 1986, p. 91).

The proportion of mares treated with contraceptives varied with population size. For each contraception-only treatment, the level of contraception was initially calibrated to achieve a stable population size. However, demographic stochasticity often resulted in populations that either grew or declined. In these situations, the rate of application of contraceptives was increased or reduced until the population declined or increased to a size that fell within the normal range. For populations regulated by contraceptives, populations were categorized as normal when they were 85 to 110% of the population objective. Contraceptive treatments were administered every year and treated mares remained infertile for one year. As with removals, females were selected for contraceptive treatments based on age, using rules that selected breeding-age females randomly, or that resulted in treatment of the oldest or youngest mares first.

Simulations that used both infertility and removal employed a constant rate of application of contraceptives and a threshold population size for determining the frequency of harvest. The rate of contraception was initially calibrated to result in removal of about 50 horses every 5 years.

2.3. Genetic analyses

Observed heterozygosity [H_o; Eq. (1)], expected heterozygosity [H_e; Eq. (2)], and the inbreeding coefficient [F_{is}; Eq. (3)] were calculated following Hartl and Clark (1997), where N is the number of loci.

$$H_o = \frac{\sum_{n=1}^{N} \frac{\text{heterozygotes at locus}_n}{\text{number of individuals}}}{N} \quad (1)$$

$$H_e = \frac{\sum_{n=1}^{N} \left(1 - \sum_{k=1}^{\infty} (\text{freq. of allele k})^2\right)}{N} \quad (2)$$

$$F_{is} = 1 - \frac{H_o}{H_e} \quad (3)$$

In the absence of agency-mandated objectives for conserving genetic diversity, changes in genetic variation were evaluated relative to a goal to achieve a 90% probability of conserving 90% of selectively neutral genetic variation for 200 years. This is a slightly less ambitious objective than suggested by Soule et al. (1986). The frequency of each allele at each locus was recorded and used to evaluate rate of loss of alleles.

2.4. Initial conditions, simulation procedures, and evaluation of results

All simulations started with an initial population of 147 horses that matched the sex and age structure of the PMWHR horse population in fall 1998. The initial population consisted of 65 males aged 1 to 22 years and 82 females aged 1 to 17 years. Treatments were evaluated from results of 500 simulations that each lasted 200 years.

A variety of output files were written to permit evaluation of the causes of differences between treatments. Each year, the age structure of the population, the age and sex of individuals removed, and the age of females treated with contraceptives was recorded. Summary files included data on age-specific fecundity and lifetime reproductive success of males and females. These outputs were used to construct life tables of simulated populations, from which standard demographic statistics such as growth rate and generation time were calculated (Carey, 1993). Annual growth rates for removal treatments accommodated removals by adding the number of horses removed back to the population, such that

$$\lambda_t = \frac{N_t}{N_{t-1} + R_{t-1}} \quad (4)$$

where λ_t is the apparent annual growth rate at year t, N is the total number of animals in the given year, and R_{t-1} is the number of animals removed from the population between year $t-1$ and t. The initial age structure led to instability for the first 10–25 years in simulations of populations regulated by contraceptives, and analyses of rates of contraception and average population processes excluded data from the first 30 years of each simulation.

3. Results

3.1. Treatment levels and demographic responses

Removal and contraceptive treatments resulted in population dynamics that were fundamentally different. Populations controlled by removals increased rapidly and declined precipitously when a removal occurred. In

contrast, populations controlled by contraceptives remained relatively stable. As a result of these dynamics, the average size of populations controlled by removals was 18–27% greater than the AML, whereas populations controlled by contraception remained within 3% of the AML (Fig. 1; dark bars referring to horses 1 year and older). Populations controlled by a combination of contraception and removal were on average 18–5% greater than the AML for population objectives of 90–180, respectively. The coefficient of variation of population size for populations controlled by removal averaged 17%, compared to 8% for populations controlled by contraceptives alone and 11% for populations controlled by contraceptives and removals.

Average annual growth rate (λ) of populations controlled by removals was 1.15 when young horses were removed, 1.16 when old horses were removed, and 1.17 for removal of random-aged horses. Population objective had no influence on average growth rate and the maximum difference in growth rate within a removal treatment (old, young, or random) was 0.004. For populations controlled by contraception and removal of younger horses, λ varied with population objective and ranged from 1.05 to 1.09 for simulated populations with objectives from 180 to 90, respectively. For these treatments, differences in λ were driven by differences in the application rate of contraceptives (Table 2), which were adjusted to achieve a removal of about 50 horses every 5 years.

To achieve a stable population with contraceptive-only treatments, an average of 78, 73, or 74% of all mares 2 years or older were rendered infertile for treatments of young, old, or random-aged mares (Table 2). Depending on population objective, this resulted in

Table 2
Percent and number of horses 1 year or older affected by simulated contraception treatments of the Pryor wild horse population, and the average number of foals in the population

	Population objective	Percent treated	Number treated (mean±1 S.D.)	Average number of foals
Contraception-only treatments				
Young age	90	78	32±7.6	5.7
	120	78	44±8.9	7.7
	150	78	54±10.1	9.6
	180	78	65±11.2	11.5
Old age	90	73	31±6.4	5.8

	120	58	37±5.2	18.3
	150	61	46±6.0	20.1
	180	64	57±6.6	21.5

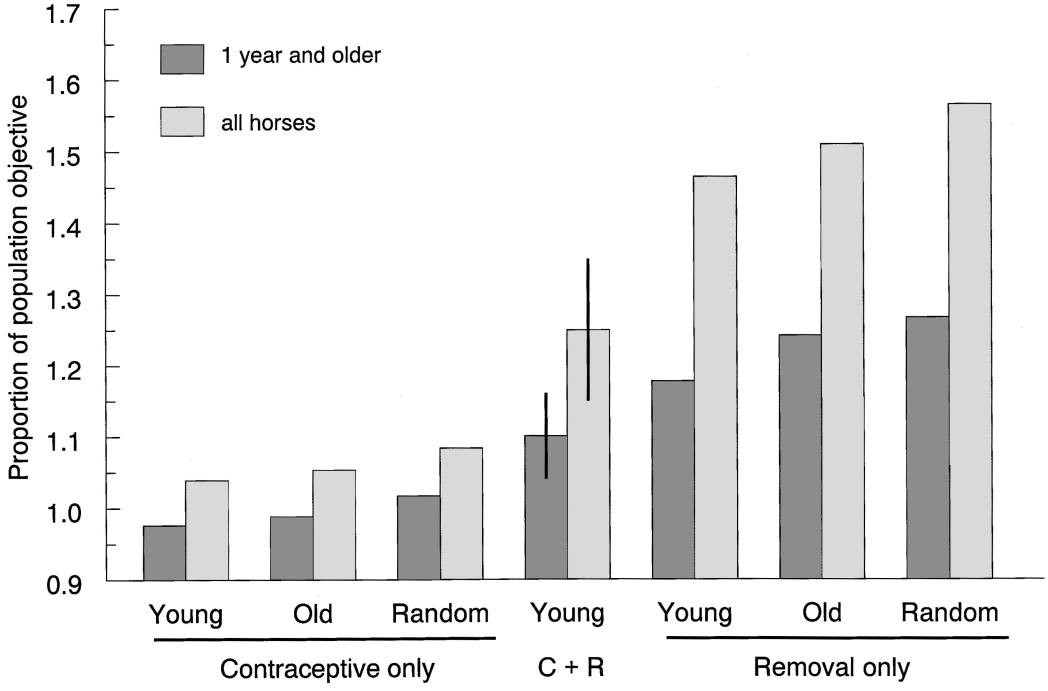

Fig. 1. Average size of populations with (dark bars) and without foals (light bars) as a proportion of population objective; C + R = control using both contraceptives and removals. Population size as a proportion of the population objective varied with the size of the population objective for only C + R treatments; vertical lines show the largest values (for an objective of 90) and smallest value (for an objective of 180).

treatment of an average of 32 to 65 mares per year. For treatments that combined both contraceptives and periodic removals, an average of 50, 58, 61 or 64% of breeding-age mares were rendered infertile each year for population objectives of 90, 120, 150, and 180 horses, respectively. These levels of infertility required treating, on average, 25 to 57 mares each year. When simulated populations were controlled by a combination of removals and contraception, more than 90% of all removals took place at a 5 or 6 year interval regardless of population objective. About 55 horses (range of means = 53–58) were culled from the population each time a removal occurred (Table 3).

For removal-only treatments, more than 90% of removals occurred at three year intervals regardless of population objective or the age of horses removed. Each time a removal occurred, an average about 35% of all horses were removed (range of means = 33 to 37%; Table 3). The number of animals removed was directly related to growth rates; the lowest rate of removal was for treatments of younger horses and the greatest was for random removals (Table 3). Removal of a random selection of horses required harvesting about 20% more horses than when younger horses were removed.

Removals and infertility treatments resulted in populations that had drastically different age structures, but differences in age structure were due entirely to the removal or contraceptive treatment and not to population objective. Within a removal or contraceptive treatment, the proportion of the population in a particular age class remained constant across all population objectives simulated. All simulated removal treatments resulted in age structures characteristic of growing populations, while contraception resulted in the flat age structure characteristic of a stable population (Fig. 2). The average number of foals in the population at the time of a removal varied from 20 to 67 depending on AML and treatment (Table 3). Because foals were not counted towards the AML, populations with a large number of foals in the year of a removal far exceeded the AML in the subsequent year. This occurred because survival rates were high for both foals and adults, and thus the number of foals was far in excess of the number of animals dying from natural causes.

Contraception of older mares or removal of older horses resulted in much shorter generation times than treatments that removed younger females or that delayed reproduction. Average generation time of mares varied by more than a factor of 3, from an average of 4.7 years (contraception of older mares) to a maximum of 16.8 years (contraception of younger mares; Fig. 3). Differences in generation time for males varied far less than that of females, from a minimum of 10.4 years to a maximum of 12.6 years (Fig. 3). Generation time for males was the same for all treatments except for removals of random or old horses; these treatments resulted in shorter generation intervals. For both sexes, differences related to population objectives were small compared to those between treatments that affected different-aged segments of the population.

Table 3
Simulated removal treatments for the Pryor horse population[a]

Age treated	Population objective	Number removed per event (mean±S.D.)	Number removed per year	Proportion removed per event	Harvest interval (years)	Foals at time of harvest
Contraception and removal treatments						
Young age	90	58±10.7	12	0.35	5	20.1
	120	54±9.7	11	0.28	5	20.8
	150	54±10.0	11	0.24	5	22.5
	180	53±9.8	11	0.21	5	23.8
Removal-only treatments						
Young age	90	61±8.3	20	0.34	3	30.2
	120	81±9.7	27	0.33	3	40.2

	180	144±11.4	48	0.37	3	67.1

[a] Mean percent and number of horses 1 year and older removed, and the average number of foals at the time of a removal.

3.2. Effects of treatments on heterozygosity

Initial H_o averaged 0.433 (range of means = 0.432–0.434; range of individual simulations = 0.388–0.479). After 200 years, mean H_o varied from a low of 0.301 (70% of initial H_o), for control by removal of old animals with a population objective of 90, to a high of 0.413 (95% of initial H_o) for populations controlled by contraception and removal of younger mares with a population objective of 180 (Fig. 4). The method of control and age of animal treated or removed had a greater effect on retention or loss of H_o than did population size over the ranges simulated. Treatments that affected older individuals uniformly resulted in more rapid declines in H_o than treatments of young animals. More than 10% of all simulated combinations of population objective and control strategy failed to retain 90% of initial H_o. Using H_o as a measure of genetic diversity, these simulated control strategies thus failed to meet the objective to achieve a 90% probability of retaining 90% of neutrally selective diversity for 200 years.

Inbreeding coefficients (F_{is}) after 200 years of simulation averaged 0.092 (range of means = 0.086–0.096) across all treatments and population objectives. F_{is} tended to be lower for small population sizes, a trend especially pronounced for populations with objectives of 90 and 120 horses. This counterintuitive trend probably resulted from the greater loss of rare alleles in smaller populations, which also reduced H_e in these scenarios (see below).

The use of allele frequencies from the Pryor population resulted in populations in which 34% of all alleles had an initial frequency of 0.05 or less and in which 12% of all alleles occurred at a frequency of 0.02 or less. With an AML of 90, all simulated control strategies resulted in an average loss of more than 25% of alleles (Fig. 5). Almost half (48%) of all alleles failed to persist

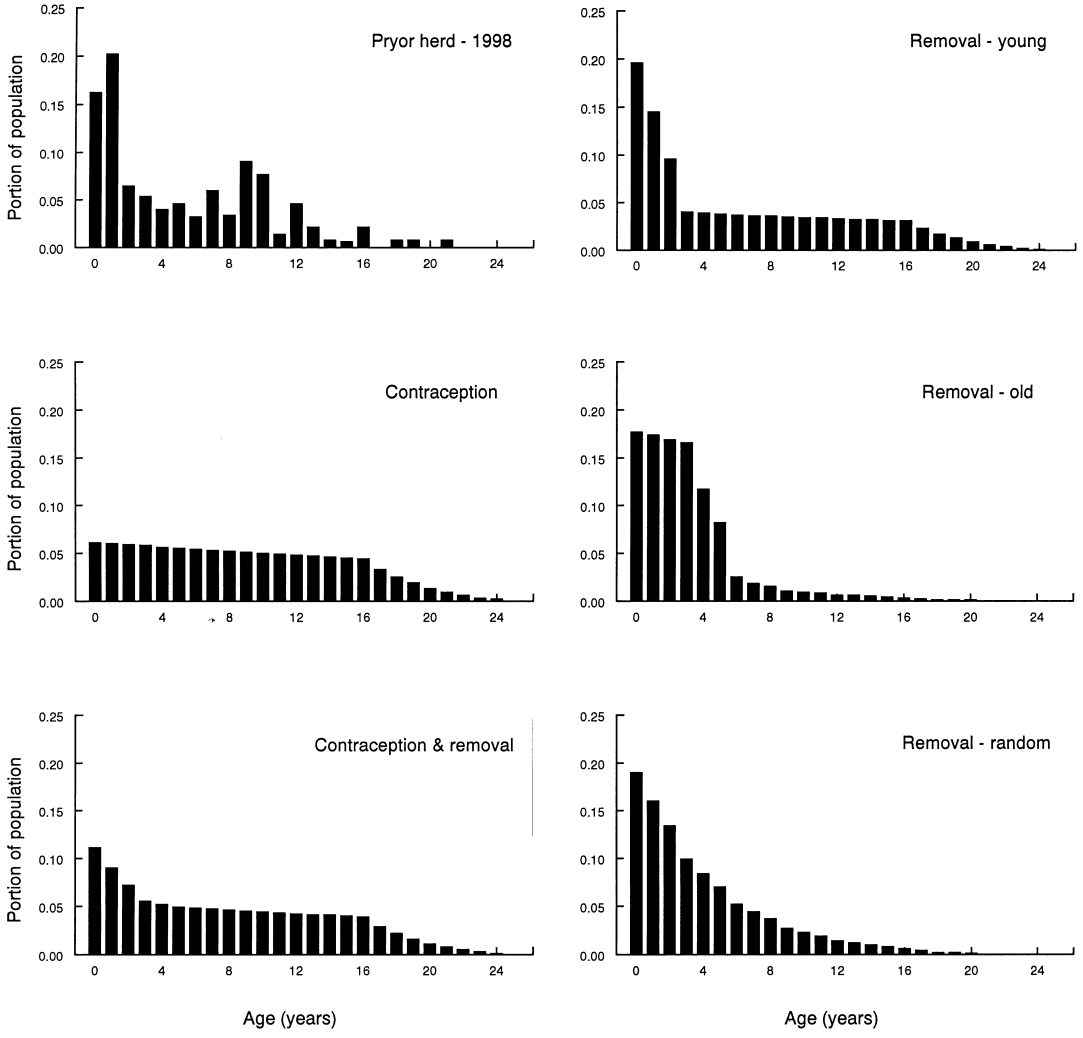

Fig. 2. Age structure of the initial population and simulated populations controlled by contraception, removal, or a combination of both. Age structure of the population was the same regardless of population objective or ages of mares rendered infertile.

for 200 years when old animals were removed from herds with a population objective of 90. Among treatments simulated, contraception of young animals or a combination of contraception and removal of young animals resulted in the greatest persistence of alleles, and an average of 83% of alleles persisted for 200 years under these treatments. These treatments had a 90% chance of retaining 76% of the initial alleles for 200 years. The lower 10th percentile of observations for other treatments included retention of as few as 47% of the initial alleles.

Rates of loss of alleles were highly and non-linearly related to allele frequency. Alleles with an initial frequency of less than about 0.025 tended to be lost very rapid during the first 50 years of simulations. The absolute rate of loss of alleles with initial frequencies greater than about 0.025 tended remain constant throughout the 200 year simulations (Fig. 6).

4. Discussion

4.1. Population control

Simulation results clearly identified contrasting effects of population control by contraception or removals. Compared to removals, infertility treatments reduced variance in population size and resulted in lower standing populations. Because the average sizes of populations managed by infertility were about 25% smaller than those managed by removals, objectives for populations controlled by infertility could be increased to reflect these differences in average size, further enhancing the retention of genetic variation.

Existing chemical contraceptive treatments are effective for a limited period, and they require repeated applications to maintain infertility. Short-duration contraceptives have been used to successfully control growth of horses on Cumberland Island, Georgia and Assateague Island, VA (Kirkpatrick et al., 1997) and they may be suitable for other populations where individuals are easily approached, such as the Pryor herd. A very intensive, and probably very expensive, effort would be required to use short-duration contraceptives as the primary means to control a free-ranging horse population. These treatments are not likely to be successfully applied to widely dispersed populations, but the advantages of contraceptives over removals has stimulated active and promising research that will likely lead to longer-acting contraceptives that can be applied via a "biobullet" or other remote means (Muller et al., 1997). Infertility treatments remain a high priority because they can be far less expensive than removal and adoption programs and they generally receive widespread public support (Garrott et al., 1992; BLM, 1997).

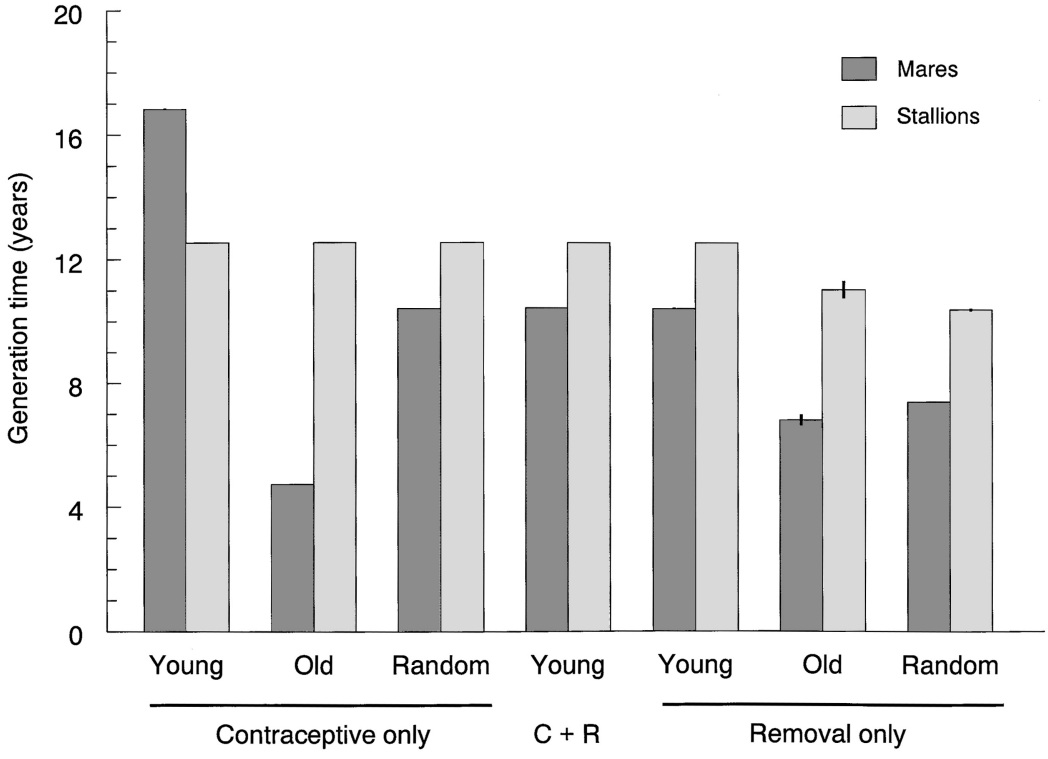

Fig. 3. Generation time of mares (dark bars) and stallions (light bars) in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or random-age horses. Vertical lines are±1 S.D. of average from populations with management objectives of 90 to 180 horses.

Regardless of the control methods used, intensive management will be necessary to restrict the size of populations with high growth potentials. Contraceptives could eliminate or reduce the need to remove and place wild horses, but a complete reliance on contraceptives can lead to other problems. Contraceptive-only treatments provide no mechanism for controlling the sex ratio of a population, which may become highly skewed, and they provide a rather weak means for controlling populations which have exceeded a size objective. The most flexible and realistic program is thus likely to combine the advantages of infertility and removals. Contraceptives can be used to slow growth rates, while removals provide a means to modify sex ratio or rapidly bring a population into compliance with a size objective.

4.2. Genetic considerations — alternatives to increasing population size?

Simulation results emphasized the importance of age structure and demography on processes that govern the rate of loss of genetic variation. Recommendations for preserving genetic variation have focused on increasing population size, and few papers even consider other strategies that may dramatically affect long-term persistence of genetic diversity. This oversight is not due to misunderstanding among geneticists (Hedrick and Miller, 1992, Fig. 5; Lande, 1995, Fig. 14.4), but rather a lack of appreciation among wildlife mangers and biologists of the important roles of generation time and effective population size in maintaining genetic variation (but see Ryman et al., 1981). Age-specific treat-

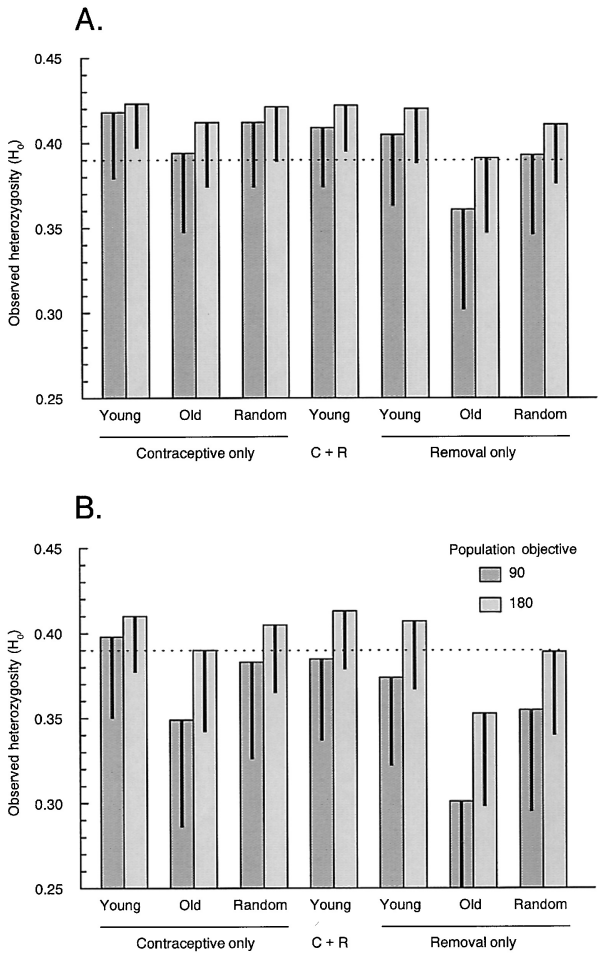

Fig. 4. Observed heterozygosity after 100 years (A) and 200 years (B) in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or a selection of random-age individuals, for population objectives of 90 (dark bars) or 180 (light bars). Vertical lines descend to the 10th percentile of observations; the horizontal line is at 90% of initial heterozygosity. Initial heterozygosity was 0.433.

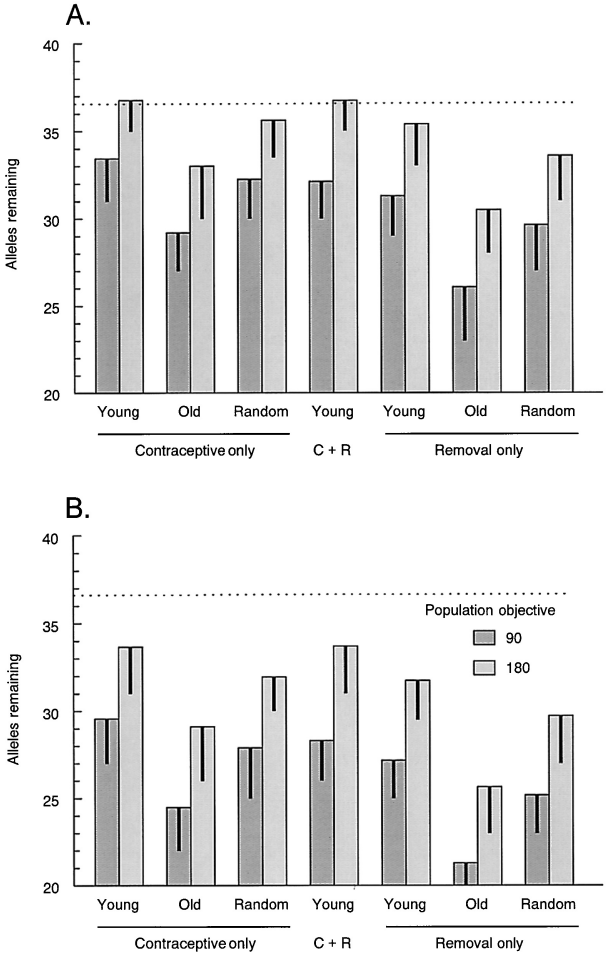

Fig. 5. Number of alleles persisting in simulated populations controlled by contraceptives only, contraceptives and removal (C + R), or removal only of young, old, or a selection of random-age individuals, after 100 years (A) and 200 years (B), for population objectives of 90 (dark bars) or 180 (light bars) horses. Vertical lines descend to the 10th percentile of observations; the horizontal line illustrates 90% of the number of alleleles that were present at the start of simulations.

ments may offer viable alternatives to increases in population size for long-lived species subject to management control. Dramatic differences in the rate of loss of genetic variation between treatments that removed young or old animals are especially pertinent to evaluating management plans because many large mammals of conservation interest are still harvested, either for sport alone or as part of a community-based conservation plan. Both types of harvest usually emphasize removal of older animals from the populations. Consistent harvest of older individuals can have a large effect on retention of genetic variation even when population size exceeds those simulated here by an order of magnitude (Ryman et al., 1981).

The use of multiple measures of genetic variation revealed that under these situations allelic diversity was a much more sensitive indicator of changes in genetic variation than was H_o. Both measures indicated a high probability ($>10\%$) of losing more than 10% of initial variation, even using the best management option simulated. Additional simulations of the contraceptive-and-removal strategy revealed that a population objective of about 500 was necessary to achieve a 90% probability of retaining 90% of alleles, and an objective of 250 was necessary to achieve a 90% probability of retaining 90% of initial observed heterozygosity. It is impossible to implement management plans that achieve levels of contraception or removals as precise as those simulated, thus rates of loss of genetic variation observed under field conditions will vary from those simulated. For treatments of young animals, observed rates of loss of variation will be greater than simulated, while the opposite will likely result from treatments of older animals.

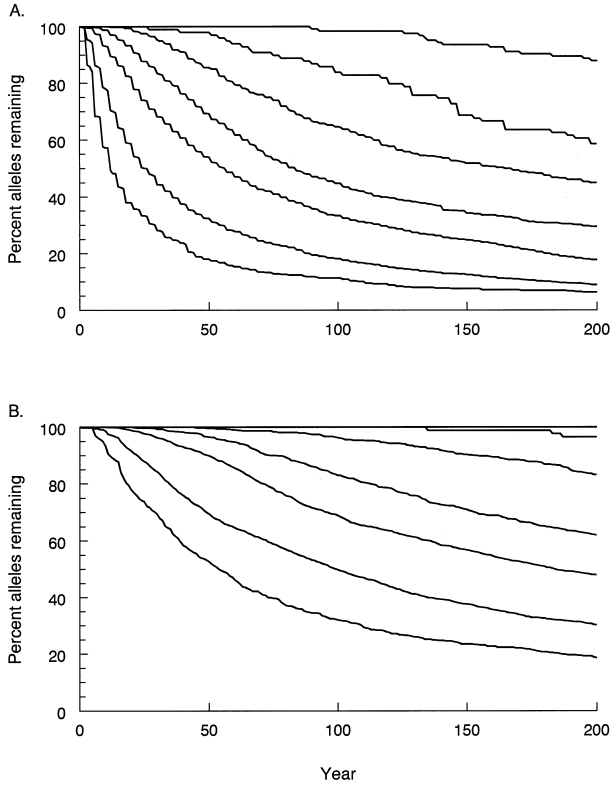

Fig. 6. Persistence of alleles with different initial frequencies over 200 years of simulation. A. Populations controlled by removal of random-aged horses with a population objective of 90. B. Population controlled by contraceptives and removal with a population objective of 150. From the bottom of the plots, lines pertain to alleles that occurred with initial frequencies of 0.005, 0.01, 0.02, 0.05, 0.10, 0.15, and 0.20.

Projected losses of genetic variation were strongly influenced by the frequency distribution of alleles used to initialize simulations. The Pryor population exhibited an unusually high level of heterozygosity (Wooten and Smith, 1985) and it contained many rare alleles. If this population had been isolated for an extended period, many of the rarer alleles would already have been lost and the effects of population size or age of treated animals would have been less. This leads to a rather surprising conclusion: as existing genetic variation declines, fewer individuals are needed to retain a high proportion of the existing variation. This can occur because rare alleles will have already been lost from the population, and those alleles that occur at a relative high frequency are lost slowly (Fig. 6). In natural populations the level of genetic variation will reflect processes that increase and decrease natural variation. Mutations increase variation, but they occur at a slow rate and new variation must be maintained to contribute to long-term heterozygosity. On the other hand, genetic drift results in loss of variation.

In this model, changes in genetic variation resulted only from genetic drift. While the inclusion of mutations would have resulted in lower rates of loss of variation, genetic drift is by far the dominant process leading to changes in gene frequencies in small populations (Nunney and Campbell, 1993; Lynch, 1996). This occurs for two main reasons. First, sampling errors are exacerbated in small populations, and second, the proportion of genetic variation that is selectively neutral increases as population size declines. Selection tends to be far less important in small populations because a much larger selection coefficient (selective advantage) is necessary for selection to act in a deterministic manner as population size declines. For quantitative characters, this situation arises from the distribution of selective forces over a large number of loci, thus selection on any one locus is small enough to be overwhelmed by random genetic drift (Lynch, 1996). A consequence of the dominance of random drift is that an allele with strongly negative effects can become fixed in the population. In large populations, a small selective disadvantage may be sufficient to reduce the frequency of a deleterious allele, whereas this is unlikely to occur in small populations.

Several factors not included in the simulation analysis could result in more rapid loss of genetic variation than these results suggest. Periodic catastrophes could lead to temporary reductions in population size. The Pryor population suffered high winter loss in 1977–1978 (Garrott and Taylor, 1990), and catastrophes are thought to be an important factor in other large mammal populations (Young, 1994, 1999; Ebb and Boyce, 1999). Other factors that may be important and that require further investigation include density dependence, compensatory reproduction, and the role of environmental stochasticity. All of these factors could increase the rate of loss of genetic variation. The results of these simulations should thus be interpreted conservatively if they are used to guide management decisions.

These simulations illustrated several important genetic and demographic concepts. For managed populations, actions that delay the age of reproduction and increase generation interval will reduce the loss of genetic variation. Allelic diversity can be a much more sensitive index to loss of genetic variation than population-level heterozygosity, especially when there are many alleles at a locus. Compared to periodic removals, use of contraceptives under simulated conditions resulted in smaller populations and a much less variation in population size. Management plans that use contraceptives to control the rate of growth and that employ occasional removals to control sex ratio and reduce population size could emphasize the advantages of both approaches, while avoiding the most undesirable characteristics. Overall, these results support use of management strategies that rely less on removal and more on infertility treatments to reduce long-term loss of genetic variation.

Acknowledgements

F. Singer and L. Coates-Markle were instrumental in identifying important processes and management strategies. F. Singer and G. Cothran graciously provided unpublished data used to initialize model runs. Comments from S. Jenkins, L. Coates-Markle, M. Kotzman, and F. Singer improved this paper. L. Zeigenfuss evaluated recent observations from the Pryor horse population. I thank all of these people. This work was supported by USGS-BRD, BLM, and NPS.

Trap–neuter–release (TNR) programs, in which feral cats are sterilized and fed in unconfined colonies, have been advocated as a humane and effective way to reduce the impacts of feral cats on native wildlife. Little is known, however, about the effects of sterilization on feral cat movements and space use, particularly where colonies are located near natural areas. We determined home-range area and overlap and characterized the long-range movements of 14 sterilized and 13 intact radiocollared cats on Catalina Island, California, from 2002 to 2004. Male home ranges were significantly larger than those of females, but no significant differences were revealed in home-range areas or overlap between sterilized and intact cats. Cats regularly moved between natural habitats in the interior of the island and human-populated areas regardless of sex or treatment status, although most (68%; 17/25) of the cats that moved long distances were female. Island-wide, the cat population was estimated to be 600–750 cats, with >70% associated with developed areas, including existing TNR colonies. The influx of subsidized cats to natural habitats, combined with their high vagility and low trappability, makes TNR an unlikely solution for controlling feral cats on a large, rugged island like Catalina and, more generally, in other locations where human populations abut ecologically sensitive areas. DOI: 10.1644/09-MAMM-A-111.1.

Domestic cats (*Felis catus*) have been introduced to islands and continental areas worldwide where they have been implicated in the extinction of native species (Dickman 1996; Nogales et al. 2004). Free-roaming cats harm native wildlife in several ways. First, cats are opportunistic predators, with large effects on prey that are naïve to cat predation (Courchamp and Sugihara 1999). Second, free-roaming cats can compete with native predators for prey. Human-subsidized cats can reach densities exceeding several hundred cats/km^2 (Liberg et al. 2000), and individuals can spill over into less densely populated wildland areas where they reduce prey for native predators (George 1974). Finally, free-roaming cats often carry diseases and parasites that can spread to wildlife (Jessup et al. 1993; Riley et al. 2004).

The introduction of feral cats has been particularly devastating for island species (Nogales et al. 2004). Although eradication and control of invasive predators has been successful on uninhabited islands, such efforts are more complicated on islands inhabited by humans and their pets and by nontarget wildlife (Levy and Crawford 2004). A nonlethal approach to controlling cat populations, known as trap–neuter–release (TNR), involves trapping and sterilizing cats and returning them to unconfined ''colonies,'' where they are fed daily by volunteer caretakers. Longcore et al. (2009), however, point out that the TNR phenomenon is received by the public as an issue of animal welfare, not one of environmental impact. As a result, although TNR is considered only an interim solution to cat overpopulation (Slater 2002), it has been widely implemented to control feral cat populations in urban, rural, and wildland areas, often with detrimental effects on native wildlife (Jessup 2005). In reality, most TNR programs are volunteer-based, understaffed, and cannot sterilize all cats in a colony or monitor colony health or population changes over time (Jessup 2004). Even in intensively managed colonies with a high rate of sterilization (75–80%), the estimated time to extinction of a TNR colony may be more than a decade (Nutter 2005). Finally, TNR research fails to address critical issues such as spillover predation by cats in adjacent wildland areas, zoonotic and wildlife disease risks, and the health and welfare of feral cats (Castillo and Clarke 2003). Thus, many of the actual

consequences of TNR remain poorly documented, making it difficult to assess the true efficacy of such programs.

The feral cat population on Catalina Island provides an ideal opportunity to assess the impact of TNR on cat populations living at the wildland–urban interface. Cats likely were first introduced to the Channel Islands off California, during the 19th century (Phillips and Schmidt 1997), and feral populations are currently resident on 3 of the 8 Channel Islands: San Nicolas, San Clemente, and Santa Catalina (hereafter, Catalina). Catalina has a human population of approximately 4,000 permanent residents and a tourism-based economy with effectively no regulation of exotic or domestic animals brought to the island (Guttilla 2007). Human activity is restricted primarily to the periphery of the island, with the interior of Catalina consisting of rugged, relatively intact native habitat. At the same time, for >20 years, the Catalina Island Humane Society has practiced TNR at designated cat colonies in Avalon and Two Harbors, the 2 largest human settlements on the island. Proponents of TNR have argued that colony-fed sterilized cats pose little threat to native species in the adjacent wildland interior and that because sterilized cats roam less than reproductively intact cats but retain their territorial behavior (Hawkins et al. 2004; Zaunbrecher and Smith 1993), they should prevent immigration of new cats (i.e., the vacuum effect—Mahlow and Slater 1996; Neville and Remfry 1984), thereby eventually leading to population decline due to attrition.

To explore the effects of sterilization on the persistence of feral cat populations we examined the home-range behavior and movements of sterilized and intact radiocollared feral cats living in the interior of Catalina. We predicted that home ranges of sterilized cats would be smaller than those of intact cats because the former would not wander as far in search of mates. In addition, we predicted that sterilized cats would be more sedentary and less territorial and would therefore exhibit greater overlap in their home ranges than intact cats (Castillo and Clarke 2003; Lee et al. 2002). We also examined the extent of movement of cats between the interior and developed areas, including TNR colonies, to determine whether these areas are a source of cats for other parts of the island. Last, we used our livetrapping efforts to estimate the population size of feral cats on Catalina Island. Although our results apply most directly to the management of cats on Catalina, they should improve our understanding of the consequences of maintaining large, unrestricted populations of human-subsidized cats adjacent to ecologically sensitive continental areas.

Methods

Study site.—Catalina is the 3rd largest (194 km^2) of the California Channel Islands, which are located approximately 35 km off the coast of Southern California (Fig. 1). The island is 13 km wide and 22 km long, with rugged terrain ranging in elevation from sea level to 631 m. It has a Mediterranean climate characterized by hot, dry summers and cool, wet winters. Annual temperatures range from 9°C to 24°C, with a mean (± 1 *SD*) annual precipitation of 300 (± 146) mm (Catalina Island Conservancy, www.catalinaconservancy.org). The predominant types of vegetation are coastal sage scrub, island chaparral, and grassland (Knapp 2005). The wet season (November–April) generally corresponds to the cat breeding season, with little reproduction by feral cats reported during the drier part of the year (May–October).

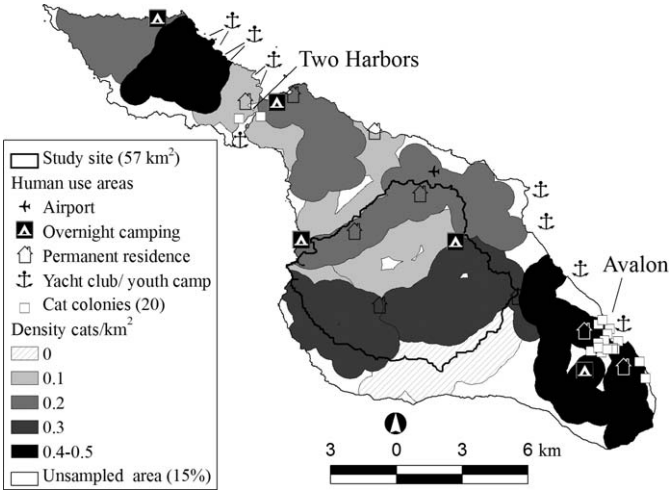

Fig. 1.—Feral cat densities estimated from 2004 island-wide stratified trap efforts on Catalina Island. Filled areas represent bands of different cat densities, on the basis of the number of captures in different trap lines (see text for procedure used to estimate area sampled for determination of densities). Human-inhabited areas and known TNR (trap–neuter–release) colonies are shown because of the higher cat densities observed near those areas. The dark line represents the boundary of targeted trapping efforts, which was approximately 57 km^2 or 30% of the island.

Animal capture and handling.—To capture cats for radiotracking we conducted targeted trapping in the Middle Canyon and Cottonwood Canyon watersheds (57 km^2) on the eastern half of Catalina (Fig. 1). Targeted trapping consisted of setting traps along roads, trails, canyon bottoms, and ridge tops where we detected fresh cat sign; trapping efforts were not standardized with respect to duration or trap placement. In 2004, these efforts were expanded with island-wide transects (250–350 m) placed systematically along the interior road system. We trapped cats with wire-mesh live traps (Model 106; Tomahawk Live Trap Co., Tomahawk, Wisconsin) that were custom-manufactured with smaller mesh to reduce tooth injuries. Traps were covered with industrial shade cloth and equipped with bite bars consisting of nontoxic plastic hose affixed to the back of traps with wire (Guttilla 2007). Traps were lined with grass and baited with wet and dry commercial cat food. We anesthetized cats in traps with an intramuscular injection of ketamine HCl (10 mg/kg) and acepromazine (0.1 mg/kg). Cats were weighed and tested for exposure to feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV). Tests for FIV and FeLV antibodies were run in-house using a commercially available enzyme-linked immunosorbent assay test kit (Snap Combo kit; IDEXX Veterinary Laboratory, West Sacramento, California). FeLV- and FIV-

positive cats were euthanized to prevent infected cats from suffering disease symptoms, to reduce opportunities for disease transmission to other cats and wildlife, and to minimize the loss of experimentally sterilized cats.

We marked adult cats with passive integrated transponder tags (AVID, Inc., Norco, California; Biomark, Inc., Boise, Idaho), which were implanted subdermally between the shoulder blades. A subset of 27 of the adult cats captured was equipped with 45-g radiocollars (Communication Specialists, Orange, California). Fourteen (7 male, 7 female) of the radiocollared cats were sterilized using standard spaying and neutering procedures (Guttilla 2007). The remaining 13 (5 male, 8 female) were left intact as controls. Cats were selected for sterilization opportunistically, as determined by the availability of a veterinarian (on contract with the Institute for Wildlife Studies, Arcata, California) on-island and the timing of cat captures (Guttilla 2007). All radiocollared cats were negative for both FIV and FeLV and weighed at least 1.5 kg. To identify cats as having been sterilized, approximately 1 cm of the distal portion of left ear was cut (tipped). Ear-tipping is common practice in TNR programs (Scott et al. 2002), and TNR colony cats on Catalina have their right ear tipped (Guttilla 2007). All procedures were consistent with guidelines set by the American Society of Mammalogists (Gannon et al. 2007) and were approved by the Institutional Animal Care and Use Committee at California State University Fullerton.

Radiotelemetry.—Before radiotracking cats we placed radiocollars at known locations to determine accuracy of directional bearings in estimating cat locations, giving an estimated bearing error of 12° (White and Garrott 1990). We radiotracked cats from November 2002 to July 2004 using an R-1000 radio receiver and hand-held 3-element Yagi antenna (Communication Specialists, Orange, California). Most locations (83%; $n = 1{,}614$) were recorded between sunset and sunrise when cats are most active (Barratt 1997). We attempted to obtain 3 locations per cat per week. For each fix a single observer moving on foot or by vehicle triangulated the location of the cat. Mean ($\pm$ 1 *SD*) time between the 1st and last bearings for a fix was 21 ($\pm$ 16) min ($n = 2{,}004$ locations). We tracked individual cats for 1–4 wet/dry seasons (mean $\pm$ 1 *SD*: 2 $\pm$ 1 seasons); tracking continued until either collar failure or death of the collared cats.

Home-range analyses.—We plotted telemetry fixes in location of a signal (LOAS 2.07; Ecological Software Solutions, Urnäsch, Switzerland) using the maximum likelihood estimator (MLE) algorithm, with best biangulation as the default estimator when MLE failed. LOAS converts radiolocation estimates into a geographic information systems format so that home-range analyses can be performed. Home-range boundaries were determined in ARCVIEW 3.2a, using the spatial analyst (Environmental Systems Research Institute Inc., Redlands, California) and animal movement (Hooge and Eichenlaub USGS, Anchorage, Alaska) extensions. Home-range boundaries were calculated using minimum convex polygon (MCP) and fixed kernel procedures (KHR, optimized by least-squares cross validation—Worton 1989); 2 procedures were used to better account for differences in the precision and assumptions associated with each estimator (Harris et al. 1990). Home-range area was calculated from 95% of the radio fixes for each animal (95% MCP, 95% KHR), assuming that the remaining 5% of fixes, as determined by the software, were outliers that represented excursions. Core home-range, defined as the area used disproportionately more than other areas (Samuel et al. 1985), was estimated using 50% KHR.

All statistical analyses were performed in SAS v. 9.1 (SAS Institute Inc., Cary, North Carolina). Home-range data were analyzed by season (breeding, nonbreeding), with 18–50 fixes (28 $\pm$ 6; mean $\pm$ 1 *SD*) per cat per season tracked. We used Pearson correlations (r) to determine if a relationship existed between the number of fixes and home-range area that would indicate that we had sufficient numbers of fixes to estimate home-range areas. Initial inspection of these data also indicated that they did not meet the assumptions of parametric tests, and thus estimates of home-range area were natural log-transformed before analysis. We used a 2-way analysis of variance (ANOVA) and Tukey honestly significant difference (HSD) tests to determine the effects of sex and reproductive status (treatment = intact versus sterilized) on the areas of the home ranges occupied by our study animals during the breeding and nonbreeding seasons. We used t-tests to compare home-range areas of cats, pooling across sexes and treatments, and Pearson correlations to determine the relationship between home-range area and body size.

Home-range overlap was calculated for all pairs of overlapping cats during a given season and year, using both 50% and 95% KHR estimates. The area of overlap for a given pair of cats was calculated as the percentage of each cat's home range during a given season and year. Percentage overlap data were normalized by arcsine-square root transformation. We used 3-way ANOVAs to determine the effects of season, reproductive status (sterilized versus intact), and sex on percentage overlap followed by Tukey HSD test for pairwise comparisons subsequent to significant ANOVA outcomes.

Long-distance movements.—We recorded long-distance movements of radiocollared cats from their home ranges in the island interior to areas associated with human activities. These were calculated as the linear distance between the last observation within a cat's home range and the 1st observation in a new area, and were equivalent to $\geq$2 diameters of a given cat's home range. Long-distance movements also were recorded for uncollared TNR colony cats trapped in the interior of the island; these animals were identified visually on the basis of their right-tipped ears. These cats came from TNR colonies located in Avalon and Two Harbors. We estimated the linear distance from trap locations to both Avalon and Two Harbors and recorded the shorter of the 2 distances. All estimates of movements and distance traveled were conservative because they did not take into account the route traveled or the topography of the island.

Table 1.—Estimates of the numbers of free-roaming feral cats in the interior of Catalina Island, California, between 2002 and 2004 on the basis of trapping, direct observations, and spotlight counts. Spotlight surveys were conducted in November 2003 and January–September 2004 (Stapp and Guttilla 2006). The estimated population size assumes that only 50% of the interior population was trapped in a given year.

Method	Year		
	2002	2003	2004
Targeted and systematic trapping	50	70	75
Known to be alive (visuals or radiocollars) but not trapped	53	66	9
Monthly spotlight surveys		5	22
Total known individuals	103	141	106
Estimated population size	128	176	144

Population size and density.—We estimated population density of feral cats from targeted and systematic trapping efforts as the number of individual cats captured divided by the effective trapping area. The effective trapping area was calculated by assuming that the area covered by each trap was equivalent to the mean 95% MCP home-range area (1.56 km^2), resulting in a 705-m radius buffer around each location; areas then were summed for each trapping transect. The total area of coverage from targeted efforts ranged from 39 to 77 km^2, whereas systematic, island-wide efforts in 2004 had an effective area of 165 km^2 (85% of the island). Trap success was adjusted to exclude disturbed traps or those that captured nontarget species. To estimate the size of feral cat population in the interior of the island we combined capture records from targeted and systematic trapping with information on radiocollared cats known to be alive (Stapp and Guttilla 2006). We also surveyed TNR colony caretakers in Avalon and Two Harbors and interior rural residents to estimate the number of colony and feral cats that were dependent on human foods. These two values were summed to estimate the total number of free-roaming cats on Catalina.

Results

We trapped 142 cats between May 2002 and October 2004. Forty-one (28.9%) of 134 cats tested positive for FeLV and/or FIV (30/73 male, 11/61 female) and were euthanized (FeLV prevalence = 15.7% [13 male, 8 female]; FIV prevalence = 17.9% [20 male, 4 female]). These included 3 (17%) of 18 previously sterilized TNR colony cats that were caught in the interior of the island. Of the remaining 101 cats, 35 sterilized (15 previously sterilized; 20 sterilized in our study) and 66 intact animals were released at the point of capture. Fourteen of the sterilized individuals (7 male, 7 female) and 13 of the intact animals (5 male, 8 female) were the radiocollared animals used to assess home-range size and overlap.

Trap success for both targeted and island-wide trapping (9,242 trap-nights) was low (combined mean $\pm$ 1 *SD* = 2.7% $\pm$ 0.4%; $n = 3$ years). Cat densities from targeted trapping (0.8 $\pm$ 0.4 cats/km^2) were higher than those for island-wide efforts (0.3 $\pm$ 0.1 cats/km^2). The highest densities during island-wide trapping were near areas of human settlement (Fig. 1). The west end of the island, which supports several camps and yacht clubs, also had high cat densities (0.5/km^2), although estimated densities near Two Harbors (0.1–0.2 cats/km^2), the location of several TNR colonies, were surprisingly low.

Feral cats were difficult to recapture; nearly 50% of cats known to be alive in 2002 and 2003 evaded traps (Table 1). Under the simple model that only 50% of the population was trappable in a given year, estimates from all sources suggested that the feral population in the interior ranged from 128 to 176 cats across years. Similarly, if we extrapolate the range of feral cat densities generated from trapping (0.3–0.8 km^{-2}) to the entire island (194 km^2), estimates of the interior feral cat population size ranged from 58 (0.3 km^{-2}) to 155 (0.8 km^{-2}) cats. Assuming that the numbers of TNR colony (471) and interior feral cats (85) reported by residents were stable over time, we suggest that approximately 614–732 free-roaming cats were on the island during our study.

We recorded 2,004 fixes for the 27 animals monitored via radiotelemetry between November 2002 and July 2004. Four cats were tracked during all 4 seasons, 9 cats were tracked for 3 consecutive seasons, 4 cats were tracked for 2 consecutive seasons, and the remaining 10 cats were tracked for 1 season. To account for differences in the number of seasons during which individuals were monitored, mean seasonal home-range sizes were calculated for the 13 cats that were tracked for 2 dry or 2 wet seasons. Mean ($\pm$ 1 *SD*) number of fixes per season per cat was 29 $\pm$ 6, with no significant correlation between the number of fixes and home-range area ($n = 61$; 95% MCP: $r = -0.005$, $P = 0.975$; 95% KHR: $r = -0.062$, $P = 0.682$).

For all 3 home-range estimators used (95% MCP, 95% KHR, 50% KHR), sex was the only factor that significantly affected home-range area, and only during the dry, nonbreeding season (dry season: overall model, $d.f. = 3, 16$, $P \leq 0.027$, sex effect $P \leq 0.004$, treatment, sex $\times$ treatment effects $P \geq 0.299$; wet season: overall model $d.f. = 3, 20$, $P \geq 0.089$). Combining treatments, mean home-range area for males was 2–4 times larger than that for females, depending upon the estimator (Table 2; *t*-tests, dry season, $P \leq 0.002$; wet season, $P < 0.064$). Although seasonal home ranges of intact and sterilized females were similar, home ranges of intact males tended to be larger (although not statistically different; $P \geq 0.173$ for the 3 estimators) than those of sterilized males during both seasons (Table 2). The large variation in 95% KHR estimates of home ranges for intact males was largely the result of 1 individual that had a home range in both the breeding (13.6 km^2) and nonbreeding (18.7 km^2) seasons that was 2–4 times larger than the average for intact males. Home-range area was not correlated with body mass for males ($n = 12$, $P \geq 0.550$ for the 3 estimators), and correlations between home-range area and mass for females were marginally nonsignificant for 50% KHR ($n = 15$, $r = -0.49$, $P = 0.065$) and 95% KHR ($r = -0.45$, $P = 0.089$).

TABLE 2.—Home-range area estimates (km^2; mean ± 1 *SE*) of sterilized and intact feral cats radiotracked during dry (nonbreeding) and wet (breeding) seasons on Catalina Island between November 2002 and July 2004.

	Dry (nonbreeding) season			Wet (breeding) season		
Treatment group	*n*	95% MCP	95% KHR	*n*	95% MCP	95% KHR
Female intact	6	0.8 ± 0.2	1.5 ± 0.3	7	1.7 ± 0.6	1.9 ± 0.4
Female sterilized	6	0.9 ± 0.2	1.7 ± 0.4	6	1.3 ± 0.5	3.1 ± 1.4
Male intact	4	2.8 ± 1.0	8.2 ± 3.9	5	3.7 ± 1.2	7.4 ± 2.1
Male sterilized	4	2.1 ± 0.3	3.8 ± 0.3	6	2.2 ± 0.6	4.1 ± 1.1
All males	8	2.5 ± 0.5	6.0 ± 2.0	11	2.9 ± 0.6	5.6 ± 1.2
All females	12	0.9 ± 0.1	1.6 ± 0.3	13	1.5 ± 0.4	2.5 ± 0.7
All cats	20	1.5 ± 0.2	3.4 ± 0.9	24	2.1 ± 0.4	3.9 ± 0.7

We observed no difference in home-range overlap between seasons, sex, or treatment groups for 50% KHR ($n = 58$ pairs; overall $F_{7,50} = 1.39$, $P = 0.231$). For 95% KHR, sex was the only factor that was significantly associated with differences in overlap ($n = 248$ pairs; overall $F_{9,238} = 2.00$, $P = 0.040$; sex effect: $F_{2,238} = 4.88$, $P = 0.008$). Males overlapped significantly more with other males (mean ± 1 *SE*: 23.5% ± 2.7%) and with females (20.6% ± 2.0%) than females overlapped with each other (10.3% ± 1.5%; Tukey HSD test, $P < 0.05$). Neither season ($F_{1,238} = 0.06$, $P = 0.811$), reproductive status ($F_{2,238} = 1.47$, $P = 0.232$), nor the interaction of sex and reproductive status ($F_{4,238} = 1.09$, $P = 0.363$; Fig. 2) significantly influenced the degree of home-range overlap.

Eighteen previously sterilized cats (13% of captures, identified by tipped right ears) were trapped in the island interior (Fig. 3a) ≥10 km from Two Harbors and Avalon. Most of these were females (12, versus 6 males). Long-distance movements from the island interior into peripheral, human-populated areas were recorded for 7 (26%) of the 27 radiocollared cats, including animals of both sexes (2 males, 5

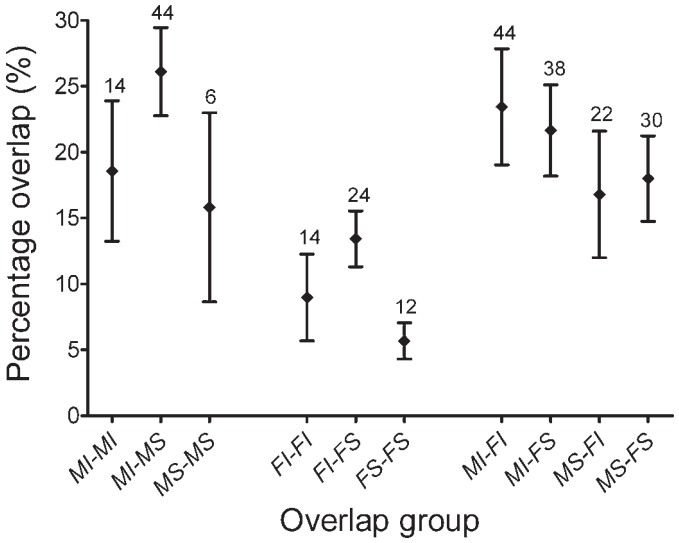

FIG. 2.—Mean percent home-range overlap (± *SE*) of intact and sterilized feral cats, grouped by sex, estimated by fixed kernel (95% KHR). Sample sizes of overlapping groups are listed above error bars. MI = intact male; MS = sterilized male; FI = intact female; FS = sterilized female.

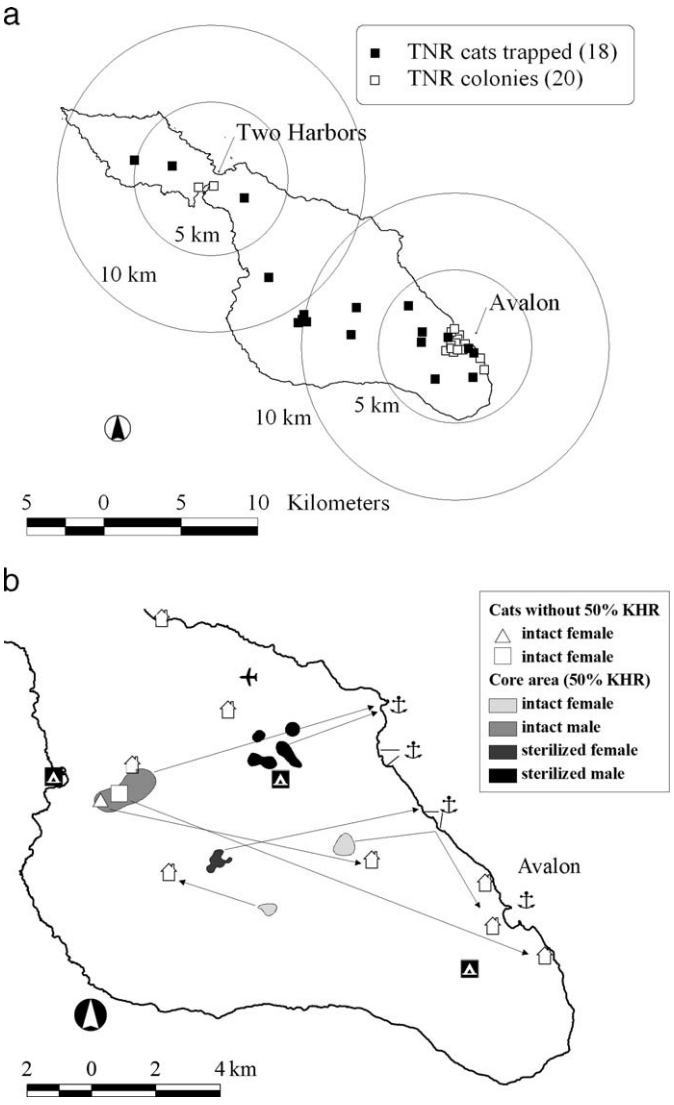

FIG. 3.—a) Trap locations of sterilized colony cats (TNR cats; $n = 18$) captured in the interior of Catalina Island in 2003–2004. Circles denote distances of 5 and 10 km from TNR colonies in Avalon and Two Harbors. b) Long-distance movements of 7 radiocollared cats from the wildland interior into human areas. Polygons are 50% KHR core home-range areas of cats before movements in the direction of the arrows. The open triangle and square denote trap locations of 2 intact females for which core areas could not be calculated before movements. See Fig. 1 for description of other symbols of human use areas.

females) and both intact and sterilized cats (5 intact, 2 sterilized). The mean (± *SD*) distance moved by radiocollared cats was 8 (± 4) km (Fig. 3b), although movements exceeding 14 km were recorded. On average, females (9 ± 4 km) tended to move farther than males (6 ± 3 km), although sample sizes were too small for meaningful statistical analysis.

Discussion

Home ranges of male feral cats were significantly larger than those of females, a finding that has been reported elsewhere (Liberg et al. 2000). However, contrary to our predictions, we found no significant differences in home-range areas of sterilized and reproductively intact cats of either sex. We caution that although we tracked many cats across multiple seasons, sample sizes, especially for males, were relatively low. We expected males to vary more in ranging behavior, suggesting that very large numbers of individuals might be needed to estimate range size with any precision. Our results, however, provide little evidence that sterilization markedly reduces ranging behavior for either sex, at least for cats sterilized as adults.

Previous studies (e.g., Fettman et al. 1997) have revealed that sterilization does not reduce feeding activity and may actually increase longevity (Levy and Crawford 2004). Together with these findings, our results suggest that sterilization likely would not reduce the impact of feral cats on native prey, which, on Catalina, includes a variety of small mammal, bird, amphibian, reptile, and invertebrate species (Guttilla 2007). In addition, the removal of diseased cats before sterilization—a common practice in some TNR programs (Hughes and Slater 2002)—may result in a healthier population than one where sterilization is not conducted. Although this may benefit free-roaming pet cats that interact with feral ones (and ultimately, wildlife), returning healthy cats, even if sterilized, to the environment has no clear ecological benefits.

Our results also revealed that, contrary to our predictions, sterilization had no effect on the degree of home-range overlap among individuals. Because uncollared cats were known to be present in our study area, our measurements of home-range overlap might have underestimated the actual overlap among feral cats. Extensive overlap among male cats has been reported for other islands (Harper 2004; Konecny 1987), although the lower frequency of male–male overlap observed for core areas relative to 95% use areas suggests that core areas may be defended. Sterilized and intact males behaved similarly, however, suggesting that territorial behavior was not affected by being neutered (see also Nutter 2005). Because home ranges of sterilized cats did not overlap more than those of intact cats, sterilization alone would not necessarily lead to an increase in cat densities.

On the surface our finding that sterilization did not significantly change the spatial distribution of feral cats appears to support the argument that sterilization prevents immigration of new animals (i.e., the vacuum effect) and therefore may lead to population decline via attrition. This argument, however, assumes that no consistent source of new, unsterilized cats exists. We found evidence of considerable long-distance movement of both sterilized and intact cats between the wildland interior and developed areas; most of the cats moving long distances were females. The presence of TNR colony cats in the island interior was either the result of cats dispersing from unnaturally high densities near feeding areas or from the deliberate, illegal release of unwanted colony cats into the interior. The number of radiocollared cats observed moving from wildland to populated areas, however, suggests that long-distance movements may be common and that these populations are not distinct.

Our study also provides the 1st estimates of population size for feral cats on Catalina (600–750 cats). These data suggest that the numbers of cats dependent on humans may be 3–4 times larger than the feral population in the island interior. The low trappability of cats in our study population suggests that this estimate is likely conservative. The higher cat densities observed near some developed areas may be spillover from overcrowded conditions associated with TNR colonies and unsterilized pets, which may affect native prey populations in areas immediately adjacent to colonies. For example, low trap success near TNR colonies at Two Harbors, where some 175 stray and colony cats were present but not caught (Guttilla 2007), corroborates previous studies (e.g., Nutter et al. 2004) suggesting that cats become trap-wary, making them difficult to capture and complicating sterilization and control efforts.

From a management perspective our study revealed that hundreds of stray and feral cats live on Catalina. Collectively, our findings suggest that an island-wide TNR program would probably fail to alleviate threats of feral cats to wildlife and would run counter to efforts to protect vulnerable species and restore native ecosystems. TNR also does not address public health risks and nuisance issues in populated areas of Catalina, and sterilized cats are still susceptible to diseases and parasites that can be transmitted to wildlife, humans, and pets (Lee et al. 2002). For these reasons and out of consideration of the welfare of the cats themselves, many animal welfare organizations, including the American Society for the Prevention of Cruelty to Animals, People for the Ethical Treatment of Animals, American Veterinary Medical Association, and Humane Society of the United States currently oppose TNR programs in and adjacent to ecologically sensitive areas where wildlife may be at risk (Guttilla 2007).

We believe that efforts to minimize the effects of feral cats on the interior of Catalina depend upon effective management and control of high-density cat populations in Avalon, Two Harbors, and other coastal areas. Until resources are available to implement more proactive control measures in these areas, cats trapped in the island interior should be removed and delivered to a shelter; if they are deemed adoptable, cats should be sterilized and added to the adoption pool on the mainland. If they are not adoptable or if there are insufficient resources to support relocation, they should be euthanized. Because TNR colonies in human-populated areas of the island

are a likely source of feral cats to maintain an interior cat population, steps should be taken to reduce and eliminate these colonies and adopt and enforce stricter policies for responsible pet ownership and regulation of the importation of exotic animals to the island.

Acknowledgments

Funding and logistical support was provided by the Catalina Island Conservancy and Department of Biological Science, California State University, Fullerton. We thank S. Timm, D. Clifford, T. W. Vickers, G. Varrin, J. Works, and Conservancy volunteers for field and laboratory assistance, and S. Porter and G. Schmidt for advice on telemetry equipment and home-range analyses. Comments from D. Sandquist, S. Walker, P. Sharpe, and several anonymous reviewers improved earlier drafts of the manuscript.

Bottlenecked but long-lived: high genetic diversity retained in white-tailed eagles upon recovery from population decline

Most of the white-tailed eagle (*Haliaeetus albicilla*) populations in Europe experienced dramatic declines during the twentieth century. However, owing to intense conservation actions and the ban of DDT and other persistent pollutants, populations are currently recovering. We show that despite passing through demographic bottlenecks, white-tailed eagle populations have retained significant levels of genetic diversity. Both genetic and ringing data indicate that migration between populations has not been a major factor for the maintenance of genetic variability. We argue that the long generation time of eagles has acted as an intrinsic buffer against loss of genetic diversity, leading to a shorter effective time of the experienced bottleneck. Notably, conservation actions taken in several small sub-populations have ensured the preservation of a larger proportion of the total genetic diversity than if conservation had focused on the population stronghold in Norway. For conservation programmes targeting other endangered, long-lived species, our results highlight the possibility for local retention of high genetic diversity in isolated remnant populations.

Keywords: bottleneck; conservation genetics; generation time; microsatellites; mitochondrial DNA; single large or several small

1. INTRODUCTION

The white-tailed eagle (*Haliaeetus albicilla*) is used as a major flagship and umbrella species for conservation work throughout large parts of Europe. The species was once widely distributed across the continent (Helander & Stjernberg 2003), but direct persecution and low reproductive success as a result of environmental pollutants led to dramatic declines during the twentieth century (Bijleveld 1974; Helander *et al.* 2002). By the 1970s, many local populations in Europe had gone extinct and most surviving sub-populations barely reached one or a few tens of breeding pairs (figure 1). However, a stronghold remained along the Norwegian Atlantic coast with at least 700–800 breeding pairs (Folkestad 2003), corresponding to more than 70% of the northern and central European population (Helander *et al.* 2003). The population along the Norwegian coast utilized relatively uncontaminated food resources from the northern Atlantic and was thus largely saved from the detrimental effects of harmful pollutants (Helander *et al.* 1982). On the other hand, around the heavily polluted Baltic Sea, white-tailed eagles suffered strongly reduced breeding success (Helander *et al.* 1982).

With the ban in the 1970s of DDT, PCB and other detrimental chemicals, European white-tailed eagle populations soon started to recover, a process that is still ongoing (figure 1). For instance, the number of territorial pairs in southern and central Sweden increased from about 40 in 1974 to 250 in 2000 (Helander 2003*a*), and in Estonia from 10–15 between 1965 and 1975 to 116 in 2002 (Volke & Randla 2003). This population expansion appears to have been based mainly on local recruitment, since almost no inter-population exchange of breeders has been recorded from ringing data. In particular, the large Norwegian population does not seem to have acted as a major founding source for recovering populations; none of the more than 3000 eagles colour-ringed in Norway has so far been found breeding outside Norway (Folkestad unpublished data). Further, among more than 150 ringed breeding birds in Sweden, all but a few individuals from the nearby Finnish coast were offspring of resident pairs (Helander 2003*b*). Similarly, most of the few recorded emigrants from the German eagle population settled to breed nearby in Poland (Köppen 2003). Given this apparent trend of local recruitment, current populations might have been depleted of genetic diversity by the recent demographic declines.

Loss of genetic diversity can reduce both short-term viability (e.g. Saccheri *et al.* 1998) and long-term adaptability (Frankham 2005). To assess the genetic impact of population declines during the twentieth century, we therefore studied the genetic variability at mitochondrial DNA (mtDNA) control region sequences and autosomal microsatellite markers in north and central European white-tailed eagle populations.

2. MATERIAL AND METHODS

Several populations from northern and central Europe were sampled, yielding a total number of 218 presumably unrelated individuals: Estonia (EST, $n=13$ samples), Germany (GER, $n=18$), Swedish Lapland (LAP, $n=24$), southern and central Sweden (SWE, $n=117$), Kola peninsula, Russia (KOLA, $n=10$) and Norway (NOR, $n=36$). Most of the samples consisted of blood, but nine samples were moulted feathers that had been collected in the field.

Polymerase chain reaction (PCR) of 26 autosomal microsatellite loci was performed (details are given in Hailer *et al.* (2005) and the electronic supplementary material). In order to directly compare

the amount of genetic variation (expected and observed heterozygosity, H_E and H_O, and the mean number of alleles per locus, N_A) between population samples, we standardized for sample size by employing a bootstrapping procedure (see electronic supplementary material). We tested for deviation from Hardy–Weinberg equilibrium (HWE) and genotypic differentiation using GENEPOP 3.4 (Raymond & Rousset 1995). GENETIX 4.05.2 (Belkhir *et al.* 2004) was used to calculate F_{ST} and its 95% confidence interval. Assignment tests were carried out using GENECLASS 2.0.d (Piry *et al.* 2004) and demographic simulations were performed in BOTTLESIM (Kuo & Janzen 2004). For the latter, population size was held constant at 300 actively reproducing pairs for 10 years, followed by a bottleneck of 30 reproducing pairs for 40 years (see electronic supplementary material for details). The program BOTTLENECK (Cornuet & Luikart 1996) was used to detect possible traces of population bottlenecks on the allele frequency spectrum, applying the recommended settings and tests for microsatellites (two-phased model: 90% one-step mutations and 10% multi-step changes; evaluation with standardized differences and Wilcoxon tests).

A part of the mtDNA control region was amplified and sequenced using the primers *HalHVR1F* (5′-CCCCCCCTATG-TATTATTGT-3′) and *HalHVR1R* (5′-TCTCAGTGAAGAGC-GAGAGA-3′) developed for *H. albicilla*, yielding a total of 500 bp for analysis. Similar to the microsatellite analyses, we used a bootstrapping procedure to correct diversity estimates for sample size (see the electronic supplementary material). DnaSP 4.10 (Rozas *et al.* 2003) was used to determine Tajima's *D* (Tajima 1989) and G_{ST}, an estimator of genetic differentiation among populations, using haplotype identity as the underlying statistic. Sequences obtained have been placed in the EMBL database (accession numbers AM156933–AM156934 and AM156936–AM156943).

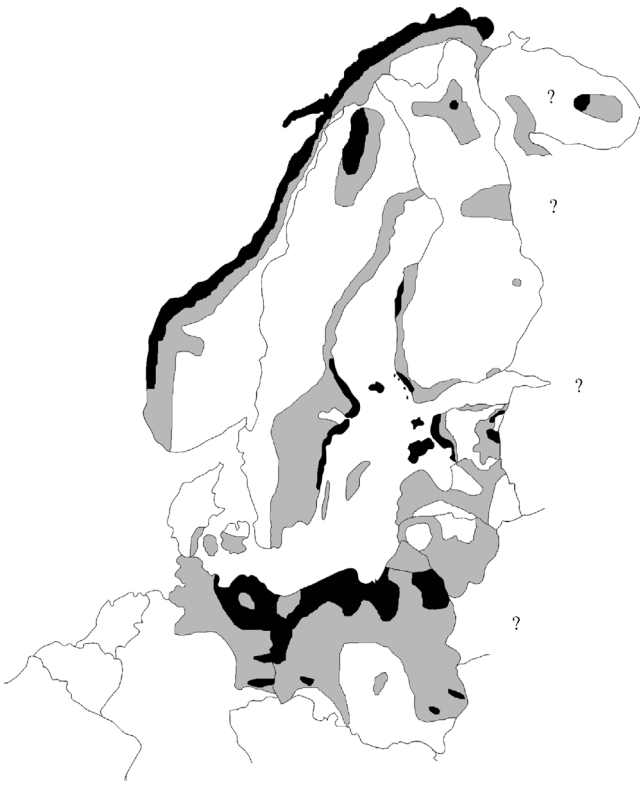

Figure 1. Distribution of the white-tailed eagle in north–central Europe. Black shading indicates regions where the species survived the mid-twentieth century population crash, light grey shading refers to regions re-colonized in the phase of population recovery since 1980.

3. RESULTS

A total of 139 alleles were observed across the 26 microsatellite markers. Significant heterozygote deficit was detected in the SWE, LAP and NOR populations. However, the signal disappeared when the locus *Hal 10* was excluded; we take this as an indication that this locus exhibits a null allele with restricted geographical distribution and that the populations otherwise do not deviate significantly from HWE.

Observed and expected heterozygosities estimated from data corrected for inter-population variation in sample size were in the range of 0.41–0.51 for all populations (table 1). Similarly, the mean number of alleles per locus did not vary much among populations, being in the range of 2.9–3.5. Importantly, there was no evidence for the large Norwegian population to show higher levels of genetic diversity ($H_E=0.48$, $H_O=0.49$, $N_A=3.1$), as compared to the other populations that had experienced a significant demographic bottleneck. Further, no population showed significant allele frequency shifts ($p>0.05$) which are expected after strong demographic bottlenecks.

One possible explanation for the homogeneous levels of genetic diversity among the populations could be that gene flow had passed unnoticed in the field surveys. Consistent with this idea, overall genetic differentiation was low ($F_{ST}=0.036$). However, F_{ST} was significantly different from zero (95% confidence intervals 0.029–0.044) and the test of genotypic differentiation found that all populations were significantly differentiated from each other ($p<0.01$ in all pairwise comparisons). Furthermore, an assignment test also indicated that populations were distinct units: despite the low overall F_{ST} value, about 80% of the analysed nestlings assigned to their natal population. Thirty-seven alleles found in other European populations were not observed in Norway, while only three of the Norwegian alleles were not found in the rest of the Europe.

Ten different mtDNA haplotypes were observed. Tajima's *D* was 1.522, but differed non-significantly from zero ($p>0.05$), compatible with neutral evolution of the DNA sequences. Haplotype frequencies differed significantly among populations, reflected by an overall G_{ST} of 0.228. The stronger population differentiation in mtDNA than nuclear markers probably reflects differences in effective population size between the marker types. Higher dispersal rates in males than in females are uncommon in birds (Greenwood 1980), and not supported by empirical data in white-tailed eagles (Helander 2003*b*).

The corrected number of haplotypes per population varied between 1.3 (Norway) and 7 (Kola peninsula; table 2), again indicating that bottlenecked populations do not contain lower levels of genetic diversity as compared to the Norwegian population. Further, our results confirm that the European populations could not have been derived largely from the coastal Norwegian population: only two mtDNA haplotypes were observed in Norway, one haplotype being very frequent (97%).

4. DISCUSSION

In summary, our data suggest that effective dispersal between populations has not been common during the past decades. We conclude that sustained genetic

Table 1. Genetic diversity at microsatellite loci. Number of samples analysed, unbiased expected (H_E) and observed (H_O) heterozygosity, mean number of alleles per locus (N_A) and their inter-locus standard deviations. For comparison between populations, standardized diversity values are also given.

population	sample size	H_E (s.d.)	corrected H_E	H_O (s.d.)	corrected H_O	N_A (s.d.)	corrected N_A
Norway	36	0.49 (0.05)	0.48	0.49 (0.02)	0.49	3.9 (2.3)	3.1
Estonia	13	0.49 (0.05)	0.48	0.50 (0.03)	0.50	3.5 (1.7)	3.1
Germany	18	0.43 (0.05)	0.42	0.42 (0.02)	0.41	3.4 (1.7)	2.9
Kola peninsula[a]	10	0.52 (0.05)	—	0.51 (0.03)	—	3.8 (2.0)	—
Lapland	24	0.51 (0.05)	0.49	0.49 (0.02)	0.49	4.2 (2.3)	3.4
mid and southern Sweden	117	0.51 (0.05)	0.51	0.50 (0.01)	0.51	4.8 (2.2)	3.5

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

Table 2. Genetic diversity at mitochondrial control region sequences. The number of analysed eagle territories (maternal lineages) is denoted by n, and N denotes the number of unique haplotypes found in each population. To correct for unequal sample sizes among populations, the mean number of alleles encountered in 100 bootstrap samples of 10 individuals each, and the standard deviation of these values, is presented.

population	n	N	corrected N (s.d.)
Norway	33	2	1.3 (0.5)
Estonia	12	5	4.0 (0.7)

Lapland	22	6	3.7 (1.0)
mid and southern Sweden	44	4	2.9 (0.6)

[a]diversity statistics of the remaining populations were standardized to sample size of $n=10$, corresponding to the number for Kola peninsula.

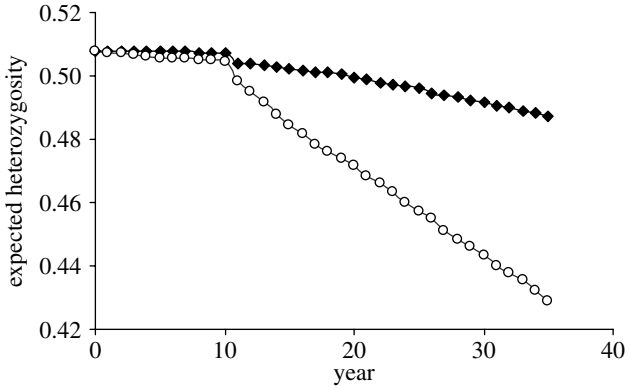

Figure 2. Loss of genetic diversity (as measured by expected heterozygosity) in a bottleneck of 30 reproducing pairs and overlapping generations. Filled diamonds and open circles consider an individual lifespan of 17 years and 1 year, respectively. The simulation was started at a population size corresponding to 300 reproducing pairs (years 0–10).

diversity in extant north–central European white-tailed eagle populations has a predominantly local origin, although some immigration may have contributed to local gene pools. We suggest that the long generation time of white-tailed eagles (average life span is around 17 years; Helander 2003*b*; Struwe-Juhl 2003) has minimized genetic drift and acted as an intrinsic buffer against rapid loss of genetic diversity. When a randomly mating population passes through a bottleneck, reduction of genetic diversity depends on population size and time according to $H_t=H_0(1-1/(2N_e))^t$; H_0 and H_t being the past and present heterozygosity, respectively, N_e the effective population size and t the time measured in number of generations. A bottleneck lasting about 20–30 years is equivalent to about two white-tailed eagle generations. Simulation of a bottleneck comprising 30 reproductive pairs (which corresponds to the situation in several European populations during the 1970s; see §1) shows that only about 4% of the original heterozygosity is expected to be lost in an eagle population during that time (figure 2). By contrast, for an organism with a generation time of 1 year, the corresponding loss of genetic diversity is considerably higher (16%; figure 2). Our results are compatible with the relatively high levels of genetic diversity seen in remnant and bottlenecked populations of other long-lived species, e.g. black rhinoceros (Swart *et al.* 1994) and greater one-horned rhinoceros (Dinerstein & McCracken 1990).

Starting in the late 1960s, several countries in Europe developed conservation programmes to protect eagles (Helander 1990). Nest site protection enabled fertile pairs to raise fledging young. Carcasses free of contaminants were laid out in winter and, as a result, juvenile survival was increased to 80% (Helander 2003*b*). Our results, therefore, indicate that these conservation efforts have led to the preservation of ample genetic diversity in local eagle populations. Moreover, conservation of eagles at local scales has resulted in the preservation of more total genetic diversity than if all conservation efforts had been centred on the coastal Norwegian population.

There has been an intense debate among conservation biologists about reserve design (the SLOSS debate—single large or several small; reviewed in Kingsland 2002). This debate was directly linked to the relative importance of local conservation versus a focus on population strongholds. Our results illustrate the high conservation value of local populations for species with a long generation time. A number of other species of conservation concern also have long generation times (e.g. raptors, turtles, large mammals and orchids) and for many of these significant genetic diversity may still exist in local populations. For the white-tailed eagle, protection of the local populations did not arrive too late.

The sampling of blood for this study was coordinated by the Swedish Society for Nature Conservation/Project Sea Eagle. We thank Kurt Elmqvist and Robert Franzén for assistance with the sampling of blood in the field in Sweden, Andreas Mertens for contributing feather samples, Torsten Stjernberg for comments on the distribution map and Mia Olsson for assistance in the lab. Deborah Dawson and Ruth Tingay kindly provided their markers prior to publication. The editor and two anonymous reviewers are thanked for constructive comments. This work was financially supported by Alvin's foundation, the Sven and Lilli Lawski foundation and the Knut and Alice Wallenberg foundation (to F.H.). H.E. is a Royal Swedish Academy of Sciences Research Fellow supported by a grant from Knut and the Alice Wallenberg foundation.

Monitoring distances travelled by horses using GPS tracking collars

BA Hampson,[a]* JM Morton,[a] PC Mills,[a] MG Trotter,[b] DW Lamb[b] and CC Pollitt[a]

Objective The aims of this work were to (1) develop a low-cost equine movement tracking collar based on readily available components, (2) conduct preliminary studies assessing the effects of both paddock size and internal fence design on the movements of domestic horses, with and without foals at foot, and (3) describe distances moved by mares and their foals. Additional monitoring of free-ranging feral horses was conducted to allow preliminary comparisons with the movement of confined domestic horses.

Procedures A lightweight global positioning system (GPS) data logger modified from a personal/vehicle tracker and mounted on a collar was used to monitor the movement of domestic horses in a range of paddock sizes and internal fence designs for 6.5-day periods.

Results In the paddocks used (0.8–16 ha), groups of domestic horses exhibited a logarithmic response in mean daily distance travelled as a function of increasing paddock size, tending asymptotically towards approximately 7.5 km/day. The distance moved by newborn foals was similar to their dams, with total distance travelled also dependent on paddock size. Without altering available paddock area, paddock design, with the exception of a spiral design, did not significantly affect mean daily distance travelled. Feral horses (17.9 km/day) travelled substantially greater mean daily distances than domestic horses (7.2 km/day in 16-ha paddock), even when allowing for larger paddock size.

Conclusions Horses kept in stables or small yards and paddocks are quite sedentary in comparison with their feral relatives. For a given paddock area, most designs did not significantly affect mean daily distance travelled.

Keywords behaviour; feral horses; foals; global positioning system (GPS); horses; paddock design

Abbreviation CI, confidence interval; GPS, global positioning system

Aust Vet J 2010;88:176–181 doi: 10.1111/j.1751-0813.2010.00564.x

Extent of movement and distances travelled by domestic horses may affect their general health and hoof quality. It is believed that domestic horses have become more sedentary since the industrial revolution, with many now maintained in small paddocks and stables because the amount of land available for horse maintenance has decreased. The Thoroughbred racehorse, for example, is an athletic horse that is typically boxed in a stable for 23 hours/day and moved to the training track for a short gallop once daily.[1] The psychological, physiological and musculoskeletal consequences of this relatively sedentary lifestyle are not fully understood, but the low level of mobility from an early age may adversely affect the shape, structure and function of the foot. Domestication has also necessitated an altered diet,[1] and horses are routinely fed high-energy food twice daily. Confinement and altered feeding patterns parallel the modern human lifestyle that is thought to be a major contributor to current high prevalences of obesity, cardiovascular disease, arthritis and diabetes. For example, the prevalence of osteochondritis dissecans was 26% in 1000 yearling Thoroughbred horses surveyed radiographically, and diet and environment were cited as contributing factors.[2] Another radiographic study of 315 yearling Standardbred horses revealed bone and joint lesions in 58% of horses, 38% of which required surgical correction.[3] Hyperinsulinaemia has recently been associated with laminitis,[4] and both a diet high in non-structural carbohydrates and low levels of activity are associated with hyperinsulinaemia.[5]

It has been hypothesised that horses move more in large paddocks and that paddock design may also affect the distance moved; for example, it has been suggested that a 'racetrack' design is a useful strategy for increasing the distance moved by horses.[6] The effectiveness of this design has not been investigated. Understanding the relationships between both paddock size and internal fence design and distances moved would allow development of practical management strategies to increase horse movement.

The velocity of horse movement varies considerably, making locomotion studies in the field challenging. Global positioning systems (GPS) are now sufficiently lightweight and accurate to measure speed variation and to distinguish small movements of fast-moving animals, so accurate determination of horse movement profiles has become feasible. GPS have been used to measure locomotion variables in horses during cross-country riding[7] and in foals at pasture.[8]

Little is known about the movement patterns of domestic horses or the effects of the various forms of yard and paddock confinement on distance travelled. Also, to the authors' knowledge, there have been no reports of the distances travelled by free-ranging, non-domesticated horses. In studies of domestic cattle, those in a rangeland environment were observed to walk up to 27 km between visits to water,[9] whereas cattle in a more intensive grazing situation walked up to 5.5 km during a 24-h period that included grazing, watering and socialising.[10] Free-ranging cattle in Africa walk about 5000 km annually (an average of 14 km/day).[11] Equidae are generally more mobile than cattle and capable of covering greater distances between feeding and watering.[12] In one study, female zebra walked approximately 15 km over a 12-h period between water and their feeding region, remaining for 3 to 4 days before walking back to water.[13]

The aims of this work were to (1) develop a low-cost equine movement tracking collar based on readily available components, (2) conduct

preliminary studies of the effects of both paddock size and internal fence design on the movements of domestic horses and (3) describe distances moved by mares and their foals. Additional monitoring of free-ranging feral horses was conducted to allow preliminary comparisons with the movement of confined domestic horses.

Materials and methods

GPS data logger

The University of Queensland Equine GPS data logger was constructed from a Wintec G-Rays GPS unit (G-Rays 2 WBT-201 data logger, Wintec Wireless Electronics, Taiwan). The store-on-board GPS unit was modified by the addition of a circuit board to control the power input from an additional three AA-battery pack. The total weight of the GPS, battery and collar for domestic horse tracking was 450 g. With the addition of a very high frequency location beacon for feral horse tracking, the collars weighed 700 g. The GPS unit was mounted on a neck collar with a full sky view, counterweighted by the battery pack, which hung under the horse's neck. The 130,000 position storage capacity of the unit and the life of a single battery power source (6.5 days) allowed data logging at the rate of a position every 5 s.

Data defining both the horizontal and vertical positions were downloaded via Google Earth Plus (Google Earth Plus-google.com). The Wintec software was used to perform distance calculations from the raw GPS positional data. The pattern of travel was superimposed on Google Earth satellite photographs and checked for plausibility and data error.

Horse movement assessments

Four preliminary studies were conducted to explore the effects of paddock design and size on distance travelled. In each study, the average daily distance moved for each horse was calculated, based on the total distance moved for the 6-day observation period. Descriptive statistics were calculated using Microsoft Excel and other statistical analyses were performed using Stata (version 10, StataCorp, College Station, TX, USA).

The project was approved by the University of Queensland Animal Ethics Committee.

Effect of paddock size. Data loggers were fitted to each of four mature-age (mean ± SD, 6.75 ± 2.2 years), pregnant (approximately 310 days of gestation) domestic Quarterhorse × Australian Stockhorse mares due to foal within 2 weeks of each other. These horses were grazed together for three consecutive 6-day periods in each of three different paddocks, sized in sequential order 0.8, 4 and 16 ha. All paddocks were on the same farm and the study mares were familiar with all paddocks. Mares were placed in each paddock at the same time. They were not hand-fed and all paddocks had sufficient pasture mass to ensure adequate feed intake over the confinement intervals.

A further seven domestic Quarterhorses (3 geldings, 4 mares; age 3–4 years) were each simultaneously tracked for 6 days on a commercial horse-training property. These horses were housed in familiar yards measuring 6 m^2 and were hand-fed twice daily throughout the study.

The relationship between paddock size and average distance moved for the group (calculated as the average of each horse's average distance moved daily) was described as a function of the natural logarithm of paddock size using data from the groups of domestic horses.

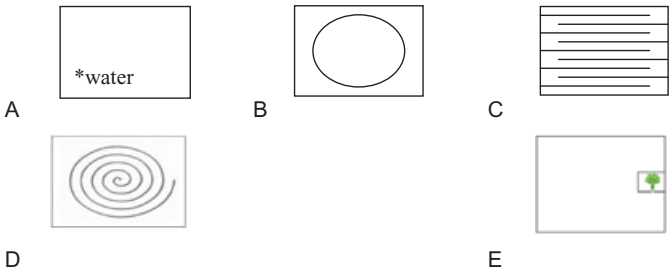

Figure 1. Internal fence designs compared in a study assessing the effects on distance travelled by horses: (A) open, B) racetrack, (C) maze, (D) spiral, (E) open and no tree. *Location of the waterpoint.

Effect of internal fence design. A 5-period cross-over design was used to assess the effect of various internal fence designs on distance travelled. Five horses (4 mares, 1 gelding; age 3–9 years) were each sequentially grazed separately in the five designs. The same rectangular paddock (100 × 50 m) was used throughout the study. There was one tree in the paddock, which provided the only area of shade for the horses, and a stationary trough was the only water point. The internal fence design of the paddock was varied using electric fencing. All horses were accustomed to electric fencing. The five internal fence designs are shown in Figure 1.

Open: The paddock perimeter was fenced with electric fencing (Figure 1A).
Racetrack: The open design with an additional internal oval ring of fencing to create an 8-m wide racetrack around the perimeter of the paddock (Figure 1B). Horses were confined to the racetrack strip and excluded from the centre of the paddock.
Maze: The open paddock was divided into 10 strips, 10 × 50 m long, with gaps at alternate ends to make all strips accessible (Figure 1C). Horses were required to move through each of the 10 strips to travel from one end of the paddock to the other, effectively travelling at least 500 m when moving from one end of the 100-m paddock to the other.
Spiral: The internal fencing had a spiral configuration so that the horses had to travel in circles of diminishing radius to move into and away from the centre of the paddock (Figure 1D).
Open and no tree: Because the horses spent a disproportionate amount of time standing under the shade tree in the open paddock, the open design was used with the tree fenced off to prevent this (Figure 1E).

The maze and spiral designs were not expected to have practical applications in horse management, but were included in the study to determine the effect of complex designs on movement. Each of the five horses were assessed separately in each paddock design, but always in the company of a subordinate yearling gelding to provide company and minimise the likelihood of separation anxiety, which may have affected the movements of the dominant horse. Each horse spent 6 consecutive days in each design, with no delay or 'washout period' between designs. The first horse was rotated through the five designs in an ad hoc order, then each of the remaining four horses was

© 2010 The Authors
Journal compilation © 2010 Australian Veterinary Association

allocated to first receive one of the designs using a random draw, followed by each other design in the same order as the first horse. The paddock was spelled for 2 weeks between each horse and pasture cover was maintained to ensure grazing without supplementary feeding during each experiment. Mean distance travelled daily was calculated for each horse for each design and log-transformed. Mean distances travelled were compared between designs using linear regression with horse fitted as a fixed effect.

Mare and foal comparison. Three days after each mare's foaling, the same four mares used in study 1 (paddock size) were grazed with their foals in the 4-ha paddock for a 6-day period. To avoid interference with development of the mare–foal bond, GPS collars were applied to each mare and foal when the foal was 3 days of age. Each mare and foal was again monitored simultaneously when the foals were aged 3 to 5 weeks while in a different paddock (5 ha) on the same farm to determine if there was a difference in activity between newborn foals (a period when they are often stabled) and more mature foals. Effects of class (mare or foal) and foal age (3–9 days vs 3–5 weeks) on average distances moved daily were analysed using linear regression with pair (mare–foal combination) fitted as a fixed effect. Effects of pregnancy/lactation were analysed using linear regression with data only from mares with mare fitted as a fixed effect. Correlation coefficients were estimated for the association between the distances moved daily by mares and foals; separate estimates were made for 6-day periods commencing when foals were aged 3 days and then at 3 to 5 weeks. The 95% confidence interval (CI) for the correlation coefficients was calculated using Fisher's transformation.

Feral horse monitoring. Three mature feral horses from different family bands (1 mare, 2 stallions) and living wild in a 4000-ha paddock were tracked for 6 consecutive days. In order to apply the collars, horses were darted with 0.7 mL etorphine hydrochloride (Imobilon, Novartis SA Pty Ltd) when they approached water. When the horse went into lateral recumbency, the collar was placed and the immobilising agent reversed using diprenorphine hydrochloride (Revivon, Novartis SA Pty Ltd, IV). Horses returned to their family band within 15 min of darting and appeared both unaware of the initial human contact and unaffected by their collars. After a minimum of 6 days, the same feral horses were relocated using the very high frequency beacon on their collar and again immobilised by darting, the collars were removed, the immobilising agent reversed and the horses released.

Results

GPS collar performance

The data logger device logged positional data at 5-s intervals for 6.5 days. The unit ran continuously and did not record either the usual gaps in data or the error often associated with reconfiguring position in relation to satellites; it was 100% reliable over 384 data logging days.

Horse movement assessments

Paddock size study. Average distances moved for the groups were greater in larger paddocks (Figure 2A). The average for the group was: 4.7 km/day (range 4.2–5.2 km/day) for the 0.4-ha paddock; 6.1 km/day (range 5.8–6.5 km/day) for the 4-ha paddock; 7.2 km/day (range 6.7–7.6 km/day) for the 16-ha paddock. The average for the feral horses in the 4000-ha paddock was 17.9 km/day (range 12.52–5.9 km/day). The average for horses kept in the 6 × 6 m yard was 1.1 km/day (range 0.2–1.9 km/day).

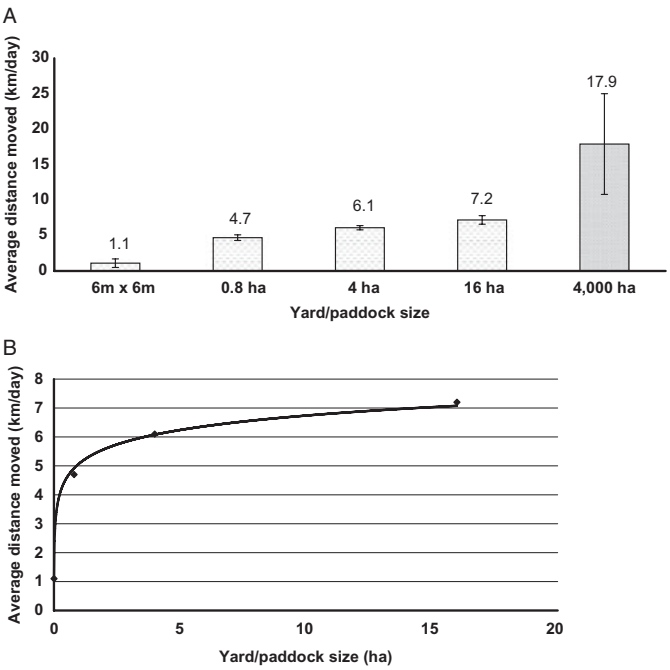

Figure 2. (A) Average distances (km/day) moved by groups of horses (± SD of each horse's distance) over 6 days in various sized yards and paddocks. Light shade indicates domestic horses; dark shade indicates feral horses. (B) Scattergraph of average distances moved by groups of domestic horses against yard/paddock area and logathithmic line of best fit of average distance moved by group as a function of yard/paddock area.

The average distances moved by the groups of domestic horses could be described as a logarithmic function of paddock area: Average distance moved/day = 0.72 (SE 0.029)**ln*(paddock size in ha) + 5.08 (SE 0.094)($R^2 = 0.997$) (Figure 2B).

Internal fence design study. Mean distances travelled daily by the five horses for each of the internal fence designs are summarised in Table 1. The average of the distances travelled by each horse was greatest for the open paddock design and smallest for the spiral design (ratio of geometric means 0.72, 95% CI 0.55–0.96, P = 0.03). There were no significant differences (P > 0.35) in the distances travelled by horses between the 'open' paddock and either the 'maze' or 'open and no tree' paddock designs. There was also no significant difference between the 'open' and 'racetrack' paddock design (ratio of geometric means 0.94, 95% CI 0.71–1.24, P = 0.63).

Mare and foal comparison study. Prior to foaling, the average distance travelled for the group of mares (derived from study 1) was 6.1 km/day (range between mares 5.8–6.5 km/day). During the 6-day periods from 3 to 9 days and 3 to 5 weeks after foaling, the average distances moved by mares were 7.2 km/day (range 6.9–7.4 km/day) and 7.7 km/day (range 5.9–10.7 km/day), respectively (Figure 3). Daily distances moved by foals were 7.3 km/day (range 4.5–9.5 km/day) and 7.3 km/day (range 4.5–9.3 km), respectively. After account-

Table 1. Distances moved by five horses in paddocks with various internal fence designs

Internal fence design	Distance moved (km/day)			Ratio of geometric means (95% CI)	P value
	Range between horses[1]	Arithmetic mean[2]	Geometric mean[2]		
Open	2.8–5.3	4.1	4.0	Reference group	
Racetrack	2.7–6.0	3.9	3.7	0.94 (0.71–1.24)	0.63
Maze	2.5–6.8	3.8	3.5	0.88 (0.67–1.17)	0.36
Spiral	2.1–5.8	3.1	2.9	0.72 (0.55–0.96)	0.03
Open and no tree	2.8–4.9	3.9	3.8	0.96 (0.73–1.28)	0.78

[1]Average of distances moved by horse daily on 6 consecutive days. [2]Means of daily average for each horse. CI, confidence interval.

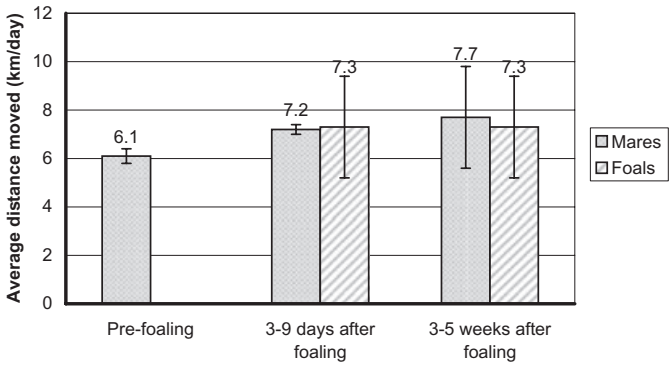

Figure 3. Mean (±SD) distances walked by mares before foaling, and by mares and their foals 3 to 9 days and 3 to 5 weeks after foaling.

ing for mare–foal pair and class (mare or foal), the difference in mean distance walked between 3 to 9 days and 3 to 5 weeks after foaling was not statistically significantly diffferent (difference between means 0.2; 95% CI −1.8–2.2; P = 0.83). The observed correlation coefficient suggested that distances moved were quite closely correlated between mares and their foals during the first tracking period (3–9 days after foaling), but the estimate was imprecise (r = 0.81; 95% CI −0.68–1.00; P = 0.19). During the second study period (3–5 weeks after foaling), the correlation coefficient was 0.47 (95% CI −0.90–0.99; P = 0.53).

Feral horse monitoring. The average distance travelled over 6 days by the three feral horses in the 4000-ha paddock was 17.9 km/day (range between horses 12.5–25.9 km/day) (Figure 2A).

Discussion

GPS collar performance

The weight of the GPS collar with the location beacon attached was approximately 0.15% of total body mass, which was substantially less than in a previous report monitoring zebra in which a collar weight of 0.4% of body mass was found to interfere less with the rate of travel during grazing than a heavier collar weighing 0.6% of body mass.[13] The effects of the collars used in the current study on distance moved could not be assessed but were assumed to be minimal. The collars did not appear to disturb the movement of the horses as neither skin abrasions nor damage to the collars was evident after horses had worn them for 6.5 days.

Horse movement assessments

Paddock size study. Results from this study should be interpreted with caution. Because the horses were run together in each paddock and because they tended to move together, the group, rather than the individual horse, should be viewed as the unit of analysis and the results reflect effects of paddock size on average distance travelled for groups, not for individual horses. (The broodmares used in the study were normally housed together and their owner did not allow the mares to be separated, fearing that this may stress the mares in this important late stage of pregnancy.) In addition, under this study design, confounding may have occurred because of differences between paddocks, other than size, and horse-level factors related to the use of different horses in yards and paddocks. External validity of this study may be low because the relationship between paddock size and distance moved may depend on feed and water availability, terrain and horse characteristics. Distance travelled by heavily pregnant mares may vary from other classes of horses. Finally, groups of horses moved through the different sized paddocks in a non-random order. If carryover effects occur, they may have confounded the results.

Despite these limitations, the substantially lower average distances moved by the study horses in small enclosures as compared with the groups in open paddocks quantifies the relative inactivity of these horses outside of scheduled training sessions. Many athletic performance horses, such as Thoroughbred racehorses, Standardbred trotters and pacers, elite dressage horses, eventers and even long-distance endurance horses, spend the majority of time inside small box stalls or yards. Arena-trained horses, such as working Quarterhorses and dressage horses, may only cover between 1 and 2.4 km in a hard 30- to 40-min training session,[14] so total distance travelled daily during both training and confinement is still substantially lower than the daily movement of the group of unworked horses in the 4-ha paddock in the present study. Similarly, many racing Thoroughbred horses cover only 2 to 3 km in each training session and progress to their first start only 68 days following the start of training preparation.[15] If movement in the box or yard is 1.1 km/day, as observed in the current study, the total distance moved would be only 3 to 4 km/day, which is less than

Journal compilation © 2010 Australian Veterinary Association

the average daily distance moved by the group of unworked horses in the 0.8-ha study paddock, is approximately 75% of that travelled by the group of unworked horses in the 16-ha study paddock and is approximately 25% of the average of the daily distances covered by the feral horses in this study. The ideal exercise regimen for racehorses has not been defined, although a total distance of between 5 and 9 km/day over a 10-week period has been proposed.[16] It is possible that athletic horses should move over greater distances daily for optimal health.

Distances moved by horses for the purpose of fitness conditioning may have different effects from the same daily distance travelled during sedentary activity, because of the differences in speed between these circumstances. Although the measured values of distance travelled serve to indicate relative movement activity, further processing of GPS positional logs into descriptors of speed, as well as the amount of movement, will add to the interpretative power of the recorded data. The low-cost, off-the-shelf GPS technology used in the present study potentially could be used for that purpose.

These results suggest that the distances travelled daily by groups of domestic horses may reach a maximum of approximately 7.5 km for paddock sizes exceeding the maximum used in this study (i.e. 16 ha). If confirmed with replicated studies in a range of environments, this would indicate that horses in paddock sizes exceeding 16 ha can be considered to be 'unconfined' for the purposes of gauging the effect on daily travel behaviour. However, the minimum paddock size that constitutes 'unconfined' is likely to depend on available feed, water resources and the number of horses in the group.

Internal fence design study. A 'trail' paddock design based on observations of feral horses, and simulated in the present study by the racetrack design (Figure 1B), has been proposed to promote natural movement of horses.[6] Interestingly, in the present study the average mean daily distance travelled was highest for the open paddock design. The study horses appeared to move less at night when exposed to complex internal fencing, possibly because of the greater risk of contacting the fences. Although the results of our study did not demonstrate that distance moved differed between the open paddock and racetrack designs, the racetrack design offers management benefits. The large central area of the paddock can be used for other activities, such as pasture rehabilitation, hay making or as an arena.

Mare and foal comparison study. The study results demonstrate that domestic newborn foals are as active as their mothers and capable of moving 5 to 10 km/day when aged 3 to 9 days. Early mobility is essential for feral horses because the mare and newborn foal must move with the family band soon after parturition; foals that do not stand and walk promptly may perish. However, conventional management practice for domesticated horses is to leave foals in box stalls or small yards until the feet and legs are 'hardened' enough to be able to withstand the rigours of outdoor mobility. In this situation, based on findings from the paddock size study reported here, foals would be unlikely to move more than 1 km/day in the first few weeks of life (compared with 7.3 km) and, because of the confined area, would be unlikely to reach speeds faster than walking. The musculoskeletal and neuromotor systems of the foal, as with most biological tissues, require mechanical stimulation to optimise growth and development. Although the effects of exercise in early foalhood are unknown, lack of early stimulation and tissue adaptation may compromise optimum development. Given adequate space, foals spend a substantial amount of their locomotion time at the trot or canter and high workloads during early development might be important in conditioning the musculoskeletal system. Researchers recently concluded that a 30% increase in foal workload did not adversely affect the musculoskeletal health of performance horses[17] and in a subsequent study there were no adverse effects of foal workload on the racing careers of these horses.[18] In a cohort study of 401 foals, the authors concluded that foals should be allowed to exercise regularly as a preventative measure for developmental orthopaedic disease and osteochondrosis, and that limiting paddock size may also help prevent cartilage damage.[19] However, it is not known whether the increased risk of cartilage damage in foals grazed in larger paddocks was because of increased exercise or because of access to a larger selection of pasture. This highlights the need to objectively measure exercise levels in horses in various environments.

Feral horse monitoring. Distances travelled by the feral horses were far greater than those observed for domestic horses and indicate that there are important behavioural differences between unworked domestic horses and feral horses, which is not surprising given the difference in resource availability (feed and water) between domestic and feral horses.

Conclusions

A lightweight GPS data logger, modified from a personal/vehicle tracker and mounted on a collar, was a practical and reliable method for measuring horse movement over extended periods. Horses kept in small paddocks are quite sedentary compared with their feral relatives and stabled horses and horses kept in small yards perform very little physical activity. Newborn domestic foals move as much as their mothers. Horse movement is limited to an extent by paddock size. Several popular paddock designs had no significant effect on distance travelled by unworked domestic horses.

OBITUARY

John Allan Macfarlane

1945–2009

At the end of 1968 Mac was called in by Prof. Marsh Edwards for a viva in veterinary medicine. Marsh said, "Well, Mac, do you know why you are here?'

'To see if I pass or fail!'

'No, no Mac, to see if you get a credit or a pass,' Marsh pointed out.

On hearing this, Mac stood up and muttered, ' Credit!! Never had one in my life, don't intend to start now!', and walked out.

In many ways, this typified John Allan Macfarlane – 'do the job, do it well and walk away when it's finished'.

John Mac died in a Brisbane hospital in May 2009 after a battle with leukemia. He was optimistic to the last, hoping for a cure.

He was born in Sydney in May 1945 and educated at Tudor House, Bowral, then The King's School, from where he gained entry to the University of Sydney to study veterinary science.

After graduation John headed to Narrabri, working for the Rural Land's Protection Board (RLPB), and there he developed a love for sheep and the sheep industry to which he devoted most of his life. In December 1986 he began work as the District Veterinarian in the Armidale RLPB and he was there till he retired in July 2007.

The control and eradication of virulent footrot, and management and advice to sheep farmers on controlling anthelmintic resistant intestinal parasites took up much of John's time, but somehow he gained a Masters Degree in Rural Science and in Natural Resources, and passed his examination in Sheep Medicine for the Australian College of Veterinary Scientists.

It was following the discovery of ovine Johne's disease (OJD) in the Central Tablelands in the 1980s, that John's veterinary prowess came to the fore. The Regional Veterinary Laboratory in Armidale where many sheep in poor condition were being autopsied was not finding OJD as the cause. It appeared that the prevalence of OJD varied around the State. That RVL was closed in 1997, but John Mac continued his surveillance of the disease. Over 400 thin sheep presented for slaughter at the local pet food abattoir were autopsied, till the RVLs at Orange and Camden asked him to stop sending samples. All samples from those sheep proved to be negative. The RLPB chose 100 flocks at random for footrot surveillance and the rangers were permitted to collect faecal samples from 100 older ewes for pooled faecal culture. These all proved negative too.

At the urging of some sheep veterinarians, leaders of the industry in New England and senior veterinary personnel in the NSW Department of Agriculture, John oversaw the formation of the NE OJD Coordinating Committee, which sought to warn sheep farmers in NE and elsewhere of the dangers of bringing OJD into the district. Through an education program, John and the Board highlighted the epidemiology of OJD so that farmers moved from an 'awareness' to an 'understanding' of this insidious disease. It is testament to his work that there are still no known infected flocks in New England.

John was not an 'upfront' person. He did not like 'leading the charge', but nevertheless he was a good leader of a team, always ready to backup a spokesman with technical details. He was adept at delegating authority to others. Whether it be at a Senate Inquiry into OJD or deliberations with the Minister for Agriculture (or his senior staff), John would provide the information and let others do the talking. It was this self-effacing feature that was one of the most appealing parts of his character.

When in 2004 the Minister for Agriculture gazetted New England and other large parts of NSW as an OJD Exclusion Area, John did not slow down, but kept up the pressure through the RLPB system to maintain vigilance lest OJD 'creep in'. The sheep industry in NE and NSW should salute him.

The veterinary profession has lost one of its great members, a good friend and quiet achiever who loved his wife and family, sailing and a good red wine. To Sally and their children Angus, Sam, Katherine and Jane, we extend our love and deepest sympathy.

Distances travelled by feral horses in 'outback' Australia

B. A. HAMPSON*, **M. A. DE LAAT**, **P. C. MILLS** and **C. C. POLLITT**

The Australian Brumby Research Unit, School of Veterinary Science, The University of Queensland, St Lucia, Brisbane, Australia.

Keywords: horse; feral horses; GPS; distance; water frequency

Summary

Reasons for performing study: **The distance travelled by Australian feral horses in an unrestricted environment has not previously been determined. It is important to investigate horse movement in wilderness environments to establish baseline data against which the movement of domestically managed horses and wild equids can be compared.**

Objectives: **To determine the travel dynamics of 2 groups of feral horses in unrestricted but different wilderness environments.**

Methods: **Twelve feral horses living in 2 wilderness environments (2000 vs. 20,000 km^2) in outback Australia were tracked for 6.5 consecutive days using custom designed, collar mounted global positioning systems (GPS). Collars were attached after darting and immobilising the horses. The collars were recovered after a minimum of 6.5 days by re-darting the horses. Average daily distance travelled was calculated. Range use and watering patterns of horses were analysed by viewing GPS tracks overlaid on satellite photographs of the study area.**

Results: **Average distance travelled was 15.9 ± 1.9 km/day (range 8.1–28.3 km/day). Horses were recorded up to 55 km from their watering points and some horses walked for 12 h to water from feeding grounds. Mean watering frequency was 2.67 days (range 1–4 days). Central Australian horses watered less frequently and showed a different range use compared to horses from central Queensland. Central Australian horses walked for long distances in direct lines to patchy food sources whereas central Queensland horses were able to graze close to water sources and moved in a more or less circular pattern around the central water source.**

Conclusions: **The distances travelled by feral horses were far greater than those previously observed for managed domestic horses and other species of equid. Feral horses are able to travel long distances and withstand long periods without water, allowing them to survive in semi-arid conditions.**

Introduction

Movement and the distances travelled by domestic horses (*Equus caballus*) may affect general health. Domestic horses have become more sedentary since the industrial revolution, with many now kept in small paddocks and stables as land available for horse maintenance has declined. The athletic Thoroughbred racehorse, for example is typically boxed in a stable for 23 h/day and moved to the training track for a short gallop once daily (Richards *et al*. 2006). Hampson *et al*. (2010) found that horses kept in small yards travelled only 1.1 km/day and those housed in a 16 hectare paddock travelled a mean of 7.2 km/day. The psychological, physiological and musculoskeletal consequences of this relatively sedentary lifestyle are not fully understood, but the low level of mobility from an early age may adversely affect musculoskeletal health. Domestication of the horse has not only affected mobility but has been associated with an altered diet. Horses in training are routinely fed high energy diets twice daily and may have an abundance of pasture and water (Southwood *et al*. 1993). Confinement and altered feeding patterns parallel the modern human lifestyle that is thought to be responsible for endemic levels of obesity, cardiovascular disease, arthritis and diabetes (Johnson *et al*. 2004; Perkins *et al*. 2005; Richards *et al*. 2006; Lepeule *et al*. 2009).

Global positioning system (GPS) technology has been shown to be able to accurately measure horse movement, including distance travelled, range use and watering patterns of wild/feral equids. This method was used previously by the current research team in a pilot study to monitor 3 feral horses in Australia and found that the mean daily distance travelled was 17.9 km (Hampson *et al*. 2010). This was significantly further than wild asses (*E. hemionus*) (8.3 km/day; Kaczensky *et al*. 2008) and wild Przewalski horses (*E. przewalskii*) (3.5 km/day; Kaczensky *et al*. 2008) in Mongolia. However, female zebras (*E. burchelli*) were documented to walk approximately 15 km over a 12 h period between water and their feeding region, where they remained for 3–4 days before walking back to water (Brooks *et al*. 2007).

A total published sample size of 3 individual free roaming horses is not representative of the population and does not allow robust comparison of movement patterns to other equids. Since there appears to be substantial variation within and between equid species in locomotory habits, the aim of this further work was to monitor free-ranging feral horses in order to compare feral horse movement with the movement ecology of other equid species and managed domestic horses.

Materials and methods

Twelve feral horses were tracked using GPS data loggers to determine movement and watering patterns.

GPS data logger

The University of Queensland Equine GPS data logger was constructed from a Wintec G-Rays GPS unit (G-Rays 2 WBT-201data logger)[1]. The store-on-board GPS unit was modified by the addition of a circuit board which controlled the power input from an additional 3 AA battery pack. The total weight of the GPS, battery, collar and a very high frequency (VHF) location beacon was 700 g. The GPS unit was mounted on a neck collar with a full sky view, counterweighted by the battery pack and VHF beacon, which hung under the horse's neck. The 130,000 position storage capacity of the unit and the life of a single battery power source (6.5 days) allowed data logging at the rate of one position every 5 s (Hampson *et al*. 2010).

Data defining both horizontal and vertical positions were downloaded via Google Earth Plus[2]. The Wintec software was used to perform distance calculations from the raw GPS positional data. The pattern of travel was also superimposed on Google Earth satellite photographs of the study area and checked for plausibility and data error. In a previous study (Hampson *et al*. 2010) the same GPS unit was determined to be sufficiently accurate to measure domestic horse movement in small paddocks and feral horse movements in large paddocks with no 'outlier' data points.

Subjects

Twelve mature feral horses, from different family bands (8 mares, 4 stallions), living in 2 different wilderness environments, were tracked for 6.5 consecutive days. Four mares and 4 stallions were tracked at one location, which was semi-arid country on a large cattle property (Babbiloora) in central Queensland (latitude –25.18, longitude 147.49). The area receives a mean annual rainfall of 528.5 mm, and 157 mm had fallen in the 6 months prior to data collection (Bureau of Meteorology, Australia). The area had a large body of feed in all areas of the paddock accessed by the horses. Four mares were tracked at the second location, which was a semi-arid environment near Kings Canyon in central Australia (latitude –24.50, longitude 132.10). This 20,000 km^2 area consists of a valley system bordered by high prominent escarpments and is surrounded by vegetated and nonvegetated sand dunes measuring 15 m in height. Mean annual rainfall is 335 mm and rainfall was 331 mm in the 6 months prior to data collection (Bureau of Meteorology, Australia). There was high competition for feed resources in this area between feral cattle, horses and camels. Vegetation was scarce within 15 km of the single permanent water hole. All other semi-permanent waterholes in the area were dry at the time of the study as confirmed by the local indigenous people and stockmen. Ground and aerial searches from helicopter also confirmed that all animal tracks converged at this single waterhole. Feral horses have inhabited both areas for in excess of 140 years (Berman 1991) and experience very little pressure from human intervention. The breed origins of the horses were uniform with influence from early Thoroughbred, Arab and station hack horses.

GPS collar placement

In order to apply the collars, horses were darted i.m. with 0.7 ml etorphine hydrochloride (Imobilon)[3] when they approached water. When the horse became laterally recumbent, the collar was attached to the upper neck and the immobilising agent reversed using 1.4 ml diprenorphine hydrochloride (Revivon)[3] injected i.v. Horses returned to their usual band within 15 min of darting and appeared unaffected by the neck collar and the initial human contact. After a minimum of 6.5 days, the same feral horses were relocated using the VHF beacon on their collar and again immobilised by darting. The collars were removed, the immobilising agent reversed and the horses released.

Watering frequency

Both study locations had only one watering point available to the horses at the time of the study. Watering frequency was determined by the frequency that horses approximated the position of the water point on the Google Earth satellite photograph of the study area.

Statistical analysis

Distances travelled were compared between groups depending on sex and location of the horses using a nonparametric Wilcoxon *t* test. Statistical significance was set at 0.05. All values are presented as mean ± s.e.

The project was approved by the University of Queensland Animal Ethics Committee (AEC-PCA) monitoring compliance with the Animal Welfare Act (2001) and The Code of Practice for the care and use of animals for scientific purposes (approval number SVS/393/07/AHF).

Results

GPS analysis of travel distance

Mean daily distances travelled by all horses over the 6.5 day period of GPS tracking are presented in Figure 1. There was a large range of mean daily distances (8.1–28.3 km) covered by the horses. The mean daily distance travelled by all horses combined was 15.9 ± 1.9 km. During the period of tracking, stallions (18.2 ± 2.91 km/day) tended to travelled further on average than mares (14.8 ± 2.5 km/day) but this difference was not significant due to the small sample size. Mean daily distance travelled was 16.8 ± 1.71 km by central Queensland horses and 14.7 ± 4.17 km for central Australian horses. The mean daily distance travelled, regardless of gender was not significantly affected by location. However, central Queensland horses tended to travel a similar distance each day and

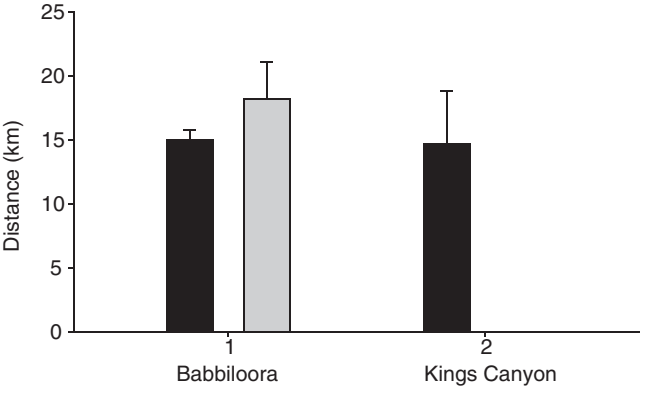

Fig 1: Mean ± s.e. daily distance (km) travelled by female (■) and male (□) feral horses in 2 inland Australian locations, Babbiloora (central Queensland) and Kings Canyon (central Australia). Distances travelled were measured by GPS tracking collar. Stallions did not travel significantly further than mares.

© 2010 EVJ Ltd

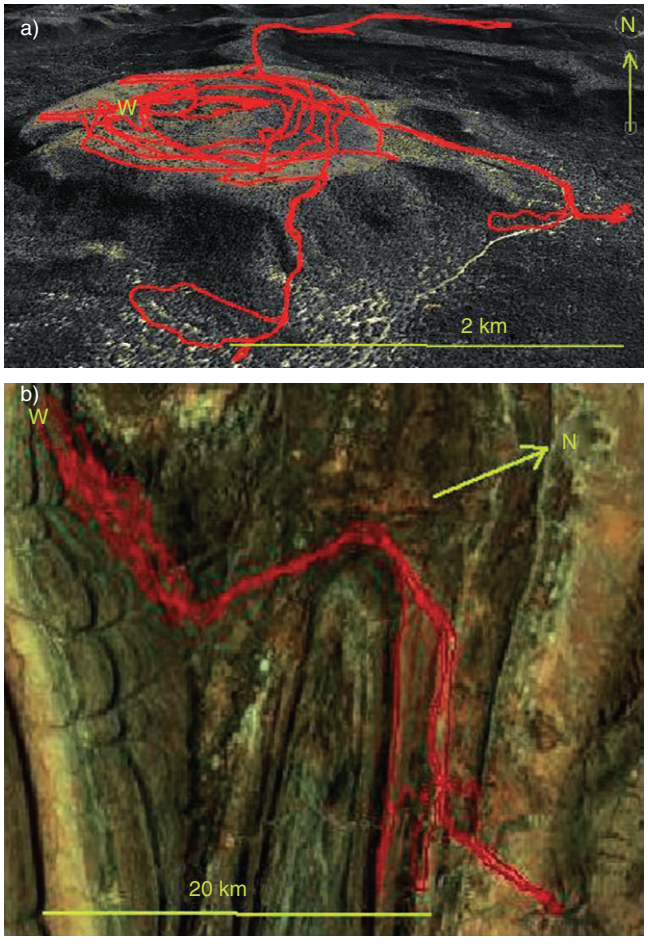

Fig 2: Comparison of typical ranges of horses in the 2 different environments. a) Shows the GPS path of a band stallion in prime grazing country. Each daily travel distance is consistent and within 3.5 km of a central waterhole (W). b) Shows the GPS path of a desert mare with a young foal at foot. Water (W) is at one end of the path and the preferred feeding ground is a distance of 22.5 km from water. True North is shown by 'N'. The end of the path is around 40 km in a straight line from the marked water.

never more than approximately 8 km from water. Central Australian horses travelled significantly greater single day distances when travelling to and from water and were frequently recorded at distances of 15–55 km from water. Long distance travelling days (mini-migrations), to and from water, were followed by short travelling days within good feeding locations (Fig 2).

Watering frequency

The mean watering frequency of central Queensland horses was 2.1 ± 0.9 days (range 1–3 days). Central Australian horses watered less frequently and this difference was significant ($P<0.05$). Their mean watering frequency was 3.2 ± 0.8 days (range 2–4 days).

Discussion

There is a large variability of range use ecology within the Equid family. There have been several previous studies reporting the home range size of feral horses determined by repeated sightings during ground based observations. The accuracy of observation vs. GPS data logging has not been established but observation has previously been the gold standard for animal ecologists (Linklater *et al*. 2000). Since the introduction of accurate and reliable GPS, animal ecologists are now able to monitor animals regularly for long periods without risk of interference. Linklater *et al*. (2000) reported a home range size for Kaimanawa feral horses of 0.96–17.7 km^2 for 48 horse bands (horse groups). Kaimanawa horses have a similar breed origin to the Australian feral horses (Halkett 1996). Linklater *et al*. (2000) found that all band home ranges overlapped with others and were located within an area of approximately 7 × 4 km. Similar spatial organisation of feral horses was reported by Klingel (1975), Salter and Hudson (1979) and Feist and McCouough (1975) in feral horse populations confined in small ranges. However, the study of arid and semi-arid habitat horses in Nevada (Berger 1986), western Alberta (Salter and Hudson 1982) and Wyoming (Miller 1983), have reported larger home ranges. These studies relate the increased size of the home ranges to resource demand. Kaczensky *et al*. (2008) were the first to report equid movement and home range size using GPS technology. Over a 4 year period in Mongolia, wild Przewalski horses had ranges of 152–826 km^2, significantly larger than reported for feral horses elsewhere. Over this 4 year period Przewalski horses travelled approximately 60 km from one end of their range to the other but the mean daily distance was 3.5 ± 0.9 km. On average, Przewalski horses ventured only 9 ± 2.9 km from the nearest water. The same study reported home ranges of 4449–6835 km^2 with a mean daily distance of 8.3 ± 0.7 km for Asiatic wild asses. Asses ventured a mean of 13.5 ± 0.9 km away from water. Other *Equidae* studied include the plains zebras which were recorded using GPS trackers walking up to 15 km away from water to feed and returning to water at 3–4 day intervals (Brooks *et al*. 2007). The current study used GPS technology to determine feral horse movement and watering patterns. We found that central Australian and central Queensland feral horses travelled larger mean daily distances than other equids reported previously. Central Australian horses, in particular, travelled up to 55 km from water and had large interwatering intervals.

The current study found that even though the average daily distance did not vary significantly between the 2 populations from contrasting habitats, the day by day routine of the horses was quite different and appeared to be dependent on resource location. In central Queensland, there was little requirement for horses to travel large distances between food and water. Pasture was widespread and pasture quantity close to water was similar to that at a distance away from water. However, in central Australia, resource distribution was scarce and patchy. Feed tended to grow solely along gully floors and low lying areas where water may have pooled and soaked the ground for several days following infrequent rain. Berman (1991) studied the ecology of feral horses in the same study area in the mid 1980s and measured the herb cover at distance intervals from the same permanent water source used by horses in the current study. Herb cover increased relative to the distance away from water (Fig 3), indicating the large competition for food resources close to water. Berman (1991) found evidence of horses 65 km away from the only available water source.

The current study located horses 55 km from Berman's (1991) water point. In consideration of the long walks the horses must make to access water from distant feed grounds it is not surprising that watering frequencies were as low as every fourth day. Scheibe *et al*. (1998) found that Przewalski horses drank less frequently than domestic horses and drank a higher volume of water relative to body size. They suggested that drinking frequency was not as

© 2010 EVJ Ltd

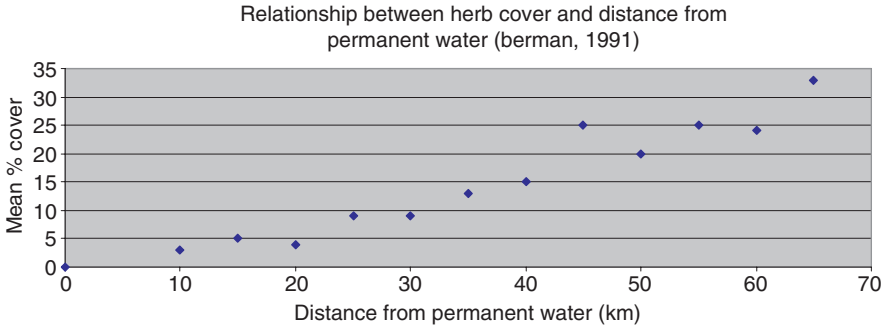

Fig 3: The relationship between herb cover and distance from permanent water in the desert horse habitat recorded by Berman (1991). Horses had to travel long distances from water to access feeding grounds. Feed within a range of 20 km from water was minimal. A similar situation existed in this location during the present study. This graph was drawn from data from Berman (1991) with permission from the author.

important to wild horses as the amount of water consumed. Horses that drank less frequently also ingested larger volumes of water. These authors, as well as Bouman and Bouman (1994) and Sneddon *et al*. (1991) all suggested that desert-dwelling horses are genetically adapted to hot and dry climates as part of the evolutionary strategy of the species. Other equid species have apparently also adapted to arid conditions. Maloiy (1970) subjected Somali donkeys (*E. asinus*) to heat stress and dehydration. Donkeys survived water loss equivalent to 30% of their original bodyweight in temperatures up to 40°C and survived up to 12 days without water. Donkeys were able to drink enough water (24–30 l) in 2–5 min to restore the deficit. Maloiy (1970) concluded that these observations represented a thermal and metabolic adaptation of desert mammals to heat and aridity. This adaptation did not totally eliminate the need to drink water, but permitted a considerable degree of dehydration. Donkeys are capable of living and reproducing in arid habitats similarly to camels in the Middle East, northern and eastern Africa and central Asia.

Central Australian horses may also be genetically adapted to arid conditions. The population of feral horses in the semi-arid areas of central Australia can be reduced by up to 75% in times of severe drought (Berman 1991). The ability to travel up to 65 km from water to access feed (Berman 1991) and survive for at least 4 days without water (present study) may represent a physiological adaptation of the original domestic horse stock that were the founders of the feral horses over 140 years ago. The strong pressure of the frequent severe droughts in central Australia for natural selection may have driven a genetic change. In contrast, domestic horses travel very small distances compared to their feral relatives (Hampson *et al*. 2010), generally have free access to water and have been documented to drink several times daily (Scheibe *et al*. 1998). Scheibe *et al*. (1998) suggested that the high water consumption of domestic horses may be a learned behaviour acquired under conditions of abundance.

The current study determined the range of 12 adult feral horses in 2 different wilderness environments over a 6.5 day period. Mean distance travelled was 15.9 ± 1.9 km/day (range 8.1–28.3 km/day). Horses in the central Queensland habitat, with plentiful pasture, tended to remain close to water (maximum 8 km from water). Central Australan horses were recorded up to 55 km from water and some horses walked for 12 h to reach water. Feed was scarce within a range of 15 km from the water point in the central Australian habitat due to competitive grazing by large numbers of feral horses, feral cattle and feral camels. These horses watered less frequently (3.2 ± 0.8 days; range 2–4 days) than central Queensland horses. Central Australian feral horses travelled longer mean daily distances and recorded longer watering intervals than other wild equids (Rubenstein 1989; Berman 1991; Scheibe *et al*. 1998; Adriansen and Nielson 2005; Brooks *et al*. 2007; Kaczensky *et al*. 2008). The unique ecology of the central Australian horse, as shown by this study, warrants further study.

The ability to survive the extreme environment of central Australia may be within the phenotype of all horses and simply a testament to the versatility of *E. caballus* as a species. On the other hand the central Australian population, subjected to the extreme selection pressure of the harsh environment, may have already inherited traits that set them apart from their domestically managed cousins.

Simple Summary: There are various fertility control methods (modalities) currently available that aim to reduce the abundance of problematic free-ranging mammalian wildlife. Here, we propose that dissimilarities in the mechanism of action indicate these methods produce great variation in animal welfare outcomes. We present a framework to assist managers in minimising animal welfare risks.

Abstract: Investigation of fertility control techniques to reduce reproductive rates in wildlife populations has been the source of much research. Techniques targeting wildlife fertility have been diverse. Most research into fertility control methods has focused upon efficacy, with few studies rigorously assessing animal welfare beyond opportunistic anecdote. However, fertility control techniques represent several very different mechanisms of action (modalities), each with their own different animal welfare risks. We provide a review of the mechanisms of action for fertility control methods, and consider the role of manipulation of reproductive hormones ("endocrine suppression") for the long-term ability of animals to behave normally. We consider the potential welfare costs of animal manipulation techniques that are required to administer fertility treatments, including capture, restraint, surgery and drug delivery, and the requirement for repeated administration within the lifetime of an animal. We challenge the assumption that fertility control modalities generate similar and desirable animal welfare outcomes, and we argue that knowledge of reproductive physiology and behaviour should be more adeptly applied to wild animal management decisions. We encourage wildlife managers to carefully assess long-term behavioural risks, associated animal handling techniques, and the importance of positive welfare states when selecting fertility control methods as a means of population control.

1. Introduction

Animal welfare has been steadily gaining importance and society now recognises it has an obligation to consider the welfare of all animals, including free-ranging species that are perceived to be overabundant or pests. As community and ethical opposition to the killing of animals has risen, especially for charismatic species (e.g., feral horses (*Equus caballus*); [1]), more focus has been devoted to non-lethal methods, particularly fertility control [2]. Fertility control methods have often been grouped together and described using terms such as "humane" [3–5], or "benign" [6,7]. These are not universal opinions though, as some authors have urged consideration of potential animal welfare impacts [8,9], including recognition that the welfare consequences of different methods may vary considerably [10].

Despite the importance of animal welfare, there are other aspects of fertility control methods that cannot be ignored. Efficacy will always need to be considered because if a method is chosen that has a reduced welfare impact on the individual, but does not achieve its animal management goals, then arguably doing nothing at all would have resulted in better animal welfare outcomes [11]. The overall welfare impacts of fertility control techniques should also be considered alongside the impacts of other control tools that may be considered as an alternative [12]. In any context, once an "optimal" decision has been made, it should not be blindly extrapolated to all species for all circumstances. With this in mind, there are large gaps in the published literature as most research has focused on the outcomes of fertility control programs in terms of reproductive output (its efficacy). Much less research has examined how each method induces decreased reproductive output, and at what cost to the animal. This evolution of research into wildlife fertility control methods appears to be tracking the same course that investigations into the use of lethal toxins for wildlife control followed, where efficacy studies preceded assessments of welfare impacts [13].

Aims of This Review

Once it has been decided that a fertility control program will be employed, there is considerable uncertainty when choosing a specific fertility control product or technique. Several authors have attempted to address the broad side-effects associated with fertility control of wildlife, including animal welfare impacts [9,14,15], but the relative risks of each fertility control method has so far escaped critical review. However, the American Zoo and Aquarium (AZA) Contraception Advisory Group has provided several articles examining the relative risks of fertility control modalities relevant to collection animals (e.g., [16]). Equivalent critical reviews have been performed for the manipulation of reproductive hormones in human medicine [17], highlighting that divergent properties of fertility control methods are related to dissimilarities in mechanisms of action, and ultimately produce variable clinical consequences.

This review attempts to demonstrate the differences between broad categories of fertility control techniques, with a view to facilitating future selection of practices. Fertility control has been applied to non-mammalian wildlife (such as birds; [18]) but this review will restrict its examination to mammalian

wildlife. The range of fertility control approaches used to manage mammalian wildlife is discussed, with a focus on mechanisms of action, the importance of maintaining natural behaviour and the need to assess all stages of animal manipulation involved in administering required treatments. We suggest principles to advance the scientific rigour behind the selection of fertility control techniques toward a "best practice" model to maximise animal welfare outcomes.

The central aim of this study is to specifically provide a framework for assessing animal welfare risks for various fertility control methods for mammalian wildlife. It cannot be disputed that efficacy and financial costs are important considerations when management decisions are being made, however, these issues have been thoroughly addressed by other reviews [2] and so will not be discussed in detail in this study. The aims of this study are not to compare fertility control with lethal methods, and not to assess side-effects of fertility control methods as a whole. This review explicitly examines animal welfare risks specific to each class of fertility control method and presents a framework for selecting fertility control methods that minimise animal welfare risks.

2. Fertility Control Methods Currently Used

A wide diversity of methods has been applied to wildlife fertility control over several decades. Table 1 lists the most commonly applied fertility control approaches in free-ranging mammals. Fertility control methods vary greatly in the mechanism of action of the treatment applied, as well as the administration method used to deliver them to animals (e.g., surgery *versus* remote injection or "darting"). Table 1 also illustrates that within individual species (e.g., white-tailed deer (*Odocoileus virginianus*)), multiple fertility control methods, representing several mechanisms of action, have been employed. These methods, and many more, have previously been reviewed in detail [2,15]. Several approaches to classifying the various fertility control methods have been suggested (e.g., physical *versus* chemical), but given the inextricable association between any method's mechanism of action and its effect, we argue that classification according to mechanism of action is the most logical approach.

2.1. Mechanisms of Action

Owing to the diversity of fertility control techniques currently available (Table 1; [2]), an appreciation of welfare impacts is not possible unless focus is first placed upon mechanisms of action. "Mechanistic" approaches have been central to rationalising and standardising the use of other wildlife management techniques. For example, rationalisation of a vast array of trade and colloquial names has been possible for toxins [13] and kill-traps [19] that are subjected to welfare assessment. All effects are produced by a mechanism of action, and dissimilarities in these processes in fertility control need to be understood to avoid misunderstanding [20]. For this reason we recommend the use of the term fertility control modalities to highlight the importance of considering how a method works and the long term welfare outcome at the individual animal level, rather than simply considering efficacy at a population level.

Table 1. Wildlife fertility control modalities that have been trialled, categorised according to their mechanism of action.

Class	Technique	Route	Description	Duration of Effect	Examples of Products	Sex Sterilized	Example Application	
							Species	Reference
Endocrine suppression	Castration (gonadectomy)	Surgical	Removal of testicles	Permanent	N/A	Male	Eastern grey kangaroos (*Macopus giganteus*)	[21]
	Ovariectomy/ovariohysterectomy (gonadectomy)	Surgical	Removal of ovaries +/− uterus	Permanent	N/A	Female	Brushtail possums (*Trichosurus vulpecula*)	[22]
	GnRH agonism	Implant	Binds to GnRH receptors	1–2 years	Deslorelin® Suplorelin®	Female Male	Tammar wallabies (*Macropud eugenii*)	[23,24]
	GnRH immunocontraception	Injection	Induced immunity to GnRH	>3 years	GonaCon®	Female Male	Wild boar (*Sus scrofa*)	[25]
	Synthetic testosterone	Injection	Suppressed spermatogenesis	Temporary	N/A	Male	Wild horses (*Equus caballus*)	[26]
	Synthetic progestins	Implant	Prevention of ovulation	3–5 years	Norplant®	Female	Koalas (*Phascolarctos cinereus*)	[27]
	Synthetic prostaglandin	Implant/biobullet	Pregnancy termination	Temporary	N/A	Female	White-tailed deer (*Odocoileus virginianus*)	[28]
	Synthetic oestrogen	Oral bait	Prevention of implantation	Temporary	N/A	Female	White-tailed deer (*O. virginianus*)	[29]
	Synthetic oestrogen	Implant	Prevention of implantation	Temporary	N/A	Female	White-tailed deer (*O. virginianus*)	[30]
Physical non-endocrine	Vasectomy	Surgical	Ligation of vas deferens	Permanent	N/A	Male	Eastern grey kangaroos (*M. giganteus*)	[21]
	Epididymectomy	Surgical	Removal of epididymis	Permanent	N/A	Male	Feral goats (*Capra hircus*)	[31]
	Tubal ligation	Surgical	Ligation of oviducts	Permanent	N/A	Female	White-tailed deer (*O. virginianus*)	[32]
	Oviduct "webbing"	Surgical	Removal of oviducts	Permanent	N/A	Female	Feral cattle (*Bos taurus*)	[33]
	Intra-testicular injection	Injection	Sclerosis of testicles	Permanent	Neutersol®	Male	American black bears (*Ursus americanus*)	[34]
	Intra-uterine devices	Implant	Endometrium irritation	Temporary	N/A	Female	Wild horses (*E. caballus*)	[35]
Chemical non-endocrine	Zona pellucida immunocontraception	Injection	Induced immunity to ovum proteins	>3 years	ZonaStat-H® SpayVac®	Female	Tule elk (*Cervus elaphus nannodes*)	[36]

2.2. Broad Classes of Fertility Control Modalities

In order to clarify the modalities for each fertility control agent, the following broad classes should be adopted: endocrine suppression methods, physical non-endocrine methods, and chemical non-endocrine methods (Table 1).

"Endocrine suppression" [37,38] (or endocrine disruption) methods alter the actions of naturally occurring reproductive hormones. Endocrine processes may be targeted centrally, depressing all reproductive hormonal activity (e.g., gonadotrophin-releasing-hormone (GnRH) agonists) or peripherally (e.g., progestin antagonists). Such is the complex nature of reproductive endocrine feedback processes that all supplementation, agonism, antagonism, or removal of endocrine hormones will ultimately lead to the suppression of natural reproductive hormone effects. Hence, we refer to all processes that affect reproductive hormones as inducing hormonal incompetence [39]. There are four main modalities in this category. Firstly, disruption can be achieved through the surgical removal of gonads (gonadectomy). Secondly, disruption can be achieved through the supply of exogenous (synthetic or externally derived) versions of naturally occurring reproductive hormones (*i.e.*, testosterone, oestrogen, progestins; Table 1) that interfere with normal feedback control and secretion of endogenous hormones. This method is commonly utilised in human contraception [17,40,41]. Thirdly, endocrine disruption can be achieved by agonism or antagonism of naturally occurring (endogenous) reproductive hormones (e.g., GnRH), via the administration of chemicals that actively compete with hormone binding sites. Finally, immunocontraception can be used to induce an autoimmune response through vaccination against naturally occurring reproductive hormones (e.g., GnRH).

Physical non-endocrine methods rely on physical (rather than chemical) means to disrupt the normal functioning of the reproductive system, and do not alter naturally occurring reproductive hormone levels. These methods encompass surgical techniques that *occlude* reproductive passages (but do not remove endocrine reproductive organs) or the use of implants that physically irritate the female reproductive tract (e.g., non-hormonal intrauterine devices; [35]). Surgical techniques that occlude reproductive passages but leave endocrine reproductive function intact include modalities that ligate (oviduct ligation, vasectomy) or remove (oviduct removal, epididymectomy) reproductive passages, but not gonads (Table 1). It is important to note that traditional surgical techniques used for fertility control in companion animals remove gonads ("gonadectomy"), including castration and ovariectomy/ovariohysterectomy (Table 1), and render reproductive hormone patterns nonfunctional [42,43]. We therefore classify these methods as inducing endocrine suppression despite their application through physical means (surgery).

Chemical non-endocrine methods rely on inducing an autoimmune response through vaccination against naturally occurring ovum proteins, most commonly the zona pellucida (ZP) [44], to prevent fertilisation of ova. This is achieved in the same way that a vaccine is used to mount an immune response against a pathogenic microbe (e.g., virus or bacterium) except that the immune response is being directed towards the animal's own ovum proteins. Once the animal's immune system disrupts the capacity for an ovum to be fertilised, affected females are rendered infertile irrespective of how many times they are mated by a male [44]. Similarities in the effects of physical and chemical non-endocrine modalities have been demonstrated by the use of physical occlusion surgeries to model the effect of ovum protein immunocontraception in epidemiological studies [45].

This first principles approach of classifying fertility control methods according to modalities should enable more meaningful comparisons and improved assessments of welfare risks at an individual animal level. This approach should also help to clarify some misconceptions arising from the oversimplification that has been used in the past to describe classes of methods (e.g., [46]). We therefore advocate a focus on modalities, rather than colloquialisms or trade names [47], when considering the implications for individual animals for any chosen treatment.

2.3. Best Practice Approaches

For some time, many contentious lethal (e.g., shooting, toxins) and non-lethal (e.g., marking) wildlife management methods have been closely scrutinised, with strong focus placed upon animal welfare impacts, rather than efficacy in isolation [19,48]. Quantitative assessment methods have allowed ranking of humaneness for many lethal wildlife control methods [12], in combination with the development of "best practice" approaches (e.g., [49]). In contrast, animal welfare assessment of fertility control methods has not been evaluated with the same level of scientific rigour and much uncertainty remains regarding animal welfare impacts [50]. As identified in reviews [9], most research into welfare risks has used qualitative, anecdotal evidence, and/or presented opportunistic, qualitative data lacking appropriate controls, sampling methodology or time scales. For these reasons, reviews have identified the assessment of welfare risks for fertility control as a research priority [9]. In the absence of quantitative humaneness assessment templates for fertility control modalities, "best practice" standards have not been developed and methods are still largely chosen on an *ad hoc* basis, and there remains much variability in how modalities are chosen and applied.

3. Animal Welfare Risks

It is proposed that any animal treatment can have short-term adverse effects on welfare (for example those caused by an injection) followed by long-term effects, which may be very different [51]. Both should be assessed. At the same time, modern approaches to animal welfare propose that avoiding negative welfare states (harms) should be considered in addition to the provision of opportunities for pleasurable experiences (such as social play, courtship or parenting [52,53]). This approach dictates that animals need positive experiences, in addition to minimised suffering [52,54]. Below we present a list of all of the animal welfare risks associated with fertility control, from administration (short term) to the response to treatment (long term) and include those imposing negative, and restricting positive welfare outcomes, respectively.

3.1. Short-Term (Administration) Negative Animal Welfare State Risks

3.1.1. Animal Capture, Restraint, Anaesthesia, Marking and Surgery

Most stages of wildlife management techniques that involve animal manipulation are likely to impose welfare costs. This is recognised for lethal wildlife control techniques, where animal welfare assessment frameworks require consideration of stages of animal manipulation prior to the killing method [12]. Some wildlife fertility control programs require animals to be captured and handled [55] or undergo anaesthesia and surgery [21] while other techniques allow animals to be darted (remotely treated)

in situ [56]. Classes of fertility control methods that currently require animal capture are shown in Table 2. These restraint procedures, required to administer a fertility treatment, may impose animal welfare costs that are in addition to the physiological and behavioural effects of the fertility control procedure or agent.

Table 2. Animal welfare risks from administration techniques used to implement common currently used fertility control modalities in mammalian wildlife. All potential stages of animal manipulation are shown to demonstrate techniques that require multiple stages of animal manipulation and those that do not.

Mechanism	Technique	Effect of Administration					
		Capture	Anaesthesia	Surgery	Remote Administration	Multiple Doses *	Frequency of Treatment
Chemical non-endocrine	ZP immunocontraception	−	−	−	+	±	3 years
Physical non-endocrine	Vasectomy	+	+	+	−	−	Permanent
	Tubal ligation	+	+	+	−	−	Permanent
Endocrine suppression	GnRH immunocontraception	−	−	−	+	−	3 years
	GnRH agonism	±	−	−	±	−	1–2 years
	Synthetic progestins	±	−	−	±		3–5 years
	Castration	+	+	+	−	−	Permanent
	Ovariohysterectomy	+	+	+	−	−	Permanent

* 2 doses are often required to ensure the efficacy of a single treatment; ± Can be administered via remote delivery or via capture, restraint and implantation.

In contrast, other fertility control programs have recognised the potential animal welfare costs of administration procedures and have chosen methods that allow for remote delivery of a single dose of an agent [57], effectively minimising stress other than that associated with potential darting injuries [58] or injection site reactions [59]. With the use of many modalities, for example, following remote drug delivery (darting) and surgical procedures, there is a requirement for visual marking of treated animals [60,61]. Marking in itself has been demonstrated to impose animal welfare impacts in many wildlife species [48].

3.1.2. Repeated Treatments

There are variations in the durations of action for different fertility control approaches. Some methods (e.g., surgical intervention) produce permanent infertility while some exogenous endocrine methods may affect fertility for less than one year (e.g., exogenous prostaglandins used to terminate pregnancy; [28]). Some chemical fertility control methods will require repeated administration every 1−2 years (e.g., GnRH agonists; [24]) or require booster administration 1−4 weeks after initial treatment (e.g., older ZP vaccines; [60]). All repeat treatments will impose additional animal welfare costs, as animals will need to be captured/injected several times. Some programs addressed the requirement for booster doses for older ZP vaccines by maintaining wild animals in captivity between injections, a process that can be highly stressful for free-ranging species [62]. For long-lived species (>5 years), multiple rounds of administration may be required to maintain infertility in treated animals [63]. An additional consideration is the aversion behaviour of wild animals after previous exposure to a stressful method.

For example, studies requiring animals to be re-darted [60] or re-trapped [64] have observed greater difficulty in re-administration of a treatment.

3.1.3. Injection or Implantation Site Local Inflammatory Reactions

Many remotely delivered immunocontraceptive modalities, being adjuvanted vaccines that rely on stimulating the immune system, have been shown to induce granulomatous inflammation at the site of injection [59,65]. Some studies have suggested that the welfare impact of such reactions is likely to be similar to the use of any adjuvanted vaccine. Likewise, many forms of chemical implants have demonstrated similar local inflammation effects associated with their administration [66]. The incidence of such adverse reactions, and their impact on welfare in free ranging species may be unknown, given the limited monitoring of many animals post-administration.

3.2. Long-Term (Treatment) Negative Welfare States Risks

3.2.1. Physiological Changes

Significant or prolonged physiological changes may be considered an animal welfare concern as they may alter an animal's ability to perform natural behaviour [67] and/or prevent adaptation to environmental challenges. Physiological responses may affect the animal directly, in terms of increased metabolic rate or redistribution of body reserves, or indirectly, in terms of loss of fitness, such as loss of appetite or decreased immunity [68]. All animals have the capacity to make behavioural changes in response to stimuli but marked physiological changes may restrict the capacity of animals to express the full range of natural behaviour [69]. Physiological changes have been demonstrated for several fertility control modalities, particularly those that derive their effect from endocrine suppression. Many studies on endocrine suppression methods have demonstrated weight gain in treated animals [25,27,70], but have considered the change to be positive or neutral, from a health perspective, without considering the effect of natural behaviour for a free-ranging species required to thermoregulate, forage, escape predators, compete with cohort animals or migrate. Immature male animals subjected to endocrine suppression generally do not grow as large as untreated males, as seen in white-tailed deer (*O. virginianus*; [71]) and tammar wallabies (*Macropus eugenii*; [66]). Endocrine suppression in immature male tammar wallabies (*M. eugenii*) also resulted in increased fat deposition [66]. Changes have also been demonstrated from endocrine suppression modalities to processes such as antler shedding in deer species [72]. Especially when endocrine suppression modalities are applied to juvenile animals, sex-specific phenotypes often fail to develop and male animals can become "feminized". This alteration in natural development means that these impacts are permanent [66,72]. Such altered physiology will likely reduce the capacity of such animals to express a full range of normal behaviour, and adapt to environmental changes.

3.2.2. Altered Behaviour

The importance of natural behaviour, and the ability of animals to experience positive welfare states, is a central tenet of modern animal welfare science [54]. Behavioural repertoires indicating satisfactory welfare should include the expression of normal patterns of maintenance and social behaviour, such as grooming, rest and play [52]. Deprivation of normal behaviour may compromise welfare by limiting

an animal's opportunities for positive experiences [52]. Changes in behaviour can be difficult to measure, but the importance of maintaining natural behaviour has been recognised for wildlife fertility control [73]. Of the few studies that have explicitly assessed behavioural changes in free-ranging wildlife (e.g., [74]), changes have been demonstrated to feeding, resting and dispersal behaviour.

For example, behavioural effects in free-ranging feral horses (*E. caballus*) subjected to endocrine suppression (GnRH immunocontraception) included observations that treated animals fed less, rested more, and travelled less [75]. Endocrine suppression in immature captive male tammar wallabies (*M. eugenii*) resulted in decreased agonistic (related to fighting) behaviour with intact males, lower dominance, and higher sexual interest from intact males [66]. Other behavioural changes are less predictable. For example, it has been demonstrated that male eastern grey kangaroos (*Macropus giganteus*) prefer to be associated with females that have not been subjected to endocrine suppression [76]. On the basis of such non-intuitive findings in an inherently complex field, we hypothesise that the real effect of altered social structures and disrupted social cohesiveness is not yet fully understood.

3.2.3. Extended Breeding Seasons

Beyond any welfare impact suffered by individual animals subjected to fertility control treatment, there are also often non-intuitive welfare costs to other animals of the same species, through social interactions. Specifically, fertility control modalities that prevent pregnancy occurring without preventing oestrus behaviour (physical non-endocrine and chemical non-endocrine methods) often induce a prolonged breeding season. This phenomenon has been observed for white-tailed deer (*O. virginianus*; [4,77,78]) and feral horses (*E. caballus*; [79]). The prolongation of natural breeding seasons can represent animal welfare risks for treated and untreated animals, specifically males. For example, the study of Ji *et al.* [80] demonstrates a pronounced impact on the body condition and welfare of male brushtail possums (*Trichosurus vulpecula*) with the extension of a breeding season through the presence of sterile, but hormonally competent, females. The average body condition of these males was significantly poorer than that of males in control areas. Similar effects have been observed in male deer [81]. It has been argued that extension of reproductive cycling may have important social consequences for feral horses (*E. caballus*; [79]) and African bush elephants (*Loxodonta africana*; [82]). In addition, increases in the cumulative number of mating attempts (social contacts) with non-endocrine modalities may increase infectious disease transmission risks [45].

3.3. Long-Term (Treatment) Positive Welfare States Risks

3.3.1. Deprivation of Parental Behaviour in Nurturing Species

Despite the central intended effects of fertility control agents in preventing the birth of offspring, and hence the opportunity for animals to express parental behaviour, the loss of this positive welfare state has not commonly been cited as a welfare concern for treated wildlife. In comparison, the welfare risks of deprivation of this natural behaviour have been recognised in zoo animals. The European Association of Zoos and Aquaria [83] stated: "limiting the opportunity to breed in species which display nurturing parental behaviour, by definition, reduces an individual animal's opportunity to express one of the most

important and complex sets of natural behaviour and can thus lead to a decrease in welfare". Contention surrounding the importance of this deprivation has been at the heart of many discussions of ethical practices in zoos worldwide [4,84,85].

The impact of this animal welfare risk is not easily demonstrated with empirical evidence. However, deprivation of freedom to express natural behaviour is universally considered an animal welfare concern [54] as it alters an animal's nature or "telos" [67]. Preventing such freedoms may affect animal wellbeing by reducing their ability to seek and gain pleasurable experiences and/or denying individuals the satisfaction of desires or preferences [86]. However, it must be noted that there are also welfare costs associated with reproduction, involving energetic costs and mortality risks that animals must trade-off with reproductive success [87]. Maternal behaviour in particular is complex, involving birth, nursing, and care of young. This loss of an important natural behavioural repertoire to many nurturing mammalian species warrants much greater discussion and consideration in the wildlife management sector.

3.3.2. Deprivation of Courtship and Mating Behaviour

Another positive welfare state that may be deprived of animals is the freedom to express natural reproductive behaviour, including courtship and mating. Endocrine suppression modalities often reduce or eliminate courtship and mating behaviour [81], through their mechanism of action targeting endocrine processes centrally, and depressing all reproductive hormonal activity [88]. For example, white tailed deer (*O. virginianus*) males subjected to an endocrine suppression modality (GnRH immunocontraception) display very few mating attempts with untreated (hormonally competent) females [78]. Courtship and mating behaviour are considered essential components of natural behaviour for many free-ranging mammal species and the deprivation of this natural behaviour must also be considered an important animal welfare impact, whether or not it is experienced as deprivation given the lack of reproductive hormonal stimulation for the behaviour to occur.

4. Fertility Control in Other Species

Many fertility control modalities currently applied in wildlife management were initially developed to meet the economic and emotional needs of owners of domesticated animals, such as companion or production animals. Some endocrine suppression modalities (e.g., GnRH immunocontraception) were developed for livestock species to intentionally alter physiology (to influence meat quality) and behaviour (to reduce aggression) to benefit production, rather than to prevent reproduction [89]. Fertility control of wildlife was initially performed as an extension of the practices used by veterinarians for domestic animal control and ownership, primarily gonadectomy [42,61]. However, gonadectomy is not a universally supported practice for companion animals, and the considerable welfare costs associated with the profound endocrine suppression it induces has seen its use considered unethical or even illegal in some countries (e.g., Sweden, Norway) [42,90]. The justification of the need for routine gonadectomy of companion animals is not uniform between countries, and these inconsistent views are based on value differences [42].

In livestock management, hormonally incompetent animals have been viewed as "modified" by many scientists, with concerns about the welfare of treated animals as well as human health from consuming treated animals [51]. Many studies of domestic animals subjected to endocrine suppression modalities

have demonstrated (often desired) physiological and behavioural changes, when observation methods have been intensive and long-term [89]. Despite the paucity of similar studies examining long-term changes in wildlife species, it would be naïve to assume that similar welfare costs would be unexpected in free-ranging animals that were similarly treated. It is worth considering if modalities that were originally considered humane in domestic animals should also be considered to be humane in wildlife.

5. Improving Assessment of Animal Welfare Risks

Animal welfare is complex and guidelines for how it should be assessed have evolved over time [91,92]. Modern approaches require that both negative and positive welfare states are considered [53], and that measures used to assess welfare states include both physiology ("health") and behavioural measures, as well as measures of mental state [93]. Fertility control studies have primarily focused on efficacy (reproductive output) in the short term but many studies have explicitly or opportunistically assessed health side-effects [9]. Few studies have assessed broader animal welfare impacts beyond short-term health effects, such as the impact on animal wellbeing when reproductive and social behaviour patterns are disrupted in response to altered physiology, or deprivation of positive welfare states.

5.1. Welfare Is More than Just Health

Although animal welfare is a complex entity, the Five Domains model was proposed over 20 years ago as a conceptual framework to simplify welfare considerations for research animals [94], but it has since been extended to incorporate positive welfare states [92]. The model proposes four physical/functional domains (nutrition, environment, health, and behaviour) and the fifth domain is mental state [94].

The majority of studies that have addressed animal welfare during fertility control programs have effectively restricted their assessments to domain 3 of the model; health, as typically only measures of injury rate, the presence of disease, and body condition have been examined [59]. The high frequency with which local reactions to chemical modalities at injection/insertion sites are described in the literature [9] suggest focus on this in the past has been disproportionally high given the low intensity and duration of suffering involved. However, it has been recognised for more than a decade that assessment of animal welfare must be based on a wide range of measures in addition to health indices [95]. Community debate about intensive livestock farming has demonstrated clearly the difference between concern for animal health and welfare. While intensively raised pigs and chickens demonstrate very high health outcomes (body condition, absence of parasitism *etc.*), their welfare is considered by a large majority of the general public to be severely impaired through impedance of natural behavior, and an absence of positive experiences, that is imposed by small, restrictive housing [69,96,97].

For the majority of wildlife fertility control studies, the length of time that any side-effects have been monitored for has been restricted to short time frames (*i.e.*, 2–3 years [55,77]). However, there have also been longer term studies performed [78]. The potential for, and occurrence of, long-term behavioural changes not detected by short-term studies, has been demonstrated for marine mammal marking techniques [48], and terrestrial chemical capture techniques (bear species; [98]). These studies have urged researchers to look beyond short-term health approaches for holistic assessment of welfare. While the "short-term health" approach is deemed appropriate for assessing lethal methods where death

is expected to be an acutely reached endpoint [19], it is less appropriate for non-lethal methods where duration of suffering may be chronic (years). Long-term welfare risks clearly exist for all fertility control modalities, but until evidence exists to the contrary it should be assumed that the magnitude of the impact of these effects on welfare could be significant.

5.2. Maintenance of Natural Behaviour in Free-Ranging Animals

Similar approaches have been used for fertility control in domestic and free-ranging animals, but there are important differences in society's perception of our duty of care for animals in each context. There is broad acceptance that the maximisation of health should be the focus of animal welfare for the keeping of companion animals [90], while the focus of stewardship for wildlife centres on the maintenance of natural behaviour. For this reason, practices such as supplementary feeding and veterinary treatment of wildlife populations have been consistently discouraged [99–101], For a discussion of the role of ethics in wildlife management decisions related to health and welfare, see the study of Rolston [102].

Many fertility control methods that do affect behaviour and physiology (e.g., altered fat deposition; [103]) for companion animals are considered acceptable (by some scientists [42]) because human owners take full responsibility for the care of these animals. Decreasing a companion animal's survival skills, such as the ability to hunt, survive adverse climatic conditions and defend itself against another competitor are deemed acceptable by society because humans can continue to provide food, shelter and protection for these animals. "Nuisance behaviour" in companion animals [104] such as fighting, roaming, territory marking, and oestrus calling, that are prevented or reduced by endocrine suppression, are all examples of natural behaviour essential for the welfare of free-ranging animals. This distinction between the behavioural needs of companion and free-ranging animals has not been adequately recognised by authors studying species that may exist in either state (e.g., feral/domestic cats (*F. catus*); [103,104]). We accept that the management of some free-ranging species blurs the line between domestic and wild animals (e.g., zoo animals; [84], or animals partially confined in fenced urban reserves; [21]). For these contexts, preservation of natural behaviour may be argued to be ethically less important if animals are not required to escape predation, or extensively forage. This consideration is particularly important given that many studies attempting to assess welfare impacts of fertility control modalities have provided *ad libitum* access to resources (water and feed) for study animals [105,106]. In some contexts where animals are not considered clearly domestic *or* wild (e.g., "street dogs" [42,61]), some management programs have explicitly aimed to modify natural behaviour when it creates conflict with human values (e.g., aggression leading to attacks on humans [61]).

The same logic should not apply for all wild animals, as the duty of care provided by humans often ends for managed wildlife at the point of release from restraint or administration of treatment (e.g., [107]). For this reason in feral horse (*E. caballus*) fertility control, approaches that impact upon androgenic (male) behaviour [26] are no longer considered humane or appropriate. In another context, it has been argued that the only fertility control options that should be considered for coyotes (*Canis latrans*) should be those that allow the animals to remain hormonally competent, such is the importance of the endocrine system for the maintenance of natural behaviour [108]. We argue that the preservation of hormonal competence is important to maximise the welfare of wild animals, due

to the profound effects of endocrine suppression on important behaviour such as mating, aggression and dominance.

6. Case Studies

To illustrate the dissimilarities in approaches that have been taken to fertility control in different species and jurisdictions, we present two case studies. The first describes refinement of modalities used for feral horses (*E. caballus*) in North America and the second describes the relative lack of refinement in modalities considered suitable for Eastern grey kangaroos (*M. giganteus*) in Australia.

6.1. Case Study: Feral Horses (E. caballus) in North America

Fertility control modalities for feral horses have been investigated for several decades in the USA [26,109]. While a range of modalities were used in the past (e.g., exogenous testosterone; [26], intrauterine devices; [35]; Table 1), more recently, remotely delivered GnRH immunocontraception [110] and particularly ZP immunocontraception [62,74,79,111], have become the focus. Importantly, it was recognised decades ago that the short-term welfare risks associated with immobilisation and capture necessitated that fertility control modalities were administered remotely [56]. Immunocontraception vaccines may be administered via remote delivery, removing the need for capture, anaesthesia or surgery, but the requirement for booster administration with older ZP vaccines led some authors to maintain horses in captivity between treatments [62]. However, ZP vaccines also often lead to extended breeding seasons, and therefore there are accompanying increased energetic costs and injury risks from increased mating attempts [112]. The focus on ZP immunocontraception developed from a formal process initiated by the Bureau of Land Management (BLM) [111] in the USA to identify the most humane and practical fertility manipulation options. This departure from *ad hoc* trials of many different methods has seen progress towards adoption of "best practice" methods.

6.2. Case Study: Eastern Grey Kangaroos (M. giganteus) in Australia

Many different fertility control modalities have been trialed for easily captured eastern grey kangaroos in Australia [20]. The fertility control modalities that have been applied to kangaroos and their accompanying welfare risks have recently been reviewed [113]. Much recent research has focused on the use of a range of endocrine suppression modalities. GnRH agonists [24,105], and synthetic progestins [20,63,114], have been the subject of several studies. Chemical non-endocrine (ZP immunocontraception; [115]) and physical non-endocrine (vasectomy; [21]) modalities have also been investigated less frequently. However, eastern grey kangaroos are still managed with physical endocrine suppression modalities (castration; [21]) that are rarely applied to other wildlife species. In addition, modalities that have been delivered via remote injection in other contexts (e.g., GnRH agonists; [116]) are often delivered to eastern grey kangaroos as implants, following capture, restraint and anaesthesia ([105]). There have been no formal attempts to standardise modalities (but see [113]), and no apparent progress toward development of "best practice" guidelines for kangaroo fertility control in Australia, and so *ad hoc* methods continue to be used without careful consideration of animal welfare impacts.

The management of Australian eastern grey kangaroos contrasts strongly with the management of American feral horses. In the USA, management goals have included minimising animal welfare impacts of fertility control on wildlife, particularly feral horses [4], by using methods that only rely on darting animals. In Australia, marsupials are still regularly caught, and subjected to anaesthesia and surgery to administer fertility control treatments that, when compared to ZP immunocontraception, have greater effects on their natural behaviour and physiology [21,63,66]. In Australia, similar modalities have not only been used in several kangaroo species [24], but also wallaby species [66,117] and koalas (*Phascolarctos cinereus*) [27,115,118].

These case studies have shown the different approaches taken towards fertility control in two wildlife contexts and highlight the need for increased consideration for the welfare risks of current practices. For this reason, we propose a framework to better enable researchers and managers to understand the animal welfare risks of any fertility control modality and to improve the balance between meeting animal interests with management needs.

7. Suggested Future Improvements

Given the several decades over which wildlife fertility control research has been performed, we contend that sufficient information exists to move from a *carte blanche* approach towards a "best practice" approach for refining methods to minimise animal welfare impacts. It is our contention that methods that induce endocrine suppression, and requiring repeated or multi-stage interventions, are likely to represent poorer animal welfare outcomes than those methods that do not (Table 3). We suggest where duration is similar, the modality inducing the least changes to natural behaviour and physiology will pose the least welfare risk. Likewise for administration risks, the total welfare risk should be considered as the cumulative total of the invasiveness of the procedure, and the duration and frequency of the procedure. For this reason, we propose that welfare risks associated with long-term treatment effects are considered a higher welfare priority than short-term administration risks.

We contend that the deprivation of parental behaviour is an unavoidable welfare cost common to all fertility control modalities. Beyond this cost, several studies have identified that the modalities that minimise welfare risks prevent pregnancy but do not disrupt endocrine function, thus ensuring that reproductive/social behaviour changes are minimised [39,79]. However, with the availability and marketing of modalities that induce endocrine suppression but have appealing ease of administration benefits (e.g., GonaCon™), many researchers have opted to induce endocrine suppression in treated animals despite the existence of alternative modalities that do not (e.g., ZP immunocontraception). We recognise that GnRH vaccines offer increased efficacy and convenience through their effectiveness against both sexes, single injection administration, and lack of extended breeding seasons. However, these efficacy advantages should be balanced against clearly increased welfare costs for a method that causes changes to natural behaviour and physiology [89].

Table 3. Suggested principles for assessing cumulative animal welfare impacts for wildlife fertility control modalities. Methods are listed from top (least animal welfare impact) to bottom (most impact). For example, administration methods requiring capture, anaesthesia, and surgery are given a +++ rating. ZP = zona pellucida. GnRH = gonadotrophin releasing hormone.

Mechanism	Technique	Impact of Treatment	Impact of Administration
Chemical non-endocrine	ZP immunocontraception	+	+
Physical non-endocrine	Vasectomy	+	+++
	Tubal ligation	+	+++
Endocrine suppression	Synthetic progestins	++	++
	GnRH agonism	++	++
	GnRH immunocontraception	+++	+
	Gonadectomy	+++	+++

We suggest that methods requiring capture, anaesthesia, and/or surgery, or frequently repeated administration (in long-lived species) represent poorer animal welfare outcomes when compared to remotely deliverable methods (Table 3). Given the above animal welfare risks associated with treatment (long-term) and administration (short-term), we contend that remotely deliverable non-endocrine vaccines (*i.e.*, ZP immunocontraception) are likely to be the most humane fertility manipulation methods currently available (Table 3). While welfare impacts are high for administration of physical non-endocrine modalities (vasectomy, tubal ligation), repeated treatments are not required and hormonal competence is maintained. For all non-endocrine modalities, important positive welfare states (courtship, mating) are maintained. However, the effects of extended breeding season associated with all non-endocrine modalities suggests that species specific traits need to be considered to avoid welfare impacts relating to large increases in mating attempts (e.g., [80]) or the birth of offspring in non-favourable seasons [78].

On the same mechanistic basis, we contend that gonadectomy represents the least humane of the currently available fertility control technique for wildlife. Gonadectomy requires capture, often major (abdominal) surgery, anaesthesia, and induces complete and irreversible reproductive endocrine suppression, and accompanying permanent changes in natural behaviour and physiology [42,90]. We suggest that the welfare impacts associated with gonadectomy render it appropriate only for domestic animals where a human duty of care is provided, and where behavioural changes are desired (e.g., [119]). GnRH immunocontraception and agonism both induce partial suppression of hypothalamic-pituitary-gonadal axis function [106], but the effects are not as profound as those of gonadectomy. GnRH immunocontraception is likely to pose the lowest welfare risks of all endocrine suppression modalities due to its' favourable administration method (Table 3). GnRH agonism and exogenous progestin modalities both induce endocrine suppression and require repeated administration (sometimes via remote delivery but often requiring capture), but not major surgery (Table 3). However, there has been progress toward developing remote delivery systems for both progestin implants [56] and GnRH agonists [116], reducing the short-term welfare risks associated with their administration.

Suggested Principles for Selection of Fertility Control Methods

In an attempt to improve the present approach to the choice of fertility approaches, some authors have suggested the use of formal criteria for the selection of methods that are appropriate for field applications [2]. While we support the criteria approach of Massei and Cowan [2] for assessing efficacy, we suggest that more holistic scientific rigour should be applied to assessing welfare impacts. We present Table 3 as a framework for assessing the welfare pros and cons of commonly used modalities. The challenging nature of making welfare decisions does not justify averting from the central tenets of scientific logic: observation, hypothesis and experiment. Many decisions on the choice of fertility control modalities have been *carte blanche* and this represents the antithesis of scientific reasoning. We have attempted to address the short-term and long-term animal welfare risks, as per Broom [51], in a framework using a weighting approach (as per Dubois and Fraser [101]). Table 3 summarises the parameters that we consider most important for selecting control methods, and we suggest the following principles for selecting the most humane fertility control methods for wildlife populations:

(1) It should be recognised that all fertility control methods impose animal welfare impacts. The deprivation of the opportunity to display parental behaviour in nurturing species is an animal welfare impact,
(2) Methods should be chosen that pose the lowest cumulative animal welfare cost, including capture, administration and frequency of treatment,
(3) All domains of animal welfare should be considered, including behaviour and the opportunity for animals to have positive experiences,
(4) Methods that maintain hormonal competence, thus promoting natural behaviour, should be chosen over methods that induce endocrine suppression, and
(5) Where uncertainty exists regarding welfare impacts, fertility control modalities should not necessarily be chosen over alternative lethal or non-lethal methods.

Any decisions regarding wildlife management will involve seeking a balance between the interests of the wildlife and other stakeholders. The suggested use of our framework in ethical decision-making has some unavoidable subjectivity relating to the difficulty in comparing various types of risks (e.g., long duration-low intensity welfare impacts with short duration-high intensity welfare impacts), which value-based ranking systems (e.g., [12]) may address. However, we contend that the proposed weighting approach will be more informative for wildlife managers than a list of comparative features without commentary. In addition, the weighting approach has been widely applied for welfare studies lacking comprehensive empirical evidence of all aspects (e.g., [101]).We present this framework as a provocation to wildlife researchers and wildlife managers to improve the rigour with which they assess management options, and to broaden their understanding of animal welfare.

We recognise that the range of species and contexts for which wildlife fertility control is desired makes the proposal of a single preferred method impossible [40]. We accept that efficacy, economic costs, ecological side-effects, and other factors are also important considerations for fertility control programs [2]. We present this framework to help with objective assessment of animal welfare, and to aid managers in achieving balance when weighing welfare impacts against other management considerations. It is an accepted reality that methods representing optimal animal welfare outcomes

may not be appropriate for all management contexts. We contend that understanding the complexities of both reproductive physiology and animal welfare science should be improved in wildlife management. Claims that fertility control modalities pose "no undesirable physiological or behavioural side-effects" from limited observations [105] are unrealistic and display a poor understanding of animal welfare. Likewise, the lack of consideration for the importance of depriving animals of positive experiences when comparing fertility control to other management options requires re-consideration. The lack of standardisation of wildlife fertility control modalities in many contexts is indicative of the enduring misconception that non-lethal reproductive manipulation is synonymous with benign outcomes. We contend that wildlife fertility control should not always be assumed to be humane.

8. Conclusions

Efforts to apply fertility control to wildlife have now been performed for over 30 years but there has been little standardisation of procedures over this time. Research into this area has primarily focused on the important aspect of efficacy but this has meant that the associated impacts on animal welfare have only seldom been addressed. Consequently, there is a growing need for more meaningful interchange between animal welfare scientists, wildlife biologists and wildlife managers [120]. Understanding the mechanisms of fertility control modalities and the resultant impacts on natural behaviour are important and have been under-appreciated. Broader understanding of modern animal welfare science and the importance of positive welfare indicators are required for wildlife managers. We contend that endocrine suppression in free-ranging animals is an undesirable outcome because of its long-lasting alterations to natural behaviour and physiology. Not all fertility control modalities induce endocrine suppression and these methods that do not should be treated preferentially. Likewise, administration methods that require capture, surgery, or frequently repeated treatment are similarly undesirable. Animal welfare impacts should be recognised and carefully balanced against existing management goals to ensure continuous improvement in wildlife fertility control methods.

Author Contributions

Jordan Hampton and Teresa Collins were largely responsible for the generating of ideas and writing of the manuscript. Tim Hyndman and Anne Barnes provided input and associated literature on specific topics, and reviewed the manuscript.

Conflicts of Interest

The authors declare no conflict of interest.

Abstract

8 adult male beagles that had previously experienced 30-40 complete matings and 8 beagles that had experienced no copulations were given 7 series of mating tests extending for approximately 8 mo. after castration. No data from various measures of appetitive behavior and consummatory responses indicated that inexperienced Ss were inferior to experienced Ss in postcastration sexual performance. Most Ss of both groups continued to mate throughout the experiment, although a definite reduction in sexual motivation was apparent soon after castration of experienced Ss. Observations of the consummatory responses of experienced Ss revealed no reduction in duration of the intense ejaculatory reaction, but a significant reduction in the duration of the copulatory lock following castration. Abstract

This study was undertaken because comparative information regarding the role of gonadal androgen in sexual behavior of adult male mammals is notably deficient in data from ungulate species. After a series of preoperative tests, eight Red Sokoto male goats were castrated and tested for sexual behavior with receptive females at 1 to 2 wk intervals for 52 postoperative wk. Only one animal was judged to have lost the ejaculatory response; this was after 18 wk of postoperative testing. Compared with observations on other species, an unusually high percentage of these goats showed a long-term retention of sexual activity after castration. Even with this long-term retention, however, there was a significant decrement in frequency of ejaculatory responses within one week after castration. The flehmen response, which some believe to be related to detection of excreted urinary pheromones, also declined in frequency after castration.

APPLIED ANIMAL BEHAVIOUR SCIENCE

The role of gonadal hormones in the occurrence of objectionable behaviours in dogs and cats [1]

Benjamin L. Hart *, Robert A. Eckstein

Department of Anatomy, Physiology and Cell Biology, School of Veterinary Medicine, University of California, Davis, CA 95616, USA

Abstract

The most common way of controlling or altering the behaviour of companion animals is through gonadectomy. Information about the behavioural effects of gonadectomy comes from extrapolation of findings from laboratory studies and from surveys of pet owners whose pets were castrated or spayed. The role of the placebo effect in the latter source of information is unknown. With these limitations in mind, both laboratory studies and pet owner surveys have provided information indicating that: (1) it is the sexually dimorphic behavioural patterns that are reduced or eliminated in males by castration; (2) not all males undergo a change in behaviour following castration; (3) experience and age at time of castration does not predict which males will be altered by castration; and (4) there are apparent species-specific differences between dogs and cats with regard to percentage of males showing a behavioural change related to castration. © 1997 Elsevier Science B.V.

Keywords: Gonadal hormones; Objectionable behaviour; Dogs; Cats

1. Introduction

In the course of human history with domestic animals, one of the oldest means of altering behaviour was by castration of male animals. The first animals castrated were livestock and, for thousands of years, castration of male cattle, sheep, goats and swine has been a routine husbandry practice. The fact that castration was so readily adopted by animal owners in early human societies is a testimony to the perceived, if not actual,

effectiveness of the procedure in altering behaviour. Clearly, these ancient animal caretakers believed that castration reduced the chance of serious fighting among adult male conspecifics as well as the tendency for male animals to be aggressive towards their human caretakers (of course, a few non-castrated animals were kept for breeding). The castration of companion animals and the practice of ovariectomy has been more recent. The time in history when it became routine for male cats to be castrated is unclear, and male dogs were never routinely castrated.

Given the current widespread practice in Europe and North America of routinely castrating male cats before adulthood to prevent objectionable behaviour and the growing practice of castration of male dogs in an attempt to alter objectionable behaviour in adults, it is important to examine what is known about the effects of castration in altering male behaviour. Issues that have received some attention are: (1) which behaviours are affected; (2) the probability that a specific behaviour in an individual will be affected by castration; (3) the role of experience in the retention of a behavioural pattern after castration; (4) species differences in response to castration; and (5) a comparison of animals castrated before adulthood (i.e. before or during puberty) with those castrated as adults. Ovariectomy or ovariohysterectomy (spaying) usually results in complete and immediate elimination of female sexual behaviour, but there are questions about changes in non-sexual behaviour associated with the operation.

Clinically relevant information about alteration of gonadal hormones comes from both experimental studies of laboratory dogs and cats and surveys of pet owners whose pets were castrated or spayed. Information from surveys of pet owners necessarily involves relying upon the owner's observations. This brings up the issue of the so-called placebo effect if the owner expects gonadectomy to alter the behaviour in some way. In clinical trials in human behavioural pharmacology, it is common to use placebo treatment in double-blind studies to differentiate drug effects from placebo effects. The placebo effect may be quite pronounced resulting sometimes in as many as 30 percent of patients responding to placebo (Benkert and Maier, 1990; Rudorfer, 1993). The degree to which a placebo effect may be involved in the reports of owners of animals about the effects of castration remains to be seen. One could argue that this effect may be less important than that in human behavioural pharmacology because the animal has no expectations of a behavioural change. On the other hand, the placebo effect could be greater because the owner does not see all of the animal's behaviour and may be biased towards expecting a favorable response and/or institutes some behavioural modification procedures without investigator's knowledge (Hart and Cliff, 1996). With regard to castration, it is not feasible to have a placebo group, except perhaps with the ethically questionable procedure of using prosthetic testicles and a sham operation. Once several double-blind placebo-controlled studies are conducted with psychoactive drugs with animals, there will be some indication of the potential for a placebo effect and this could possibly be factored into the results of studies where client reports are used to create the data base. Until that time, the only alternative is to report the results from carefully conducted clinical surveys where an effort is made to acquire unbiased responses from pet owners. A placebo effect, if it does exist, is probably greater with the more subjective evaluations such as changes in aggressive behaviour than with less subjective judgements such as changes in urine deposits in the house.

In the text below, we lay some groundwork for discussion of the effects of gonadectomy on clinically relevant behaviour by covering the concept of sexually dimorphic behavioural patterns and the effects of castration on sexual behaviour as studied in the laboratory. The discussion then turns to the effects of castration on clinically relevant behaviours of adult male cats and dogs, followed by a comparison with males castrated before or at the time of puberty. Finally, there will be some mention of the effects of gonadectomy on aggressive behaviour of female dogs.

2. Concept of sexual dimorphism

A well-established concept in mammalian sociosexual development is that males experience a surge in testosterone secretion late in prenatal life, early in neonatal life, or across both periods. This surge apparently acts on the brain to bring about gender-specific cytoarchitectural changes in the hypothalamus and other areas of the brain that are related to the later display of male sex-typical behaviour (Arnold and Gorski, 1984). Actually, the mediation of the effects of testosterone in male brains is through local aromatization of testosterone to estrogen which brings about early organization of both the sexually dimorphic structures in the brain and behaviour (Hutchison and Beyer, 1994). Hypothalamic areas of the female brain are structurally organized in a feminine direction due to the lack of testosterone (and estrogen). Developmentally, the female phenotype is shaped first and through the action of androgens (aromatized to estrogen), the male phenotype is reshaped from the existing female pattern.

The above concept, developed from work on laboratory rodents and primates, presumably applies to all, or almost all, mammalian species, including dogs and cats. However, the hormonal profiles of dogs and cats during the prenatal period have not been characterized. Measurements of serum testosterone from newborn dogs from birth through 7 weeks postpartum, revealed only slightly higher levels in males than females. The levels in males were too low to represent a neonatal testosterone surge (Hart and Ladewig, 1979). Thus, assuming that a perinatal surge in testosterone occurs in dogs (and cats) as it does in other mammals studied, it would probably be prenatal.

Once the period of perinatal brain development has passed, the tendency towards masculinity in males and femininity in females seems to be permanently built into the brain. It is important to point out that both males and females appear to have the basic neural circuitry for the behavioural patterns typical of both sexes (Hart and Leedy, 1985). The difference in brain organization relates to the probability or frequency with which the masculine or feminine system is activated.

Prior to puberty, and presumably before biologically significant amounts of gonadal hormones are produced, males differ from females behaviourally. This has been documented with regard to play in rodents (Thor and Holloway, 1983; Meaney et al., 1985), primates (Owens, 1975) and ungulates (Crowell-Davis et al., 1987; Gomendio, 1988). Male and female dogs and cats may also differ in play (Deag et al., 1988), but differences have not been profiled to the same degree as rodents or primates. One prominent difference between juvenile male and female dogs is the urination posture; male dogs use a stand-lean urination posture and female dogs a squat posture.

As mentioned previously, sexually dimorphic differences between males and females are of degree or frequency, not absolute. Among sexually dimorphic traits there is also an apparent difference in the degree to which males and females differ. For example, leg lift urination is obviously a highly dimorphic trait in which males almost always differ from females. Territorial guarding, if sexually dimorphic, would appear to differ less frequently between males and females. A systematic survey of canine authorities regarding differences between male and female dogs was conducted as part of a project on behavioural profiles of dog breeds (Hart and Hart, 1985a). This survey revealed a continuum with regard to degrees of sexual dimorphism among 13 behavioural traits. Those that were considered to be most characteristic of males or females by authorities interviewed are shown in Fig. 1. Urine marking in the house and mounting other dogs or people were not included in the original survey but they are already acknowledged as highly dimorphic; these two traits are added to the data of Fig. 1.

As will be discussed below, it is the most sexually dimorphic, male sex-typical behaviour that one would expect to be altered by castration of males. Thus, in reference to Fig. 1, urine marking, mounting, aggression to other dogs and aggressive dominance towards people should be altered more readily than activity level or watchdog barking.

Some females display male sex-typical behaviour more than other females. In exploring the possible role of perinatal hormones in this difference among females, investigators have found that intrauterine position can alter the degree to which females of a number of rodent species display male-like sexual behaviour. There are two mechanisms for such intrauterine effects. One is that when females develop in-utero between two males, they are partially masculinized by diffusion of androgens through the amniotic membranes (Clemens et al., 1978; vom Saal and Bronson, 1978). This

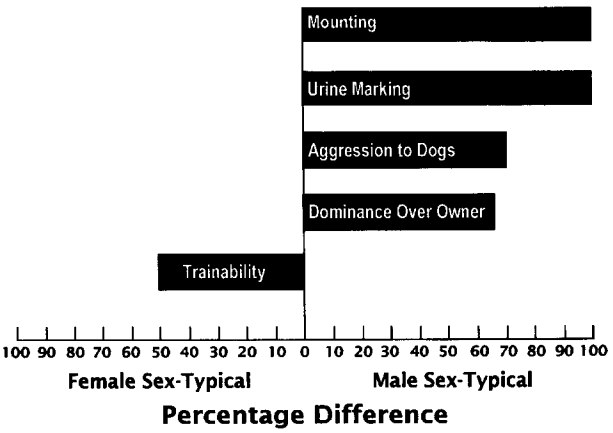

Fig. 1. Degree of sexual dimorphism of behavioural characteristics of dogs as represented by the projected consensus of canine behaviour authorities as to whether a behavioural characteristic was more prominent in male or female dogs. Data taken from Hart and Hart (1985a); Beach (1974); Beach et al., 1982 and Beach and Kuehn (1970). A rating of 100 in either the male sex-typical or female sex-typical direction implies virtually unanimous consensus; a rating of 0 implies that authorities either rated neither sex stronger on that trait or as many rated males stronger as females (see Hart and Hart, 1985a for calculating details). Only traits scoring at least 50 in either the male or female direction by this procedure are listed.

mechanism has been supported by studies on mice and gerbils (Clark et al., 1990; vom Saal, 1981). The other mechanism is that because uterine blood flows from the cervix rostrally, androgens from caudally-located male fetuses may androgenize rostrally-located females through the fetal blood supply (Meisel and Ward, 1981). Support for this mechanism exists for rats, hamsters and ferrets (Houtsmuller and Slob, 1990; Richmond and Sachs, 1984; Vomachka and Lisk, 1986; Krohmer and Baum, 1989).

These studies raise the interesting possibility that the occurrence of objectionable masculine behaviour seen in a small proportion of female cats or dogs could be due to intrauterine position. This possibility has not been tested experimentally in cats or dogs but was explored to a limited degree in a clinical survey involving interviews of cat owners who were familiar with the litters from which their cats were adopted (Hart and Cooper, 1984). In this survey of those owners who knew the littermate composition of their cats, two of the five female cats who urine sprayed frequently, and four of the 14 females that fought frequently, came from all female litters. Since all-female litters could not supply any androgen to adjacent fetuses or up-stream fetuses for masculinization, these data are not consistent with the fetal masculinization effect. Furthermore, of 22 female cats that did not spray or fight, eight came from litters in which there were three or more male littermates (average litter size of six), a condition where masculinization was at least possible. Until more information is available, these results suggest that the tendency for some cats to engage in male sex-typical urine spraying or fighting is not due to intrauterine masculinization.

3. Behavioural effects of castration on sexual behaviour

One of the behavioural patterns most readily affected by castration is sexual behaviour, including mounting, copulatory intromission, and the display of the ejaculatory pattern. These behavioural patterns are readily measured in the laboratory and can be easily evoked in experimental animals. Thus, there is considerable experimental literature on the effects of castration on sexual behaviour in a variety of mammalian species including rats, cats, dogs, rhesus monkeys, and goats. In all of these studies, changes in the behaviour, such as increased latency in response (mounting) to the female, are apparent soon after castration (Hart, 1974). The behaviour that is first lost is that of the ejaculatory pattern followed eventually in some animals by loss of mounting and even interest in females. A comparison of a variety of animals reveals considerable species differences in the rate at which the ejaculatory pattern is eliminated (Fig. 2). According to the studies that were cited in preparing Fig. 2, within 5 weeks following castration, 50% of male cats will no longer showed the copulatory pattern, whereas in male dogs, 80% still showed the pattern, at least occasionally, 15 weeks after castration. The change in sexual behaviour of male rats was about the same as male cats, whereas, goats resembled dogs; rhesus monkeys were intermediate. An evolutionary explanation of these differences in response to castration has been offered (Hart, 1974).

As is apparent from these data, there is considerable individual variation within species in the persistence of sexual behaviour following castration. Thus, in male cats, 20% of animals were still responding to females with the copulatory pattern 15 weeks

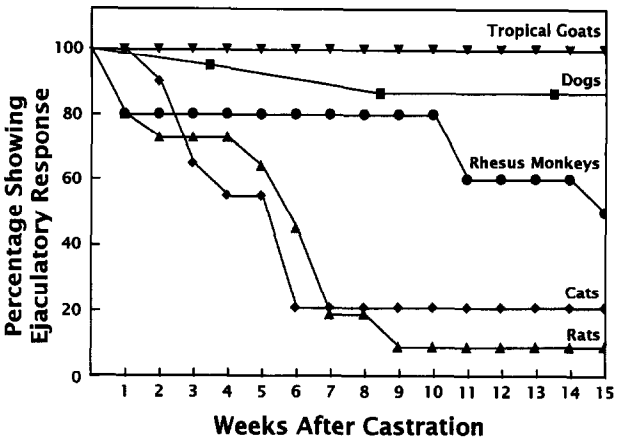

Fig. 2. Species comparisons of differences in persistence of ejaculatory response as a function of duration of time since castration (data from Hart, 1974; Hart and Jones, 1975).

after the operation while 80% no longer responded. In male dogs, 80% were still responding with the copulatory pattern 15 weeks after castration, and 60% one year later (Hart, 1968).

Finding individual differences in response to castration raises the issue of the role of copulatory experience in the loss of copulatory behaviour. This issue has been directly addressed in dogs and laboratory rodents. In a study on dogs designed to explore this issue, animals in the inexperienced group were allowed no copulations prior to castration but were habituated to females by being allowed to mount them. Animals of the experienced group were allowed 30 copulations prior to castration. In tests starting the week after castration and continuing for one year, there was no difference in any parameter of sexual behaviour between the two groups (Hart, 1968). Similar results have been reported with rodents (Hart, 1974). From these laboratory studies and data represented in Fig. 2, three important concepts are established that can probably be extrapolated to clinically relevant behaviour of companion dogs and cats: (1) there are pronounced species differences in behavioural changes after castration; (2) there are pronounced individual differences within a species after castration; and (3) experience in performing the behaviour in question appears to have no predictive ability as to whether or not the animal will change its behaviour.

4. Behavioural effects of castration on objectionable behaviour of male cats

The objectionable behavioural patterns shown by adult male cats that are generally recognized as sexually dimorphic are fighting with neighborhood males, urine spraying and roaming. A retrospective clinical survey (interview of owners) was conducted for 42 gonadally-intact adult male cats presented for one or more of these behavioural patterns (Hart and Barrett, 1973). Castration was effective in eliminating the problem behaviour in 80–90% of the animals (Fig. 3). According to the clients surveyed, in about one-half

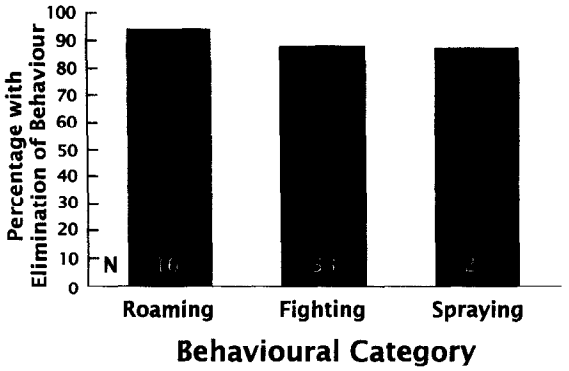

Fig. 3. Percentages of adult male cats in which objectionable roaming, fighting with neighborhood males, and urine spraying in the house were eliminated (problem resolved according to owner's report) following castration. The N is shown at base of bars (from Hart and Barrett, 1973).

of the cases involving aggression towards other males, the cats changed rapidly (within a week or two after castration) with the other half showing a more gradual change. The same was true of roaming behaviour. For cats engaging in urine spraying, most of the animals seemed to undergo a rapid change in the behaviour. Although the clients said the problem behaviour was resolved or eliminated, it is entirely possible, if not likely, that some occurrence of the behavior in question went unnoticed. When cats were presented with more than one of the problem behaviors, an elimination of one behavior did not predict a change in the other problems. The only other behavioural change reported was that 25% of cat owners mentioned their cats became more docile. There was no indication, judging by the age of the animals at the time of castration, that the animals which were older, and presumably more experienced in performing the problem behaviour, were affected any less than the younger, presumably less experienced, males. For example, the median age at time of castration of the cats which showed no decline in spraying was 12 months compared with 18 months for cats that showed either a rapid or gradual elimination of the behaviour.

5. Behavioural effects of castration on objectionable behaviour in male dogs

As mentioned above, the most dimorphic behaviour patterns in dogs are urine marking, mounting, aggressive dominance towards owners and aggression towards other male dogs. A retrospective clinical survey, similar to the one conducted for adult male cats, was conducted on 42 gonadally intact male dogs presented for: urine marking in the house; mounting other people or dogs; intermale fighting and/or roaming (Hopkins et al., 1976). According to the owners, urine marking, mounting and fighting were markedly reduced or eliminated in 50–60% of the animals (Fig. 4). Interestingly, roaming was reduced in 90% of dogs. Data were also available on eight dogs with territorial aggression and four with fear-related aggression but there was no change in any of these dogs. Aggressive dominance directed towards the owners was not included

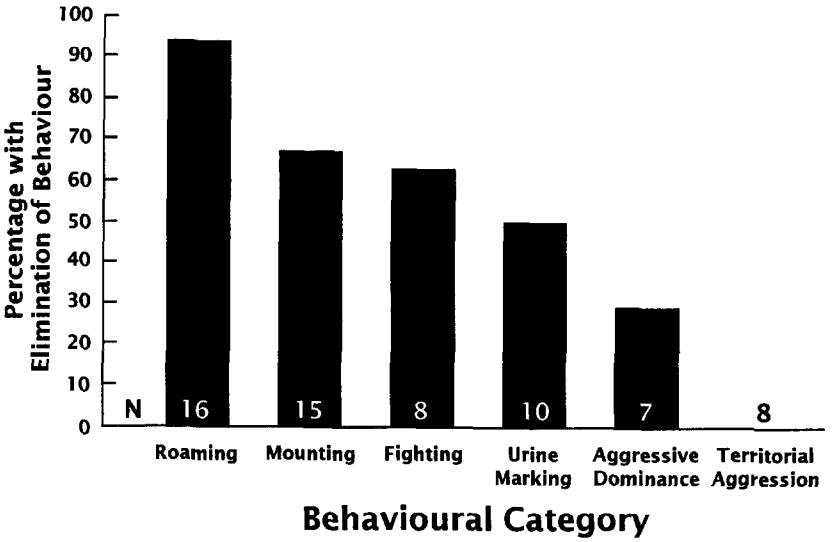

Fig. 4. Percentages of adult male dogs in which objectionable roaming, mounting of people or other dogs, fighting with non-household male dogs, urine marking in the house, aggressive dominance towards the owner and territorial aggression towards strange people were eliminated (problem resolved according to owner report) following castration. The N is shown at the base of the bars (data from Hopkins et al., 1976 and unpublished preliminary results for aggressive dominance).

in the original survey but a recent preliminary study has shown that of seven male dogs presented for this problem, castration resulted in resolution of the behaviour in 2 individuals. These recent data are included in Fig. 4. As with cats, there was no indication that dogs castrated later in life were more likely to persist in the behaviour following castration than those castrated earlier. Even with aggressive dominance involving the owner, experience seemed to play no role as a determinant in response to castration. Of the two dogs that responded to castration, the problem aggression had existed for 5–6 years; in the five dogs that did not appear to respond, the problem aggression had existed for a median of 3 years (range 2–5).

The results of the clinical survey are in line with what would have been extrapolated from laboratory studies on the effects of castration on sexual behaviour. With the exception of roaming, castration was effective in a smaller proportion of dogs than cats, and experience appeared to play no predictive role in which animals changed after castration. The rather uniform effect of castration on roaming in dogs is puzzling. Perhaps, roaming was affected in such a high proportion of dogs because it is a sexually motivated behaviour, and a decrement in sexual motivation which consistently follows castration, may result in major reduction in roaming (even though copulatory performance may still occur).

There are two possibilities for differences in the response of various males to the effects of castration, neither of which has been tested. One is simply genetic differences among individuals related to the sensitivity of neural tissue to the withdrawal of androgenic support (Hart, 1974). Some indication of this possibility might be revealed

by a study of genetic relatedness and persistence of problem behaviour after castration. A second possibility for such differences may reflect the fact that in fetal life some males experience greater exposure to testosterone from other male fetuses located more caudally in the uterus, an effect that has been shown to enhance male sexual behaviour in male rats (Houtsmuller et al., 1994).

The persistence of undesirable male behaviour following castration is apparently not due to any residual amounts of testosterone. It has been documented in a number of laboratory species (e.g. Resko and Phoenix, 1972) and cats (Hart, 1979) that testosterone is metabolized within hours after removal of the testicles. The persistence is not due to compensatory adrenal androgen secretion. Sexual behaviour, for example, persists even after adrenalectomy (Hart, 1974).

6. Behavioural effects of castration before adulthood

It is customary to castrate male cats before they reach full sexual maturity, that is, sometime between 6 and 10 months of age, to prevent fighting, roaming and urine spraying. This practice brings up the question of differences in the effects of castration performed at this earlier age versus after puberty. This question was addressed in a retrospective clinical survey of 134 male cats castrated between 6 and 10 months of age (Hart and Cooper, 1984). Spraying and fighting on an occasional basis occurred in 29 and 44%, respectively, of the cats as adults. Ten percent of the male cats became frequent urine sprayers later as adults revealing that the proportion of male cats that take up frequent spraying as an adult is about the same as the proportion of male cats that persist in urine spraying once they have started the behaviour as adults and are then castrated (Fig. 3).

The mean age of castration for those that sprayed and/or fought occasionally was 8.5 months and for those that engaged in neither behaviour 8.2 months. This small and statistically insignificant difference is consistent with the concept of no relationship within the early castrated animals of age of castration and occurrence of problem behaviour. The same study found that 5% of ovariohysterectomized female cats became frequent urine sprayers as adults, demonstrating that females do engage in male sex-typical behaviour, albeit at a lower probability than castrated males. The only study of prepubertal castration in dogs is one of sexual behaviour in males which found that males castrated prepubertally had the same frequency and tendency to mount females as those castrated as adults (LeBoeuf, 1970). The question of whether cats or dogs castrated well before puberty, for example as early as 2 months of age, will differ from those castrated at 6–10 months of age is yet to be fully tested. The preponderance of evidence revealing no effect of experience and no relationship within the 6–10 month age range between time of castration and later behavioural effects, suggests that no further effect on problem behaviour will be found with very early castration. Early castration of male cats does have permanent effects on morphology, especially in reducing the size of cheeks and jowls. Thus, cats castrated before puberty are visibly different than tom cats and Turner (1995) has suggested this may play a role in evoking

male sex-typical behaviour in males castrated as adults. As a general rule, cats should be castrated before adulthood for best management of problem behaviour.

7. Treating male sex-typical behaviour in gonadectomized males and females

A word should be said about clinical approaches to dealing with objectionable male behavioural patterns of animals previously castrated. With feline urine spraying, eliminating olfactory stimuli that might evoke the behaviour by cleaning up the marked areas with an enzymatic cleaner and blocking visual stimuli from cats outside the home may prove useful. Discouraging marking of previous target areas through the use of remote punishment, or feeding and watering the cats at target areas, has also been recommended (Hart and Hart, 1985b). Although some behavioural therapists have reported a high degree of success with such behavioural measures (Turner, 1995), others find the behaviour difficult to control (at least in the homes of most clients) and pharmacological approaches to this problem have been favored by veterinarians. This treatment has evolved over the last two decades starting with the use of progestins (Hart, 1980) and moving more recently to drugs that enhance gamma-aminobutyric acid (e.g. diazepam) or serotonin (e.g. buspirone). Both diazepam and buspirone suppressed spraying in a higher percentage of animals than progestins (Cooper and Hart, 1992; Marder, 1991; Hart et al., 1993). In prospective studies, both diazepam and buspirone resulted in 55% of cats showing an elimination or marked reduction in the behaviour, but buspirone did not have the undesirable side effects associated with diazepam of transient sleepiness, ataxia, appetite stimulation, and dependency with long-term use (Hart et al., 1993). Although with buspirone and diazepam the proportion of male and female cats responding was not significantly different, with buspirone more cats from multiple-cat households responded than did those from single-cat households. With progestin therapy a higher proportion of male cats than female cats responded.

The treatment currently recommended with buspirone is 5–7.5 mg per cat given twice daily for 1–2 weeks as a trial to see if the drug will eliminate or markedly reduce the behaviour. If the behaviour is altered, it is recommended that the cat be treated 8 additional weeks before gradually tapering off over the ensuing week or two. About half the cats can be expected to resume spraying after the drug is discontinued (Hart et al., 1993). Those that resume spraying can be placed on long-term treatment for another 6–12 months with the expectation that after the drug is then tapered off some animals will continue to be suppressed while others will resume spraying and may be continued on indefinite treatment. A major difference is seen between buspirone and diazepam in the tendency for cats to resume spraying once drug treatment is discontinued. In one study with diazepam, 90% of animals that were on 8 week treatment began spraying when the drug was tapered off (Cooper and Hart, 1992), compared with 50% with buspirone (Hart et al., 1993). The resumption of spraying with diazepam may be because diazepam produces behavioural and physiological dependency, and taking animals off the drug, even gradually, undoubtedly produces some rebound emotional effect that may predispose the animal to resume spraying.

Both buspirone and diazepam may suppress spraying in cats that were previously treated with progestin but did not respond. Based upon the fact that progestins utilize different receptors and perhaps even a different neurological pathway than antianxiety drugs, a model of urine spraying was proposed consisting of two neurological systems, one relating to male sexuality and one to anxiety. Progestin administration, which presumably suppresses neural elements that are normally activated by testosterone, may work with those cases where urine spraying is more of an expression of male sexuality. Antianxiety drugs may suppress urine spraying related to anxiety-provoking situations such as introduction of new cats or moving to a new house. With regard to treatment of objectionable male sex-typical behaviours other than spraying, there is some indication that progestin administration may alter intermale aggressive behaviour in castrated male dogs (Hart, 1981).

8. Behavioural effects of ovariectomy

There is little clinical or experimental research relevant to the behavioural effects of ovariectomy. As mentioned previously, during prenatal and neonatal development of females, there is no behaviourally significant amount of estrogen or progesterone secreted and the organization of feminine responses occurs as a function of development without testosterone.

Among dog handlers and trainers, one may hear of references to calming (or mellowing) effects of allowing female dogs to experience one or more estrus periods or even parturition and care of a litter of puppies. The degree to which removal of female gonadal hormones might result in permanent changes in behaviour was explored in a

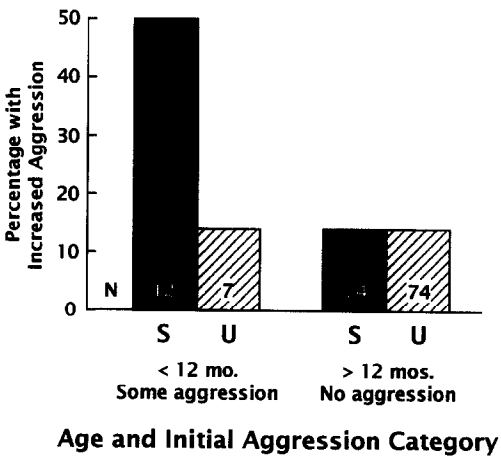

Fig. 5. Percentages of female dogs showing increased aggression after ovariohysterectomy (spay) as a function of age at time of the operation (less or greater than 12 months) and whether they showed signs of some aggression prior to the operation. Only dogs that were spayed (S) at less than 12 months of age and showing some aggression exhibited an increase in aggression compared with unspayed controls (U) who also showed some aggression (from O'Farrell and Peachey, 1990).

study of 150 spayed and 150 unspayed female dogs by O'Farrell and Peachey (1990). Owners were interviewed via questionnaire at the time the female dog was spayed and 6 months later. Owners of a control group of age-matched unspayed dogs were also interviewed twice at an interval of 6 months. In both groups there were changes over time in some dogs but the only two behaviour patterns in which spayed females showed a change that differed significantly from the control group was in aggressive dominance towards owners and in indiscriminate eating. The increase in aggression was only apparent in females spayed at less than 12 months of age and that already showed some aggression (Fig. 5). Females that were older than 12 months at time of being spayed presented no risk of increase in aggression.

One possible explanation of these results is that spaying removes the source of progestin production if done shortly after estrus. Female dogs that cycle twice a year are in a progestational state for about 2 months following each estrus period. Given that progesterone has some calming influences, removal of progesterone in some animals may increase aggressive or irritable tendencies especially if the dogs are spayed when progesterone levels are high producing a sudden change in this hormone. Once a female has gone through more estrous cycles, and perhaps been disciplined for aggressive behaviour, spaying may have less of an impact.

9. Conclusions

This review reveals the complexity of the role of gonadal hormones in companion animal behaviour and in the alteration of these hormones for changing objectionable behaviour. Two overriding concepts should be very apparent: (1) gonadal hormones have pronounced effects on behaviour and must be taken into account in any program designed to treat or manage problem behaviour; and (2) the alteration of gonadal hormones, particularly castration of males, does not affect all dogs or all cats similarly. One cannot extrapolate from experience with one or two dogs or cats in predicting the effects of castration or ovariectomy. There is a need for additional research in understanding the basis of such pronounced individual differences in the effects of hormones on behaviour.

EFFECTS OF FERTILITY CONTROL ON POPULATIONS OF UNGULATES: GENERAL, STAGE-STRUCTURED MODELS

N. THOMPSON HOBBS,[1] Colorado Division of Wildlife and Natural Resource Ecology Laboratory, Colorado State University, Fort Collins, CO 80523, USA

Abstract: Regulating the abundance of ungulate populations using hunting can prevent populations from reaching levels that cause harm to natural and human dominated systems. However, there are an increasing number of cases where hunting is infeasible, and in such cases, fertility control has been widely advocated as an alternative means for controlling populations. Here, we develop simple analytical models offering general insight into the feasibility of using fertility control to regulate the abundance of ungulates. The models are structured in stages to represent variation in the duration of effect of fertility control agents. Analysis of these models offers several predictions, amenable to testing in field studies. (1) More than 50% of fertile females will need to be maintained infertile to achieve meaningful reductions in ungulate numbers even when fertility rates are low. (2) The relationship between the proportion of females maintained infertile and the steady state density is highly nonlinear. This means that small errors in estimating levels of infertility can lead to large errors in achieved density. It also means that managers should expect to see little change in steady-state density across a broad range of delivery rates. (3) The efficacy of fertility control as a management technique depends strongly on the persistence of the effect of the fertility control agent and the ability of managers to recognize previously treated animals. (4) Fertility control using long-lived agents can be more efficient than culling in regulating ungulate numbers. (5) Treating small populations with irreversible agents magnifies the likelihood of population extinction relative to treatment by culling. As with all techniques, managing population fertility must extend from a sound understanding of the influence of management actions on the state and dynamics of the population.

JOURNAL OF WILDLIFE MANAGEMENT 64(2):473–491

Key words: contraceptives, hunting, management, population persistence, modeling, fetility control, sterilization, ungulate.

Controlling the abundance of ungulates by regulating harvest is one of the prevailing activities of wildlife managers throughout North America. Regulated harvest offers a variety of benefits to society, including recreation for citizens and revenue for agencies and private enterprise. An additional benefit is a reduction in animal numbers, which if left unchecked, can cause significant harm to natural and human-dominated systems (Jewell and Holt 1981, Diamond 1992, Garrott et al. 1993, McCullough et al. 1997).

Although harvest can be an effective method for manipulating ungulate numbers, there are a growing number of situations where it is not feasible. The rapid expansion of urban and suburban areas during the last decade has brought populations of ungulates in close proximity to high densities of people (Adams 1994, McCullough et al. 1997). This proximity restricts the use of hunting as a management tool because it poses unacceptable risks to human safe-

ty (Decker and Connelly 1989, Brush and Ehrenfeld 1991, McAnnich 1993, Wright 1993), and because urban residents often oppose hunting animals on ethical grounds (Decker and Connelly 1989, McCullough et al. 1997). In addition, there are many conservation areas, national parks prominent among them, where hunting is proscribed by law and policy (Leopold et al. 1963, Wright 1993, Porter et al. 1994, Wagner et al. 1995, Frost et al. 1997, Porter and Underwood 1999). In all of these situations, culling animals to regulate populations has significant liabilities, and as a result, wildlife managers are seeking innovative alternatives to lethal methods of population control (Kirkpatrick and Turner 1985, Bomford 1990, Brush and Ehrenfeld 1991, Diamond 1992, Garrott et al. 1993, McCullough et al. 1997).

Fertility control has been widely advocated as an alternative to culling (reviewed by Kirkpatrick and Turner 1985, Bomford 1990, Tuyttens and Macdonald 1998). Field and laboratory studies have evaluated efficacy of delivery of contraceptives to ungulates (Jacobsen et al. 1995, McCallum 1996, DeNicola et al. 1997, Fayrer Hosken et al. 1997, Kirkpatrick et al. 1997, Nielsen et al. 1997, Turner et al. 1997), and models have been developed to represent effects of fertility control on the population dynamics of individual species (Garrott and Siniff 1992, McAninch 1993, Swihart and DeNicola 1993, Boone and Wiegert 1994, Seagle and Close 1996). However, despite these efforts, a broad understanding of effects of fertility control on ungulate populations has failed to emerge. The absence of such understanding retards efforts to apply fertility control as a method to control ungulate numbers.

Here, we develop a general theory of regulation of ungulate populations using fertility control agents. Specifically, our objective was to develop simple analytical and simulation models offering general insight into the following questions. (1) What proportion of females in a population must be infertile to maintain the population at target densities? (2) How does fertility control compare with culling as a means to regulate ungulate populations? (3) How does duration of efficacy of contraceptives influence the number of animals that must be treated to achieve target population levels? (4) To what extent does timing of delivery (pre- or post-breeding) influence the ability of contraceptives to regulate ungulate numbers? (5) Do assumptions on the operation of density dependence modify the insights gained above? (6) Is fertility control a "safe" method for regulating small populations vulnerable to stochastic, local extinction? We provide a general mathematical basis for screening the feasibility of fertility control before developing detailed, species-specific models or conducting extensive field applications.

METHODS

Base Model

Because our purpose was to develop general insights, we used a model that was as simple as possible (Levins 1966, Starfield et al. 1990, Starfield and Bleloch 1991, Starfield 1997). The model needed to be sufficiently detailed to mimic the behavior of ungulate populations in a reasonable way, but it also needed to avoid detail peripheral to the questions posed above. To meet this challenge, we began with a simple formulation and incrementally added detail needed to meet our objectives.

Our starting point was a stage-structured model representing species where adult survivorship is high and where density dependence operates primarily on recruitment, characteristics that are particularly faithful to the life histories of many species of ungulates (McCullough 1979, Houston 1982, Skogland 1990, Bartmann et al. 1992, Gaillard et al. 1993, Putman et al. 1996). The model was formulated as

$$F_{t+1} = F_t(S + m - \beta(F_t - H_t)) - H_t, \quad (1)$$

where F_t is the density of females at time t, S is the annual per-capita survival rate of females, m is the maximum number of breeding females annually recruited to the population per breeding female, β is the linear slope of the relationship between recruitment of females to breeding age and female density, and H_t is the number of females culled at time t. The model predicts the preharvest population density of females using 3 parameters (S, m, β) and a single decision variable, H_t. Although the model represents a single stage explicitly (adult females), it implicitly represents sexually immature juveniles via the recruitment term. The explicit juvenile stage drops out of equation (1) via model reduction (Caswell 1989:100).

The model is based on several simplifying assumptions. First, we assume that the probability of survival of adults does not change with age. Thus, we treat longevity as the outcome of a

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

series of independent Bernoulli trials rather than being fixed at a specific age (Gurney and Nisbet 1998:80). Culling is assumed to occur after breeding, but before recruits are born. We assume that density dependence is linear and operates entirely on recruitment. That is, the number of new breeding females recruited to the population is directly proportionate to the postharvest population density of females. Effects of nonlinear density dependence will be included as part of the analysis of the model.

It is possible to formulate the model using an explicit parameter for the density at which recruitment = 0 (i.e., $K_r = m/\beta$). Alternatively, we can represent effects of density dependence using a slope (β) and intercept (m) for the relationship between density and recruitment. We used this approach because we believe these parameters offer useful biological interpretations; the parameter β represents the "strength" of density dependence and the parameter m represents the maximum possible recruitment rate. Both of these representations prove useful when interpreting model analysis.

Although this model is extremely simple, it can represent the dynamics of ungulate populations with reasonable fidelity (Fig. 1). A more detailed model would achieve higher levels of realism, but only at the expense of reduced clarity and generality.

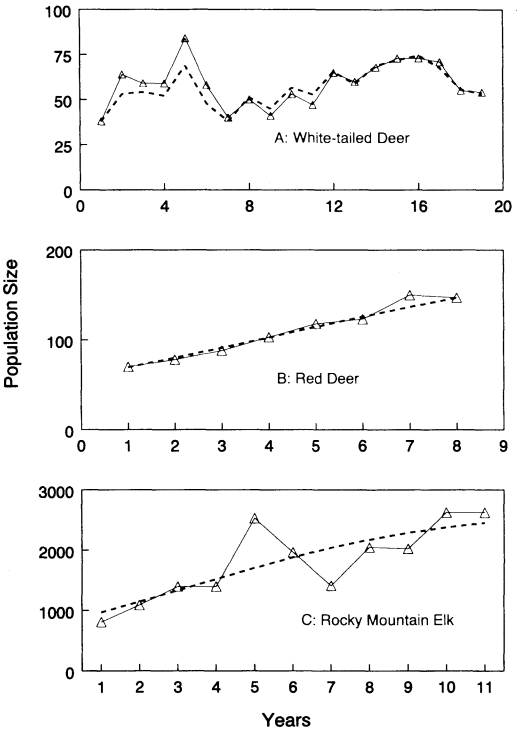

Fig. 1. Comparison of model projections (dashed line) with observed trajectories of ungulate populations (triangles). Model parameters were estimated by minimizing the squared difference between observations and predictions. A close fit between observations and predictions allows the conclusion that the model contains sufficient detail to reasonably represent trajectories of ungulate populations if its parameters are properly estimated. Data are from [A]—McCullough (1979: Table 3.2), [B]—Clutton-Brock et al. (1982), [C]—Houston 1982.

Model Development

We modified equation (1) to represent effects of fertility control as an alternative to culling. Node diagrams and the matrix form of the model are shown in Fig. 2. Here, we summarize our modifications using finite difference equations.

We defined the number of animals harvested annually as

$$H = cF_t. \quad (2)$$

Thus, c is the per capita rate of culling, the number of breeding females culled annually per breeding female in the population. It follows that the effects of culling can be represented in the model as

$$F_{t+1} = F_t(1 - c)(S + m - \beta(1 - c)F_t). \quad (3)$$

We will refer to equation 3 as the culling model.

To allow comparison with fertility control, we redefined c as the per capita rate of delivery of contraceptives. There are now 2 stages that we wish to track in the population; females that are fertile (i.e., F_t) and those that are infertile (i.e., I_t). We define fertile animals as those that are capable of breeding and carrying a fetus to term. We define infertile animals as those that cannot successfully breed. When the effect of the contraceptive persists for a single breeding season, then the dynamics of the fertile (F_t) and infertile stages (I_t) can be represented as

$$F_{t+1} = F_t(1 - c)(S + m - \beta N_t) + (1 - c)I_t, \text{ and} \quad (4)$$

$$I_{t+1} = F_t c(S + m - \beta N_t) + I_t Sc, \quad (5)$$

where

$$N_t = F_t + I_t. \quad (6)$$

However, if the effects of the contraceptive persist for more than 1 breeding season, then we must account for the time since the animal was treated. This accounting can be accomplished

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

by adding stages to the model. If the duration of the contraceptive is finite, then the dynamics of the fertile and infertile stages can be represented as

$$F_{t+1} = F_t(1-c)(S + m - \beta N_t) + (1-c)I_{\tau_t} \quad (7)$$

$$I_{1_{t+1}} = F_t c(S + m - \beta N_t) + I_{\tau_t} Sc \quad (8)$$

$$I_{2_{t+1}} = I_{1_t} S, \quad (9)$$

$$I_{3_{t+1}} = I_{2_t} S, \quad (10)$$

$$I_{4_{t+1}} = I_{3_t} S, \quad (11)$$

$$I_{\tau_{t+1}} = I_{\tau-1_t} S, \quad \text{and} \quad (12)$$

$$N_t = F_t + \sum_{i=1}^{\tau} I_{i_t}, \quad (13)$$

where τ = the duration of the contraceptive in number of breeding seasons. Thus, the number of stages in the model is $\tau + 1$, 1 stage for the breeding females and 1 stage for each year that animals are infertile following treatment. The total population of females is the number of animals summed across stages (equation 13). We will refer to equations 7–13 as the fixed duration model.

It is possible to develop agents that will render animals infertile for life (reviewed by Muller et al. 1997, Tuyttens and Macdonald 1998). To represent effects of such agents, only 2 stages need to be tracked (fertile and infertile animals), and the dynamics of these stages are connected only by the rate of addition of animals to the infertile pool and the effect of total density on recruitment. Thus, the dynamics of the population are given by

$$F_{t+1} = F_t(1 - c)(S + m - \beta N_t), \quad (14)$$

$$I_{t+1} = F_t c(S + m - \beta N_t), \quad \text{and} \quad (15)$$

$$N_t = F_t + I_t. \quad (16)$$

We will refer to equations 14–16 as the lifetime duration model.

The fixed and lifetime duration models depend on the same set of assumptions described for the culling model. However, these models require the additional assumptions that treatment is applied immediately before breeding occurs and that managers can differentiate between animals that have been treated and those that have not been treated. We will examine the consequences of these assumptions as part of model analysis. Time of census in the model is

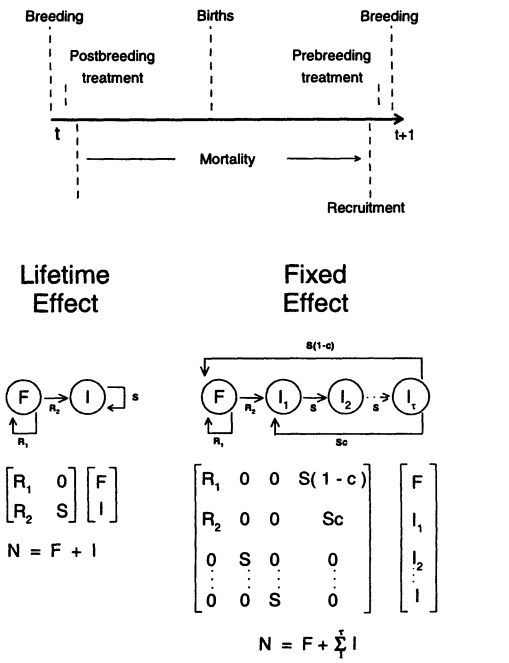

Fig. 2. Schematic of model structure and assumptions. The upper panel depicts assumptions on timing of events represented in the model. The central panel shows the structure of the model in node and matrix formats. The lower panel shows representations of assumptions about timing of delivery and the operation of density dependence.

assumed to occur annually, immediately after breeding (Fig. 2), and all fertile animals are assumed to be bred at the time of census. We chose breeding rather than births as the point of reference for census because the state of the animal that influences model behavior is its fertility rather than its age.

Model Analysis

Deterministic Analysis.—We used standard matrix techniques and algebraic manipulations (see Appendix I for details) to derive several quantities of interest. These included: K_e, the equilibrium density of animals in the absence of fertility control or culling; K_c, the equilibrium

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

density of animals as a function of delivery or culling rate; c^*, the delivery rate required to maintain a target population density; P, the proportion of the population that must be infertile to maintain a target population density; and n^*, the number of animals that must be treated or culled annually to maintain a target population density. To examine the effects of timing of delivery on model predictions, we changed model formulations to represent delivery after breeding (Fig. 2). In this case, delivery of contraceptives did not prevent birth by treated animals during the current time step (because treated animals were assumed to be pregnant at the time of delivery) but did prevent births during the subsequent time step (Fig. 2). To examine effects of nonlinearity in density dependence, we reformulated the model (Fig. 2) so that recruitment remained relatively constant at low population density and then declined as threshold densities were reached (Bartmann et al. 1992). To examine consequences of relaxing assumptions on known fertility status of animals, we developed an estimator to show how many animals must be treated to achieve a treatment target, given unknown fertility status. This estimator deals with the multinomial case of sampling with replacement, and estimates necessary treatment rates, assuming that animals could be treated more than once.

Stochastic Analysis.—We performed Monte Carlo simulations to examine the relative ability of culling and fertility control to regulate animal numbers near a target density. These simulations were organized in 4 model scenarios that included 2 types of management and 2 sources of stochastic variation. Management types include static and adaptive. Static management applied the same per capita rate of delivery annually, a rate that would achieve a target population density if applied accurately. Adaptive management changed the delivery or culling rate in response to differences between realized density and an acceptable range of target densities. The acceptable range was defined as the target ±25%. If the population exceeded the target by ≥25%, then the culling or delivery rate was increased by 10% until the population returned to acceptable levels. If the population dropped below the target by ≥25%, then culling or fertility control was discontinued until the population recovered to a density within the acceptable range.

In addition to 2 types of management, model scenarios included 2 sources of stochastic variation; process and observer. Process variation was included to mimic density independent effects of the environment on population dynamics. To represent this variation, adult survival varied according to a log-normal distribution with mean 0.9 and variance 0.1. We varied the effect of density on recruitment (i.e., β) using a normal distribution with a mean of 0.009 and variance 0.01. To assure that stochastic effects on mortality and recruitment were correlated, we derived them from the same normally distributed variate at each time step. Observer variation was included to mimic the error in estimates of population size that are typical in managing ungulate populations. To represent observer variation, delivery and culling rates were based on an estimate of the current population density derived by sampling from a normal distribution with a mean equal to the model density at time t (F_t) and a standard deviation equal to 15% of the mean. Initial conditions for population density were set at the target density. Initial conditions for population composition (i.e., fertile–infertile stages) were set at levels equivalent to the deterministic steady-state at that target density. We conducted 1,000 model runs of 50 years each for 2 target densities, set as percentages (25 and 75%) of the steady state that would occur in the deterministic model when culling or fertility control was not applied (i.e., K_e). We applied 4 methods of population control: culling, and fertility control with the duration of treatment equal to 1 year, 3 years, and lifetime. For each set of model runs, we recorded the total number of animals treated or culled, the overall variance in population density, and the number of years that the population was outside the acceptable ranges. We also recorded the frequency of extinction and the persistence time of the population.

Procedures for Analysis and Plotting.—Analytical results were obtained using Maple V (Waterloo Maple, Waterloo, Ontario, Canada). All analytical results were checked for accuracy using simulation of difference equations with Microsoft Excel (Microsoft Corporation, Redmond, Washington, USA). Monte Carlo simulation experiments were conducted using Visual Basic for Applications running under Excel. For the purpose of illustrating analytical results in plots, we chose parameter values that are reasonable for white-tailed deer (*Odocoileus virginianus*; $m = 0.6$, $S = 0.9$, $\beta = 0.005$) and that

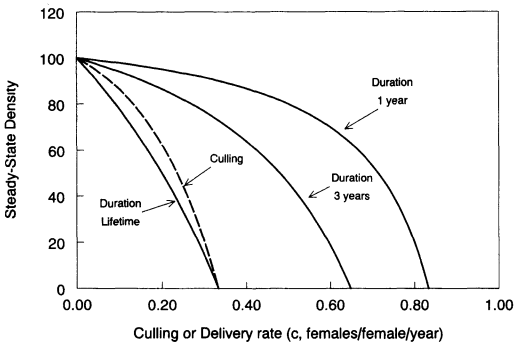

Fig. 3. Model predictions (equation 18) of steady-state density as a function of culling or delivery rate using parameter values $m = 0.6$, $S = 0.9$, $\beta = 0.005$. Different lines show differences due to variation in duration of efficacy of contraceptives.

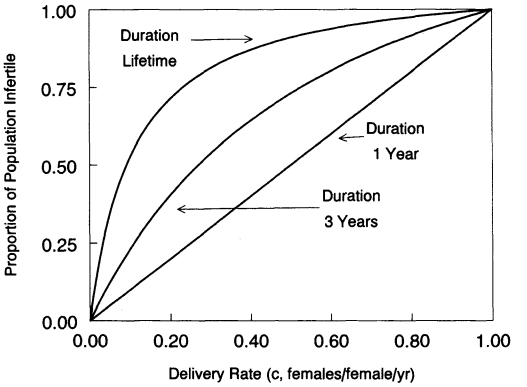

Fig. 4. Model predictions (equation 19) of effects of delivery rate on the proportion of the female population that is infertile. Different lines show differences due to variation in duration of efficacy of contraceptives. Parameter values are $m = 0.6$, $S = 0.9$, $\beta = 0.005$.

produced an equilibrium value of population density = 100 in the absence of any treatment or culling. Because density can scale to any unit area, our plots can be viewed in absolute or relative terms. For example, $N = 90$ can be accurately interpreted as an absolute density (e.g., 90 animals per unit area) or as a percentage of steady state population density that would be achieved in the absence of treatment (e.g., 90% of K_e).

RESULTS

Equilibrium Population Density and Composition

In the absence of treatment or culling (i.e., $c = 0$), all models predicted that the population would reach a steady state density, K_e,

$$K_e = \frac{S + m - 1}{\beta}. \quad (17)$$

As the rate of treatment with contraceptives increases, models predicted that steady state density declines in a nonlinear fashion (Fig. 3) according to

$$K_c = \frac{S + m + S^{\tau}c - Sc - cm - 1}{(1 - c)\beta}. \quad (18)$$

In the lifetime case, the S^{τ}_c term drops out of equation (18).

Fixed-effect models predicted a nonlinear, threshold relationship between equilibrium density and treatment rates. We found a broad range of treatment rates that exert relatively weak effects on steady state density, particularly for short-duration models (Fig. 3). Increasing duration of fertility control tended to make this relationship more linear (Fig. 3).

Fixed-effect models illustrated that when the duration of the contraceptive is 1 breeding season, the proportion of the population that is infertile (P) is equal to the treatment rate (i.e., $P = c$). However, when effects persist beyond a single season, infertile animals accumulate in the population treated annually, and as a result, $P > c$ (Fig. 4). Analysis of the model (Appendix A) suggests that the relationship between P and c depends on the duration of the effect of the contraceptive and the adult survival rate, i.e.,

$$P = \frac{(1 - S^{\tau})c}{1 + Sc - S - S^{\tau}c}, \quad (19)$$

but does not depend on birth rate (m) or the strength of density dependence (β). In the lifetime case, this simplifies to

$$P = \frac{c}{1 - S + Sc}. \quad (20)$$

The relationship between target density (N^*) and the proportion of the population that is infertile (P) is identical for all fertility control models (Fig. 5),

$$N^* = \frac{S + m - Pm - 1}{\beta(1 - P)}. \quad (21)$$

Equation 21 shows that increasing dependence of recruitment on density amplifies the effect of fertility control on the steady state population size. That is, achieving a given target density will require a smaller proportion of infertility in populations where density-dependent effects

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

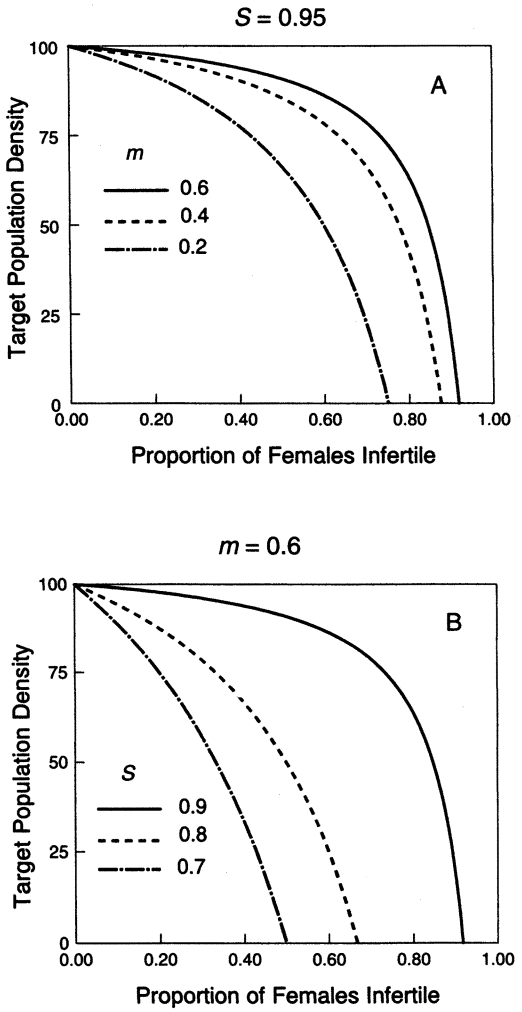

Fig. 5. Model predictions (equation 21) of the proportion of the females that must be infertile to achieve a target population density assuming a constant ecological carrying capacity of K_e = 100. Panel A shows this proportion with adult female survival rate held constant (S = 0.95) and maximum recruitment rate varying. Panel B shows this proportion with maximum recruitment rate held constant (m = 0.6) and survival rate varying.

are stronger than in populations where such effects are weak.

Population managers need a relatively easy way to estimate the proportion of the population that would need to be maintained infertile to achieve a given target density. This can be obtained as follows. By rearranging equation 21, we find P as a function of the target density:

$$P = 1 - \frac{1 - S}{m - \beta N^*}. \quad (22)$$

This result simply says that for any steady-state population density, N^*, the proportion of the population that is fertile (i.e., $1 - P$) must equal the adult per capita mortality rate divided by the per capita recruitment rate (i.e., females per female per year). When this is true, the number of animals recruited will equal the number that die.

Note that the duration of the contraceptive determines the rate of delivery that must be applied each year to achieve a given level of population infertility, (equation 19), but the duration does not affect the level of infertility required to achieve a given steady-state density (equation 22). Equation 22 also illustrates that the necessary proportion infertile will increase with increasing adult survival and maximum recruitment. It will decline with increasing "strength" of density dependence.

Equation 22 requires an estimate of β, which can be difficult to obtain. However, it is possible to derive an expression for P that does not depend on estimating β. Defining Δ as a proportion of the steady-state density (i.e., $N^* = \Delta K_e$) and substituting the right hand side of

$$\Delta K_e = \Delta\left(\frac{S + m - 1}{\beta}\right) \quad (23)$$

for N^* in equation 22, we obtain an expression for the proportion of animals that must be infertile to achieve a target density specified as a proportion of the untreated steady state, i.e.,

$$P = 1 - \frac{1 - S}{m + \Delta(1 - S - m)}. \quad (24)$$

Thus, when $\Delta = 1$, there is no reduction in density; when $\Delta = 0$, the population goes extinct. Equation 24 is an important result because it provides a general rule of thumb for estimating the effort required to regulate a population using fertility control without knowing the strength of density dependence. This rule requires estimates of only 2 parameters (adult female survival rate and maximum recruitment rate of females) and a decision on the targeted reduction, Δ.

Vital Rates and Population Composition at Equilibrium

Equation 24 also reveals that a relatively large proportion of the population must be infertile in order to achieve meaningful reductions in density (Fig. 5). When adult survival is high (>95%),

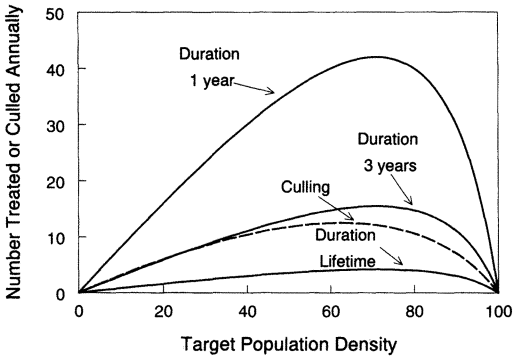

Fig. 6. Model predictions (equations 25–28) of the number of animals that would need to be treated or culled to maintain a population at the specified target density. Parameter values are $m = 0.6$, $S = 0.9$, $\beta = 0.005$. Different lines show differences due to variation in duration of efficacy of contraceptives.

it is reasonable to assume that >60% of the breeding females will need to be infertile to achieve meaningful reductions in population density, even for species with very low intrinsic rates of increase (e.g., $m = 0.2$, Fig. 5). The shape of the relationship between the proportion of the population that is infertile and steady-state density is more sensitive to differences in adult survival than to differences in maximum rates of recruitment. This relationship remains strongly nonlinear as long as adult survival is high. However, as adult survival declines, the relationship approaches linearity (Fig. 5).

Number of Animals Treated or Culled at Equilibrium

When effects of fertility control agents persist for only 1 year, then the proportion of the population that is infertile equals the delivery rate. Moreover, in this case, the number of animals that must be treated the first year to achieve a given target is the same as the effort required in subsequent years. However, when regulating populations with fertility control agents that persist for >1 breeding season, there are 2 types of effort required: the effort required to achieve a specified level of infertility in the population, and the effort required to maintain that level of infertility. Here, we examine this maintenance effort and compare it with culling.

In populations regulated with culling, the number of animals harvested annually (n) to maintain a given target density, N^*, at steady state is simply

$$n = c^*N^*, \quad (25)$$

where c^* is the culling rate needed to maintain a population at the target density. For the culling model, c^* is given by

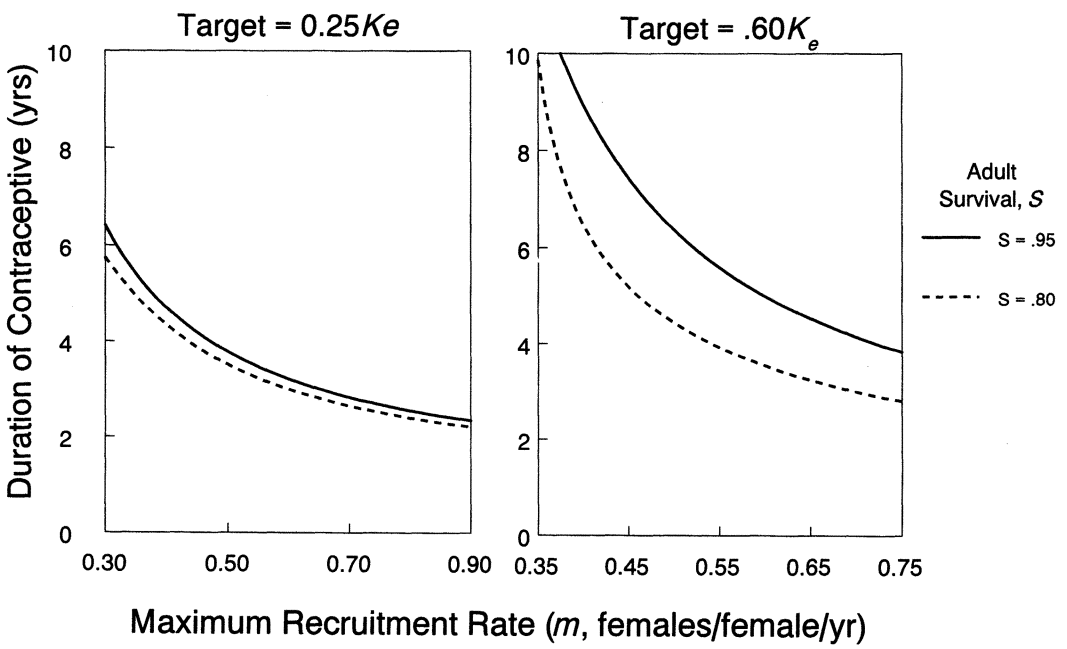

Fig. 7. Model predictions of the duration of contraceptive delivered to an animal needed to cause the same effect on population growth as culling the animal (equations 25 and 28).

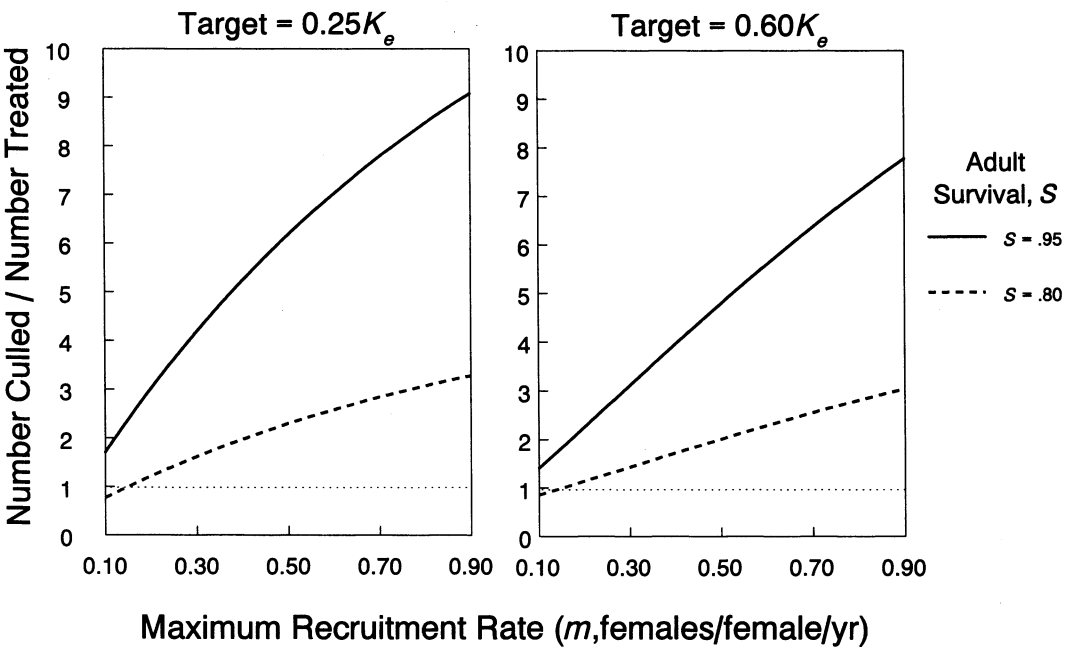

Fig. 8. Model predictions of the ratio of the number of animals that would need to be culled relative to the number treated with contraceptives to maintain steady states at target densities. The horizontal dotted line shows where the number culled equals the number treated (equations 25–28).

$$c^* = \left(2N^*\beta - S - m + \sqrt{S^2 + 2Sm + m^2 - 4N^*\beta}\right)/(2N^*\beta). \quad (26)$$

In populations regulated with fertility control, there are 3 cases relevant to the number of animals treated annually (n) to maintain a given target density. In the case of fixed duration agents lasting a single year, the delivery rate at equilibrium (c^*) is the same as the proportion of the population that is infertile, so using equation 22, we calculate the number treated as

$$n = c^*N^* = PN^* = \left(1 - \frac{1 - S}{m - \beta N^*}\right)N^*. \quad (27)$$

In the case of agents with duration >1 year and greater than a lifetime, the number that must be treated annually is

Table 1. Results of 1,000 model runs of 50-year duration with stochastic variation. Static management applied a constant, per capita culling or delivery rate needed to achieve the target density. Adaptive management adjusted the culling or delivery rate to keep the population within ±25% of the target density. Process variation mimicked stochastic environmental effects on adult survival and juvenile recruitment. Observer variation mimicked uncertainty in estimating population size. Control methods included culling and 4 contraceptives differing in duration, compared with the no management case (i.e., "Natural"). Results include average population size (*N*) and its coefficient of variation. We also report percentage of runs for which population density dropped below 1 (% extinct) and mean time to extinction averaged across model runs (persistence time in yr).

Management type	Variation type	Control method (duration of contraceptive)	Target density							
			25				75			
			N	CV	% extinct	Persistence time	*N*	CV	% extinct	Persistence time

Table 2. Modeling estimates of proportion of the target sex that must be infertile to achieve target population objectives. Assumed annual growth rate in absence of treatment = 1.49.

Species	Population objective	% infertile	Reference
White-tailed deer	Negative growth rate[1]	90%	(Swihart and DeNicola 1993)
Feral horses	Reduce population from 600 to range of 300–600	68–82% depending on treatment regime	(Garroutt et al. 1992)
White-tailed deer	Maintain at ½ carrying capacity	80%	(Boone and Wiegert 1994)
Feral horses	Reduce growth rate (i.e., lambda) to 1	90–95%	(Garrott and Siniff 1992)
White-tailed deer	Reduce population size	>50%	(Seagle and Close 1996)
White-tailed deer	Maintain at ½ carrying capacity	96%	(Nielsen et al. 1997)

$$n = c^*(1 - P)N^*(S + m - \beta N^*) + c^*\rho N^*, \quad (28)$$

where c^* is the treatment rate required to achieve a given target density, N^*P is the portion of the population that is infertile at time t as a result of applying c^*, and ρ is the proportion of the population that becomes fertile during $t \rightarrow t + 1$ given a treatment rate = c^*. The components of equation 28 are as follows. The variable P is given by equation 22. The equilibrium treatment rate is

$$c^* = \frac{S + m - 1 - \beta N^*}{S + m - S^\tau - \beta N^*}. \quad (29)$$

The proportion of the population that will become fertile during a time step is

$$\rho = \frac{S^{\tau-1}(1 - S)c^*}{1 + Sc - S - S^\tau}. \quad (30)$$

In the lifetime duration case, the S terms with exponents drop out of the expression for c^* and $\rho = 0$.

Equations 25 and 28 allow comparison of the effort required to control populations using culling or fertility control. Because these equations predict the number of animals that must be treated or culled to maintain populations below K_e (Fig. 6), they are analogous to classical production functions, also known as yield curves (Roughgarden 1997).

Effect of Duration of Contraception

We asked the question, "On average, how long must the effect of a contraceptive persist in an animal to exert the same effect on population-level production as culling that animal?" To address this question, we chose a broad range of parameter values to represent diverse life-history characteristics of ungulates, and applied those values to equations 25 and 28. Models suggested that for a broad range of assumptions about survival and maximum recruitment, delivery of a contraceptive to an individual animal would have the same effect as culling that animal if the effects of the contraceptive persisted for 2–5 years (Fig. 7). Briefer duration is needed when adult survival rates are low. Increasing strength of density dependence reduces the required duration; weakening it increases the required duration.

When contraception persists for the lifetime of the animal, models predicted that in most cases, the effort required to regulate a population at a specified density using fertility control will be less than the effort required by culling (Fig. 8). Exceptions to this result occur when adult survival is low and recruitment is low, that is, when populations grow slowly (Fig. 8). For species with high rates of adult survival and high recruitment rates, the number of animals culled could be almost an order of magnitude greater than those treated with contraceptives at the same target density (Fig. 8). Thus, if we define efficiency of control in terms of the number of animals that must be culled or treated annually to maintain a population at a specified target, then culling will be more efficient than lifetime duration contraception only for slowly growing populations. In all other cases, models suggest that treatment with lifetime effect contraceptives is likely to be more efficient than culling. However, it must be understood that these estimates of effort specify the number of animals that must be treated annually to maintain a steady state population with a proportion infertile, P (equation 22). These are not estimates of the effort required to achieve P in the pretreatment population.

Consequences of Changing Model Assumptions

Assumed Pre-breeding Delivery.—In all results above, we assumed that contraceptives were delivered to females before breeding occurs. It is possible to change the model to represent delivery after breeding by assuming that treated animals give birth during the current time step but are infertile during the subsequent one (Fig. 2). An important result emerged from this analysis. We found that when contraceptives are delivered postbreeding, there is a fundamental limit to the magnitude of the reduction in population density that can occur using fertility control,

$$N^* \geq \frac{m - 1}{\beta}, \tag{31}$$

or, solving in terms of a proportionate reduction,

$$\Delta \leq \frac{m - 1}{S + m - 1}. \tag{32}$$

The right-hand-side of equation 32 gives the steady-state density of females that occurs when the delivery rate = 100%. At this density, each fertile female produces exactly 1 female offspring surviving to reproductive age and the proportion of fertile females in the population equals the adult mortality rate.

Equations 31 and 32 are important because they reveal that it may not be possible to achieve meaningful regulation of populations where contraceptives are delivered after animals have been bred, even when the entire population of fertile females is treated. If animals can breed at 1 year of age, then a cohort of animals always escapes the postbreeding treatment, and this escape may allow populations to grow to levels that are close to K_e, if recruitment rates are sufficiently high. Equations 31 and 32 raise serious doubt about the efficacy of fertility control as a means of regulating populations whenever yearlings contribute significantly to breeding and contraceptives are delivered after they are bred.

Assumed Linear Density Dependence.—Changing the form of the relationship representing density dependence from linear to nonlinear did not change the qualitative results obtained above (Fig. 2). The composition of the population at equilibrium (i.e., equations 19 and 20) does not depend on the form of density-dependent relationships. However, the relationship between equilibrium population size and the proportion of the population infertile changed when we changed the formulation for density dependence. In the case of nonlinear density dependence,

$$N^* = \frac{\ln\left(\frac{S + m - Pm - 1}{1 - S}\right) + \alpha}{\theta}, \tag{33}$$

where α and θ are parameters controlling the shape of the nonlinear relationship between recruitment and density.

Note that this expression does not depend on the duration of the effect of the contraceptive, as we saw earlier for the linear case. Plotting equation 33 shows that nonlinearity in density dependence can sharpen the threshold relationship between N^* and P (Fig. 9). In the neighborhood of this threshold, small errors in estimating the proportion of the population that is infertile can lead to very large errors in equilibrium population size. Nonlinear density dependence amplifies the consequences of such errors. Nonlinearity in density dependence also expands the range of levels of infertility in the population (i.e., P) over which we expect virtually no change in equilibrium density (Fig. 9).

Assumed Knowledge of Fertility Status.—One of the assumptions of our base model is that managers can differentiate between fertile and infertile animals when delivering fertility control treatments. There are cases where this assumption is reasonable, for example, when treated animals can be visually marked, or when it is possible to achieve the desired delivery rates by treating young of the year. However, there will be many cases where the fertility status of animals is unknown. This means that some animals are likely to be treated more than once, thereby increasing the number of "doses" of fertility control agents that must be delivered to achieve a target delivery rate.

This is essentially a problem in multinomial sampling with replacement. That is, after an animal is given a dose of contraceptives, it is released into the population unmarked, and is subject to "resampling" a later time. Because it is unmarked, its fertility status is unknown, and it will be redosed if it is resampled. We are interested in estimating the number of doses (d) that must be delivered in order to treat a target number of animals (η) in a population of size

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

N. We first consider the case where the duration of contraceptives is a single breeding season and all infertile animals must be dosed annually to maintain infertility. In this case, it can be shown (Appendix B) that the number of animals (d) that must be dosed to expect η animals to be infertile at the end of the treatment campaign can be estimated as

$$d = \frac{\ln\left(\frac{N-\eta}{N}\right)}{\ln\left(\frac{N-1}{N}\right)}. \quad (34)$$

Alternatively, when the duration of contraceptives persists for more than a year, there will be some animals in the population that will remain infertile and do not need to be retreated. Define I as the number of animals in the population that are infertile at the start of a treatment campaign and that remain infertile during the subsequent year. In this case the number of animals that must be dosed to expect that η additional animals are infertile is given by

$$d = \frac{\ln\left(\frac{N-I-\eta}{N-I}\right)}{\ln\left(\frac{N-1}{N}\right)}. \quad (35)$$

Equations 34 and 35 portray the large inefficiencies associated with treating a significant proportion of a population whenever treated animals are not easily distinguished from untreated ones (Fig. 10). For example, a population of 100 fertile animals would require dosing 160 animals to reasonably expect 80 infertile animals in the population after treatment (Fig. 10). A population of 100 animals, 80 of which are infertile at the time of delivery, would require dosing 69 animals to expect that only 10 additional animals would be infertile during the subsequent year. This result illustrates that the feasibility of treating populations with fertility control agents depends in a fundamental way on knowing the fertility status of individual animals at the time of treatment. In the absence of such knowledge, achieving meaningful reductions in steady state density could require delivering doses in excess of the total number of females in the population.

Stochastic Models

We compared the ability of different control regimes to maintain populations at target densities in the face of environmental stochasticity and error in estimation of population size. For all model runs, simulations of fixed-effect fertility control with single year duration showed the lowest coefficients of variation around target population densities, lowest likelihood of extinction, and longest persistence times (Table 1). Results from the culling model resembled those of single-year duration fertility control, but tended to show slightly higher variability and slightly greater probability of extinction. Lifetime effect fertility control models predicted the highest levels of variability and greatest chance of extinction. In the extreme case, extinctions occurred in >40% of all model runs for lifetime effect representing static application of fertility control with process and observer variation to populations at 25% of K_e (Table 1). Population variability and indicators of extinction risk for models of fertility control with 3-year duration showed effects intermediate to the culling model and the lifetime model. For all models, simulations of adaptive management scenarios increased variability in population density (as measured by coefficients of variation), but reduced probability of extinction and increased persistence time.

DISCUSSION

Relationships to Earlier Models

The models we offer differ in 4 fundamental ways from previous modeling efforts directed at understanding effects of fertility control on vertebrates (Garrott 1991, Garrott and Siniff 1992, Swihart and DeNicola 1993, Boone and Wiegert 1994, Seagle and Close 1996, Pech et al. 1997, White et al. 1997). First, our models are structured in stages where each stage represents the time since a female was treated. Earlier models have been structured by animal age, irrespective of time since delivery. As a result, previous efforts failed to consider effects of duration of contraceptives or the interaction of duration with other model parameters. Stage structure allows us to offer the first analysis of the consequences of variation in the duration of fertility control agents. As a result, we are able to show that animals with long lifetimes (i.e., high adult survival rates) can be effectively controlled with long duration contraceptives, even

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

when they have relatively low fertility rates. This contrasts with earlier efforts that argued that r-selected species with short lives and high fertility were most appropriate targets for regulation by controlling fertility (e.g., Hone 1992).

Second, we offer closed-form solutions for relationships among delivery rate, proportion of the population infertile, number of animals treated, and target population densities. In the past, estimating these relationships demanded laborious trial and error using simulations (Garrott et al. 1992, Boone and Wiegert 1994, Seagle and Close 1996). Unlike previous results, our models enjoy analytical solutions that provide a rapid and general way to approximate the effort required to stabilize a population using fertility control, without developing detailed simulation models.

Third, our models are the first to consider effects of different fertility control regimes on risks of extinction of small populations. We demonstrate that small populations regulated with long-lived contraceptives will be vulnerable to stochastic extinction.

And finally, we are the first to explicitly consider the inefficiencies associated with resampling unmarked animals when delivering fertility control agents. We show that failing to know the fertility status of individuals can create large inefficiencies in achieving desired levels of infertility in real-world populations.

Although our models differ in important ways from earlier ones, we also reinforce previous findings. Similar to other modeling results, we found that more than half of the breeding females must be infertile to achieve meaningful reductions in population density (Fig. 5). It is true that a smaller infertile fraction may be required for species with low adult survival and low recruitment rates (Fig. 5), but these are not usually the species that cause problems of overabundance. These general results are consistent with several, more detailed studies of effects of fertility control on ungulates (Table 2), as well as, field tests in small mammals (McCallum 1996). It follows from these results that there may be situations where it is logistically impossible to treat a sufficient portion of the population to achieve population objectives. This may explain, in part, why field studies have failed to demonstrate that fertility control can maintain populations at lower densities (McCullough et al. 1997). We should not expect any change in steady state when the proportion of the population treated is small (McCullough et al. 1997).

Our models reveal that this problem is exacerbated by the nonlinear relationship between the proportion of the population treated and the steady-state density (Fig. 4). That is, there is a broad range of levels of infertility producing essentially no change in population equilibrium. This relationship could make it very difficult to assess the effect of different levels of population infertility in field studies because widely differing levels of infertility could result in very similar steady-state densities. Similar nonlinear relationships have been identified in other modeling efforts (Boone and Wiegert 1994, McCallum 1996, Seagle and Close 1996). This problem is magnified in populations where the fertility status of animals is not known (e.g., equations 34 and 35, Fig. 10). In this case, the number of doses that would need to be delivered to achieve a meaningful reduction in population density could easily exceed the total number of animals in the population.

Efficiency of Fertility Control Relative to Culling

There is broad disagreement about the relative efficiency of lethal and nonlethal means of controlling animal abundance. It has been argued that fertility control is more efficient than culling because infertile animals remain in the population, maintaining density-dependent feedback to recruitment and survival (Knipling 1959, Sturtevant 1970, Knipling and McGuire 1972). In contrast, others contend that there are virtually no circumstances in which fertility control will be more efficient than lethal methods (Bomford 1990, Garrott 1995, Nielsen et al. 1997, Swinton et al. 1997). Some workers even assert it is not possible to reduce population numbers with nonlethal control (Seal 1991).

The models we offer can resolve these differences of opinion. There are 2 types of efficiency in population regulation. The first type assesses the amount of time required to bring an overabundant population to an acceptable lower density. There is no question that culling is more efficient than fertility control when efficiency is defined in these terms. Using lethal methods, it is theoretically possible to bring a population to a desired lower density in 1 season of effort. In contrast, the maximum rate of reduction of a population regulated by fertility control is simply $1 - S$, the natural adult mor-

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

tality rate. Assuming that all fertile females are treated ($c = 1$), our models show that the annual growth rate of the population (λ) is S. Because $S < 1$, the population will decline when $c = 1$, but it may decline very slowly if the adult survival rate is high.

In contrast, it is also possible to define efficiency in terms of the number of animals that must be treated annually to maintain a population at a specified target density. By defining efficiency as the number of animals that must be treated, we deliberately ignore the time required to treat them or the monetary expense of treatment. These costs are highly variable and situation specific. Thus to achieve generality, we will restrict our discussion to the number of animals that must be treated or culled and will allow the reader to apply cost estimates to weight efficiency in a case-specific fashion.

When efficiency is defined in terms of the number that must be treated annually, our models reveal that long-duration fertility control agents can be more efficient than lethal methods if the fertility status of treated animals is known. Although this result may be surprising at first glance, a small thought experiment reveals the intuitive basis for our result. Assume that you have 100 breeding animals with a survival rate of 0.9. On average, each of these animals produces a single female offspring every year. Nine of these offspring must enter the population to offset the losses of adults who die annually. It follows that 91 recruits must be culled to maintain the population at 100 animals. Now, presume instead that the population is stabilized by controlling fertility. Ninety animals are sterilized, leaving 10 fertile. One of the fertile animals dies each year after reproducing. Thus, there are 10 fertile offspring, replacing 9 infertile deaths and 1 fertile death. Only 9 of the recruits must be sterilized to maintain a level of infertility in the population = 90%. However, this result does not hold for short-duration agents. In this case, the 90 fertile adults and 90 recruits must be treated to maintain 90% infertility in the population.

Obviously, this is a grand oversimplification of population dynamics, but it illustrates the fundamental logic underpinning the efficiency of fertility control relative to culling. The number of females that must be treated or culled to maintain a given density depends on the difference between the total number of births and the total number of natural deaths. When a large proportion of long-lived species is sterile, this difference will be likely smaller than in fertile populations that are culled because very few animals will be reproducing. Reducing the duration of the fertility control agent increases the number that must be treated annually until this number eventually exceeds the number culled.

MANAGEMENT IMPLICATIONS

We can provide 4 general insights for implementing fertility control relative to culling. First, the efficacy of fertility control as a means to regulate populations pivots on the ability to develop agents with persistent effects. Second, we also point out that the expense of fertility control will never compete favorably with the revenue that can be provided by licensed hunting, regardless of the duration of contraceptives. Fertility control will only be cost-effective for situations where recreational hunting isn't feasible and where population control can only be achieved by professional treatment, lethal or nonlethal. Third, the feasibility of achieving target levels of infertility in the population will require knowledge of fertility status of individuals. In cases where this status is not known, the inefficiencies associated with redosing animals can increase the number of animals that must be treated by several fold. Finally, the greatest efficiency can be obtained by combining culling with contraception such that an initial reduction in animal numbers is maintained by annual treatment of marked animals with long-acting fertility control agents.

The reason that lifetime duration fertility control can be an efficient method for maintaining a population at target densities also explains why the approach is difficult to implement initially and why it poses grave risks to the persistence of small, closed populations. Our models suggest that it is relatively easy to maintain a population near a given steady state, once a sufficient number of animals have been sterilized. Achieving this initial level of infertility in the population will often be a formidable task, however, and accomplishing that task means that the breeding population will be small. Such breeding populations are subject to stochastic risks of loss of genetic variability and even extinction, as our models illustrated. It follows that while fertility control may not affect survival of individuals, it can easily be lethal to populations.

This creates a genuine dilemma for manag-

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

ers. Small, closed populations are the most likely candidates for regulation by fertility control. This is simply because delivery of fertility control agents to a sufficient number of animals is most likely to be logistically feasible when populations are small and bounded in space. However, these populations are also the most prone to extinction if managers make mistakes in applying fertility control agents. The nonlinearity in many of the relationships we observed magnifies the likelihood of such errors. It follows that although fertility control can be an efficient means of regulating animal numbers, that efficiency creates risk for the population manager. As with all other techniques, managing population fertility must be grounded in a fundamental understanding of the state of the population and the role of management in influencing its dynamics. This simple fact reinforces the conclusions of Garrott (1995) that careful field studies applying control techniques over long time periods are needed to thoroughly understand effects of fertility control.

We offer a suite of predictions that can be usefully tested in field studies. Our models provide a sketch of the dynamics of populations regulated by fertility control. Offering a sketch rather than a blueprint requires that we avoid many details. Understanding those details will no doubt prove necessary to minimize unpleasant surprises in managing fertility of ungulate populations (Caughley et al. 1992, Nettles 1997). However, by offering general rather than detailed models, we provide broad insights useful as a starting point for future studies.

We identify 2 urgent needs for future work on fertility control agents. Development of techniques that render animals infertile with a single dose offer a promising alternative to culling in situations where it is feasible to mark animals to know their fertility status. Thus, work at the level of the individual animal should emphasize increasing the duration of effect of fertility control agents. Studies at the level of the population must demonstrate that fertility control can achieve meaningful reductions in rates of increase in the field. Although models like ours can suggest situations where fertility control could be efficacious in controlling abundance of ungulates, such efficacy remains in doubt until field studies demonstrate such control in real-world populations.

AKNOWLEDGMENTS

Discussions with G. C. White and B. C. Lubow motivated our analytical approach. We appreciate helpful comments on manuscript drafts from J. E. Gross, P. J. Weisberg, D. M. Swift, L. Clark, and 2 anonymous referees. R. B. Gill provided administrative support and encouragement.

APPENDIX A

Example Derivation of Deterministic Results

We used a standard series of steps to analyze all models. Here, we illustrate those steps using fixed-effect model, assuming prebreeding delivery of contraceptives. We begin with a state vector $[F\ I_1\ I_2\ I_3]$ for the case where duration of fertility control persists for 3 years. The corresponding projection matrix is

$$\begin{bmatrix} (1-c)(S+m-\beta N) & 0 & 0 & S(1-c) \\ c(S+m-\beta N) & 0 & 0 & Sc \\ 0 & S & 0 & 0 \\ 0 & 0 & S & 0 \end{bmatrix} \quad (36)$$

We obtain the characteristic polynomial of the matrix:

$$0 = \lambda^4 - \lambda S^3 c - S\lambda^3 - m\lambda^3 + \beta N\lambda^3 + Sc\lambda^3 + cm\lambda^3 - c\beta N\lambda^3. \quad (37)$$

By iterating over several values of τ, we observe a general series in characteristic polynomials for all $(\tau + 1 \times \tau + 1)$ matrices:

$$0 = \lambda^{\tau+1} - \lambda S^\tau c - S\lambda^\tau - m\lambda^\tau + \beta N\lambda^\tau + Sc\lambda^\tau + cm\lambda^\tau - c\beta N\lambda^\tau. \quad (38)$$

When the population is at equilibrium, $\lambda = 1$. Therefore, to find a general expression for the equilibrium density as a function of delivery rate we set $\lambda = 1$ and solve equation 38 for N, obtaining:

$$N^* = \frac{S + m + S^\tau c - 1 - Sc - cm}{\beta(1-c)}. \quad (39)$$

Solving for c, we find the delivery rate (c^*) needed to achieve a specified target density (N^*),

$$c^* = \frac{S + m - N^*\beta - 1}{S + m - N^*\beta - S^\tau}. \quad (40)$$

To find the composition of the population (i.e., the proportion of each stage of infertility in the population) we obtain the eigenvectors of several projection matrices corresponding to different values of τ. For each matrix, we extract the first element ($v[1]$) of the normalized vector (corresponding to an eigenvalue of 1), which gives the proportion of the population that is fertile,

$$v[1] = \frac{1-c}{(1-c)/c + 1 + S + S^2 + S^3 \ldots + S^\tau}. \quad (41)$$

To find the infertile proportion (P), we subtract $v[1]$ from 1 and simplify,

$$P = \frac{(1 - S^\tau)c}{1 + Sc - S - S^\tau c}. \quad (42)$$

In a similar way, we observe the last normalized element of the eigenvector for several values of τ and find that the proportion of the population that is in the final stage of infertility (ρ) is given by a series which simplifies to

$$\rho = v[\tau + 1] = \frac{(1-S)S^{\tau-1}c}{1 + Sc - S - S^\tau c}. \quad (43)$$

We then derive a general expression for the proportion of the population (P) that must be infertile to achieve a target density N^*. We substitute the right hand side of equation for c in equation 42, and after some algebra, obtain

$$P = 1 - \frac{1-S}{m - N^*\beta}. \quad (44)$$

This content downloaded from 159.189.162.80 on Tue, 11 Apr 2017 16:57:34 UTC
All use subject to http://about.jstor.org/terms

To remove β from the denominator, we observe from equation 39 that the equilibrium density in the absence of fertility control (i.e., $c = 0$) is

$$K = \frac{S + m - 1}{\beta}. \quad (45)$$

Defining Δ as the proportional reduction in population density below K (i.e., $N^* = \Delta K$), it follows that

$$N^* = \Delta K = \frac{\Delta(S + m - 1)}{\beta}. \quad (46)$$

Substituting the right hand side of equation 46 for N^* in equation 44,

$$P = 1 - \frac{1 - S}{m + \Delta(1 - S - m)}. \quad (47)$$

To derive an expression for the number of animals treated (n) to maintain a target density, we observe from the projection matrix and the state vector that the number of animals treated at equilibrium is

$$n = c^*F_t(S + m - \beta N^*) + c^*I_{t_\tau}, \quad (48)$$

which is simply the treatment rate multiplied by the steady state number of fertile females at time t plus the number of females that are recruited plus the number that regain fertility during $t \rightarrow t + 1$. Substituting $(1 - P)N^*$ for F_t and ρN^* for I_{t_τ} we have

$$n = c^* (1 - P)N^* (S + m - \beta N^*) + c^* \rho N^*, \quad (49)$$

Substituting the right-hand-side of equation 40 for c^*, rhs equation 44 for P and rhs equation 43 for ρ provides the needed expression for n in terms of the decision variable N^* and the parameters m, S, and β.

APPENDIX B

Derivation of an Unbiased Estimator for the Number of Doses that must be Delivered to a Population of Unknown Fertility to Achieve a Target Level of Infertility

We assume that a simple random sample of d animals is selected with replacement from a population of N animals. All of the animals in the sample are dosed. At the beginning of the sampling effort, the population contains I infertile animals. In order to establish the results shown in equations 34 and 35 we note that equation 35 is a special case of equation 36 where $I = 0$. We define t_i as an indicator random variable that equals 0 if the *ith* fertile animal is still not dosed after d selected animals are treated and equals 1 if it has been dosed at least once for $i = 1, 2 \ldots, N - I$. We define a as the number of additional infertile animals that are added to the population after d doses are delivered,

$$a = \sum_{i=1}^{N-I} t_i. \quad (50)$$

The expected number of additional infertile animals is given as

$$\eta = E(a) = \sum_{i=1}^{N-I} E(t_i) = (N - I)E(t_i). \quad (51)$$

Define $P(t_I = 1)$ as the probability that $t_i = 1$; then,

$$E(t_i) = P(t_i = 1) = 1 - P(t_i = 0) = 1 - \left(\frac{N - 1}{N}\right)^d. \quad (52)$$

Thus,

$$\eta = (N - I)\left(1 - \left(\frac{N - 1}{N}\right)^d\right). \quad (53)$$

Solving equation 53 for d gives equation 35. The variance of a can also be easily determined.

EFFECT OF OVARIECTOMY ON PREGNANCY IN MARES

D. W. Holtan*, E. L. Squires†, D. R. Lapin and O. J. Ginther

Department of Veterinary Science, University of Wisconsin, Madison, Wisconsin 53706, U.S.A.

Summary. Pony mares were bilaterally ovariectomized at different stages of pregnancy between Days 25 and 210. Abortion or fetal resorption occurred within 2 to 6 days after operation in all 14 mares ovariectomized between Days 25 and 45 and after an interval of 10 to 15 days in 9 of 20 others ovariectomized between 50 and 70 days. All 12 mares ovariectomized on either 140 or 210 days carried their foals to normal term. The termination of early pregnancy was preceded by a loss of uterine tone and of a palpable uterine bulge. The mean length of gestation in all mares in which pregnancy was not interrupted by ovariectomy was not significantly different from that in a group of contemporary control mares. Plasma progestagen concentrations dropped to <2 ng/ml after ovariectomy, whether or not pregnancy was maintained. Mares ovariectomized on Day 25 and injected with 100 mg progesterone daily for 10 or 20 days remained pregnant during treatment but showed a loss of uterine tone and the fetal bulge disappeared within 4 to 6 days after the end of treatment. Non-pregnant ovariectomized or intact seasonally anoestrous mares injected i.m. with 50 or 100 mg progesterone daily for 8 weeks showed changes in uterine tone, length and thickness similar to those occurring in mares during early pregnancy.

INTRODUCTION

It has been well accepted that some source of progesterone is necessary for maintenance of pregnancy in mammals. The maternal ovaries with a functional corpus luteum (CL) appear necessary almost throughout gestation in the rabbit, rat, sow, cow, goat and bitch but for a much smaller proportion of pregnancy in the ewe, guinea-pig, mare and primates, the latter species deriving their progesterone from the placenta (Gomes & Erb, 1965). Although the mare placenta contains high levels of progesterone (Short, 1957), peripheral blood levels reflect ovarian sources of the hormone during early pregnancy when CL are functional (Squires, Wentworth & Ginther, 1974b;

© 1979 Journals of Reproduction & Fertility Ltd

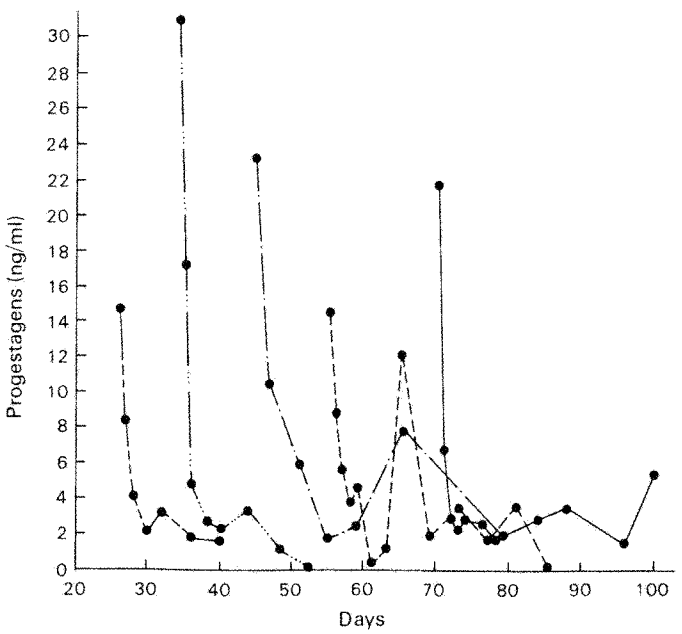
Holtan, Nett & Estergreen, 1975). The placenta presumably takes over progesterone production at some stage during the first half of gestation (Squires & Ginther, 1975) but it is not known exactly when the ovaries become dispensable. Early reports indicated that ovariectomy at Days 150 (Amoroso, 1955) and 200 (Hart & Cole, 1934) of gestation does not lead to abortion.

The present experiment tested the effects of ovariectomy performed between Days 25 and 210 gestation on the maintenance of pregnancy in Pony mares. The effects of daily injections of progesterone on peripheral blood progesterone levels and on the tone, thickness and diameter of the uterus were also studied.

MATERIALS AND METHODS

Mature Pony mares weighing 150–300 kg were routinely examined for the occurrence of oestrus and ovulation as described by Ginther, Whitmore & Squires (1972). Following either natural service or artificial insemination, pregnancy was diagnosed by rectal palpation of the uterus as described by van Niekerk (1965).

A total of 50 mares were bilaterally ovariectomized at selected times between 25 and 210 days of gestation (Day 0 = ovulation) spread over 3 separate years. Mares were anaesthetized, placed in dorsal recumbency and the ovaries exposed via a midline laparotomy as described by Ginther & First (1971). The ovarian pedicle, including the ovarian artery, was ligated and the ovaries removed. The location and size of the fetus and the sizes and number of follicles and CL were noted. After the operation the uterus was palpated daily for 4 days, on alternate days for the next 8 days and once weekly thereafter. Termination of pregnancy was designated as the first day the fetal bulge was not palpable since fetal resorption could not be distinguished from abortion during early stages of gestation. The stage in pregnancy when ovariectomy was performed and the number of mares operated are given in Table 1. During the third year, another 4 mares were ovariectomized on Day 25 and at the same time were treated with progesterone (100 mg, i.m. daily) for 10 or 20 days (2 mares each). Peripheral plasma samples were collected at 4-day intervals following ovariectomy and assayed for total progestagen concentrations as described by Squires *et al.* (1974b). The sensitivity of the assay was 0·15 ng/ml plasma and the inter- and intra-assay coefficients of variation were 19·1 and 9·9% respectively.



Six non-pregnant ovariectomized mares were injected i.m. daily with 50 or 100 mg progesterone for 8 days and plasma progesterone concentrations monitored. Subsequently, 17 seasonally anoestrous mares were treated similarly with progesterone for 8 weeks; half of these animals were treated for another 2 weeks with 250 μg oestradiol-17β i.m. daily) and the same regimen of progesterone. Ovarian changes and the occurrence of oestrus and the tone, length and thickness of the body and horns of the uterus were assessed twice weekly by rectal palpation by an individual who was unaware of the treatments being administered.

Table 1. Effect of ovariectomy on the maintenance of pregnancy in Ponies during the 3-year experimental period

	Year of ovariectomy and Day of gestation

	70	140	210	50	70	25	35	45	55	70
No. of mares	2	6	6	1	7	4	5	5	5	5
Pregnancies maintained	0	6	6	1	5	0	0	0	2	3

RESULTS

Table 1 shows that abortion (or resorption) of the conceptus occurred in all 14 mares ovariectomized before Day 50 of gestation, that pregnancy was maintained in 11 of 20 mares after ovariectomy between Days 50 and 70 and that pregnancy was not interrupted in any of 12 mares ovariectomized on Days 140 or 210. Since there were no sham-operated controls the possible effect of surgery alone remains unknown. Text-figure 1 shows peripheral plasma progestagen concentrations in individual mares after ovariectomy on Days 25, 35, 45, 55 and 70. These mares each had a single CL which is considered to be the primary CL of ovulation, according to previous work in this laboratory (Squires, Garcia & Ginther, 1974a). The precipitous decline in progestagen levels preceded loss of uterine tone in all cases and the pregnancy bulge disappeared between 2 and 6 days after ovariectomy on Days 25 and 35 and between 10 and 15 days following ovariectomy at later stages of gestation. There appeared to be a slight rise in progestagen concentration after the initial

Text-fig. 1. Plasma progestagens after ovariectomy at 25, 35, 45, 55 and 70 days gestation. One mare each with a primary corpus luteum only.

decline which roughly coincided with the first noted absence of a pregnancy bulge. However, mares which did not abort showed similar progestagen patterns but exhibited only a slight loss of uterine tone. Pregnancy was maintained in 4 mares ovariectomized on Day 25 and treated daily with 100 mg progesterone for 10 or 20 days (2 mares each) but was terminated in all 2–6 days after treatment ceased.

Gestation length (mean ± s.e.m., number, range) was not significantly altered ($P > 0{\cdot}05$) by ovariectomy (328·3 ± 4·0, 6, 317–347) compared to contemporary intact controls (330·2 ± 5·7, 6, 309–350). When data for all 3 years were compared, there was no effect of day of ovariectomy on gestation length in those mares which carried their pregnancies to term. All foals were born healthy and fully developed, and no differences were noted in placental retention, mammary development or milk production between ovariectomized and intact mares.

Among the groups of mares ovariectomized during the third year (see Table 2) only those operated on Days 25 and 35 had only one CL and their number in mares operated later in pregnancy was significantly greater. There was no significant difference between the total number of follicles or the number of small, medium or large follicles and the days on which ovariectomy was performed except on Day 45. There was, however, a difference ($P < 0{\cdot}05$) between the average numbers of small (6·0), medium (2·4) and large (1·4) follicles when totalling the figures obtained over all days of ovariectomy (Table 2).

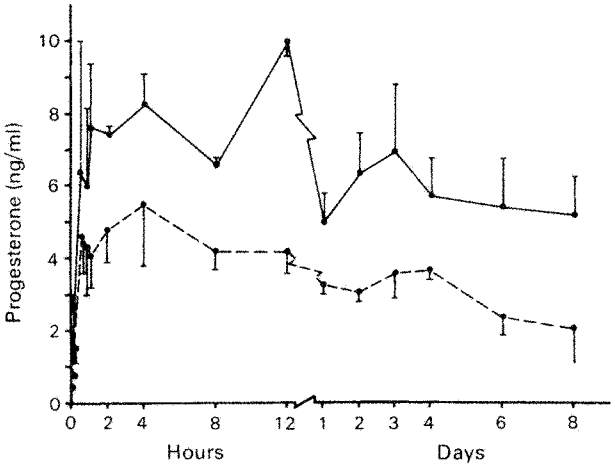

Table 2. Numbers of follicles and CL found at different days of ovariectomy

Day of ovariectomy	No. of mares	Mean no. of follicles				Mean no. of CL
		Small (<10 mm)	Medium (11–20 mm)	Large (>20 mm)	Total	
25	4	4·2	2·2	1·8	8·2	1·0
35	5	5·6	2·6	2·2	10·4	1·0
45	5	4·4	2·2	0·4	7·0	1·4
55	5	8·8	2·4	1·2	12·4	2·6
70	5	6·8	2·8	1·4	11·0	4·8

Mean number of follicles within size was different ($P < 0{\cdot}05$) while mean number between days was not ($P > 0{\cdot}05$).

The incidence of side of primary ovulation (12 left, 12 right) and side of placentation (10 left, 14 right) was not different ($P > 0{\cdot}05$). However, the conceptus was situated in the uterine horn contralateral to the side of ovulation, indicating transuterine migration, in 15 of 24 mares (7 from left to right and 8 from right to left). There was no apparent relationship between the side of placentation and the locations and numbers of accessory CL.

The effect of daily injections of progesterone on peripheral blood levels in 6 non-pregnant ovariectomized mares is shown in Text-fig. 2. Progestagen concentrations of >2 ng/ml were maintained during injections of 50 mg and >5 ng/ml during injections of 100 ng. A subjective increase in uterine tone was also noted at the end of the treatment (Day 8) in both groups. Subsequently, in

Text-fig. 2. Mean ± s.e.m. plasma progesterone concentrations in 3 ovariectomized mares following daily i.m. injections of 50 (– – –) or 100 (——) mg progesterone.

a well controlled long-term trial in which daily intramuscular injections of 50 and 100 mg progesterone were given to seasonally anoestrous mares, a significant increase ($P < 0{\cdot}05$) in mean uterine tone, measured in arbitrary units, occurred by the third week (untreated controls, 1·4; 50 mg/day, 2·2; 100 mg/day, 2·5) and was maximum by the 5th week (controls, 1·1; 50 mg/day, 2·8; 100 mg/day, 2·9) after the start of treatment. Both treated groups of mares exhibited tense and turgid uteri at this time which were similar in texture to the uteri in mares between 18 and 25 days of pregnancy. Length of the uteri decreased ($P < 0{\cdot}05$) by 2 weeks while diameter of the horns and thickness of the body of the uterus increased ($P < 0{\cdot}05$) by 3 weeks after the start of treatment. Subsequent treatment of some mares with progesterone and 250 μg oestradiol-17β daily for 2 more weeks did not significantly change either uterine or ovarian parameters; behavioural oestrus was initiated in 2 of 3 controls treated with oestradiol-17β alone. Following withdrawal of treatment uterine tone declined rapidly and was similar to that of untreated control mares by 1 week. The length and diameter of the uterine horns also could not be distinguished from those of controls by 2 weeks after treatment. Total ovarian size and the numbers and sizes of follicles were not significantly different between control or treated mares, either during or after progesterone treatment.

DISCUSSION

The present study indicates that the ovaries of the mare are dispensable between Days 50 and 70 of gestation, considerably earlier than the figure of 150 given by Amoroso (1955) or 200 days by Hart & Cole (1934). Our findings of a precipitous decline in peripheral plasma prostagen after ovariectomy on Days 25–70 (Text-fig. 1) indicate that the ovaries are the primary source of progestagens during this time. This agrees with Squires & Ginther (1975) who found uterine vein progesterone concentrations significantly higher than those

in jugular vein plasma at Days 80 and 100, thereby indicating that a non-ovarian source may be of major importance in maintaining pregnancy after this time. This non-ovarian source, possibly the placenta (Short, 1957) or conceptus, is evidently not sufficiently established until after Day 45, as ovariectomized mares maintained with exogenous progesterone daily from Days 25 to 45 subsequently aborted following treatment.

These data question the necessity and function of PMSG in accessory follicle and CL formation. Some mares with only a single CL (Text-fig. 1) had progestagen concentrations higher than those in mid-dioestrus. Thus PMSG may only be luteotrophic as might be suggested from the in-vitro work of Squires, Stevens, Nett & Pickett (1978). However, high progestagen concentrations on Days 25 and 35, before the expected appearance of PMSG in the peripheral circulation, may suggest that the conceptus (Flood & Marrable, 1975) or gonadotrophins other than PMSG may be stimulatory before Day 40. It is tempting to speculate that PMSG may be more important for its anti-immunological properties (Allen, 1975) than its gonadotrophic effects.

The fact that exogenous progesterone can increase uterine tone in non-pregnant anoestrous mares and maintain tone and pregnancy after ovariectomy would suggest that it is a major component of early pregnancy. However, progesterone is obviously not totally responsible for increased tone as non-pregnant mares with a prolonged CL maintain progesterone concentrations without increased uterine tone (Hughes, Stabenfeldt & Evans, 1975). In the present experiments using Pony mares daily injections of 0·25 mg oestradiol-17β, in addition to 100 mg progesterone, failed to stimulate uterine tone further. In later work Berg & Ginther (1978) found that twice this dose of oestradiol-17β stimulated uterine tone to the condition seen during early pregnancy. During early pregnancy (i.e. Days 18–30) peripheral plasma progesterone actually decreases (Holtan *et al.*, 1975) during the very time increasing uterine tone is noted. There may be an additive effect of hormone production and or metabolism by the conceptus during this period (Flood & Marrable, 1975). In any event, the reported short half-life of progesterone (Ganjam, Kenney & Flickinger, 1975), along with the results of the present study, would question the efficacy of less than daily therapy of exogenous progesterone to prevent abortion during early pregnancy in mares.

This work was supported by The College of Agricultural and Life Sciences, University of Wisconsin and by Grant No. 630-0505 A from the Ford Foundation and by Public Health Services Training Grant No. 5-T01-HD-00104-08. We thank Ms Linda Schuler for assistance with the assay of plasma progestagens.

Effects of bilateral ovariectomy via colpotomy in mares: 23 cases (1984–1990)

R. Neil Hooper, DVM, MS; Tex S. Taylor, DVM, MS; Dickson D. Varner, DVM, MS; Terry L. Blanchard, DVM, MS

Summary: *Postoperative performance and behavioral patterns were investigated retrospectively in 23 client-owned mares after bilateral ovariectomy via colpotomy. The interval from surgery to postoperative inquiries ranged from 9 to 67 months. Information obtained from review of the medical record and client interviews included the reason for ovariectomy, postoperative complications, problems identified by owners after discharge of the mare from the hospital, postoperative level of athletic performance, postoperative signs of estrus, and overall owner satisfaction. Reasons given by owners for having mares ovariectomized were behavioral modification (16 mares), use as embryo-transfer recipients (3 mares), use as mount mares for collecting semen (2 mares), elimination of chronic colic during estrus (1 mare), and sterilization for registration (1 mare). Postoperative complications developed in 4% (1/23) of the mares; however, problems were noticed by the owners of 4 other mares after discharge from the hospital. Continuing signs of behavioral estrus were detected in 35% (8/23) of the mares, but in only in 9% (2/23) was the behavior judged to be objectionable by the owner. Of 12 mares used in performance events prior to bilateral ovariectomy, 10 were judged to be competing at greater than preoperative levels, 1 was judged to be competing at the same level, and 1 was judged to be competing at less than preoperative level of performance. Of 18 owners, 14 were satisfied, 2 were undecided, and 2 were dissatisfied with their mare after it had had bilateral ovariectomy.*

Horse owners tend to discriminate against the use of mares with intact ovaries for performance events because of undesirable behavior during estrus. Two methods typically used to minimize estrus behavior in mares are long-term administration of exogenous progestins[1-4] and bilateral ovariectomy.[5-7] Use of exogenous progestins may be less desirable than ovariectomy, unless mares are eventually to be used for breeding. Commercially available progestins are expensive when administered orally on a long-term basis and can induce myositis if repeated injections are given IM.

Use of ovariectomized mares in performance events has increased in popularity.[7] Although colpotomy has been used for ovariectomies throughout the 20th century, this technique is gaining renewed interest among veterinarians because of the development of improved analgesics that facilitate implementation of the procedure.[7] Owners prefer the reduced cost of surgery and more rapid postoperative return of mares to use in bilateral ovariectomy via colpotomy, as opposed to via celiotomy.[5,7]

Review of the literature revealed several reports describing ovariectomy by colpotomy and potential complications,[5-11] but few reports incorporate a large number of cases and specific postoperative problems[7] with changes in estrus behavior and level of athletic performance. The primary objective of the study reported here was to examine the effects of bilateral ovariectomy via colpotomy on subsequent estrus behavior and athletic performance in mares.

Criteria for Selection of Cases

A computer search of the veterinary medical record system indicated that 69 mares had undergone ovariectomy between 1984 and 1990. All 23 mares that had had a bilateral ovariectomy via colpotomy during the study period were included. Information was obtained by review of medical records and by phone contact with owners, trainers, or referring veterinarians. Time from surgery to postoperative inquiries ranged from 9 to 67 months. Information obtained from medical records or owners included the reason for ovariectomy, postoperative complications that developed prior to discharge from the hospital, postoperative problems detected by the owner after discharge of the mare from the hospital, change in performance of the mare, detection of signs of estrus after ovariectomy, and overall owner satisfaction with the mare after surgery.

If objectionable behavior (ie, excessive estrus

From the Department of Large Animal Medicine and Surgery, The Texas Veterinary Medical Center, Texas A&M University, College Station, TX 77843-4475.

behavior) was given as the reason for ovariectomy, owners were asked whether behavior of the mare prior to surgery was constant or cyclic (ie, associated only with physiologic estrus). Owners who indicated a mare's behavioral problems had been associated only with estrus were asked whether behavior of the mare was still a problem after bilateral ovariectomy. In addition, owners were asked what they considered objectionable about their mare's behavior prior to surgery.

Owners of mares that competed in performance events (ie, competed for a purse) were asked whether they believed their mare performed at a lower, equivalent, or higher level after bilateral ovariectomy, compared with preoperative performance. Owners who indicated their mare had been observed showing signs of estrus after ovariectomy were asked to rate the signs as mild (ie, infrequent signs of estrus, but not in a cyclic or repetitive pattern), moderate (ie, intermittent signs of estrus, sometimes in a cyclic or repetitive pattern), or strong (ie, consistent signs of estrus, in a cyclic or repetitive pattern). Owners also were asked to indicate whether they found postoperative signs of estrus to be objectionable (ie, interfered with training, performance, or general use). Assessment of owner satisfaction was based on owner perception of the mare after ovariectomy and on willingness to have another mare ovariectomized under similar circumstances.

Ovariectomies had been performed by use of the technique described by Walker and Vaughan.[8] Food had been withheld, and mineral oil (4 L) had been administered by nasogastric intubation, 24 hours prior to surgery. Procaine penicillin G (20,000 U/kg of body weight, IM, q 12 h) had been administered 2 hours prior to surgery and had been continued through the third day after surgery. After ovariectomy, each mare had remained tied for at least 5 days to discourage recumbency. The incision site had been examined through a vaginal speculum every other day, beginning on the fifth day after surgery. When the diameter of the incision had decreased to < 2 cm, the mare had been released. Owners had been asked to turn the mares out for a minimum of 2 weeks before starting to ride them again.

Results

Four owners had had more than 1 mare ovariectomized during the period studied. Reasons given by owners for ovariectomizing their mare were behavioral modification to correct objectionable estrus behavior (16 mares), use as embryo-transfer recipients (3 mares), use as mount mares for collection of semen (2 mares), elimination of chronic colic detected only during estrus (1 mare), and sterilization as required for registration (1 mare). Postoperative complications were reported in the medical record of only 1 of the 23 mares. That mare developed clinical signs of peritonitis (ie, fever, lethargy, and anorexia) 1 week after surgery, but bacteria were not detected in peritoneal fluid by histologic examination or by culture. That mare responded to administration of trimethoprim/sulfamethoxazole (30 mg/kg, PO, q 12 h), and problems have not recurred during the 2-year period after surgery. Problems reported to have developed in the interval between discharge from the hospital and follow-up interview were episodes of mild to moderate colic that recurred every 2 to 3 months in 2 mares, and signs of chronic lumbar pain in 1 mare and bilateral hind limb pain in another mare that, in each owner's opinion, limited athletic performance of each mare.

Seventy-four percent (17/23) of the mares were bilaterally ovariectomized to alter behavior. All 15 owners indicated that objectional behavior occurred primarily during estrus. When asked specifically what behaviors were found objectionable, 11 owners (with 11 mares) indicated inconsistency in performance during estrus, 2 owners (with 3 mares) objected to aggressive behavior toward the owner and toward other horses during estrus, 1 owner (with 2 mares) objected to outward signs of estrus, and 1 owner (with 1 mare) objected to recurrent episodes of colic during estrus. After the mare was ovariectomized, 13 owners believed behavior was no longer a problem (in 14 mares), whereas 2 owners believed behavior was still a problem (in 3 mares). One owner objected because 2 of these mares still showed signs of estrus, whereas the other owner objected because the third mare began to perform erratically 6 months after ovariectomy.

Signs of behavioral estrus were still detected in 35% of the mares (8/23) after bilateral ovariectomy. Of the mares showing signs of estrus after surgery, 5 mares displayed signs of estrus classified by the owners as mild, 1 mare displayed signs classified as moderate, and 2 mares displayed signs classified as strong. However, only the owner of the 2 mares that had strong signs described the postoperative intensity of signs of estrus as objectionable, because the mares showed signs of estrus and would stand to be mounted when confined in a pasture with a sexually aggressive gelding.

Twelve owners had used mares in performance events prior to bilateral ovariectomy. When owners were asked to compare the preoperative and postoperative level of performance in these mares, 10 owners believed that performance was improved after surgery (in 8 mares), 1 owner believed that performance did not change (in 1 mare), and another owner believed that performance was worse (in 1 mare). The reason given for improvement after ovariectomy was the elimination of fluctuations in behavior and performance associated with estrus, which resulted in more consistent performance. The mare in which performance was the same after surgery was ovariectomized because of recurrent bouts of colic associ-

ated with estrus. After ovariectomy, recurrent colic returned in 6 months, and the mare was euthanatized 2 months later. Necropsy to determine the cause of colic was not done. The owner who believed that performance was worse after surgery indicated that the mare performed as desired for 6 months, then began to misbehave and perform as erratically as before bilateral ovariectomy.

Two additional mares were intended for use as performance horses, but had not entered training prior to surgery; therefore, the owners could not comment on the effects of bilateral ovariectomy on performance of these mares. One owner was pleased with the way the mare performed after it was trained. The other owner sold the other mare because of poor performance during race training.

Of the 18 owners, 14 indicated that they would consider having another mare ovariectomized, 2 were undecided, and 2 would not choose to have another mare ovariectomized. Reasons given for owner dissatisfaction with ovariectomy included poor performance in 1 mare and continuing display of estrus behavior in 2 mares. Repeated colic after surgery in 2 mares and failure to meet the owners expectation of racing performance in 1 mare were reasons given by the 2 owners for being undecided about having additional mares ovariectomized.

Discussion

Primary indications for ovariectomy in mares have traditionally been ovarian tumors and nymphomania (ie, continuous estrus behavior),[6,7,12,13] but bilateral ovariectomy continues to gain popularity among owners as a method to alter undesirable behavioral patterns of mares in estrus. Additionally, ovariectomized mares have been shown to be beneficial for research, for collection of semen from stallions, and as embryo-transfer recipients.[7,14,15] Colpotomy is well suited as an approach for ovariectomy in performance mares because of reduced postoperative recovery time and decreased expense, compared with that of celiotomy.[5,7]

Behavioral changes associated with estrus in mares can interfere with training and performance. In theory, bilateral ovariectomy should eliminate behavioral signs of estrus by eliminating the primary source of estrogen production; however, some mares continue to exhibit estrus behavior (albeit of reduced intensity) after ovariectomy. It has been suggested that the production of estrogens by the adrenal cortex may be sufficient to cause mild signs of estrus.[16] In support of this concept, administration of glucocorticoids (which would likely suppress adrenal production of steroid hormones) to ovariectomized mares is reported to suppress behavioral signs of estrus.[1] However, a study[17] involving ovariectomized mares suggested that the adrenal glands do not produce detectable amounts of estradiol in response to stimulation with ACTH. Therefore, in ovariectomized mares, estrogen either does not play a role in the exhibition of behavioral estrus or there is another source of estrogen production. Conversely, removal of the major source of progesterone (ie, corpora lutea), which inhibits the outward expression of estrus, could be the primary reason that some ovariectomized mares continue to show mild signs of behavioral estrus.[18] In support of this concept, ovariectomized mares are successfully used as mount mares in horse breeding operations.

Most ovariectomized mares fail to exhibit signs of estrus unless they are teased by a stallion or sexually aggressive gelding. A few ovariectomized mares occasionally exhibit mild signs of estrus without being teased.[1] Ovariectomized mares rarely exhibit strong signs of estrus behavior that would be considered objectionable in performance horses. Ovariectomy may improve performance by promoting more consistent behavioral patterns. Changing economics of the horse industry may lead owners to consider ovariectomy to modify behavior and maximize performance of mares not valued as breeding prospects.

Mares that exhibit extreme aggression toward other horses and human beings are rarely treated effectively by ovariectomy.[1,5-7,19] Strong consideration should be given to euthanatizing these potentially dangerous mares.[5,19]

Problems after ovariectomy via colpotomy in this study were minimal. Postoperative complications that have been reported after bilateral ovariectomy via colpotomy include peritonitis, evisceration, abscess or hematoma formation at the incision site, abdominal adhesions, and delayed healing of the incision.[5-7] Evaluation of peritoneal fluid from mares that have undergone bilateral ovariectomy via colpotomy revealed development of a mild subclinical peritonitis, but bacteria were usually not detected during cytologic examination of the peritoneal fluid.[5-7] Although 5 mares in our study had problems (repeated colic in 2 mares, signs of lumbar pain in 1 mare, signs of bilateral hind limb pain in 1 mare, and clinical signs of peritonitis in 1 mare) after surgery, evidence is inconclusive in each as to the role played by surgery.

Intestinal adhesion to the incision site after ovariectomy could predispose to recurrent colic.[5,7] The 2 mares that experienced repeated episodes of colic did not develop these problems until 2 years after ovariectomy. Both mares belonged to the same owner and were managed similarly. One mare was subsequently euthanatized during severe colic; necropsy revealed entrapment of the small intestine in the epiploic foramen. Adhesions were not found involving the gastrointestinal tract or urogenital tract.

Ovulation has been reported as a cause of cyclic colic in mares.[20] Confirmation of this observation was based on elimination of signs of colic when mares were administered altrenogest daily. The mare in our study that had repeated bouts of colic

had been treated repeatedly by the same veterinarian for > 2 years. On the basis of historical data and repeated clinical observation by the veterinarian, colic appeared to develop in association with estrus. To confirm the diagnosis, the mare was administered altrenogest[a] (0.44 mg/kg, PO, q 24 h) for 60 days prior to bilateral ovariectomy and did not have signs of colic.

The cause of the signs of lumbar pain (in 1 mare) and of bilateral hind limb pain (in 1 mare) observed by 2 owners is unknown. One mare had a history of signs of back pain prior to admission. The owner and referring veterinarian believed the pain originated from the ovaries because of misbehavior and erratic performance when the mare was in estrus. After ovariectomy in this mare, performance met the owner's expectations for 6 months before the same behavioral problems recurred. In the owner's opinion, surgery was not successful because the mare began to perform erratically again after surgery. The other mare was 15 months old at surgery and was ovariectomized to be eligible for breed registration, and was subsequently trained for racing. Performance of this mare never met the owner's expectations, and the mare was sold prior to completion of race training.

On the basis of discussions with owners, trainers, or referring veterinarians, bilateral ovariectomy via colpotomy generally did not adversely affect ability to perform in athletic events, nor did it totally eliminate all signs of estrus in mares. Our study suggested that use of ovariectomized mares in performance events should continue to gain popularity among horse owners. Whereas bilateral ovariectomy usually does not eliminate all signs of estrus behavior in mares, the attenuation in signs is generally beneficial to performance because it promotes more consistent behavior.

Characterization of Bone Mineral Composition in the Proximal Tibia of Cynomolgus Monkeys: Effect of Ovariectomy and Nandrolone Decanoate Treatment

R. Y. HUANG,[1] L. M. MILLER,[2] C. S. CARLSON,[3] and M. R. CHANCE[1]

[1]*Department of Physiology and Biophysics, Albert Einstein College of Medicine, Bronx, NY, USA*
[2]*National Synchrotron Light Source, Brookhaven National Laboratory, Upton, NY, USA*
[3]*College of Veterinary Medicine, Department of Veterinary Diagnostic Medicine, University of Minnesota, St. Paul, MN, USA*

Like postmenopausal women, ovariectomized cynomolgus monkeys (*Macaca fascicularis*) experience accelerated loss of bone mass. Treatment of ovariectomized monkeys with nandrolone decanoate results in an increase in bone mass to levels comparable to those of intact animals. The changes in bone composition that occur with these treatments, however, are less well characterized. In the present study, we used synchrotron Fourier-transform infrared microspectroscopy (FT-IRM) and curve-fitting methods to monitor specific changes at cortical, subchondral, and trabecular bone regions in the proximal tibia. Four groups were studied: (1) sham-operated (sham); (2) ovariectomized and treated with placebo for 2 years (ovx); (3) ovx + nandrolone decanoate for 2 years (NAN); and (4) ovx + nandrolone decanoate beginning 1 year after ovx (dNAN). The results demonstrate that ovariectomy and nandrolone treatment did not affect the degree of mineralization as defined by the phosphate/protein ratio, but acid phosphate content (HPO_4^{2-}) in cortical and subchondral bone was increased by ovariectomy, suggesting this bone to be less mature due to increased remodeling that occurs after ovariectomy. In the subchondral and cortical bone regions, ovariectomized monkeys showed a lower total carbonate content (CO_3^{2-}/matrix ratio) than sham controls, specifically due to the decrease in labile carbonate content. In the trabecular region, no change of carbonate content was observed. Treatment with nandrolone decanoate was found to restore the loss in carbonate, where the resulting mineral had a larger quantity of type B carbonate. Finally, we correlated carbonate content with dual-energy X-ray absorptiometry measurements, and found a positive correlation between bone mineral density and type A carbonate in bone, which is stoichiometrically related to the amount of calcium in bone. Therefore, the results presented herein identify significant differences in bone chemistry after ovariectomy and nandrolone treatment, which may help explain previous findings that, although nandrolone decanoate treatment increased bone mass, it could not reverse the decrease in bone strength due to ovariectomy (Aerssens et al., *Calcif Tissue Int* 53:269–277; 1993). Introduction

Osteoporosis is characterized by low bone density and microarchitectural loss of bone tissue leading to increased susceptibility to fracture.[9] The association of estrogen deficiency with postmenopausal osteoporosis has long been recognized. Increased activity of several mediators secondary to estrogen deficiency results in increased osteoclast activity and a higher bone resorption rate, resulting in loss of bone.[11] However, decreased bone density alone cannot explain the change in bone strength, because the correlation between bone density and bone strength is only moderately strong.[19] Thus, it is likely that chemical and morphological differences, such as mineral apatite composition and organic matrix maturity and organization, may contribute to bone strength and disease severity.[5,10,18,19]

Infrared (IR) spectroscopy has been widely used to examine bone composition because it can detect alterations in several major biological constituents of bone.[31,32] In synthetic and animal bone IR studies, bone of greater maturity is associated with a higher mineral/matrix (phosphate/Amide I) ratio,[6,26,28] a higher degree of crystallinity,[4,6,23,26,29] and a lower acid phosphate (HPO_4^{2-}) content.[23,26,30] Osteoporotic bone has a lower mineral/matrix ratio than normal bone, suggesting that it is less mature than normal bone.[3,25,30] However, when comparing the degree of crystallinity of osteoporotic bone to that of normal controls, some investigators have reported a higher degree,[2,3,12,25,30] whereas others observed a lower degree[14,30] or no difference.[24] These conflicting results may have arisen due to the variability among human bone specimens,[2,12] as well as different methods of inducing osteoporosis, including nutritional deprivation,[30] ovariectomy,[24] and biological menopause.[2,12]

The most common method of examining bone samples with IR spectroscopy is by homogenization of the bone. However, diseased bone is affected differently at distinct anatomical sites,[1,17] which may respond to drug treatment differently.[7,15] Localized effects in bone disease are particularly relevant in osteoarthritis (OA), where subchondral bone thickening and

sclerosis parallel disease severity.[8] Treatments for osteoporosis that increase bone mass may also increase the potential for subchondral bone thickening, which may predispose the individual to the development of osteoarthritis (OA). Thus, examination of treatment effects on different regions of bone (i.e., cortical, trabecular, and subchondral bone) is important. With the combined advantages of infrared spectroscopy and optical microscopy, Fourier-transform infrared microspectroscopy (FT-IRM) has been used to examine bone samples in situ, with a spatial resolution near the diffraction limit (3–20 μm).[20]

In the present study, tissues from ovariectomized cynomolgus monkeys (*Macaca fascicularis*) were used to examine the mineral and matrix chemistry of bone under conditions of chronic estrogen deficiency. Ovariectomized cynomolgus monkeys are a well-recognized model of postmenopausal bone loss in women.[15,16,27,33] Two ovariectomized groups of monkeys received nandrolone decanoate, an anabolic steroid hormone that enhances bone density in osteoporotic women[27] and inhibits bone turnover in ovariectomized monkeys.[8,15,16,33] Bone from the proximal tibia of animals in these two treatment groups was analyzed at three distinct anatomical regions: cortical, subchondral, and trabecular bone. The results were compared with those in the same location from nontreated intact and ovariectomized control animals.

Materials and Methods

Animals and Study Design

Fifty-nine young adult female cynomolgus monkeys were group-housed and fed identically for the study, which was conducted at the Comparative Medicine Clinical Research Center, Wake Forest University School of Medicine. The details of the trial have been described previously.[16] Briefly, the subjects were randomly assigned to four treatment groups for the 24 month study: (1) sham-operated (sham; n = 15); (2) ovariectomized, treated with placebo for 2 years (ovx; n = 15); (3) ovx + nandrolone decanoate for 2 years (NAN; n = 15); and (4) ovx + nandrolone decanoate beginning 1 year after ovx (dNAN; n = 14). The treated groups (NAN and dNAN) were given 25 mg nandrolone decanoate intramuscularly every 3 weeks, and the nontreated groups (sham and ovx) were given sterile vehicle intramuscularly every 3 weeks. At the time of ovariectomy (or sham operation), 1 year after surgery, and 2 weeks before necropsy, all animals were administered fluorochrome labels (tetracycline HCl, calcein, and alizarin complexone, respectively) intravenously on a 1-7-1-7 schedule.[16] One tibia from each animal was obtained at the termination of the study. This site exhibits changes in bone mineral content and bone mineral density in response to hormonal therapies that are similar to those occurring in the vertebrae.[7] A midcoronal section from each proximal tibia was embedded in methylmethacrylate/dibutylphthalate. The blocks were sectioned at a thickness of 5 μm with a sledge microtome, and tissue sections from five SHAM, seven OVX, six NAN, and six dNAN animals were air-dried and mounted in an IR sample cell.

Spectral Data Collection

Infrared spectra were collected using a FT-IR microscope (Spectra Tech, Shelton, CT), equipped with confocal 32× Schwarzchild objectives, a motorized x-y stage, and an external MCT/B detector (Belov Technology, New Brunswick, NJ) cooled to 77K. The microscope was attached to a Nicolet Magna 860 spectrometer that receives its light source from Beamline U2B (National Synchrotron Light Source, Brookhaven National Laboratory, Upton, NY). For data collection, the bone section was secured in a compression cell (Spectra Tech) with the center portion exposed to the beam path. A video camera was mounted on the microscope to capture visible light images before each data collection. An adjustable aperture was placed before the objective to limit the IR illumination area of each data point to 20 μm × 20 μm, calibrated using a visible light image at its focal point. Absorption due to water vapor and CO_2 was minimized by purging the system with nitrogen gas. For each animal, 900, 600, and 400 spectra were collected from randomly chosen cortical, subchondral, and trabecular regions, respectively. At all chosen regions, data acquisition was done in a rectangular-sized map format using ATLμS software (Nicolet Instruments, Madison, WI) with 20 μm steps using the x-y motorized stage. A spectrum was acquired for each data point using 64 coadditions and Happ–Genzel apodization at 4 cm^{-1} resolution. Prior to starting a map, a light image of the map area was taken using the same coordinate as the map for visual guidance in later data filtering, and a background spectrum through air (no sample) was collected for an absorbance reference.

Bone Density Measurements

Bone mineral content (BMC) and density (BMD) of whole body, lumbar vertebrae L2–4, and knee (distal femur and proximal tibia) were measured under anesthesia at the termination of the study using dual-energy X-ray absorptiometry (DEXA; Norland Model XR-26, Fort Atkinson, WI), and these results have been reported previously.[7,16]

Data Analysis

Curve-fitting and area integrations were carried out on two spectral regions: $\nu_2CO_3^{2-}$ (905–825 cm^{-1}) and $\nu_4PO_4^{3-}$ (650–500 cm^{-1}) using GRAMS32 v5.1 (Galactic Industries Corp., Salem, NH) software. Both spectral regions were baseline-corrected by a cubic function to account for the underlying broad peaks.[23] The integrated Amide I band (1600–1700 cm^{-1}) was used to represent the total protein content in the bone, where >90% is collagen. The center positions for each subpeak were determined based on previous assignments[23,31,32] and confirmed by using second-derivative peak analysis. All peaks were fitted by a Gaussian function with the center position limited to ±2 cm^{-1} from the initial position and the width limited to 30 cm^{-1} (for broad bands, 40 cm^{-1} was used) to avoid alternative convergent solutions. Macro routines were developed to process all spectra using the same initial fit parameters. The convergence criteria were determined by reduced chi-square statistics and the root-mean-square (RMS) noise level. A maximum of 50 iterated optimization algorithms were done in each fit routine until the convergence criteria were met. Nonconverging spectra were discarded. Several initial conditions were tested to ensure reproducibility and validity of the final fit. Spectra from nonbone regions were identified and filtered out by their higher absorption intensity from 1700 to 1760 cm^{-1} due to the presence of embedding material. All peaks and subpeaks of interest were area-integrated and expressed as ratios to account for sample thickness heterogeneity. The calculated ratios were tabulated into histograms and then fitted to a normal distribution curve. The center and width values from all normal fits were analyzed by one-way analysis of variance (ANOVA) followed by pairwise multiple comparisons using Fisher's exact test. $p < 0.05$ was considered statistically significant. Adequate transformation was applied to each data set if it did not meet the assumptions for ANOVA. The variances of two data sets (see *Results*) were inhomogeneous and resistant to the available transformations, so a pooled *t*-test was applied to the ovx and sham groups. Paired

Bone Vol. 30, No. 3
March 2002:492–497

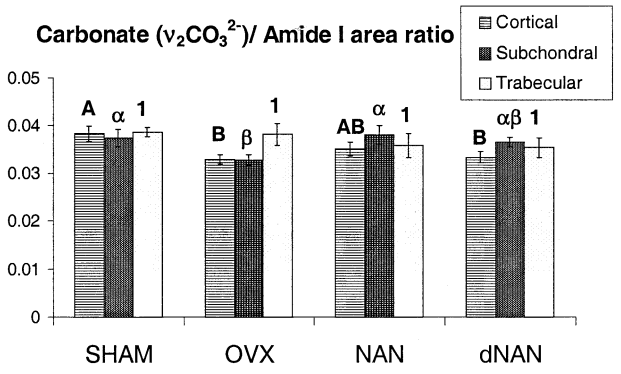

Figure 1. The column height represents the mean values of each test group and the error bar indicates the standard error of the mean (SEM) where the number of subjects is between five and seven in each treatment group (600 spectra from subchondral, 400 from trabecular, and 900 from cortical region were collected for each subject). The letter or number above each column indicates that, for any two groups that have no letter in common, a statistical difference between these two groups was detected after ANOVA with multiple comparisons ($p < 0.05$). For example, in the cortical region, sham (A) differs from ovx (B) and dNAN (B), but not NAN (AB). Ovx differs from sham, but not NAN or dNAN. Comparisons were only made among groups in the same bone region.

t-tests were used to compare means from cortical regions with those from subchondral regions for each animal. The mineral(including carbonate and phosphate components)-to-matrix ratios were compared and also to the DEXA data obtained previously (see earlier) using correlation analysis. All statistical analyses were done using Microsoft EXCEL 97 with an ANALYZE-IT v1.50 add-in.

Results

Mineral-to-Matrix Ratios

The peak assignments for the carbonate ($\nu_2CO_3^{2-}$) and phosphate ($\nu_4PO_4^{3-}$) bands have been characterized.[23,31,32] The mineral/matrix ratios, $\nu_2CO_4^{3-}$/Amide I and $\nu_4PO_4^{3-}$/Amide I, are indices to represent the degree of mineralization.[3,23,25] The $\nu_4PO_4^{3-}$/Amide I ratio among the four groups was the same in all three bone regions (data not shown). Conversely, the $\nu_2CO_3^{2-}$/Amide I values for the ovx animals were significantly lower than the sham controls ($p < 0.05$) in the cortical and subchondral bone regions (**Figure 1**). Nandrolone treatment for 2 years restored these ratios to sham levels ($p < 0.05$ in the subchondral region). In the trabecular region, no significant differences in $\nu_2CO_3^{2-}$/Amide I values were detected among the four groups (Figure 1).

Composition of $\nu_2CO_3^{2-}$ Carbonate Peak

Curve-fitting of the $\nu_2CO_3^{2-}$ (905–825 cm^{-1}) region resulted in three subpeaks, at 878 cm^{-1}, 872 cm^{-1}, and 866 cm^{-1}. The peaks at 878 cm^{-1} and 872 cm^{-1} were assigned respectively to the apatitic carbonate that occupies the OH^- (type A carbonate) and PO_4^{3-} (type B carbonate) sites in the hydroxyapatite lattice. The peak at 866 cm^{-1} was the remaining, nonapatitic or "labile" carbonate.[26] The labile carbonate content (866 cm^{-1}/total $\nu_2CO_3^{2-}$) was higher among sham controls compared with the ovx group in the cortical and subchondral regions (+15%, $p < 0.05$), but this difference was not seen in the trabecular bone region (**Figure 2**A). The two treated groups were not compared due to their larger variances. The ratio of type A/type B carbonate was unchanged between SHAM and OVX animals in all three bone regions, but both treated groups had lower ratios ($p < 0.05$ for all regions except for the NAN group in the trabecular bone region) than the two nontreated groups (Figure 2B).

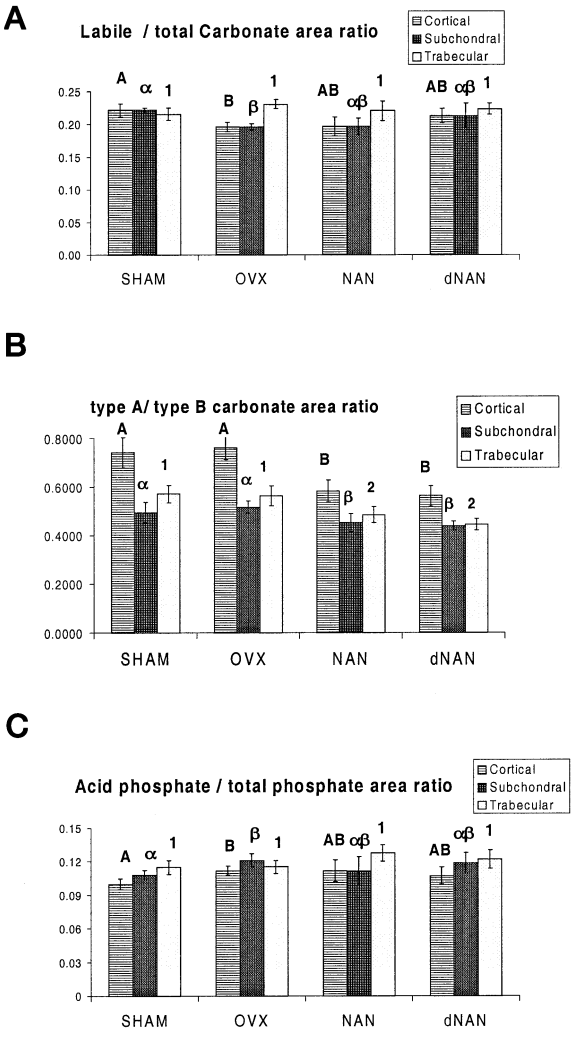

Figure 2. The results from curve-fitting of $\nu_2CO_3^{2-}$ and $\nu_4PO_4^{3-}$ were compared among the four test groups: (A) labile carbonate/total carbonate; (B) type A carbonate/type B carbonate; and (C) acid phosphate/total phosphate. The error bar represents the standard error of the mean (SEM). The letter designation above each column is described in Figure 1. (A) and (C) were tested by pooled *t*-test between ovx and sham, because the treated groups had a significantly larger variance that could not be tested by ANOVA.

Composition of $\nu_4PO_3^{2-}$ Phosphate Peak

Curve-fitting of the $\nu_4PO_4^{3-}$ band (650–500 cm^{-1}) resulted in five components that have been assigned previously.[23,32] The peaks at 613 cm^{-1} and 536 cm^{-1} represent labile phosphate, with the latter more closely related to labile acid phosphate (HPO_4^{2-}). The other three peaks, at 603 cm^{-1}, 578 cm^{-1}, and 563 cm^{-1}, correspond to apatitic phosphate. We used the ratio of integrated 536 cm^{-1} peak to total $\nu_4PO_4^{3-}$ to represent relative amount of labile acid phosphate content vs. total phosphate content.[23] In the subchondral and cortical regions, but not the trabecular region, the ovx animals had a higher acid phosphate content than sham controls (+12%, $p < 0.05$) (Figure 2C).

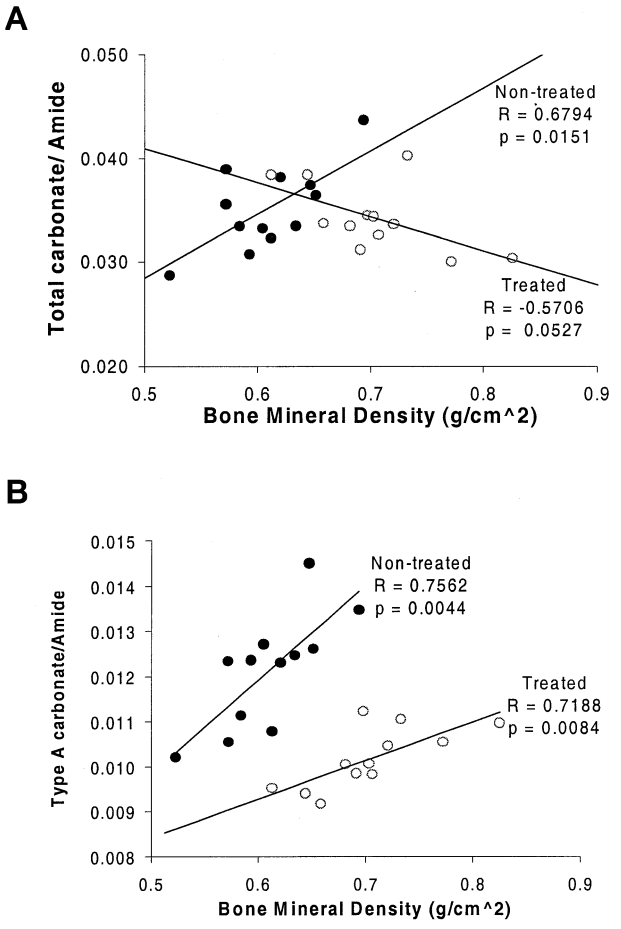

Figure 3. Whole body bone mineral density using DXA was correlated with (A) total carbonate ($\nu_2CO_3^{2-}$)/Amide I and (B) type A carbonate/Amide I. Pearson's correlation coefficient (R) and p value were calculated and are shown in each plot.

Correlation of Mineral-to-Matrix Ratios With Bone Mineral Density

No correlation was found between $\nu_4PO_4^{3-}$/Amide I and bone mineral content (BMC) or density (BMD) in any of the sites among any of the treatment groups (data not shown). Conversely, **Figure 3**A illustrates the correlations of $\nu_2CO_3^{2-}$/Amide I with whole body bone mineral density (WBBMD). The $\nu_2CO_3^{2-}$/Amide I ratio positively correlated with whole body bone mineral density and whole body bone mineral content ($R = 0.679$, $p < 0.05$) for both ovx and sham groups, but not in the two treated groups, which showed a weak negative or no correlation. Figure 3B shows positive correlations between type A carbonate/Amide I and whole body bone mineral density (WMBMD) in both treated and nontreated groups. Correlations were significant between type A carbonate and whole body bone mineral content (WBBMC). BMC and BMD measurements of proximal tibiae and lumbar vertebrae (L2–4) also correlated with type A carbonate/Amide I (**Table 1**).

Discussion

The results presented herein demonstrate that the average phosphate/matrix ratio is indistinguishable between normal and osteopenic bone, and is not altered by treatment with nandrolone decanoate. These findings are consistent with results obtained by Bohic et al.[3] using global spectroscopy and biochemical methods in a rat model of osteoporosis. In contrast, a recent FT-IR study of lumbar vertebrae from similar monkeys demonstrated a lowered phosphate/Amide I ratio in the trabecular bone after ovariectomy.[13] This discrepancy may have been due to differences in tissue sampling. In the present study, a large number of spectra (400–900) were randomly collected from a larger number of animals,[5–7] minimizing the effect of variations in bone composition at distinct locations within an osteon.[21,25] In the previous study, the small number of spectra (15 per animal) and animals (3 per control group) were not sufficient to demonstrate a statistical significant difference.

The results of the present study, however, do not exclude the possibility of an increase in one type of phosphate (e.g., apatitic phosphate) with a simultaneous decrease in another (e.g., labile phosphate), with the total phosphate remaining unchanged. This hypothesis was examined by studying the individual components of $\nu_4PO_4^{3-}$. By curve-fitting the $\nu_4PO_4^{3-}$ contour, we observed a significant increase in the amount of acid phosphate (HPO_4^{2-}/total phosphate) in the cortical and subchondral bone, but not the trabecular bone, of the ovx animals. Acid phosphate has been shown to be abundant in young bone, and the content decreases as bone matures.[32] Thus, high acid phosphate content in the bone of ovx animals suggests that the mineral apatite in these animals is similar to that of young bone. Most likely this related to increased bone turnover occurring after ovariectomy, and has been supported by morphometric studies done on these animals.[17] The mineral apposition rate (MAR) in the periosteonal and osteonal regions of the cortical bone[17] of the second lumbar vertebra and in the subchondral bone (unpublished data) of the proximal tibia increased significantly after ovariectomy, whereas there were no significant differences in the mineral apposition rate in the trabecular bone of the second lumbar vertebrae.[17]

Unlike the phosphate/matrix ratio, the $\nu_2CO_3^{2-}$/Amide I ratio indicates a significant decrease in carbonate content after ovariectomy in the cortical and subchondral bone regions. This de-

crease in carbonate content is in sharp contrast to the abnormally high carbonate content in the subchondral bone of monkeys with severe osteoarthritis.[22] As bone ages, the carbonate content increases.[28] Thus, the lower carbonate content in the bone of the ovx animals supports the conclusion from the acid phosphate content result that the bone is more newly formed in these animals. The trabecular bone region had no change in carbonate content with ovariectomy, similar to the acid phosphate results and concurring with a recent study on ovariectomized rats in which Bohic et al. also demonstrated, using FT-IR spectroscopy and microspectroscopy, that the carbonate content in trabecular bone was unaffected by ovariectomy.[3] Although chemical analysis of the whole ovx rat vertebrae demonstrated a decrease in overall carbonate content, this is most likely due to the fact that the samples examined contained areas of cortical bone, which would have contributed to a decrease in carbonate content. By curve-fitting the $\nu_2 CO_3^{2-}$ band, we found that the decrease in total carbonate in the ovx group at cortical and subchondral bone regions was attributed to the loss of labile (surface) carbonate (Figure 2A). These findings are consistent with a similar study performed on ovariectomized rats.[3]

Although the nature of the apatitic carbonate (i.e., types A and B) was not affected by ovariectomy in our study, the two nandrolone-treated groups had significantly lower type A/type B carbonate ratios than the two untreated groups (Figure 2B). Because the overall carbonate/matrix ratio increases with nandrolone treatment, this observation suggests that nandrolone treatment results in an increased formation of apatite with carbonate occupying the phosphate position of hydroxyapatite (type B carbonate). Furthermore, treated animals showed greater spatial as well as intersubject variations in their labile carbonate, possibly explained by a nonuniform drug response at different anatomical regions (i.e., drug diffusion rate and selective uptake), which has been documented previously, albeit at a macroscopic level.[8,15,33] Taken in concert, these findings suggest that ovariectomy results in a decrease of carbonate content in the subchondral and cortical regions without alteration of the ratio between the amount of type A and type B carbonate. Nandrolone decanoate treatment restores the total carbonate content to levels almost as high as those of sham controls by introducing more type B carbonate.

Bone mineral density (BMD) is significantly decreased with ovariectomy, and is restored with nandrolone treatment.[17] To determine how bone composition may be related to this important disease marker, we correlated our FT-IR data with bone mineral density measurements from the same animals. We found that, for the sham and ovx animals, there was no correlation between BMD and phosphate/matrix ratio (measured at several anatomical sites), but there was a positive correlation between BMD and carbonate/matrix ratio. The latter finding is consistent with earlier evidence that the carbonate content in bone increases as bone ages and mineralization increases.[28] However, we did not observe a correlation between BMD and carbonate/matrix ratio in the nandrolone-treated animals (Figure 3A). The nature of the different correlations between treated and nontreated animals was investigated by plotting the type A carbonate/Amide I ratio vs. BMD (Figure 3B). Positive correlations were seen in both the treated and nontreated groups with similar strength ($R =$ 0.759 and 0.715, $p < 0.05$), indicating that, in general, high BMD values in bone are also associated with increased type A carbonate content in bone. However, when the type A carbonate/Amide I ratios of all four treatment groups were plotted together against bone mineral density, the correlations were lost because the treated groups had a flatter slope compared with the nontreated groups. This result is evidence that, although a correlation was observed between BMD and mineral stoichiometry, they are not necessarily dependent variables. For example, BMD is affected by bone porosity, whereas FT-IR microspectroscopy is not. Thus, changes in BMD with treatment may also occur from altered bone porosity, independent of altered mineral/matrix ratios or stoichiometry. However, mineral stoichiometry may also be directly related to altered BMD; for example, when bivalent CO_3^{2-} ions substitute into the hydroxyl position in hydroxyapatite (type A carbonate), the resulting net gain of a negative charge will require the addition of cation (i.e., a calcium ion) to maintain electroneutrality. Thus, type A carbonate substitutions into the apatite lattice could increase the "true density" of the bone. Although BMD and the "true density are not equivalent (because BMD takes into account factors such as porosity), it is possible that an increased "true density" of the bone can also result in an increase in BMD.

Abstract

Ricefield rats (*Rattus argentiventer*) in south-east Asian rice fields and house mice (*Mus domesticus*) in Australian grain fields are major pest species. They cause damage before and after harvest and carry zoonotic diseases. For both species, management techniques have been pursued using the approach of immunocontraceptive vaccination. We review results from a series of enclosure and field studies conducted with these species to assess the effects of fertility control in small rodents. In the experiments, fertility control was simulated by tubal ligation, ovariectomy or progesterone treatment. A once-off sterilisation of 50–75% of enclosed founder females considerably reduced reproductive output of ricefield rat populations until the end of the reproductive period. In house mice, similar success was achieved when a sterility level of 67% of female founders and offspring was maintained. Repeated antifertility treatments are required because of the much longer breeding period of house mice versus ricefield rats. Comparing the results of enclosure trials with the outcome of simulation models suggests that partial compensation of treatment effects can occur through enhanced reproduction of the remaining fertile females and improved survival of juveniles. However, such compensatory effects as well as behavioural consequences of sterility in field populations are not likely to prevent the management effect at the population level. The challenge for effective fertility control of small rodents in the field is the wide-scale delivery of an antifertility treatment to founders at the beginning of the breeding season and to fertile immigrants that are recruited into the population, which otherwise contribute to the reproductive output at the population level. Future research efforts should focus on species-specific techniques and on agents that can be effectively delivered via bait.

Received: 24 June 1996 / Accepted: 3 September 1996

Abstract. Agents for prevention or treatment of osteoporosis must now be tested in a large animal species that exhibits bone remodeling. Ovariectomized, nonhuman primates provide one such model, and they consistently develop osteopenia accompanied by high bone turnover rates. The goal of this study was to further characterize this model, and particularly to determine the effect of ovariectomy on bone strength in vertebrae and femoral necks. Longitudinal evaluations of spinal bone mass and serum markers of bone turnover were performed in 19 sham-ovariectomized (SHAM) and 18 ovariectomized (OVX), domestically reared cynomolgus monkeys, aged >9 years. OVX monkeys lost bone relative to both baseline values and SHAM controls. Serum markers of bone turnover were increased by OVX. After 72 weeks, both vertebral bone compressive strength and femoral neck breaking strength were significantly decreased in OVX animals compared with SHAM. Ovariectomized cynomolgus monkeys, like postmenopausal women, develop accelerated bone loss, increased bone turnover, and reduced bone strength, and provide a suitable large animal model for efficacy studies with agents for prevention or treatment of osteoporosis.

Key words: Osteopenia — Bone density — Nonhuman primates — Osteoporosis — Bone biomechanics.

Recent recommendations and draft guidelines for drug registration require that agents for prevention or treatment of osteoporosis be tested in the ovariectomized rat model and in one larger remodeling species [1, 2]. The primary purpose of these studies was to provide direct evaluation of bone quality, because validated techniques for noninvasive assessment of bone strength in humans are not currently available. The rat model has been extensively validated, and like postmenopausal women, develops high bone turnover rates and osteopenia after ovariectomy. Relatively few studies of the effect of ovariectomy have been done in the larger species, which include dogs, pigs, sheep, ferrets, and nonhuman primates. Consequently, there is little information available to guide selection of species or experimental design for regulatory studies.

Correspondence to: C. P. Jerome

Several studies in dogs were reviewed, with the conclusion that mild osteopenia develops after ovariectomy, but the bone dynamic changes may not model those occurring in postmenopausal women [3]. Ovariectomized, moderately calcium-restricted minipigs developed spinal osteopenia, cancellous microstructural changes, and reduced normalized maximum compressive load of lumbar vertebral cancellous bone, but no increase in bone turnover rates was observed at 6 months after ovariectomy [4]. Sheep developed spinal osteopenia after ovariectomy, but the effect was dependent on both site evaluated [5] and on the time of year at ovariectomy [6]. Preliminary data from the ferret suggest that they may be a useful model [7].

More studies have been done in nonhuman primates than in any other species except rats and mice, and those studies have consistently demonstrated development of osteopenia accompanied by high bone turnover rates after ovariectomy. In monkeys ovariectomized for 2 years, spinal osteopenia ranged from 11% to 15% lower mean bone mass in ovariectomized animals than in intact animals [8–10]. Bone turnover rates were increased for up to 2 years in ovariectomized monkeys as evidenced by increased serum and urine markers [8–11] and increased bone formation rates measured histomorphometrically [8, 9, 11–13].

The goal of this study was to further characterize the nonhuman primate model of estrogen deficiency bone loss, and particularly to determine the effect of ovariectomy on bone strength by mechanical testing of vertebrae and femoral necks. The intent was both to further validate the model, and to provide information to guide experimental design such as appropriate sample size, experimental conditions, and duration. The experiment was designed to provide favorable conditions for bone loss by selection of older female animals and provision of a diet lower in calcium than usually provided to captive monkeys (but still comparable to human calcium intake). Bone mass data for the first year of this study have been reported previously [14].

Materials and Methods

Animals and Experimental Design

From a breeding colony of domestically reared cynomolgus monkeys, 48 colony-born animals aged 9–15 years and 5 domestically reared, imported animals housed in the colony at least 7 years, sexually mature upon importation, and estimated at 11–15 years of

age were selected. They were housed in one-third acre outdoor pens containing up to 25 animals. Although the pens usually provide abundant space, the animals cannot be allowed outside when the temperature drops below 40°F, and the indoor pen size is limited (9′ × 12′ × 12′). In the case of this experiment, formation of new social groups in these pens coincided with the onset of cold weather. This combination of relative confinement and social upheaval resulted in weight loss early in the experiment.

The 48 animals were assigned to one of two groups with equivalent group means and variances for body weight and spinal bone mass. Twenty-four animals were bilaterally ovariectomized (OVX), and the remainder were sham-ovariectomized (SHAM). All surgeries were done under surgical anesthesia; SHAM animals had both ovaries exteriorized and replaced. One animal designated OVX was eliminated from the experiment when endometriosis was diagnosed on laparotomy. Two SHAM and three OVX animals died due to fight trauma during formation of the social groups, and two SHAM and one OVX animal died subsequently. One animal from each group was excluded from final analysis due to obesity (terminal body weights $\geqslant$7.12 kg relative to overall mean ± SD for all animals surviving at end of study of 4.23 ± 1.21 kg). Thus, there was a final total of 18 OVX and 19 SHAM animals.

All animals were fed purified diets containing 0.8% Ca and 0.7% P initially, switching to a diet containing 0.14% Ca and 0.14% P at approximately 3 months (mean: 11.7 weeks, range: 9.0–14.7 weeks) after OVX or SHAM and remaining on this diet for the rest of the experiment. All animals were necropsied for collection of tissues 69–76 weeks (mean: 72 weeks) after OVX or SHAM. Some data from this experiment have been reported previously [14].

Dual Energy X-Ray Absorptiometry (DXA)

Bone mineral content and density of lumbar vertebrae 2-4 (LVBMC, LVBMD) were measured using a Norland XR26 DXA [15] before and at 17, 34, 47, and 72 (mean) weeks after OVX or SHAM (maximum deviation from mean time at any timepoint was 5 weeks). Precision of the measurements was determined by measuring one adult cynomolgus monkey six times in 1 day with repositioning, and 6 times at weekly intervals. The coefficients of variation (CV) for LVBMC and LVBMD on the same day were 1.7% and 1.3%, respectively, and at weekly intervals were 2.2% and 2.1%.

Serum and Urine Biomarkers

Serum was collected at SHAM or OVX and at 10, 23, 37, 52, and 72 (mean) weeks after OVX or SHAM (maximum deviation from mean time at any timepoint was 4 weeks). Serum total alkaline phosphatase and tartrate-resistant acid phosphatase were assayed using standard reagents and methods for the COBAS FARA analyzer (Roche Diagnostic Systems, Inc., Branchburg, NJ). Serum bone-Gla protein (osteocalcin) was assayed by radioimmunoassay using bovine standards (Diagnostic Systems Laboratories, Inc., Webster, TX).

Ash Weights

Lumbar vertebra 1 (LV1) was removed at necropsy, cleaned of soft tissue, and frozen at −20°C pending further analysis. The posterior elements were removed by cutting the neural arches at their attachment to the body using a low-speed diamond saw (Isomet, Buehler, Lake Bluff, IL). The anterior and posterior portions were ashed at 900°C overnight (or until constant weight was obtained) and then weighed.

Mechanical Testing of Bone

Lumbar vertebrae 3 (LV3) and 4 (LV4) and the right proximal femur were removed at necropsy, frozen at −20°C, and shipped on dry ice from Bowman Gray School of Medicine to Indiana University Medical Center for mechanical testing. The specimens were kept at −20°C up to the time of testing.

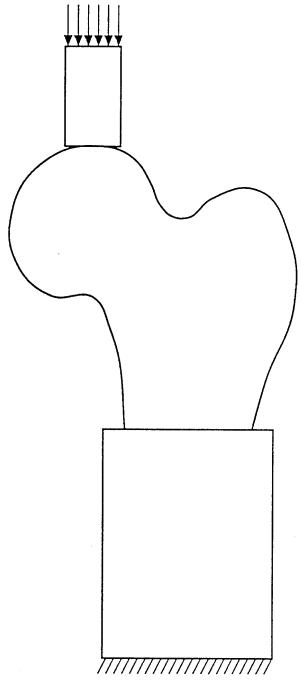

Fig. 1. Diagram of mechanical loading for femoral neck strength tests. The femoral shaft was mounted vertically in a chuck and a downward force was applied on the femoral head to cause fracture.

Immediately before mechanical testing, the vertebral specimens were thawed, cleaned of soft tissue, and the posterior elements were removed using a low-speed diamond wafering saw (Isomet, Buehler). The cranial and caudal ends of each vertebral body were removed using the wafering saw to obtain a 6–8 mm-thick specimen with two parallel surfaces. Width in the medial-lateral (a) and anterior-posterior (b) directions and thickness were measured using digital calipers. Cross-sectional areas of the vertebrae were estimated from the medial-lateral and anterior-posterior widths using the formula area $= \pi ab/4$. The specimens then were mechanically tested in compression between pivoting platens in a 37°C saline bath. Loading was applied using a servo-hydraulic testing machine (MTS 810, MTS, Minneapolis, MN) at a rate of 50 N/second until failure occurred. The maximum load at failure and stiffness were measured from the load-displacement curve using a commercial software package (Sigmascan, Jandel Scientific, San Rafael, CA) and the toughness (energy to failure) was measured as the area under the stress-strain curve [16]. Mean values for LV3 and LV4 from each animal were calculated and used for statistical analysis.

The femoral specimens were thawed and cleaned of soft tissue before testing. The femoral shaft was mounted vertically in a chuck, and a downward force was applied on the femoral head to cause fracture (Fig. 1). Force was applied using an MTS 810 servo-hydraulic machine at a stroke rate of 1 mm/second. All tests were done at room temperature (approximately 23°C). The maximum load at failure was measured from the load-displacement curve using Sigmascan.

In five animals (one OVX and four SHAM), the femoral specimens broke just proximal to the gripping chuck, so femoral neck strength could not be calculated.

Statistical Analysis

All data were tested for normality and equality of variances and transformed if necessary before further analysis. Longitudinal data (body weight, DXA, bone biomarkers) were analyzed by repeated measures analysis of covariance (ANCOVA), where baseline data were used as covariates and multiple post-baseline data were re-

Table 1. Baseline data from SHAM and OVX animals

	SHAM		OVX		
	Mean ± SEM	n	Mean ± SEM	n	*P*
Age (year)	12.3 ± 0.3	19	12.0 ± 0.4	18	0.59
Body weight (kg)	4.97 ± 0.23	19	4.94 ± 0.30	18	0.94
Bone mass					
LV2-4 BMC (g)	6.06 ± 0.17	19	6.25 ± 0.22	18	0.51
LV2-4 BMD (g/cm^2)	0.60 ± 0.01	19	0.61 ± 0.02	18	0.45
Serum measurements					
BGP (ng/ml)	6.13 ± 0.78	19	8.01 ± 0.95	17	0.13
ALP (U/liter)	193 ± 15	19	222 ± 19	17	0.24
TRAP (U/liter)	4.71 ± 0.19	19	5.05 ± 0.35	17	0.39

ALP = alkaline phosphatase; BGP = bone-Gla protein; BMC = bone mineral content; BMD = bone mineral density; TRAP = tartrate-resistant acid phosphatase

peated measures. For these analyses, the significance (*P*) of the group effect (OVX versus SHAM), time effect, and group X time interaction are reported. Terminal data (bone ash weights, mechanical data) were analyzed using Student's *t*-test, or in some cases by ANCOVA, using appropriate baseline data as indicated in the results. All tests were 2-tailed. Significance values ≥ 0.1 are reported as not significant (NS) and values <0.1 are indicated in the results. All data are presented as means ± SEM except as indicated. Statistical power calculations were performed using an iterative method [17], with $\alpha = 0.05$ and $\beta = 0.2$.

Statistical Power and Sample Size

Statistical power calculations were done to determine sample sizes required to detect the observed differences in bone mass and strength between intact and OVX monkeys. For bone mass, a difference of 12%, with a CV of 17% (the averages for a number of experiments) were used, whereas in the present experiment, there was a mean 15% difference in fracture force for lumbar vertebrae and femoral neck, with a mean CV of 16%. For good statistical power ($\beta = 0.2$), a sample size of 29 is required to detect bone mass differences, and 19 to detect differences in bone strength.

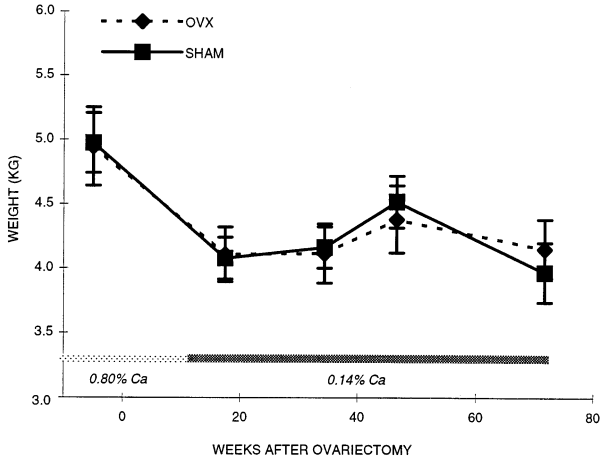

Fig. 2. Body weight (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8% or 0.14% Ca diets were fed. Effect of treatment (SHAM versus OVX) not significant (NS); effect of time $P < 0.0001$; interaction effect not significant.

Results

Baseline Values

There were no significant differences between groups for any variables at baseline (Table 1).

Body Weight

There was no significant effect of OVX on body weight, but both groups changed in body weight over time (Fig. 2, Table 2). Both groups lost weight during the first 4 months (SHAM group, −16.71 ± 2.44%; OVX group, −15.17 ± 2.59%), but subsequently stabilized.

TRAP	<0.1	<0.0001	NS

[a] *P*-values are given for the effects of group, time, and interaction between group and time

DXA and Vertebral Ash Weight

Ovariectomy decreased spinal BMC (Fig. 3, Table 2) and BMD (Fig. 4, Table 2). There was a slight drop in spinal BMC and BMD in SHAM monkeys during the experiment (final BMC relative to baseline = −2.14 ± 1.49%; final BMD = −4.55 ± 0.99%), but OVX monkeys lost more (final BMC = −10.34 ± 1.65%; final BMD = −11.45 ± 1.45%).

Mean ash weight of the anterior portion of LV1 was significantly lower in OVX (633 ± 25 mg) than in SHAM (718 ± 28 mg, $P < 0.05$). Mean ash weight of the posterior

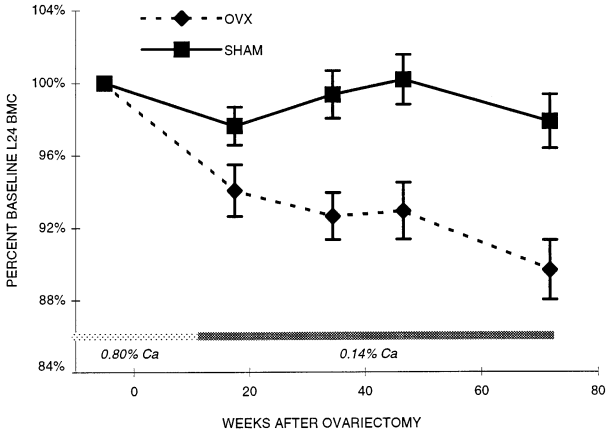

Fig. 3. Lumbar vertebrae 2-4 BMC as percent of baseline value (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8 or 0.14% Ca diets were fed. Effect of treatment (SHAM versus OVX) $P < 0.0001$; effect of time $P < 0.05$; interaction effect $P < 0.05$.

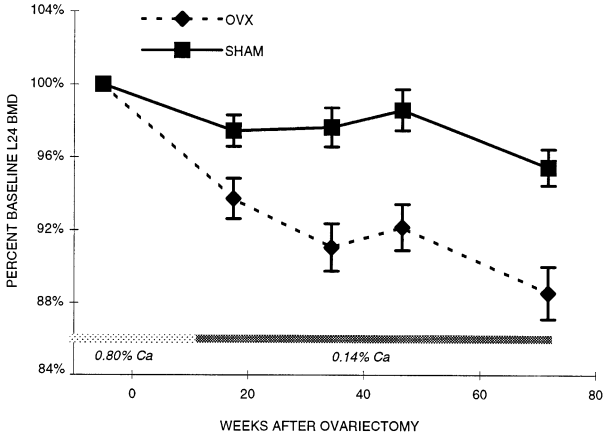

Fig. 4. Lumbar vertebrae 2-4 BMD as percent of baseline value (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8% or 0.14% Ca diets were fed. Effect of treatment (SHAM versus OVX) $P < 0.0001$; effect of time $P < 0.0001$; interaction effect $P < 0.05$.

portion was nonsignificantly lower in the OVX group (1,008 ± 53 mg) than in the SHAM group (1,062 ± 38 mg). The anterior portion of the vertebra contained approximately 40% of the total vertebral ash.

Serum Biomarkers

Serum bone-Gla protein (BGP) was significantly increased by OVX (Fig. 5, Table 2). There was a trend toward increased serum total alkaline phosphatase, with a significant group × time interaction (Fig. 6, Table 2), and serum tartrate-resistant acid phosphatase also tended to be increased (Fig. 7, Table 2). Both alkaline phosphatase and tartrate-resistant acid phosphatase rose in both SHAM and OVX animals after reduction of dietary calcium.

Bone Strength

All parameters of bone strength were reduced in OVX ani-

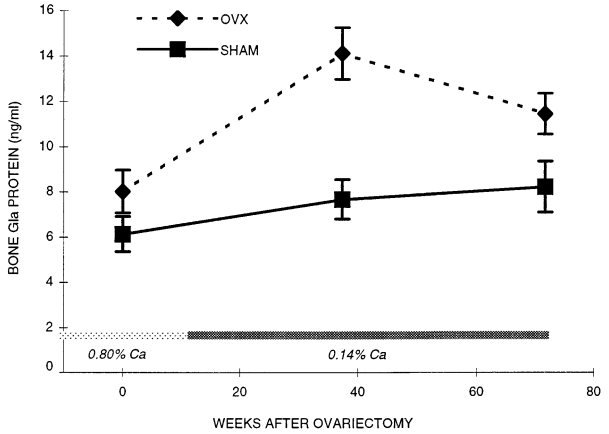

Fig. 5. Serum bone-Gla protein (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8% or 0.14% Ca diets were fed. Effect of treatment (SHAM versus OVX) $P < 0.0005$; effect of time NS; interaction effect $P < 0.01$.

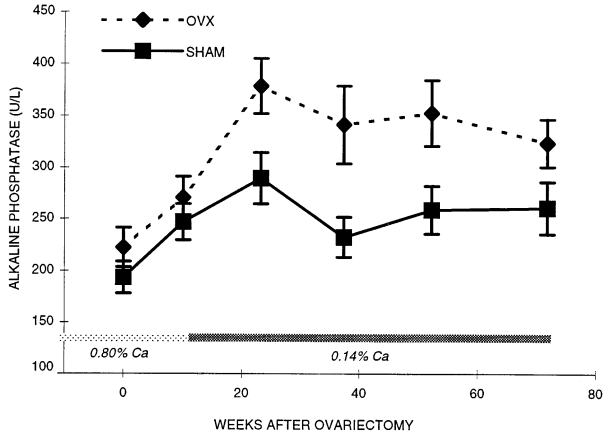

Fig. 6. Serum total alkaline phosphatase activity (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8% or 0.14% Ca diets were fed. Effect of treatment (SHAM versus OVX) $P < 0.1$; effect of time $P < 0.0001$; interaction effect $P < 0.05$.

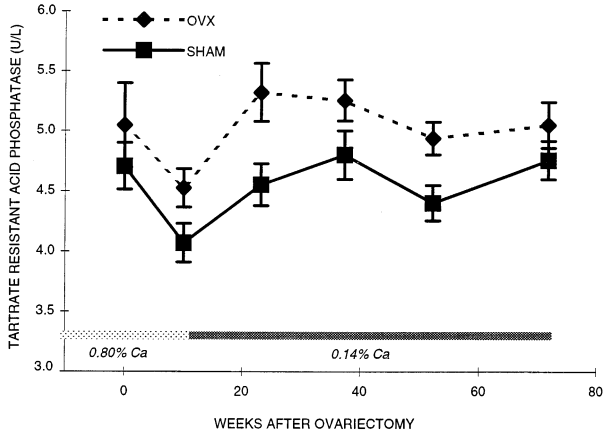

Fig. 7. Serum tartrate-resistant acid phosphatase activity (mean ± SEM) before, and throughout 72 weeks after SHAM or OVX. Horizontal bar represents time during which 0.8% or 0.14% Ca diets were fed. Table 3. Bone strength in SHAM and OVX animals 18 months after ovariectomy

	SHAM (n = 19)	OVX (n = 18)	*P*
Femur neck[a]			
Fracture force (N)	1386 ± 51	1226 ± 43	<0.05
LV 3-4 (mean)			
Fracture force (N)	2587 ± 82	2127 ± 75	<0.001
Stiffness (N/mm)	10018 ± 507	8669 ± 491	<0.1
Toughness (MPa)	1.30 ± 0.12	0.947 ± 0.074	<0.05

[a] For this parameter, n = 15 in Sham group and n = 17 in OVX group

mals (Table 3). Force required to fracture was significantly lower in OVX than in SHAM animals for both femoral neck and lumbar vertebrae. Analysis of these data covarying for BMC at baseline of the same vertebra or of whole body did not affect the results of these analyses. Vertebral fracture force correlated with BMC and BMD of the same vertebrae measured just prior to necropsy ($r = 0.5$, $P < 0.01$ for both). Vertebral toughness correlated with BMC ($r = 0.4$, $P < 0.05$) and BMD ($r = 0.5$, $P < 0.01$), but vertebral stiffness did not correlate with BMC or BMD.

Discussion

Following natural or surgical menopause, women experience a period of rapid bone loss, accompanied by high bone turnover rates [18–21]. This phenomenon precedes the development of osteoporotic fractures, which can be prevented by estrogen therapy [22]. Thus, estrogen deficiency in women causes accelerated bone loss, increased bone turnover, and reduced bone strength. The results of the present study demonstrate that the OVX cynomolgus monkey models each of these features of postmenopausal osteoporosis.

This is the first study to demonstrate decreased vertebral and femoral neck strength in OVX monkeys. There have been few previous evaluations of bone strength in OVX monkeys. Elastic modulus, shear modulus, and failure shear stress of whole tibiae were significantly lower in ovariectomized than in intact animals, but trabecular bone from the femoral head of the same animals showed no differences between intact and OVX monkeys [23]. In a previous study, the mechanical properties of femoral diaphysis, cortical beam specimens, femoral neck trabecular cylinders, vertebrae, and vertebral trabecular cylinders were not different between intact and OVX baboons, although the sample size (seven per group) was small [8].

This also is the first study to demonstrate unequivocal bone loss relative to baseline in OVX animals. In previous longitudinal studies, relative spinal osteopenia was due at least in part to failure to gain bone in OVX animals [8, 10, 13, 24], with a component of absolute spinal osteopenia in two studies [13, 24]. Based on this and other experiments, we believe that absolute bone loss after OVX occurs only in animals that have reached stable bone mass prior to OVX. Stable bone mass is partly a function of age. Growth plates close in cynomolgus monkeys at approximately 6 years, whereas peak bone mass is achieved at 9 years in domestically reared animals [25]. However, wild-caught animals with radiographic and dental characteristics consistent with ages >9 years are osteopenic relative to domestically reared monkeys, and gain bone for approximately 1 year after importation [14]. We hypothesize that if OVX were performed after 1 year of captivity, absolute bone loss would occur. Such studies are rarely performed, but preliminary data from one experiment in our laboratory in which animals were captive for 2 years before OVX do show significant bone loss. The animals in the present study were known to have reached stable bone mass prior to OVX, being both domestically reared and >9 years of age.

On a caloric basis, we estimate that 0.14% Ca fed to a monkey is approximately equivalent to 750 mg of Ca consumed by a woman, which implies that normal laboratory diets grossly oversupplement with Ca. The relatively low dietary Ca fed during most of the present study does not appear to have contributed significantly to the rate of bone loss, although the rise in serum alkaline phosphatase and TRAP after the switch to low Ca is suggestive of an increase in turnover rate. Rapid bone loss occurred in OVX animals during the first 4 months, during which time 0.8% Ca was fed. Conversely, SHAM animals maintained or slightly gained bone after initiation of the 0.14% Ca diet. Most previous studies of bone loss in OVX nonhuman primates have used dietary Ca levels of 0.6% or greater. The single exception is a study in which 0.1% Ca was fed to intact and ''chemically ovariectomized'' monkeys; in that study, intact animals continued to gain bone on the low Ca diet [24]. Therefore, it appears that Ca levels of 0.1% or higher permit bone gain in intact animals, and that levels as high as 0.8% do not prevent bone loss in OVX animals. It also has previously been shown that 0.14% Ca supports normal skeletal development in young baboons [26].

The findings in this study provide some additional information pertinent to the use of this model. Careful attention must be paid to the social situation of nonhuman primates. Though it is highly desirable to house monkeys in pairs or groups, group housing can also engender problems. All-female groups in particular tend to fight upon initial group formation, and high morbidity and mortality can result. Also, as in this study, social upheaval can result in loss of body weight, which can in turn potentially confound a study. Steps should be taken to minimize fighting during formation of social groups, including provision of adequate space and of perches, barrels, and other large objects which permit vertical and/or visual separation of animals within the cage. We have also found that formation of pairs rarely results in conflict. Fighting is substantially reduced if larger groups are formed from pairs which have been co-housed for a month or longer.

The statistical power calculations suggest that a sample size of 19 could be used for future experiments where bone strength is the primary outcome. A larger sample is required to detect differences in bone mass (in a single timepoint comparison), because the effect of OVX is less dramatic and the CV is slightly higher. For the time being, we suggest

using the more conservative estimate of sample size required to detect the observed differences in bone mass, until more data are available to confirm the magnitude of the effect on bone strength.

Ad libitum feeding following ovariectomy in female Beagle dogs: effect on maintenance energy requirement and on blood metabolites

By I. Jeusette[1], J. Detilleux[2], C. Cuvelier[1], L. Istasse[1] and M. Diez[1]

Summary

The aim of this study was (i) to evaluate the effect of ovariectomy on daily energy requirement in Beagle dogs, and (ii) to evaluate the effects of *ad libitum* feeding with a high energy diet on energy consumption, body weight gain and blood metabolites in these spayed dogs. Four young adult female Beagle dogs were used. Ovariectomy induced a significant decrease of daily energy requirement in dogs. *Ad libitum* feeding, initiated 6 months after spaying, induced a significant increase in consumption in spayed dogs. This overconsumption was greatest during the first month of *ad libitum* feeding but continued for the entire 4 months of this period. When fed *ad libitum*, dogs gained excess body weight without significant effect on plasma cholesterol, triglycerides, glucose and insulin, at short term. These data suggest that energy intake should be strictly controlled to avoid excess weight gain in spayed dogs.

Introduction

Obesity and excess body weight (BW) are estimated to affect approximately 25–44% of dogs receiving veterinary cares in Western countries (Lewis, 1978; Norris and Beaver, 1993). It is the more common nutritional disease. It is agreed that a lot of factors contribute in the development of obesity. Obesity is more frequent in females than in males (Krook et al., 1960), except in older dogs (Lewis, 1978) and is nearly twice as high in spayed females as in the total population (Anderson, 1973; Edney and Smith, 1986).

Ovariohysterectomy can result in significant weight gain after surgery in bitches fed *ad libitum* (Houpt et al., 1979) whereas ovariectomized bitches fed a fixed amount of food and exercised regularly gained no weight (Le Roux, 1983). The aim of this study was to determine the daily energy requirement to maintain stable BW after ovariectomy in adult Beagle dogs (experiment 1) and to determine the effect of *ad libitum* feeding on weight gain and blood metabolites in spayed female Beagle dogs (experiment 2).

Materials and methods

Animals and experimental set-up

Experiment 1

Four young adult 2-year-old female Beagle dogs were ovariectomized. The four dogs were maintained together in their usual kennel and were fed individually. The size of the kennel

U. S. Copyright Clearance Center Code Statement: 0931–2439/2004/8803–0117 $ 15.00/0 www.blackwell-synergy.com

was 4 m × 3 m. The BW at the day of sterilization was considered as the optimal BW, based on body condition scoring in a 9 points scale (optimal 5/9) (Laflamme et al., 1994). Food consumption and BW were determined weekly during 32 weeks, 6 weeks before surgery (period I) and 26 weeks after surgery (period II). After surgery, the amount fed was reassessed each week and adjusted if necessary to maintain optimal BW by a reduction or an increase of 5% of the amounts offered. Dogs received a maintenance diet (Premium Croc; Royal Canin, Aimargues, France, crude protein 24.0%, fat 16.1%, calculated metabolizable energy 15 605 kJ/kg as fed) during the experiment. Metabolizable energy was calculated using modified Atwater factors (NRC, 1985). The room temperature was maintained at (mean ± standard error of the mean) 15.1 ± 0.4 °C.

Experiment 2

The same four spayed female Beagle dogs received a high-energy commercial dog food (Energy Croc; Royal Canin, Aimargues, France, crude protein 30%, fat 20%, calculated metabolizable energy 16 284 kJ/kg as fed) during 16 weeks (period III) after a transition period of 3 weeks. During the transition period, dogs received high energy food at maintenance level. During period III, the amount offered was twice the amount that maintained BW. Dogs were fed once a day. Food left uneaten after 1 h was collected and weighted. Plasma cholesterol, triglycerides, glucose and insulin were measured at the end of the transition period between periods II and III and then every 2 weeks during period III (cholesterol reagents, triglycerides reagents and glucose reagents; Technicon RA, Bayer Diagnostics, Puteaux Cedex, France; INS-IRMA; Biosource Europe, Nivelles, Belgium). Period III could be divided into four subperiods of 4 weeks. This division of the data was performed to facilitate a quantitative comparison of the changes in the measured parameters as the trial progressed. For statistical analysis, each subperiod was compared with mean values of period II for energy consumption and BW or with values at the end of the transition period between periods II and III for cholesterol, triglycerides, glucose and insulin.

Statistical analysis

All values are expressed as mean ± standard error of the mean. Data were normally distributed and were submitted to a one-way analysis of variance (anova) for repeated measurements with an autoregressive structure of first order (SAS Proc Mixed; SAS Inst. Inc., Cary, NC, USA). Differences were considered statistically significant at $p < 0.05$.

Results

Experiment 1

The mean BW of the Beagles at the day of the sterilization was 13.7 ± 0.8 kg. Mean BW during period I was 14.0 ± 0.3 kg. During period II, mean BW was 13.7 ± 0.1 kg which corresponds to optimal BW (Fig. 1). Before ovariectomy, dogs received 720 ± 13 kJ/kg $BW^{0.75}$. After surgery, energy offered had to be significantly decreased to maintain ideal BW. During period II, dogs received 506 ± 8 kJ/kg $BW^{0.75}$, which corresponds in a 30% decrease (Table 1).

Experiment 2

When a high energy food was allowed in double amounts, dogs spontaneously ate significantly more food with mean food amounts corresponding to 761 ± 21 kJ/kg $BW^{0.75}$. During the first 4 weeks of period III, mean energy consumption was 883 ± 38 kJ/kg $BW^{0.75}$ and dogs consumed almost all the proposed food. Then, the ingested amounts

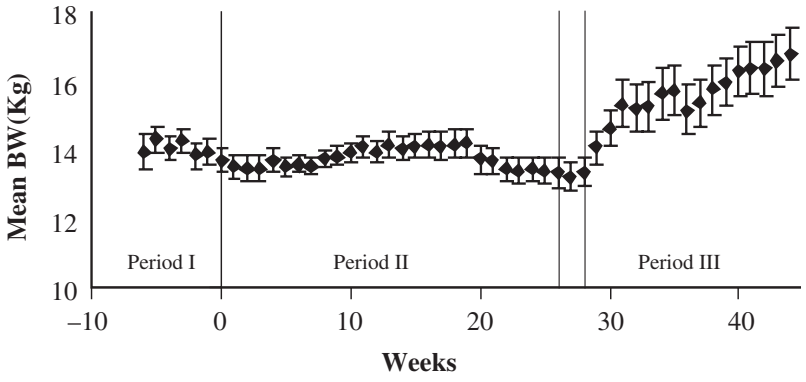

Fig. 1. Evolution of mean body weight (kg) during periods I, II and III.

Table 1. **Mean energy consummations (kJ/kg body weight$^{0.75}$ and kJ) of dogs during periods I, II, III and subperiods III.1, III.2, III.3, III.4**

	Period I	Period II	Period III			
KJ/kg BW$^{0.75}$	720 ± 13	506 ± 8	761 ± 21			
KJ	5209 ± 59	3602 ± 29	5866 ± 96			
P-value		<0.01[1]	<0.01[2]			
			III.1	III.2	III.3	III.4
KJ/kg BW$^{0.75}$			883 ± 38	757 ± 50	736 ± 42	669 ± 29
KJ			6611 ± 138	5728 ± 222	5749 ± 197	5372 ± 176
P-value			<0.01[3]	<0.01[4]	<0.01[5]	<0.01[6]

The p-values give the significant level of differences between periods I and II[1], between periods II and III[2], and between period II and different subperiods of period III, respectively[3,4,5,6]. P-values were the same for kJ/kg body weight$^{0.75}$ and kJ. Values are expressed as mean ± standard error of the mean

decreased spontaneously. Mean energy consumption was 757 ± 50, 736 ± 42 and 669 ± 29 kJ/kg BW$^{0.75}$ for each following subperiod. These increases were all significant when compared with period II. As BW changed during period III, it was interesting to present total intake as well as intake per BW. Statistically, the results were the same. Mean consumption of the dogs was 5866 ± 96 kJ for the whole period III and 6611 ± 138, 5728 ± 222, 5749 ± 197 and 5372 ± 176 kJ for each subperiod of period III. For period II, energy consumption was 5209 ± 59 kJ (Table 1). The BW increased once dogs were fed *ad libitum* (Fig. 1). At the end of period III, mean BW was 16.7 ± 0.8 kg, which represents a significant increase of BW of 22%. All dogs became overweight or obese (body condition score of 7 or 8/9). No significant modification was observed for plasma cholesterol, triglycerides, glucose or insulin during period III (Table 2).

Discussion

Before ovariectomy, dogs received 720 kJ/kg BW$^{0.75}$. It was a high energy intake to maintain BW but dogs were housed together, that could induce a higher activity level. Moreover, temperature was of 15.1 °C, which was not very high. It seems that ovariectomy could induce a significant decrease of daily energy requirement in female Beagle dogs. This

Table 2. **Mean values of plasma cholesterol, triglycerides, glucose and insulin at the end of the transition period between periods II and III and during period III, expressed as mean ± standard error of the mean**

	End of the transition period High energy diet at maintenance level	Period III High energy diet *ad libitum*	Reference values (Kaneko et al., 1997)
Cholesterol (mmol/l)	5.22 ± 0.33	5.07 ± 0.15	3.5–6.99
Triglycerides (mmol/l)	0.42 ± 0.08	0.63 ± 0.05	0.2–1.3
Glucose (mmol/l)	5.92 ± 0.06	5.86 ± 0.11	3.61–6.55
Insulin (pmol/l)	56.10 ± 8.71	85.79 ± 6.09	36–144

decrease was 30%, as approximately observed in cat (Flynn et al., 1996; Harper et al., 2001). The underlying mechanism is unknown, but authors suggest a decrease in physical activity in dog (Le Roux, 1983; Sibley, 1984; Sloth, 1992), which was not confirmed in cat (Flynn et al., 1996).

Ad libitum feeding a high energy diet induced overconsumption in spayed Beagle dogs. Overconsumption was maybe due to a decrease in the oestrogen level in spayed dogs. Indeed, oestrogen has been shown to inhibit food intake in a variety of species (Houpt and Hintz, 1978). However, oestrogen implication is not obvious because more than 6 months run between ovariectomy and *ad libitum* feeding and overconsumption was observed during 16 weeks, which was the length of the study, but was more important the first 4 weeks. A second hypothesis was the inability of spayed dogs to control caloric intake at short term, as observed in cats (Goggin et al., 1993; Flynn et al., 1996). It would have been of great interest to use a control group of intact females fed *ad libitum* with a high energy diet and a spayed group fed *ad libitum* with a maintenance diet to conclude that weight gain is unique to spayed females or to high energy food. Indeed, even if the calorie difference between the maintenance diet and high energy diet was not large, the higher content in protein and lipids in the high energy diet could increase the palatability and thus the consumption. At the end of the study, all dogs became obese. Weight gain was probably a consequence of the overconsumption but the importance of the activity level, the metabolic rate and the efficiency in the utilization of nutrients were not evaluated. In neutered cats, increased food consumption appeared to be a major cause of the weight gain (Flynn et al., 1996; Fettman et al., 1997). Indeed, no effect was observed on activity level (Flynn et al., 1996) or on nutrient digestibility, but a decrease in fasting metabolic rate was observed in spayed female cats (Fettman et al., 1997). It seems that *ad libitum* feeding induced increased plasma triglycerides and insulin concentrations but these increases were not significant. Obesity has been shown to cause insulin resistance in dogs (Mattheeusws et al., 1984). Two phases in the development of obesity have been recognized: an initial growth phase followed by a static phase. During the initial phase, energy intake exceeds utilization and the excess calories are deposited as fat. It is during this phase that the dogs gain excess BW. The static phase begins when excess fat has been deposited. Several separate feedback mechanisms reduce dietary energy intake but BW remains constant in the obese state (Sibley, 1984). Dogs in our study were in the initial phase and it is maybe why we observed no significant effect on the measured blood metabolites. But conclusions are difficult to draw because the number of dogs was very small and moreover blood values of period III were compared with only one value for each dog at the end of the transition period between periods II and III.

In conclusion, a control of the food intake seems necessary to maintain ideal BW after gonadectomy in female dogs. Spayed female dogs seem unable to control food intake, at least at short term, when a high energy food is allowed *ad libitum*. Our data suggest that obesity has no significant consequence at short term on cholesterol, triglycerides, glucose and insulin.

Summary

The objective of this study was to evaluate the effects of ovariectomy (i) and *ad libitum* feeding (ii) on energy intake, body weight (BW), body composition, thyroid status, leptin and ghrelin plasma concentrations. Four young adult female Beagle dogs were fed a maintenance diet for 6 weeks prior to ovariectomy, then 6 months after. Food allowance was adjusted in order to maintain optimal BW. Then, a diet slightly higher in energy concentration was fed *ad libitum* for 4 months. The maintenance diet was then fed *ad libitum* for one additional month. The maintenance of optimal BW after ovariectomy required a significant decrease in energy allowance. No increase in fat mass was observed. Ghrelin concentration remained unchanged. During the first month of *ad libitum* feeding, plasma ghrelin concentration and energy intake increased, then they decreased. Mean BW, plasma leptin, thyrotropin (TSH), total triiodothyronine (TT3) and total thyroxine (TT4) concentrations significantly increased over the study. The BW increase was exclusively due to an increase in body fat. In conclusion, energy allowance should be strictly controlled in spayed female dogs. The results suggest that in dogs, thyroid hormones, leptin and ghrelin concentrations change in response to a positive energy balance in an attempt to limit weight gain. However, the significant weight gain shows that this goal was not achieved.

Introduction

Obesity and excess body weight (BW) are estimated to affect approximately 25–44% of dogs receiving veterinary care in Western countries (Norris and Beaver, 1993). Two phases in the development of obesity have been recognized: an initial growth phase followed by a static phase. During the initial phase, energy intake exceeds utilization and the excess energy is deposited as fat. It is agreed that a lot of factor contribute to the development of obesity. Obesity is more frequent in females than in males dogs except in older dog and is nearly twice as high in spayed female than in the total population (Edney and Smith, 1986; Robertson, 2003). Ovariohysterectomy can result in significant weight gain after surgery in bitches fed *ad libitum* (Houpt et al., 1979) whereas ovariectomized bitches fed a fixed amount of food and exercised regularly gained no weight (Le Roux, 1983). The circulating peptides

leptin and ghrelin have actions that include reciprocal effect on appetite-regulating neurons in the hypothalamus. In addition to its growth hormone (GH)-releasing properties, exogenous ghrelin injections stimulate food intake and adiposity in rodents (Tschop et al., 2000; Wren et al., 2001a), in humans (Wren et al., 2001b) and in dogs (Yokoyama et al., 2005). In human as in dog studies, ghrelin was found to decrease in case of obesity (Tschop et al., 2001; Shiiya et al., 2002; Jeusette et al., 2005). Leptin is a protein synthesized and secreted primarily by adipocytes, and the circulating leptin concentration is elevated in obese humans and rodents. Plasma leptin concentration is a good index of adiposity in dogs (Ishioka et al., 2000). The increase in thermogenesis observed after thyroid hormones administration has led to speculate whether thyroid, acting on energy expenditure, could affect BW (Silva, 1995). The aim of this trial was first (i) to study the effects of ovariectomy on energy requirement and body composition and secondly (ii) to study the effects of *ad libitum* feeding on BW, body composition, thyroid hormones, leptin and ghrelin concentrations in plasma.

Materials and methods

Animals and experimental set-up

Four young adult, 2 years of age, female Beagle dogs were used. The four dogs were maintained together in their usual kennel and were fed individually during all the experiment. The size of the kennel was of 4×3 m. Before the study, the dogs were trained to be fed once a day and to finish their meal in 10 min.

The schedule of the experiment is presented in Fig. 1. The study was divided in four phases, one before ovariectomy (P0) and three after ovariectomy (P1, P2 and P3).

During the 6 weeks of P0 and the 6 months of P1, the dogs received, in order to maintain stable BW, a maintenance commercial extruded (dry-type) diet (Premium Croc; Affinity Petcare, Barcelona, Spain) that was formulated to contain 24.0% (wt/wt) crude protein, 16.1% fat, 38% starch, 2.5% crude cellulose, 6% ash, 17.1 kJ/g measured metabolisable energy (MME). The amount fed was reassessed each week and adjusted, if necessary, by 5% reduction of the amount offered. The BW was considered as the optimal BW, based on body condition scoring (BCS) on a 9-point scale (optimal 5/9) (Laflamme et al., 1994).

During P2, the four spayed female Beagle dogs received a high-energy commercial extruded (dry type) diet (Energy croc; Affinity Petcare, Barcelona, Spain) that was formulated to contain 30% crude protein, 20% fat, 18.0 kJ/g MME during 4 months. The amount offered was twice the amount that maintained BW. Dogs were fed once a day and food left uneaten after 90 min was collected and weighed. P2 could be divided into four sub-periods of 1 month. This division of the data was performed to facilitate a quantitative comparison of the changes in the measured parameters as the trial progressed.

In P3, the four dogs were fed *ad libitum* during 90 min the maintenance diet again during 1 month.

Individual food intake was recorded daily and BW weekly. Body compositions were determined at P0, at the end of P1 and P3. Total body water was measured using the isotopic dilution of ^2H_2O. On the day of the measurement, 24-hour food deprived dogs were placed in individual cages for water restriction and body water equilibration 4 h after the tracer injection. Dogs were injected with ^2H_2O (99.9% $^2H/H$, Leman, Saint-Quentin-en-Yvelines, France) sub-cutaneously (1.5 g/kg BW). Blood samples were collected from the cephalic vein before and 4 h after the tracer injection. Deuterium was assayed by Fourier transform infrared spectroscopy. Total body water was estimated from the deuterium pool value. Fat free mass was obtained from total body water divided by 0.744 (Ferrier et al., 2001). The body fat content was further calculated from BW and fat free mass. Fat free mass and fat mass were expressed in kg.

Blood samples for measurement of ghrelin, leptin, total thyroxine (TT4), total triiodothyronine (TT3), reverse triiodothyronine (rT3), free thyroxine (FT4) and thyrotropin (TSH) serum concentrations were taken at the beginning and at the end of P1, at the beginning and the end of P2 and at the end of P3. Blood samples from all the dogs were collected between 9 and 10 AM after a 24-hour fast on tubes

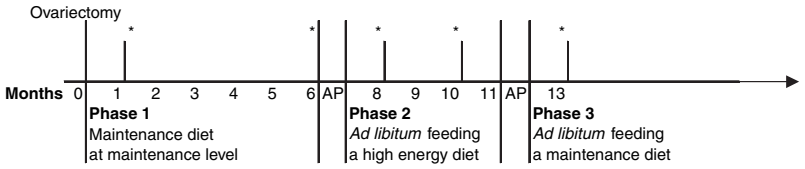

Fig. 1 Schedule of the experiment, indicating the diet fed in each phase and the timing (month) of blood samples (*) in each phase.

with clot activator (thyroid hormones) or EDTA (leptin and ghrelin). Serum or plasma aliquots were frozen at –20 °C (thyroid hormones) or –80 °C (leptin and ghrelin) in plastic tubes until assayed. Total plasma ghrelin concentrations were measured using commercial radio-immuno assay (RIA) human kits performed for dogs (Total ghrelin RIA kit, Linco research, MO, USA). Leptin plasma concentrations were assayed using a canine specific ELISA method validated by Iwase et al. (2000). Determinations of TT4 and TSH serum concentrations were performed through previously validated RIA (Clinical Assays Gammacoat M Total T4 125I RIA Kit, Diasorin, Stillwater, MN, USA; Coat-A-Count canine TSH IRMA, Diagnostic Products, Los Angeles, CA, USA) (Sauve et al., 2003). Reference ranges for TT4 and TSH serum concentrations were 15–67 nmol/l and 0–0.68 ng/ml respectively. Determination of FT4 serum concentrations after equilibrium dialysis (FT4D) was performed using a commercial assay kit (Nichols Institute Diagnostics, San Juan Capistrano, CA, USA) (Daminet et al., 1999). The reference range for FT4 serum measurements was 6–42 pmol/l. Total T3 concentrations were measured through a validated in-house charcoal separation assay (Panciera, 1994). The reference range for TT3 serum concentrations was 1.0–2.4 nmol/l. Reverse T3 serum concentrations were measured through a validated RIA method (Biodate S.p.A., Rome, Italy) (Center et al., 1984). Reference range for rT3 was 0.41–0.95 nmol/l. All the thyroid assays were performed at the Endocrine Section, Animal Health Diagnostic Laboratory, Michigan State University.

The room temperature was maintained at [mean ± standard error of the mean (SEM)] 59.18 ± 1.57 F (15.1 ± 0.4 °C) during the experiment. Drinking water was provided *ad libitum* during all the experiment. The activity level was not measured. The protocol was approved by the Animal Use and Care Advisory Committee of the University of Liège.

Statistical analysis

All the values are expressed as mean ± SEM. Data were normally distributed and were submitted to an univariate analysis of variance (ANOVA) for repeated measurements. A compound symmetry or an autoregressive structure of first order was assumed to account for the tendency between repeated measures (SAS Proc Mixed). A Pearson's correlation analysis (SAS Proc Corr) was performed on the data. Differences were considered statistically significant at $p < 0.05$.

Results

Results are presented in Tables 1 and 2.

At the beginning of the study (P0), all the parameters were within reference ranges in all four spayed dogs.

BW, body composition and energy intake

The mean BW of the Beagles at the day of the sterilisation was 13.7 ± 0.8 kg. Mean BW during P0 was

14.0 ± 0.3 kg. During P1, mean BW was 13.7 ± 0.1 kg which corresponds to ideal BW (IBW) (Table 1). Before ovariectomy, dogs received 807 ± 13 kJ/kg $IBW^{0.75}$. After surgery, energy offered had to be significantly decreased to maintain ideal BW. During P1, dogs received 573 ± 13 kJ/kg $IBW^{0.75}$, which corresponds to a 30% decrease (Table 1). A decrease in fat mass was observed at the end of P1. The ratio fat free mass on fat mass was improved.

When a high-energy food was allowed in double amounts, dogs spontaneously ate significantly more food with mean food amounts corresponding to 912 ± 13 kJ/kg $IBW^{0.75}$. Mean ingested food amounts during P2 increased with 59%, when compared to P1. However, the increase in ingested food amounts was of 80% during the first month of P2 and dogs consumed almost all the food that was offered. Then, the ingested amounts decreased spontaneously during the following months of P2 and P3 although the total energy intake remained statistically higher when compared with P1 (Table 1). The BW increased once dogs were fed *ad libitum*. At the end of the 4 months of P2, mean BW was 16.7 ± 0.8 kg, which represents a significant increase of BW of 22%. At the end of P3, mean BW was 17.8 kg (+30%) (Table 1). All the dogs became overweight or obese (BCS of 7 or 8/9). The weight gain during P2 and P3 consisted exclusively of fat gain (+156%).

Blood parameters

Ghrelin plasma concentration remained constant during the 6 months of P1. When comparing mean values of the entire P1 and the entire P2, the increase in ghrelin plasma concentration was not significant. By contrast, when comparing mean ghrelin plasma concentration during P1 and at the beginning of P2, a very high increase was observed (+281%). Then, ghrelin plasma concentration decreased at the end of P2 and P3. When compared with P1, the decrease in ghrelin plasma concentration at the end of P2 and P3 was not significant (Table 1).

When compared with P1, plasma leptin concentration was increased more than twofold at the end of P2 and this increase was maintained in P3 (Table 1).

One month after the beginning of P2, when compared with P1, no significant modification was observed for thyroid parameters except a mild but significant increase in TSH serum concentration (Table 2). At the end of P2, mild non-significant increases in TT4 and TT3 concentrations were observed. However, at the end of P3, when compared with P1, significant increased serum concentrations were observed for TT4, TT3 and TSH. No changes were found in rT3 and FT4D serum concentrations (Table 2).

Discussion

The first objective of this study was to assess the effects of ovariectomy on energy requirement and body composition. A first study (Houpt et al., 1979) showed that during a period of 3 months after surgery, a 20% increase in food consumption of four-female dogs was observed, resulting in BW gain. The aim of the present study was to determine the energy requirement to maintain IBW after ovariectomy. The energy requirement before ovariectomy was high. A possible explanation is that experimental dogs are different from pet dogs; moreover, these experimental dogs were housed together

that can increase physical activity. A 30% decrease in energy consumption was necessary to maintain IBW after ovariectomy. This restriction seems to be high, but Beagle are prone to obesity. Two hypothesis can be proposed to explain this observation: a decrease in basal metabolism, as observed in female cats (Fettman et al., 1997) or a decrease in physical activity as suggested in dogs by Le Roux (1983) and Sloth (1992). Indeed, spayed female fed a fixed amount of food and exercised regularly gained no weight (Le Roux, 1983). The present study cannot validate one of these hypothesis, physical activity or basal metabolism being not measured. The control of food intake in order to maintain IBW resulted in an improvement of the ratio fat free mass to fat mass. No increase in fat mass was observed. The increase in fat mass after ovariectomy is not an inevitable result.

The second objective of this study was to assess the effects of *ad libitum* feeding in spayed dogs on BW, body composition and blood parameters. *Ad libitum* feeding of a high fat, high protein, and presumably more palatable, diet resulted in over consumption and weight gain in spayed Beagle dogs. Over consumption could be due to the decrease in the oestrogen level in spayed dogs. Indeed, oestrogens have been shown to inhibit food intake in a variety of species (Houpt and Hintz, 1978). This over consumption was more important during the first month and decreased thereafter. The same phenomenon has been previously reported in male or female cats (Flynn et al., 1996; Kanchuk et al., 2003) and in one study in female dogs (Houpt et al., 1979). Weight gain – consisting exclusively of fat – was probably a consequence of the over consumption but the importance of the activity level, the metabolic rate and the efficiency in the utilization of nutrients were not evaluated. Dogs have continued to gain weight when they were fed their maintenance diet in P3. This implies that there is little difference in the response of the dogs to the two levels of energy in the two diets. A higher difference in energy concentration between the two diets should have been used to compare the effects.

Simultaneously to BW and body fat gain, increases in plasma leptin, TSH, TT3 and TT4 concentrations were observed. The increase in leptin level probably reflected the increase in body fat because leptin concentration is highly correlated with body fat in dogs (Ishioka et al., 2002; Sagawa et al., 2002). Plasma leptin concentration could be one of the first parameters to be modified during weight gain, before plasma insulin, cholesterol or triacylglycerols (Jeusette et al., 2004). As expected, leptin in our study correlated positively with BW. Leptin plays a role in energy intake and energy expenditure. In dogs, leptin injections inhibit food intake (Lebel et al., 1999). In rodents, leptin increases also energy expenditure (Pelleymounter et al., 1995). Therefore, the increase in leptin concentrations could be an attempt of the organism to limit weight gain. Another attempt to counteract the development of obesity is the increase in TSH serum concentration. Most studies in obese humans report normal basal TSH serum concentration although a recent study reported high TSH level in some obese children and adults. High leptin levels observed in obese humans might contribute to this finding through stimulation of thyrotropin-releasing hormone (TRH) release (Stichel et al., 2000). An increase in TT3 and TT4 concentrations was observed with weight gain. The increase in TSH serum concentrations most likely contributes to the increase in TT4 observed in our study in overfed obese dogs. Increased total binding globulin concentrations have also been suggested in older studies to explain higher TT4 levels in obese humans (Scriba et al., 1979). However, increased TSH concentrations remained in the reference range and therefore would not lead to misdiagnosis of primary hypothyroidism in overfed obese dogs. In obese humans, rT3 levels remained unchanged in most studies (Roti et al., 2000), which corresponds to our findings. In our study, the concentration in FT4D was not influenced by weight gain. Therefore, FT4D is reliable to evaluate thyroid function in dogs that gain weight, which is in accordance with several studies showing that FT4D is less influenced by non-thyroidal factors than TT4 measurements (Scott-Montcrieff and Guptill-Yoran, 2000).

Ghrelin is also an important hormonal mediator. Recent studies in humans, rodents and dogs suggest that ghrelin may provide a peripheral signal to the brain to stimulate food intake and adiposity (Tschop et al., 2000; Wren et al., 2001b; Yokoyama et al., 2005). A decrease in ghrelin concentration is observed in obese humans, in fatty rats, and in obese dogs (Tschop et al., 2001; Shiiya et al., 2002; Jeusette et al., 2005). In the present study, over consumption resulted in a very high increase in plasma ghrelin concentration during the first month after which ghrelin concentration decreased. So, it seems that the change for a high palatable diet, after a period of restriction, promoted food intake in dogs. The objective could be to store fat when energy is available. However, it would have been of great interest to use a similar group of dogs fed *ad libitum* the

maintenance diet to determine whether the observed modifications were unique to *ad libitum* feeding compared to *ad libitum* feeding a high energy diet. *Ad libitum* feeding induced weight gain. After the initial increase, plasma ghrelin concentration decreased with weight gain although not significantly. The lack of significance of the decrease in ghrelin concentration was maybe due to the small number of dogs. Indeed, in a previous study with a larger effective, the decrease in plasma ghrelin concentration in obese dogs was significant (Jeusette et al., 2005). Another hypothesis could be that there was no modification in ghrelin concentration with obesity on the short term while in the previous study, dogs were obese for at least 1 year before entering the study and they were not in an overfeeding state.

In conclusion, the restriction of energy intake seems necessary in dogs after ovariectomy. Indeed, the BW of spayed female dogs increases rapidly once fed *ad libitum* and the BW gain is exclusively a fat gain. The control of food intake after ovariectomy allows the dogs to have an optimal body composition. During the dynamic phase of obesity, thyroid hormones, leptin and ghrelin plasma concentrations change as a result of counteract weight gain. However, the significant weight gain suggests that this goal is not achieved. In dogs, leptin is one of the first parameters to be modified during weight gain.

Survival and behaviour of castrated Soay sheep (*Ovis aries*) in a feral island population on Hirta, St. Kilda, Scotland

P. A. JEWELL

Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ

(*Accepted 19 March 1997*)

(With 5 figures in the text)

The free-living population of Soay sheep on the island of Hirta, St. Kilda, in the Outer Hebrides, has been intensively studied since 1959. The present study was initiated to throw light on the causes of the high mortality rate of adult rams in comparison to that of ewes. In 1978, 1979 and 1980, a total of 72 male lambs was castrated within a day or two of birth. The survival of these castrates has been much longer than that of the entire rams, marked as controls, and longer than that of ewes of the cohorts of the same years. The daily activity pattern of the castrates was similar to that of ewes rather than that of rams. In particular, during the rut the castrates spent most of the daylight hours grazing, in contrast to the rams who were continuously moving and involved in agonistic and sexual encounters. This study substantiates the earlier assertion that the costs in energy of reproduction are a major cause of mortality in temperate zone ungulates. The social organization of some castrates was similar to that of females in that they remained with the home-range group of ewes into which they were born, but other individuals resembled males in that these castrates clubbed together in their own groups. These patterns of behaviour persisted throughout life.

Introduction

Many species of ungulates exhibit marked sexual dimorphism, and there is a higher mortality rate among males than among females; there is intense competition between males to become successful sires (Jewell, 1976). In these ungulates, the ratio of males to females at birth is usually close to 1:1 (Parkes, 1926) but, in the adult breeding population, females may greatly outnumber males. The feral Soay sheep that occupy the island of Hirta, St. Kilda, the most westerly of the Outer Hebrides in Scotland, show this condition to a marked degree. This population, showing cyclic fluctuations around 1200 head, has been studied continuously since 1959 (Jewell, Milner & Boyd, 1974; T. H. Clutton-Brock *et al.*, 1991, 1992; Jewell, 1995), and it is recorded that mortality among rams is very high with a heavy incidence in ram lambs and yearling rams: the ratio of adult rams to ewes varies from 1:3 to 1:12 through the phases of the cycle (see Fig. 2). Most sheep die in late winter when all suffer from inanition but it is presumed that the events of the rut, occurring in November, further reduce the chances of males surviving over winter. In the rut, not only are males in physical competition with each other for access to females, but they spend much less time feeding (Grubb & Jewell, 1974). In Soay rams, as the mating season approaches, testosterone levels rise and there is a marked increase in aggressive behaviour (Grubb & Jewell, 1973; Lincoln & Davidson, 1977). It is well known that castration reduces libido and aggressiveness (Mattner, 1980; Wodzicka-Tomaszewska, Kilgour & Ryan, 1981), and that castrated rams (also commonly called wethers) are placid animals, although sexual drive can be restored in them by the injection of testosterone (Fulkerson, Adams & Gherardi, 1981). In an attempt to reveal some of the sex-specific factors involved in the differential mortality of males, a number of male lambs on Hirta was castrated in the years 1978, 1979 and 1980. It

© 1997 The Zoological Society of London

was hypothesized that the castrates would not attempt to participate in the rut and that their survival rate would be much better than that of 'entire' (uncastrated) rams.

One of these castrates of 1980 is still to be seen alive today, nearly 17 years later (spring 1997)*, but all the entire rams of the same cohort are long since dead. It seems an appropriate time, therefore, to record the results: a preliminary note on the greatly enhanced survival of castrates has been published (Jewell, 1986). Intriguingly, there was an early observation on the survival of castrates on Hirta: when Soay sheep were introduced to Hirta from the adjacent island of Soay, in 1932, the consignment of 107 sheep included 22 wethers, these being male lambs of the year that had been castrated. Sixteen years later, James Fisher visited Hirta (Fisher, 1948) and afterwards remarked to Morton Boyd (Boyd, 1953) that he had seen some castrates still alive, recognizable by their 'knob horns'.

There is a very extensive literature describing the behaviour of sheep (recently reviewed by Lynch, Hinch & Adams, 1992), mostly relating to husbanded animals. While much quantitative ethology has been performed on ewes and lambs, there is little specifically about wethers. Much research has been carried out on the relationship between ewes and lambs, and on the sexual behaviour of rams (Lindsay & Pearce, 1984), but in commercial flocks the age structure and sex ratio are strikingly dissimilar to those in wild populations. The feral Soay sheep have afforded an opportunity to study behaviour in free-living conditions and with a full complement of rams (Grubb & Jewell, 1966, 1973; Jewell, Milner & Boyd, 1974; Jewell, 1995), and it is in this context that the behaviour of the castrates is particularly interesting. I know of no other study of a large mammal in which a group of castrates has been liberated into a free-living, unmanaged population in this way.

Methods

Soay sheep

Soay sheep are a relic population of primitive domestic sheep similar to those that were widespread in Britain in the Bronze Age (Ryder, 1983). In their feral form they survived only on the small island of Soay in the St. Kilda group, but Soays were being brought to parks in mainland Britain at the beginning of the century (Elwes, 1913). After the evacuation of people from the nearby larger island of Hirta in 1930, a founding population of Soay sheep was established there. Over the years their numbers fluctuated between 600 and 1800 on the whole island, but the study was carried out on the sub-population that occupied the Village Glen and the nearby promontory of Ruaival (see Fig. 1), numbering 300 to 500 animals.

Soay sheep are polymorphic for fleece colour and horns (Boyd *et al.*, 1964). The 2 basic fleece colours are light fawn (L) and dark brown (D) and, as with species of wild sheep, the fleece is usually cast completely every summer. The rams usually carry heavy horns in a close spiral, although occasionally crumpled horns are to be seen, and, very rarely, polled. Almost half the ewes have horns that are finer and more upright than the rams horns and almost half are completely polled (without horns); the remainder have small knobs of horn, or very poorly developed horns, called scurs.

A description of home-range organization among Soay sheep is given in Jewell (1966) and Grubb & Jewell (1966), and the social behaviour of Soay sheep is described in detail in Jewell, Milner & Boyd (1974).

Castration

In 1978, in a pilot study, 14 male lambs were castrated within 1 or 2 days of birth using the usual method for husbanded sheep of applying a rubber ring round the scrotum ('Elastrator', Elastrator Co., Blenheim,

*This castrate died on, or a day or two before, 23 March 1997. He was born on 22 April 1980 and so was one month short of 17 years old.

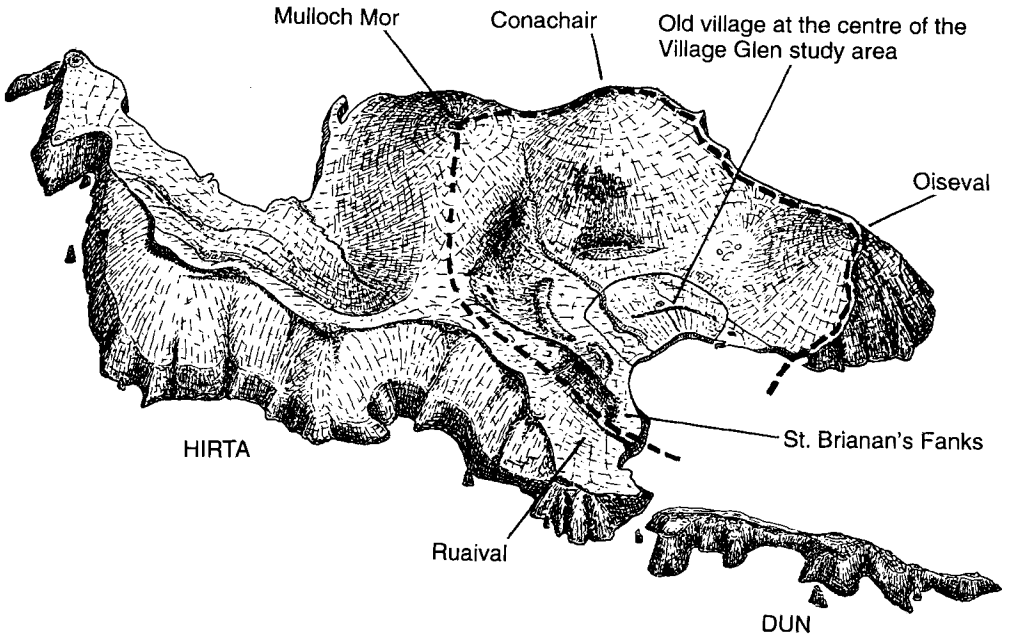

FIG. 1. Block diagram of Hirta and Dun giving an oblique aerial view from the south. A scale is provided by the island of Dun which is 1425 m long (after Macgregor, 1960). The dashed line encloses the Village Glen study area.

New Zealand). Fourteen other male lambs, caught concurrently, were tagged but not castrated to serve as controls (entire rams) see Table I. These lambs were caught over what proved to be the peak of the lambing period between 14 April and 22 April (median date April 19/20, see Jewell, 1989). An additional 16 male lambs (not shown in Table I) and 54 ewe lambs were tagged.

No problems having arisen in the pilot study, a second visit was made in 1979 . This proved to be a crash year for the sheep population, however (see Fig. 2), and there had been heavy mortality in February and March. The surviving ewes were in poor condition, the lambs were light in weight, and many died before the end of the lambing period. No attempt was made, therefore, to castrate a large sample and only 8 castrates and 8 controls (3 of which died neonatally) were tagged, together with 33 other ram lambs and 44 ewe lambs.

The following year, 1980, was one of recovery for the sheep (see Fig. 2). No dead sheep were found in the village area. A hundred male lambs were caught of which 50 were castrated and 50 became controls; 83 ewe lambs were caught . The male lambs were assigned to be castrated at random and the colour and horn types into which they grew had to be recorded later when they became mature. Forty-two castrates were seen in July 1983 and categorized in this way (see **Results**).

Tagging

Lambs were given small Dalton plastic ear-tags each with a unique number and of a different colour for each year. The size of the numbers on these tags is too small to be read at a distance, even with field glasses, but small tags were used for aesthetic reasons as many National Trust parties visit the island.

The island of Hirta

The island (Fig. 1) lies at 57° 49′ N lat., 08° 34′ W long., and is 637 ha in extent (Macgregor, 1960). It is treeless but provides productive grazing and abundant shelter for the sheep. The sheep feed on the old pastures in the

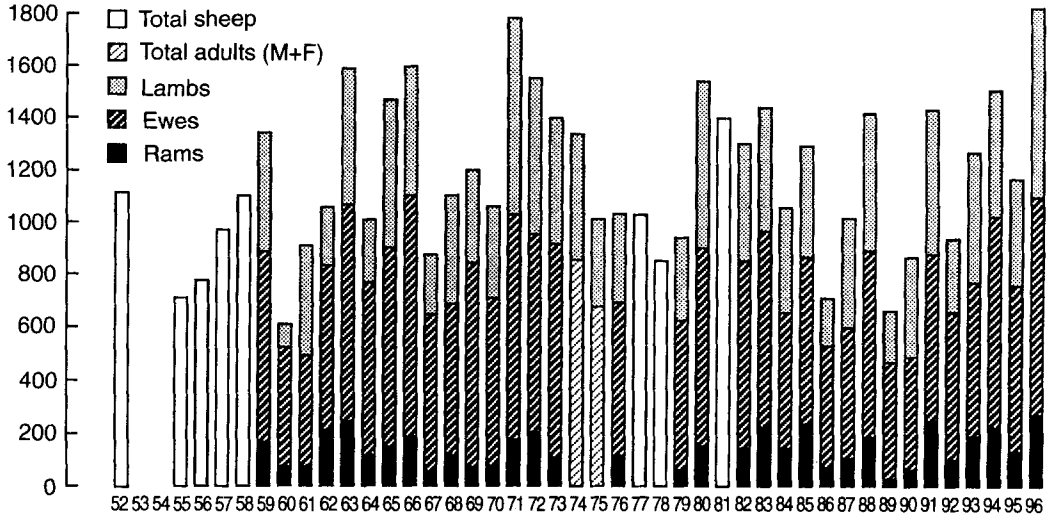

FIG. 2. Year-to-year fluctuations in numbers of Soay sheep on Hirta, St. Kilda, taken from the summer census in May or June from 1952 to 1996. In some years a breakdown into the several categories of sheep was not achieved, and some counts were made by inexperienced volunteers.

deserted village, on the heather-dominated hill slopes, and on cliff ledges and gulleys. A standard annual census of the sheep on the whole island was, and continues to be, made every year in early summer (Fig. 2) but intensive study is limited to the village area, Fig. 1 (T. H. Clutton-Brock *et al.*, 1991). Detailed accounts of the environment and the general methods of study are given in Boyd *et al.* (1964), and Jewell, Milner & Boyd (1974) where a large-scale fold-out vegetation map is also to be found.

Visits

Following the last year in which castrations were carried out (1980), I visited the island in October–November 1981, July–August 1983, October–November 1984, April 1985, August 1987, and July 1990. Other people from the Soay Research Project and the Large Animal Research Group at Cambridge have been on the island in every year from 1985 to the present.

Recording behaviour

Focal animal follows were carried out on selected castrates and entire rams. When possible, 2 observers worked together, one following a castrate and the other following a control ram; activity was recorded every 5 minutes. *Activity surveys*: to compare the activity of rams, ewes, and castrates, all visible animals were recorded as grazing, resting, or engaged in some other activity (standing, walking, sexual, or agonistic encounters) in surveys through the village at half-hour intervals through the daylight hours. *Continuous watches* of castrates and rams provided details of behaviour; when a castrate who was a member of a group was selected, information on the behaviour of the whole group could be obtained as they remained together.

Results

Physical types

The range of colours seen in the fleeces of castrates was the same as in other Soays, but in many

castrates, as they grew older, the fleece was not fully cast and old matted fleece was retained. Many of the castrates, despite being male, failed to grow horns and remained polled (P); others grew small crumpled horns (Crump), rather larger than the scurs of ewes; most of the castrates, however, grew horns (H) that were similar to the horns of ewes (see photograph in J. Clutton-Brock *et al.*, 1990). In a check of 42 castrates seen in July 1983, the categories recorded were: L,11; D,31 and of these LH,6; LCrump,3; LP,2; DH,19; DCrump,3; DP,9. Castrates are much larger than ewes, and are taller and less stocky than rams and have longer limbs (for skeletal measurements see J. Clutton-Brock *et al.*, 1990).

Social organization

The small numbers of castrates and controls of the 1978 cohort of lambs were observed in April 1979, one year after birth. Their numbers had been reduced by the heavy mortality in the whole population in the winter of 1978/79 (see Fig. 2) and only six castrates and five controls out of the original 14 in each category were seen. These young animals, just becoming yearlings, were still in their maternal home-range groups and no unusual behaviour was recorded.

Observations between 29 October and 9 November 1981 found many of the castrates still with females, presumably adhering to those groups into which they had been born. Typical, and persistent, grazing groups comprised one or two castrates, three or four adult ewes and the several lambs of these ewes. This behaviour of the castrates was not different from that of some young rams of the same age and many female groups had one-and-a-half-year-old rams among them: some groups had both castrates and entire young rams. The behaviour of the few older castrates (surviving from the 1978 and 1979 cohorts) was of great interest in being of two different kinds, some showing persistent association with particular female groups whilst others had associated together in 'castrates only' groups, none having joined existing ram groups. This behaviour was in contrast to that of rams of the same age many of whom had joined groups of older rams. Three such groups of castrates were regularly seen in the meadows of the village, one group of six individuals and two of four. (A few of the younger castrates of 1980 also adhered to these groups.)

Observations in July–August 1983 revealed several stable groups of castrates as a conspicuous feature of the village sheep. One group of eight individuals that moved in the centre of the village and on the slopes of Oiseval in the east comprised two five-year-olds, one four-year-old, and five three-year-olds. This group was seen on almost every day of the visit and they were always together; they moved freely through the home ranges of ewes and the central village rams and no unusual interactions were observed. Another group of four moved at the east end of the village also using Oiseval, and a group of seven moved between the west meadows and the hill slopes to the west of the village. Yet another five castrates occupied a home range at the west end but they were often accompanied by ewes and a ram who behaved as an adherent to the group. Similarly, five castrates on Ruaival, further west, associated in a group that included ewes and their lambs. Notwithstanding the formation of these distinctive home-range groups, there were several castrates who did not associate with others of their kind but who remained as members of ewe home-range groups. The castrates moved freely through the home ranges of ewes and the rams that lived in the central village and no interactions were observed.

A visit to Hirta between 23 October and 21 November 1984 covered the first half of the rut (as judged from the median date of lambing, 23 April 1985, see Jewell, 1989). The castrates were still associated in the conspicuous all-castrate home-range groups. All eight members of the central village group (all could be recognized individually) had survived and were still together. They had recruited another 1980 castrate making a group of nine. A second group of eight that ranged over the mid-village comprised one from 1978, one from 1979, and six from 1980. A group of seven castrates (two born in

1978, one in 1979, four in 1980) was frequently seen on the slopes above the west end of the village. A large number of castrates moved between St. Brianan's Fanks (fanks are old stone-walled exclosures formerly used for the growing of crops) further to the west and the promontory of Ruaival (see Fig. 1). They were seen most often as two distinct groups of four (one of 1989, three of 1980) and of six (one of 1978, five of 1980). Other castrates using the west side of the village appeared not to be adherents to stable peer groups but associated with ewe groups and occasionally with young rams.

The alternative type of social organization also persisted. Certain castrates remained with ewe home-range groups and, in at least one instance, the castrate's dam was known individually and she was a stable element of the group. Four castrates were known to have spent their entire lives in this way.

The persistence of stable home-range groups, of castrates only, also remained a feature of this class of sheep throughout their lives. As castrates died, and the original groups became smaller, so an amalgamation of the survivors was noted, as in groups of entire rams.

Survival

The persistence of the castrates in the population is a striking phenomenon (Table I). Their survival rate and longevity are evidently greater than that of entire rams. Although only one castrate is still alive today (spring 1997), 26 castrates were still alive in April 1991 at a time when all the rams from the same cohorts were dead.

Quantifying the sequence of mortality has not been simple because of the impossibility of making a complete census during a short visit to the island. The sheep move widely and are often out of sight behind rocks or walls, or are out on the cliff ledges. Moreover, 10 lambs had originally been caught on Ruaival outside the area subsequently used for intensive studies. In addition, some wethers and entire rams born in the western meadows of the village may have taken up residence beyond the study area. Not all dead animals are found, but regular intensive searches at the end of March ensures that most deaths, which occur in late winter, are enumerated. Very few adult animals die between April and January. In any survey of the living animals, only a proportion of the tagged ones are seen. Although some wethers lost ear-tags, their distinctive appearance ensured that, with persistent counting, the total number of survivors (from the three cohorts combined) could be recorded (Table I). These total numbers are dominated by the large cohort of 1980, so it has proved practical to take the numbers present in that year as the starting point for the graph (Fig. 3) comparing the relative survival of rams, castrates and ewes.

Longevity

The longest-living ram amongst the controls was 10 years old. The longest living ewes in the cohorts under consideration here were one from 1978 who died at 15 in 1993, one from 1979 who died at 14 in 1993, and one from 1980 who died at 14 in 1994. In July 1983, I saw a 13-year-old ewe who was successfully rearing twins. The longest-lived castrate is the one seen alive in March this year (1997) who was born in 1980 and so is over 16 years old. It will be recalled (see **Introduction**) that James Fisher in his visit to Hirta in 1948 saw some castrates that were by then 16 years old.

Reproductive behaviour

The visit to Hirta in October–November 1981 coincided with the early phase of the rut.

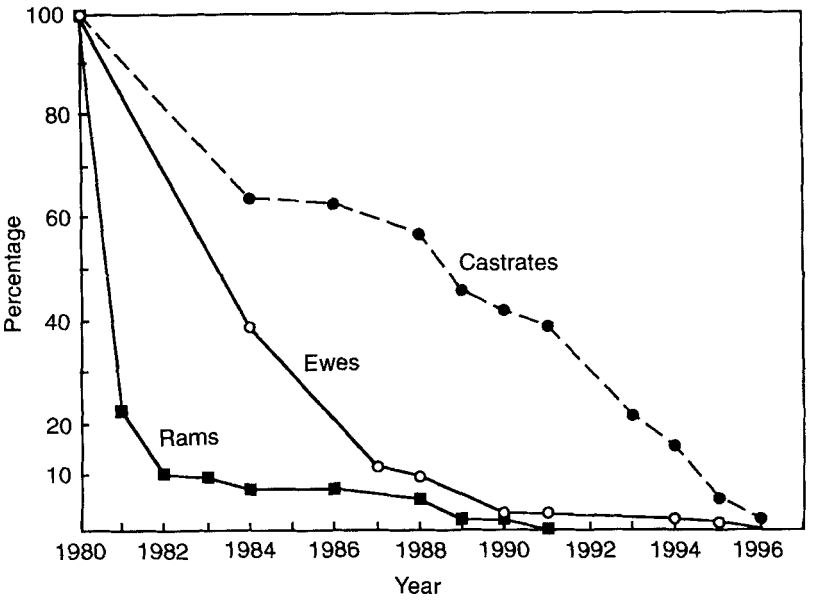

FIG. 3. The survival of castrates (-●-) compared with that of entire rams (-■-) and ewes (-○-) standardized as a percentage of the starting numbers (given in Table I).

Occasionally, rams threshed clumps of vegetation and showed low-level aggression among themselves. Rather perfunctory investigation of ewes by rams and ram lambs was seen with frequent flehmen, but with no attempts to mount. No investigation of ewes by castrates was seen. The similarity of appearance of castrates and ewes was notable. There was some low-key interaction between rams and castrates: rams occasionally sniffed castrates and showed flehmen and head-twist towards them. Usually they ignored each other, although the castrates sometimes contested rams with head-butting intention movements. Ram lambs provoked reaction from castrates by approaching them and sniffing as if the castrates were ewes. The castrates either walked away or rebuffed the ram lambs by butting them. This could develop into chasing, reminiscent of the play of lambs. Sometimes mature rams also appeared to mistake castrates for ewes. A six-year-old ram made a low-stretch approach to the rump of a three-and-a-half-year-old castrate. The castrate stood still briefly and the ram then sniffed the ground just behind the place where the castrate had been standing and exhibited flehmen. This was the typical reaction shown to ewes who would normally urinate on the ground behind themselves following such an approach (see description and photographs in Jewell & Grubb, 1974).

The visit in October–November 1984 covered the first half of the rut and at this time the castrates were between four-and-a-half and six-and-a-half years old, ages at which rams are in their prime. Courtship of ewes by rams and mating activity increased in intensity throughout the period; the first mounting was seen on 2 November, a few mountings were seen daily after this and from 16 November onwards seven or eight mountings, between different ram and ewe pairs, were seen each day. Consortships were numerous, the rams making frequent testing of the urine of the ewes.

In most respects, the activities of the castrates could not have been more different. Indeed, the group of nine castrates that moved in the central to east side of the village was seen out on the cliffs of Oiseval on 6 November and was not seen in the village again during the remainder of our visit. These castrates had distanced themselves from the main mating arena of the village. The castrates that

remained in the village seemed relatively indifferent to the mating activity that was going on around them. Castrates continued lying, cudding, or grazing despite agonistic encounters between rams, or mating activity, nearby; such circumstances usually provoked entire rams to participate, or join in the chasing of ewes. Nevertheless, a few encounters involving castrates were noted. A castrate did nudge a ram, and some castrates on seeing young rams blocking nearby ran over and broke up the confrontation. Two castrates engaged in a head to head confrontation before lying down. Only once was a castrate seen to investigate a ewe and to nudge her from both sides and rise to mount. Many of the encounters were provoked by the activity of entire males. A large ram (6 years old) sniffed castrates and performed kicks and twists towards them; on this occasion the castrates simply moved on. Occasionally castrates did urinate before moving off and then the ram would sniff the urine patch and make flehmen. Ram lambs were persistent in approaching castrates and 'annoying' them; these young males were butted and shown off by the castrates. The castrates were larger (at least taller) than most rams and so could hold their own and carry on with their own preferred activities.

Activity patterns

The proportions of sheep engaged in different activities over the daylight hours is set out in Fig. 4. Activity on five selected days in 1984 is presented extending from the end of October (pre-rut) to 20 November (near the peak of the rut). It will be seen that the ewes, as expected, spent most of the time grazing, and the castrates presented a similar pattern: throughout November the wethers spent between 60 and 70% of the daylight hours grazing. The rams, in contrast, show a progressive reduction in the time spent grazing and, by mid November, this proportion had been reduced to about 25% of the daylight hours (a result similar to that recorded in November 1964, see Grubb & Jewell, 1974, fig. 7.4).

Continuous records of the activity of selected individuals illustrate these activity patterns in more detail (Fig. 5). The distribution of bouts of grazing through the daylight hours demonstrate how intensively a ewe grazed (Fig. 5a). The castrate of Fig. 5b only differed in spending more time resting. The continuation of grazing through the afternoon and on into darkness characterizes the ewes and wethers. The record of a mature ram, however (Fig. 5c) shows how little time is spent grazing, most time being spent in moving or in social and sexual encounters. A castrate (Fig. 5d), recorded concurrently with the ram, was relaxed at midday, even apparently being asleep with its head on the ground, and showed the characteristic period of continous grazing as darkness supervened.

Discussion

This study was initiated to throw light on the marked difference in survival rate of rams and ewes in this feral population. The population is limited by food and experiences intermittent 'crashes' in numbers followed by recovery over a few years (Boyd, 1974); analysis reveals an exaggerated cycle of 'boom and bust' (T. H. Clutton-Brock *et al.*, 1991), but ewes survive better and live longer than rams despite the demands of pregnancy and lactation.

It was postulated in earlier research (Boyd & Jewell, 1974) that a key factor bringing about this difference was the feeding behaviour of the two sexes during the rut in late autumn. Support came from the observation that rams spend much less time grazing than ewes during the whole period from late October to early December (Grubb & Jewell, 1974). The hypothesis proposed at the outset of the present research was that castrated males should not participate in the rut and should not reduce the time spent feeding. This is exactly what has been found. The feeding pattern of castrates was similar to

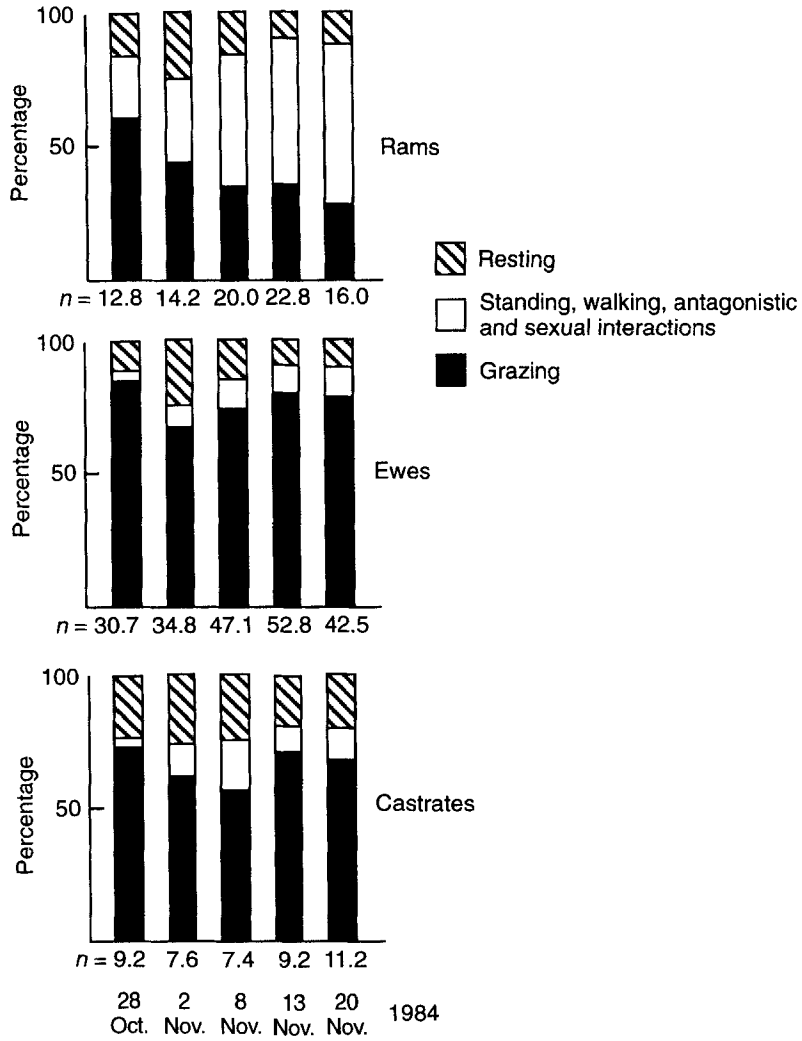

FIG. 4. The proportionate activity of sheep through the daylight hours, based on half-hourly scans, on selected days leading up to the peak of the rut (22 November) in 1984. *n* = the mean numbers of individuals seen at each half-hour scan.

that of ewes and their survival was even better. Stephenson (1994) has been able to support this interpretation by showing that ram lambs 'hormonally castrated' by the injection of a progestagen (which only lasts for the duration of the rut) spent more time feeding and survived better than intact ram lambs.

The effects of overpopulation are so severe that the prospects of survival of animals born into successive cohorts in pre-crash, crash, and post-crash years are markedly different (T. H. Clutton-Brock *et al.*, 1991, 1996). The castrates have survived four crash years and so have experienced several kinds of cohort- and age-related privations. This is a particularly revealing outcome of castration that permanently deprives males of the hazards and misfortunes of masculinity.

A notable feature of male life histories on Hirta is the precocity of rams. Ram lambs, at seven

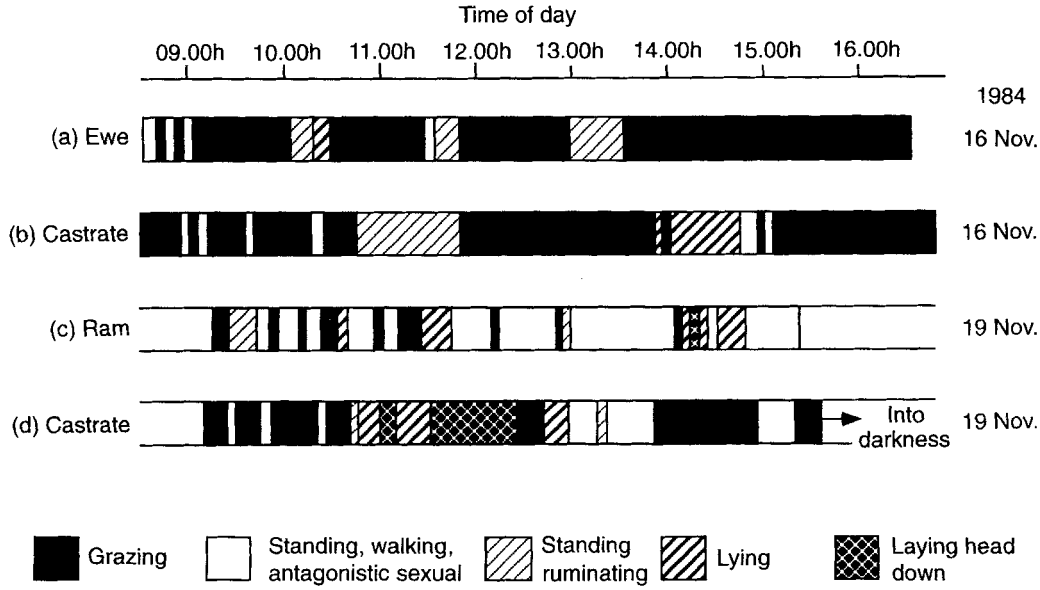

FIG. 5. Continuous activity records of sheep through the daylight hours in the first part of the rut in 1984.

months of age, join in the rut, and are even more persistent in their endeavours to mate as yearlings at 19 months old. I had thought (Boyd & Jewell, 1974) that the experience gained in this way, and possibly the improvement of their position in the hierarchy of young rams, conferred reproductive success that compensated for heavy mortality. But a further factor was identified when it became clear that the mortality of mature rams, in the winter that terminates in a crash, can be so severe that the young rams form the majority of the male population in the next rut (Jewell, 1989). The direct reproductive success that the young rams gain in this way has been established (Bancroft, 1993; Stephenson & Bancroft, 1995). Notwithstanding this benefit, it may be noted that the survival rate of castrates as lambs and yearlings was high, demonstrating the benefit of not participating in the rut at that age.

Physical castration alters many aspects of the anatomy and physiology of the male mammal affecting, amongst other things, the immune system, parasite load, and fat storage (Parkes, 1966; Glucksmann, 1978). (I observed castrated Soays, kept near Cambridge, to have considerable fat reserves in the omentum, and in commercial breeds of sheep, wethers are known to be relatively fatter than entire rams [Ritar *et al.*, 1988; Thompson & Butterfield, 1988]. Conspicuous deposits of fat, however, may give a false impression of adequate reserves since it has been shown that even the abundant fat reserves of reindeer suffice to meet only a small part of energy requirements in winter [Tyler, 1987*a*, *b*].) It must be noted that through most months of the year the survival rate of entire males and castrates is similarly good, and that deaths are concentrated in late winter in the months of February and March, when inanition takes its toll. Castration averts this disaster by promoting a continuous intake of energy through the late autumn and early winter. This results from the elimination of libido (Wodzicka-Tomaszewska *et al.*, 1981) and reduced aggressiveness of wethers (Mattner, 1980) and is not due to a difference in appetite because it has been shown in research on housed sheep (Gordon, 1964; Brown *et al.*, 1979) that wethers exhibit a reduction of voluntary food intake in winter in the same way as rams.

The longevity of the Soay castrates, at nearly 17 years, has been greatly superior to that of entire rams at 10 years (Grubb, 1974, also recorded a few rams surviving to this age). There is little published work that permits comparison with other mammals. Parkes (1966), quoting several authors, concluded that "in animals castration does not seem to have a beneficial effect on longevity". Data from humans are conflicting: Hamilton & Mestler (1969) showed that eunuchs living in an institution for the mentally retarded had better survival than entire men, but Darwin, in 1856, noted: "Yet Eunuchs nor cut Stallions nor nuns are longer lived" (Barrett *et al.*, 1987), and Nieschlag, Nieschlag & Behre (1993), in an analysis of historical documents on the longevity of male singers, found that the mean life span of castrati was not significantly different from normal singers. In cats (Hamilton, Hamilton & Mestler, 1969) and in rats (Talbert & Hamilton, 1965), castration does prolong life, and in observations on bank voles (*Cleithrionomys glareolus*) living in a natural outdoor enclosure it was shown that castrated males survived better than entire males (Gipps & Jewell, 1979).

The present observations comprise the first experiments in which a substantial number of castrates has been released into a free-living population. Short (1979), working on the island of Rum, observed two castrated male red deer calves (castrated within a week of birth) and these animals remained closely attached to their mothers, within their respective groups of hinds, for the rest of their lives. An unexpected and interesting outcome of the present study is that the wethers displayed two distinct types of social cohesion. Some individuals stayed with females, known to be, or presumed to be, their mothers, in their natal home-range groups, and behaved socially very like females throughout their lives. Other castrates associated together in their own permanent castrate groups and in this respect were like normal males. These groups were apparently given cohesion by mutual recognition and acceptance.

In physical appearance the castrates looked like ewes, even to the extent of showing similar horn types ranging from polled, through scurred (or crumple-horned), to horned. This effect of castration has long been known (Seligmann, 1906; Marshall & Hammond, 1914), but it is also certain that the odour of the castrates was changed (Izard, 1983). The different physical responses to castration have a genetic basis and it can be asserted that the different behavioural types, revealed by castration, have a genetic basis too (McGill, 1978). These novel observations would not have been revealed if adequately large numbers of lambs had not been castrated.

In their review of the ethology of free-ranging domestic animals, Arnold & Dudzinski (1978) make only passing reference to wethers, and they have not been the subject of any previously published studies of behaviour. Yet wethers have been of very great importance in animal husbandry from ancient times (Trow-Smith, 1957; Killen, 1964), through the Middle Ages (Lloyd, 1977–78; Ryder, 1983) and on into the present century (Fraser & Stamp, 1957). Even today, on the island of North Ronaldsay in Orkney, where the sheep are traditionally confined to the foreshore (Hall, 1975) and eat only seaweed, I have observed that a high proportion of the sheep are wethers and serve as a 'walking larder' (J. Clutton-Brock, 1989). The data presented here provide a new dimension to the many factors considered by Boyd & Jewell (1974) for the management of the Soay flock on Hirta.

I thank the National Trust for Scotland and Scottish Natural Heritage for permission to work on St. Kilda, and the St. Kilda Detachment of the Royal Artillery and the Royal Corps of Transport for logistic support. I am grateful to Howard Payton for his assistance in the field, to Professor Colin Finn MRCVS and Drs Robert Gibson and Philip Armitage for assistance with the castrations, and to Professor T. H. Clutton-Brock and members of the Large Animal Research Group at Cambridge for much help in collating information. Dr J. Morton Boyd, Professor Stephen Hall and Professor Roger Short kindly made valuable comments on a preliminary draft. I am grateful to the National Geographic Society for financial support.

Clients' Perspectives on the Effects of Laparoscopic Ovariectomy on Equine Behavior and Medical Problems

J. Lacy Kamm, DVM, and Dean A. Hendrickson, DVM, MS, DACVS

ABSTRACT

Because laparoscopic surgery eliminates the side effects of general anesthesia, the success and therefore the use of laparoscopic surgery continues to broaden. Laparoscopic ovariectomy, once only used to treat medical problems such as granulosa cell tumors, is now being expanded to treat behavioral problems in mares. Thirty-five mares with behavioral or medical problems were treated with ovariectomies, and their owners were later contacted and questioned concerning the effect of ovariectomy on their mares.

Behavioral improvement was seen in 83% (19/23) of mares treated for behavior-related problems. Aggression problems improved in 86% (12/14) of cases, general disagreeable demeanor improved in 81% (17/21), and excitability improved in 75% (12/16) of cases in which these behaviors were previously observed. Kicking and biting improved in 73% (8/11), problems in training improved in 72% (13/18), and frequent urination and problems with other horses improved in 64% (7/11 and 9/14, respectively) of cases.

Owners with nonovariectomized mares also were contacted to compare the normal progression of mare behavior over time with the behavioral change in ovariectomized mares. A statistically significant change in behavior of ovariectomized mares over nonovariectomized mares was seen in the categories of decreased aggression ($P < .01$), decreased training problems ($P < .025$), decreased frequency of problem behaviors ($P < .001$), and improved overall behavior ($P < .01$).

In cases in which medical problems such as granulosa cell tumors, ovarian cysts, and cycle-related colic were treated with ovariectomy, all of the clients were very satisfied with the treatment, whereas clients attempting to treat cycle-related laminitis were dissatisfied.

INTRODUCTION

Various techniques of standing equine laparoscopic ovariectomy have been described for the removal of equine ovaries by Dechant and Hendrickson,[1] Palmer,[2] Ragle and Schneider,[3] Hand,[4] and Hanson and Galuppo.[5] Standing laparoscopic surgery reduces complications associated with general anesthesia, which reportedly causes death in 0.12% to 0.9% of equine patients.[6,7] Laparoscopy requires multiple small incisions, with one to two incisions enlarged only enough to remove the ovary, thereby decreasing scar size and recovery time compared with other flank and ventral approaches. The approach described by Dechant and Hendrickson[1] uses three 1-cm incisions on the right, two 1-cm incisions on the left, and one incision on the left side large enough to remove both ovaries. The surgery can be performed in less than 1 hour using a localized bilateral flank block and an epidural between the first and second coccygeal vertebra.[1] Intraoperative pain can be decreased using a mesovarian injection of 10 ml 2% lidocaine before operating on the ovary.[8]

Complications associated with laparoscopic surgery are generally related to procedural errors.[1] These include injury to the sublumbar muscles, spleen, gastrointestinal organs, or kidney and can be reduced with careful technique. Other complications include incisional infection, inappetence, lack of hemostasis when using only one staple on the ovarian pedicle,[5] mild tachycardia postoperatively relating to abdominal discomfort,[1] and mild fever.[4]

Bilateral equine ovariectomy was first described for use in mares with behavioral problems in 1993.[9] The commercial success of mare hormonal supplements documents the strong desire for suppression of problem behaviors such as aggression, disagreeable demeanor, excitability, kicking and biting, training problems, problems with other horses, frequent urination, or problems during estrus. Removing the ovaries eliminates the production and release of estrogen because this hormone is primarily made in the theca and granulosa cells of developing ovarian follicles.[10] Estrogen is released during estrus, a potential time of increased aggression and behavioral problems, and has been found to be a contributing factor to mare behavioral problems.

The purpose of this report is to evaluate the clients' perception of the effectiveness of laparoscopic ovariectomies in correcting behavioral and reproductive medical problems in the mare. This study delineates the different types of mare behavioral problems that cause owners to seek an

ovariectomy and evaluates the likelihood that the frequency of these behaviors will be decreased after surgery. The benefits and consequences of ovariectomy by laparoscopic surgery versus the conventional ventral midline laparotomy are discussed.

CRITERIA FOR SELECTION OF CASES

Records of 80 horses were evaluated when either a unilateral (in most medical problem cases) or bilateral ovariectomy (in behavioral problem cases) had been performed between 1996 and 2005. Of 80 horses, 35 of the owners were available to survey, and all responses were included in the study. Because earlier cases were more commonly unavailable for follow-up, the average time between surgery and evaluation was 3.6 years. The longest follow-up was 9 years, and the shortest was 12 months. Seventeen owners of nonovariectomized mares were randomly selected and contacted. Temperaments of these control mares were unknown to the researchers before contacting their owners. The average length of ownership for control group mares was 5.4 years.

METHODS

A questionnaire was developed that contained questions relating to the overall satisfaction level of the entire experience, reasons for surgery, effectiveness of the surgery in resolving the primary behavioral (aggression, disagreeable demeanor, excitability, kicking and biting, training problems, problems with other horses, frequent urination, overall demeanor, and frequency of behavioral problems) or medical problems, healing time (incisional healing, return to work), and appearance of incision sites. Clients were contacted by telephone and asked 10 to 20 questions, depending on the primary problem. Owners of mares treated for behavioral problems were questioned on changes in the following behaviors after surgery: duration of heat (based on owner's perception), aggression to both people and other horses, training problems (such as disobedience), problems around other horses, frequency of urination, kicking and biting, excitability, frequency of problem behaviors, and overall demeanor. Owners of nonovariectomized mares were contacted and asked similar questions about changes in their mare's behavior. Clients chose answers from predetermined answer categories of return to activity, issues surrounding heat cycle, aggression to people and other horses, response to training, problems with other horses, overall satisfaction with experience, frequent urination, kicking or biting, excitement, overall demeanor, time to behavioral or medical change, and satisfaction with medical improvement. Responses were set at: very satisfied, satisfied, impartial, dissatisfied, or very dissatisfied. The mares were housed in whatever environment they were accustomed to after the second postoperative week.

Data were compiled using the answer choices of the clients and univariant descriptive statistics including chi-square tests, odds ratios, and confidence intervals were performed. Statistical significance in this study was defined as $P \leq 0.05$.

RESULTS

Of the 35 ovariectomized mares, overall satisfaction levels for behavioral and medical problems (granulosa thecal cell tumor, ovarian follicular cysts, cycle-induced colic, laminitis) was 57% (20/35) very satisfied, 20% (7/35) satisfied, 9% (3/35) impartial, 6% (2/35) unsatisfied, and 9% (3/35) very unsatisfied. Client satisfaction with ovariectomy as a treatment for behavioral problems was 52% (12/23) very satisfied, 26% (6/23) satisfied, 13% (3/23) impartial, and 9% (2/23) very unsatisfied. The most common source of dissatisfaction in behavior patients was a lack of behavioral change after surgery. Aggressive behavior and general disagreeable demeanor were most likely to be improved with 86% (12/14) and 81% (17/21), respectively, of cases showing these improvements. Aggressive behavior included threatening gestures and actions whereas a disagreeable demeanor included behavior such as ear-pinning and pawing. Excitability, kicking and biting at horses, and training problems including resistance to training, bucking, and other behaviors related to estrus were only slightly less likely to improve after surgery, with scores of 75% (12/16), 73% (8/11), and 72% (13/18), respectively. Problems with other horses and frequent urination were less likely to be altered, with 64% (9/14 and 7/11, respectively) improved in each category.

Behavioral changes in ovariectomized mares were compared with the changes observed over time in nonovariectomized mares. Owners of nonovariectomized mares were asked whether change had occurred in levels of aggression, disagreeable demeanor, excitability, kicking and biting, training problems related to estrus behavior, problems with other horses, frequent urination, frequency of problem behavior, and overall demeanor over the time of ownership. Problem behaviors were all of those listed previously, with additional behaviors not given as options. Changes in temperament were compared between ovariectomized mares and nonovariectomized mares to eliminate the variable of improvement with time rather than the improvement with surgery alone. Control mares were less likely to have behavioral problems than mares presented for ovariectomy, and therefore, they were less likely to show behavioral improvement.

In all categories studied, ovariectomized mares were more likely to have a decrease in the adverse behavior than nonovariectomized mares. Statistically significant (greater than 95% confidence interval) improvements of ovariectomized versus nonovariectomized mares were seen in the categories of decreased aggression ($P < .01$), decreased training problems ($P < .025$), decreased frequency of problem behavior ($P < 0.001$), and improved overall behavior ($P < 0.01$) (Table 1).

Table 1. A Comparison of Behavioral Changes between Ovariectomized and Nonovariectomized Mares over Time

Improved Behavior	Odds Ratio	95% Confidence Interval
Duration of heat	1.5	0.1–18.3
Aggression	17.5 (*)	1.1–154.4
Training problems	6.1 (*)	1.4–27.1
Problems around other horses	1.5	0.4–5.9
Frequency of urination	18.1	1.0–344.6
Kicking/biting	8	0.9–72.1
Excitability	3.5	0.9–14.2
Frequency of problem behaviors	21.3 (*)	3.7–121.6
Overall demeanor	6.8 (*)	1.6–28.9

NOTE. The statistics show the likelihood that a problem behavior will decrease in duration or frequency in an ovariectomized mare as compared with a nonovariectomized mare. Average follow-up for ovariectomized mares was 3.6 years after surgery, and average time of ownership for nonovariectomized mares was 5.4 years. Categories marked with a (*) are significant ($P \leq .05$).

Medical problems treated with ovariectomy in this study included eight mares with granulosa cell tumors, one with ovarian follicular cysts, one with follicular cysts and cycle-induced colic, and two mares with cycle-related laminitis in which the horses would show signs of acute laminitis when in heat. This did not appear to be associated with increased exercise. Mares with granulosa cell tumors had only one ovary removed, whereas the others had a bilateral ovariectomy. Ovarian follicular cysts were diagnosed on histopathology, and owner complaints were inability to become pregnant and cycle-induced colic. No research has been performed on cycle-related laminitis, and its existence is anecdotal. Overall satisfaction levels were 67% (8/12) very satisfied, 8% (1/12) satisfied, 17% (2/12) unsatisfied, and 8% (1/12) very unsatisfied. Sources of dissatisfaction were related to price of treatment and inability of the surgery to treat the problem. Eighty-three percent (10/12) of the clients with mares with medical problems were very satisfied with the treatment of the medical problem. The other 17% (2/12) of clients were very unsatisfied with the treatment. These two patients with very unsatisfied results were being treated for cycle-related laminitis. The owners of all mares (8/8) treated for granulosa cell tumors were very satisfied with the outcome of the procedure.

Age of the equine patient at the time of surgery played a role in the overall satisfaction levels of customers when treating medical problems. Owners of mares younger than 10 years that were treated for medical problems were unanimously very satisfied (4/4) with the outcome of the surgery. For mares 10 to 14 years of age and treated for medical problems, satisfaction scores were 67% (2/3) very satisfied and 33% (1/3) unsatisfied. Patients older than 14 years had a score of 40% (2/5) very satisfied, 20% (1/5) satisfied, and 40% (2/5) unsatisfied.

For behavioral problems, satisfaction and age of mares were not related. Mares younger than 10 years at surgery had scores of 42% (5/12) very satisfied, 42% (5/12) satisfied, and 17% (2/12) impartial. Mares aged 10 to 14 years had scores of 57% (4/7) very satisfied, 14% (1/7) impartial, and 29% (2/7) very unsatisfied. Patients over 14 years of age had scores of 75% (3/4) very satisfied and 25% (1/4) satisfied.

Healing time for laparoscopic ovariectomies was quantified by the time it took for the patient to return to full activity. Owners were asked to limit activity of mares for 2 weeks after surgery or longer if the incision sites appeared to be healing slowly. Owners gradually returned the mares to activity according to a schedule that they believed suitable. Fifty-four percent (15/28) of mares returned to their preoperative work level within 2 to 4 weeks of surgery. Another 29% (8/28) were in full activity between 1 and 2 months of surgery. The remaining 18% (5/28) took longer than 2 months. Cases of prolonged healing were attributable to infection of the incision site or inability of the owner to provide activity for the animal.

For the 83% (19/23) of clients who observed a behavioral change after surgery, most (16/17) of the clients noted the change in behavior occurred less than 1 year after the surgery. Forty-seven percent (8/17) observed the behavioral change less than 6 months after surgery, and another 47% (8/17) observed the behavioral change between 6 months and 1 year from the surgery date. Twenty-nine of 30 patients undergoing laparoscopic surgery were very satisfied with the appearance of the incision sites after healing. Almost all claimed that the sites were not visible through the horse's coat. One owner stated that white hairs appeared at the incision sites.

DISCUSSION AND CONCLUSION

The possible benefits of ovariectomy on behavioral problems has previously been reported by researchers at Texas Veterinary Medical Center.[9] This study found that 83% (10/12) of mares treated with a bilateral ovariectomy via colpotomy for behavioral problems obtained a higher level of performance after the ovariectomy was performed. Eighty-two percent (14/17) of the mares no longer had behavioral problems after the ovariectomy as reported by their owners, trainers, and referring veterinarians. When comparing the results of the earlier study with this study, satisfaction levels are comparable.

Based on the results of these studies, laparoscopic ovariectomy in the mare is a practical treatment for behavioral and medical problems. Bilateral laparoscopic ovariectomy proved successful in more than 75% of the mares with the behavioral problems studied. Most clients were very satisfied with the change in behavior that followed the surgery.

Some clients noticed only small changes in behavior, whereas a few clients were disappointed with the complete lack of improvement of behavior.

More generalized behavioral problems were more likely to be corrected with an ovariectomy than more specific behavioral issues. Aggressive behavior and a generalized disagreeable demeanor were most commonly corrected, followed by excitability, kicking and biting, and problems during training that related to estrus-like behavior. Problems with other horses and frequent urination were less likely to be improved after surgery; nevertheless more than half of the mares with these problems improved after surgery.

The results of this study were comparable with previous results, which stated that 20 to 35% of mares continued to have estrus-like behavior after having an ovariectomy performed.[2,9] It is generally accepted that ovariectomized mares can continue to be used for stimulating stallions for semen collection. In cases in which ovariectomy did not correct the behavioral problem, the inappropriate behavior can likely be explained as a learned response instead of one that is triggered by estrogen. However, in most cases, blood work was not performed before or after surgery to evaluate hormonal levels.

When comparing data between ovariectomized and nonovariectomized mares, ovariectomy proved favorable to time in improving behavioral problems. By studying the behavioral changes over time for nonovariectomized mares, variability for normal behavioral change with aging was taken into account. Data comparing the mares with a decreased frequency of a particular behavioral problem are listed in Table 1. The number of mares with an increased frequency of the behavioral problem was negligible in nonovariectomized mares and was nonexistent in ovariectomized mares. Behaviors that were most likely to decrease because of ovariectomy rather than aging were aggression, training problems, and frequency of problem behavior. Overall behavior also was improved.

Cycle-related laminitis was the only medical problem not helped by ovariectomy in this study. In both cases, the lameness associated with laminitis became more evident after estrus. Because only two patients with this problem were included, and the relationship between estrus and laminitis is only anecdotal, little can be concluded.

In this study, clients were satisfied with laparoscopic ovariectomy as a treatment for behavioral and medical problems, appearance of incision sites after surgery, and recovery time after the surgery. This study was based only on clients' opinions of the surgery and can be used to guide the veterinary practitioner to the likelihood that a client will be satisfied with the procedure. Standing laparoscopic ovariectomy can be considered a beneficial and safe method to treat mares with behavioral and reproductive medical problems.

Causes of natal dispersal and emigration and their effects on harem formation in Misaki feral horses

Y. KASEDA, H. OGAWA and ASHRAF M. KHALIL

Faculty of Agriculture, Miyazaki University, Miyazaki-shi, 889-21, Japan.

Keywords: horse; harem formation; Misaki; feral; behaviour; ethology

Summary

Misaki feral horses were separated into 2 herds and the difference between dispersal from natal group (natal dispersal) and dispersal from natal area (natal emigration) was studied. The causes of dispersal and emigration and their effects on harem formation were studied 1979–1994. The number of horses ranged from 73 (mature males: 8, mature females: 26, young males: 8, young females: 3, colt foals: 6, filly foals: 10 and geldings: 12) in 1979 and 86 (mature males: 14, mature females: 37, young males: 12, young females: 7, colt foals: 5, filly foals: 7 and geldings: 4) in 1994 when the present study ended. All 29 males which survived to age 4 years and 58 females which survived to age 3 years left their natal or mother groups at age one to 3. Seventeen of 22 dispersing males and 29 of 39 dispersing females left their natal groups around the birth of their siblings and significant correlations were found between natal dispersal and birth of a sibling. The number of emigrating young males correlated negatively and significantly with the total number of young males in another herd and the number of emigrating young females correlated positively and significantly with the total number of young females in the natal herd. All 13 emigrating stallions which survived to age 5 years formed stable harem groups and a significant correlation was found between natal emigration and harem formation. Twenty-three of 35 resident mares formed stable consort relations with harem stallions and a significant correlation was found between residence and formation of stable consort relations.

Introduction

Dispersal is a widely observed behaviour in many species. A number of proximate factors have been hypothesised, but these causes are not consistent even in equids (Rutberg and Keiper 1993). One of the important factors related to female dispersal is sexual maturity and first oestrus (Berger 1986; Tyler 1972; Penzhorn 1984; Rutberg and Keiper 1993). Oestrous mares are abducted from their family group by other stallions (Klingel 1969; Penzhorn 1984) or young mares in oestrus are sometimes met with aggression from older mares (Klingel 1982). Young males are often reported to leave voluntarily from their natal band (Klingel 1967, 1969; Tyler 1972; Welsh 1975). Prior to the birth of the next foal, a zebra mare becomes aggressive towards her previous foal and invariably threatens if it approaches her (Penzhorn 1984). However, when they do not foal or have lost their newborn foal most mares do not change in their behaviour towards their yearling (Klingel 1969; Feist and McCullough 1975, 1976; Kaseda *et al.* 1984; Tyler 1972). It seems that birth of a sibling is one of the proximate causes of natal dispersal. Dispersal of young males is affected by the presence or absence of peers in the natal group (Klingel 1969; Tyler 1972; Harris and White 1992). Rutberg and Keiper (1993) observed that male dispersal age was correlated with the number of peers in the natal group.

Greenwood (1980) stated that natal dispersal is a permanent movement from birth site to first breeding or potential breeding site. Bekoff (1977) proposed that dispersal is the movement of an individual from its natal site and out of the home range of its parent(s) to another site where it breeds. Berger (1986) stated that in equids it is important to distinguish between dispersal from the natal band and the natal area. In nonterritorial and harem-dwelling equids, 'dispersal from natal band' is easily understandable because it means separation from the parent's band, but 'dispersal from natal site' is difficult to define if the border of the natal band is not clear. Klingel (1968) reported that there was no evidence of any social organisation above the level of the families and stallion groups. However, Miller and Denniston (1979) and Miller (1982) proposed that 'a herd' is defined as a structured social unit made up of groups of horses that follow similar movement patterns within a common home range (McCort 1984). Assuming this social unit of 'a herd', dispersal from natal site can be considered to be a movement from the natal to another herd. The Misaki feral horse lends itself to a study of the difference between dispersal from natal band

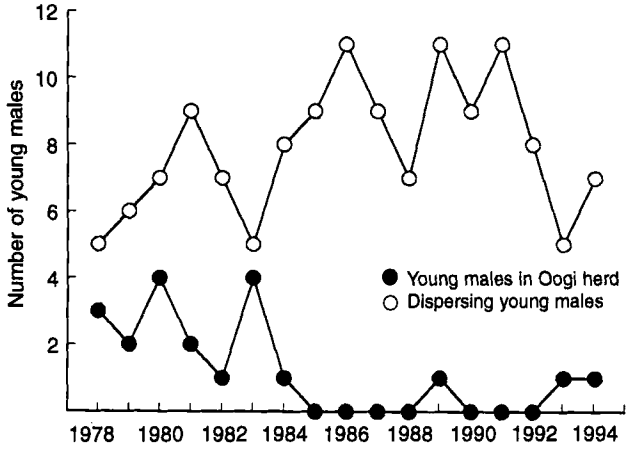

Fig 2: Change in the total number of young males under age 3 years in the Oogi herd and the total number of young males which moved from Komatsu to Oogi between ages one and 3 years. A negative and significant correlation was found between them (r_S = 0.517, n = 17, P<0.05).

(hereafter defined as natal dispersal) and that from natal site (hereafter defined as natal emigration), because the population is separated into 2 herds mainly by topographical conditions.

The purpose of the present study was to establish the causes of natal dispersal and emigration and their effects on harem formation in Misaki feral horses.

Materials and methods

Study area

The Misaki horse range covers an area of about 5 km^2 in Cape Toi, the southeast end of Kyushu Island. There are 2 hills in the centre of the Misaki range, Komatsu and Oogi, about 290 m above sea level. They are separated by 2 valleys which run down from the 2 mountains into the sea dividing the range into 2 areas, Komatsu and Oogi, which are similar in size, topographical and ecological characteristics. Komatsu and Oogi hills are covered with various kinds of native grasses, and other areas are occupied by artificial forests with Japanese cedars and a variety of copses.

Study animals and population characteristics

Misaki horses have been living freely in the range since 1697. Management practices are minimal and a small amount of

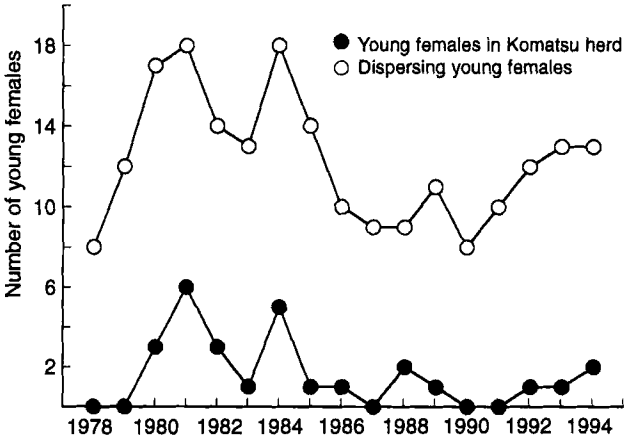

Fig 3: Changes in the total number of young females under age 3 years in Komatsu herd and the total number of young females which moved from Komatsu to Oogi between ages one and 3 years. A positive and significant correlation was found between them (r_S = 0.786, n = 17, P<0.01).

supplementary grass is fed during severe winters only. Since 1972, the range has been patrolled daily, in order to record any births, deaths or accidents; and the population dynamics of the horses and individual reproductive success and home range of each animal have been recorded. The number of horses ranged from 73 (mature males, 8; mature females, 26; young males, 8; young females, 3; colt foals, 6; filly foals, 10; and geldings, 12) in 1979 and 86 (mature males, 14; mature females, 37; young males, 12; young females, 7; colt foals, 5; filly foals, 7; and geldings, 4) in 1994, when the present study ended (Kaseda 1981, 1983, 1991).

Most animals were observed to move between Komatsu and Oogi from late September to late March, but very little movement between the 2 areas was seen during the breeding season from early April to late August (Kaseda 1983). It is, therefore, possible to separate Misaki horses into 2 herds (Komatsu and Oogi), according to their home range, during the breeding season. A herd in this context is defined as a structured social unit made up of harem groups which followed similar movement patterns within a common home range, as proposed by Miller (1981).

During the study period the number of stallions (≥ 4 years) ranged from 3–6 in Komatsu and from 2–7 in Oogi. The number of mares (≥ 2 years) ranged from 16–30 in Komatsu and from 8–20 in Oogi. About one half of animals (1–3 years) which left their natal groups or their dams and most geldings migrated from the Komatsu area to the Oogi area in the nonbreeding season. Some harem groups which were formed by all stallions with mature mares and maternal groups, which consisted of dams and their offspring, were found in the Komatsu area, while some harem groups, some mixed peer bands which consisted of young males and females, and a few gelding groups were seen to live in the Oogi area during the study period (Kaseda 1991). In Misaki feral horses, almost all mature mares were found to have stable consort relations with their harem stallions. However, some mares had no stable consort relations with any particular stallion and were observed to wander solitarily or with their offspring, remaining with particular stallions in order to mate during oestrus only transiently for a few hours or days (Kaseda *et al.* 1995). Maternal groups were usually formed by such wandering mares and their offspring. A few males were castrated because of their mixed breed during their third autumn from 1973 to 1979.

TABLE 2: Change in number of females in 5 group types relating to age

	Age (year) of female			
Group type	0	1	2	3
Natal harem	48	19	5	1
Mother[a]	10	14	3	
Other harem[b]		13		
Mixed[c]		12	30	25
New harem			20	30
Died				2
Total	58	58	58	58

[a]dam or dam and her offspring.
[b]dam and other stallion than natal harem stallion.
[c]nonreproductive young males and/or females.

Such geldings survived longer than intact males and had totalled 14 (60% of mature males) in 1980 and decreased gradually to 4 (22%) in 1994. Numbers of investigated young animals were 29 males which had survived to the age of 3 years and 58 females which had survived to the age of 2 years during the study period.

Field observation of social behaviour

Misaki horses were identifiable by their coat colour, sex, body size, markings and the number branded on the hip (Kaseda 1981). Every animal had been recorded individually in the stud book since 1972. Field observations were made twice or more a month between 1979 and 1987 and once a week between 1988 and 1994. When a horse was sighted in the field, the location and branded number of the animal, and its behaviour were recorded on field maps. In this way, data on members of social groups were collected throughout the study period. Detailed observations were made on the social behaviour, such as social relationships between stallions and mares and their offspring, group membership, and harem group formation of young stallions and mares.

Definitions of stability of consort relations between harem stallions and mares.

The horses were observed at least 8 times in the breeding season from early April to late August (at least once in April and August, and at least twice in May, June and July). A consort relation between a harem stallion and a mare was defined as stable if a particular mare was seen with the same stallion on every observation throughout the breeding season of one year. Consort relations were defined as unstable if a mare was found to change stallions or if she was seen to live solitarily or with her offspring on every observation.

Statistical analysis

Data are presented as means ± s.d. We analysed the data with 'Statview' and employed Spearmans rank correlations (r_s), Chi-squared tests on 2 x 2 tables and Fisher's exact probability test to estimate the relationship between 2 variables. The significance of all tests were established at $P<0.05$.

Results

Natal dispersal

Almost all foals were born in harem or maternal groups consisting of dams and their offspring. Out of 29 males which survived to the age of 4 years, 8 left their natal groups or dams at age one year, 14 at age 2 years and 3 at age 3 years, and all joined mixed groups. Six and 12 young stallions formed their stable harem groups at age 4 and 5, respectively (Table 1). Seven young stallions died between age 4 and 5 years. Out of 58 females which survived to age 3 years, 12 left their natal groups or dams at age one year and 18 at age 2 years (Table 2). Twenty 2-year-old females joined newly formed harem groups or existing harem groups and kept stable consort relations with their harem stallions. Thirty young mares (53%) became stable harem members at age 3 years. Eight females did not leave their natal or maternal groups at age 2 years and one female remained within her natal group until age 3 years, but no males and females were found to remain in their natal or maternal groups after age 4 years. All of the mares which remained in their natal groups after maturity (age 2 years or older) did not foal in their natal groups. Sex difference in age of dispersal from natal or maternal groups was not significant (males, 2.0 ± 0.86 years, n = 28; females, 1.98 ± 0.10 years, n = 58; t = 0.102, df = 84, $P>0.05$).

There were significant correlations in dispersing males and females, age one and 2 years, and both of siblings (males: 17 out of 20, $Ch^2 = 13.487$, df - 1, $P<0.001$. Females: 29 out of 39, $Ch^2 = 4.963$, df = 1, $P<0.05$).

Natal emigration

Investigation of movements of young animals between Komatsu and Oogi during the study period showed that animals under age 3 years moved more frequently from Komatsu to Oogi; conversely, horses age 4–6 years moved more often from Oogi to Komatsu (Fig 1). Five stallions which moved from their natal area (Komatsu) to Oogi between ages 1–3 years developed to their sexual maturity and then returned to their natal area and successfully formed new harem groups. The total number of young males which moved from Komatsu to Oogi between ages 1–3 years was found to correlate negatively and significantly with the total number of males under the age of 3 in the Oogi herd ($r_s = 0.517$, n = 17, $P<0.05$), but not with the total number of young males under the age of 3 in the Komatsu herd ($r_s = 0.455$, n = 17, $P>0.05$) (Fig 2). The total number of young females which moved from Komatsu to Oogi between age 1–3 years was found to correlate positively and significantly with the total number of young females under the age of 3 years in the Komatsu herd ($r_s = 0.786$, n = 17, $P<0.01$).

Differences in the age at which males (mean ± s.d. 1.93 ± 0.884 years, n = 15) vs. females (mean 2.04 ± 0.903 years, n = 22) first emigrated from their natal area were not significant (t = 0.362, df = 35 $P>0.05$). A significant difference was found for males in the ages at which young animals under age 3 years left their natal groups between nonemigrants (mean 2.57 ± 0.507 years, n = 14) and emigrants (1.60 ± 1.01 years, n = 15) (t = 3.292, df = 27, $P<0.05$), but not for females (mean 2.05 ± 0.695 years, n = 38) and (1.85 ± 0.587 years, n = 20) (t = 1.110, df = 56, $P>0.05$). Two of 15 emigrating males and 5 of 14 nonemigrating males died at age 4 or 5 years, but there was no significant correlation between emigration and death ($Ch^2 = 1.981$, df = 1, $P>0.05$) (Fig 3).

Relationship between emigration and harem formation

All 13 stallions which dispersed and survived to age 5 years successfully formed stable harem groups, while only 5 of 9 stallions which stayed in their natal area formed stable harem

groups by age 5 years. A significant correlation was found between emigration and harem formation ($Ch^2 = 7.062$, df = 1, $P<0.01$).

Seventeen mares emigrated from their natal area at age one year and only 2 of these joined existing harem groups, while 18 of 41 mares which stayed in their natal area until age 2 years joined existing or newly formed harem groups. Moreover, only 7 of 21 mares which emigrated at age 3 years were able to join existing or new harem groups, while 23 of 35 mares which stayed in the natal area until age 3 years formed stable consort relations with new harem stallions or existing harem stallions. There was a significant correlation for mares between residence in their natal area and formation of a stable consort relation ($Ch^2 = 5.494$, df = 1, $P<0.05$ at age 2 years; $Ch^2 = 5.533$, df = 1, $P<0.05$ at age 3 years).

For 2- to 3-year-old mares, a positive and significant correlation was found between stability of consort relation between mares and harem stallions and foaling rate in the next year ($Ch^2 = 7.999$, df = 1, $P<0.05$).

Discussion

Cause of natal dispersal

Individuals are generally born in permanent stable harem groups in wild and feral equids (Klingel 1969; Feist and McCullough 1975, 1976; Salter and Hudson 1982), but Misaki feral horses are sometimes born not only in harem groups but also maternal groups which consist of a dam and/or her offspring. Natal dispersal should therefore be observed in maternal in addition to harem groups. Many authors report various kinds of causes for dispersal from natal groups, but they are not always consistent even in equids. It is often reported that oestrus or onset of sexual maturity relates to female dispersal (Klingel 1969, 1982; Tyler 1972; Penzhorn 1984; Berger 1986; Rutberg and Keiper 1993). It seems that young oestrus mares are abducted by stallions other than their natal stallions, or that they often meet with a certain amount of aggression from their dams (Klingel 1982). However, some authors report that yearlings or 2-year-olds left their natal bands (Salter and Hudson 1982; Keiper 1986) and joined other mixed groups. Twelve one-year-old females were observed to leave their natal or maternal groups and join other mixed groups in the present study. Dispersal from natal groups is reported to be attributable to the birth of new siblings (Klingel 1969; Penzhorn 1984).

Almost all one- to 2-year-old males and females left their natal or maternal groups around the birth of their siblings and significant correlations were found between natal dispersal and birth of siblings in the present study. Detailed observations on the behaviour of dispersers around the birth of their siblings is needed to make clear the relationships between dispersal and birth of a sibling. However, it is probable that dispersal from the natal group may be affected, to a certain extent, by the birth of a sibling. Most mares are found either to threaten or avoid their yearlings or older offspring immediately before parturition when they approach to suck (Tyler 1972), but yearlings are sometimes allowed to suck if the mare failed to breed or lost its foal at an early age (Tyler 1972; Kaseda *et al.* 1984). These threatening or avoiding behaviours of mothers toward their offspring may be in preparation for their newborn foals and have the function of weakening or cutting the bond between dam and offspring (Klingel 1969).

It is reported that the number of intraband playmates influenced the ages at which dispersal occurs in Plain's zebra (Klingel 1969), but there was no association between the number of peers and dispersal age for feral horses in the Great Basin (Berger 1986). However, Rutberg and Keiper (1993) reported that male dispersal age was strongly and significantly correlated with the number of peers in the natal group and males dispersing with peers were significantly older than males dispersing without peers. On the other hand, some males who remained in their natal groups after the birth of their siblings were thereafter observed to leave with the siblings (Kaseda *et al.* 1984). However, the relationships between dispersal and number of peers in the natal group were not difficult to analyse because of very few examples in which dispersers had their playmates in the same group. Eighty-six per cent of females and males left their natal groups by age 2 and 3 years, respectively, but no definite proximate causes were found to explain every dispersal from the natal group. It is possible in wild and feral equids that the attachments or bonds of almost all young animals with their parents or dams may be gradually weakened by the mother's rejection of nursing or antagonistic behaviour of parents at the births of their siblings and their dispersals may be caused by such triggers as inducement of young stallions or playmates.

Cause of natal emigration

Dispersal from the natal group does not always mean dispersal from the natal area, because the natal area is usually in the home range of their parents in nonterritorial harem-dwelling equids. About a half of one- to 3-year-old males and females emigrated from their natal area to another area during the period of study. Young animals were mainly observed to move from Komatsu to Oogi because the number of foals in the Komatsu herd exceeded that in the Oogi herd until 1986, but only a few migrations between 2 areas were found thereafter because of the nearly equal number of young animals in both herds (Kaseda et *al.* 1991).

The highly negative correlation between total number of migrating males from the Komatsu herd and total number of young males in the Oogi herd indicates that migration of young males may depend on their density in the destination, in other words, that young males may emigrate when there are a few rival young males in their destination. On the other hand, a highly positive correlation was found between total number of emigrating young females from the Komatsu herd and the total number of young females in the Komatsu herd. This indicates that female emigration may depend on the density of the young of the same sex in a natal herd, and some of them may emigrate when density increases in their natal herd. Many authors report that dispersal is density-dependent and is related to regulation of population and improvement of reproductive success (Greenwood 1980; Reiter *et al.* 1981; Berger 1986; Flowerdew 1987; Clarke and Low 1992). Both sexes of the young animals seem to disperse in accordance with the density of same sex animals in their natal herd or destination (Kaseda 1991).

Effects of natal emigration on harem formation

Some remarkable sex differences were found in dispersal from the natal area in Misaki horses. More dispersing young males left their natal groups at a younger age and formed a new harem groups in their destination than did residents who did not disperse. Male dispersers exceeded residents in survivorship and ability to form harem groups. To summarise, it is possible that young potential males may actively leave their natal area for another area where they have a few rivals over mates and where

there is a high possibility of forming new harems, while 2- and 3-year-old resident females more easily joined existing or new harem groups and formed more stable consort relations with their harem stallions than dispersing females. It seems likely that young females who are socially subordinate and less potential in their natal herd may tend to disperse from their natal area to avoid competition for stallions in the existing or new harem groups, because individuals forced to disperse are frequently the socially subordinate, younger and weaker members of the population (Greenwood 1980).

Since harem stability directly affects the reproductive success of both sexes (Berger 1986; Stevens 1990; Kaseda *et al.* 1995), it is possible that natural selection would favour advantageous behaviour for the formation of stable harem groups: e.g. emigration of males from the natal area or residence of females in the natal area as observed in Misaki feral horses.

APPLIED ANIMAL BEHAVIOUR SCIENCE

Effect of natal dispersal on the reproductive strategies of the young Misaki feral stallions

Accepted 9 October 1998

Abstract

We have reported previously that there are two remarkable stages between the separation from the mother and harem formation for male Misaki feral equines. The first stage, in which the young stallion commits more time to social play than to aggressive interactions, starts after the separation and is called the developmental stage. The second stage begins immediately before the young males succeed in forming their own harems, and is called the pre-harem formation stage. The present study was carried out to investigate the behavioral characteristics of the young male Misaki feral horses in the pre-harem formation stage. We observed the behavior of a total of 12 young male Misaki feral horses once a week from January 1988 to March 1997. Seven young males started the pre-harem stage in the non-breeding season, and the duration of time spent at this stage ranged between 0.08 and 0.6 years, with an average of 0.3 years. The other five started in the breeding season, and the duration of time spent at this stage ranged between 0.01 and 3 years, with an average of 1.3 years. The difference between these two averages was significant ($P < 0.05$). Seven of 12 stallions formed harems at about same age as a result of the effect of the female-biased sex ratio which makes it easier for all stallions to obtain harems at 5 years old. During this pre-harem stage, the young males have been shown to join wandering female groups more frequently than mixed sex groups, other harem groups and bachelor groups. Hence, the young males have a good chance of picking wandering females with which to establish their own harems. The results suggest that the age of separation has a great effect on the reproductive strategies in males after separation through its effect on the duration of the period between

separation and harem formation in Misaki feral horses. © 1999 Elsevier Science B.V. All rights reserved.

Keywords: Feral horse; Young stallion; Pre-harem formation stage; Reproductive strategies

1. Introduction

Misaki feral horses live in a wild-like state and have occupied parts of Southern Japan for up to 300 years. The Misaki population is far from having been unmanaged. From 1697 to 1953, the breeding sex ratio was kept at 1 male to 20–30 females, almost all colts being removed (Kaseda, 1981). But until recently, little was known about their ecology and behavior. Attention has been paid to some aspects of the social behavior of young group-living equids in different areas of the world, such as their separation from their native harem groups and the causes underlying that separation (Klingel, 1969; Tyler, 1972; Welsh, 1975; Berger, 1986; Rutberg and Keiper, 1993; Kaseda et al., 1995; Khalil and Kaseda, 1997); other studies have been carried out on the reproductive success of the young stallions after they form their own harem groups (Kaseda and Khalil, 1996; Tyler, 1972). However, few investigations have been made on the period between the separation from their natal harem groups and subsequent harem formation for feral equids. Our investigations have shown that there are two remarkably basic stages during this period. The first stage starts just after the separation from the mother in which the young stallion commits more time to social play than to aggressive interactions: this is called the developmental stage (Khalil and Kaseda, 1998). The second stage, upon which no previous investigations have been made, begins immediately before the young males succeed in forming their own harems; this is called the pre-harem formation stage. In other words, all young males eventually separate from their natal bands or mothers, but the age of dispersal can vary considerably depending on the environmental circumstances (Waring, 1983). For example, young males may leave their natal groups voluntarily and earlier, when there are few peers in the group (Klingel, 1969; Rutberg and Keiper, 1993), or the birth of a sibling may be one of the main causes of the separation of young males in Misaki area (Kaseda et al., 1984). Finally, another proximate cause of male natal emigration is forced eviction by the stallion of the natal group (Berger, 1986; Rutberg and Keiper, 1993). Almost all young males leave their natal band or mother at between 1 and 4 years old, with the average age being 2.3 years old (Khalil and Kaseda, 1997). Therefore, most stallions form harem groups at the age of 4–6 years in the Misaki area (Kaseda and Khalil, 1996), and at 6–8 years in Great Basin horses (Berger, 1986). The Misaki feral horses lend themselves to the study of the possible causes for the differences in harem formation age among the young stallions due to the uneven breeding sex ratio and because they could be observed individually as a result of the small area of Cape Toi Island.

The objective of the present study was to provide an overview of some of the behavioral characteristics of the pre-harem formation stage. We analyzed the correlation between the different stages of the young males and their separation from their natal band until they formed their own harems, the effect of the female-biased sex ratio on the

behavior of the young stallions and suggest that the time of separation and the reproductive strategies of males for harem formation are related.

2. Materials and methods

2.1. Study location

Cape Toi, at approximately 5 km^2, is located at the southeastern end of Kyushu Island. There are two hills in the center of the Misaki range; Komatsugaoka hill (287 m above sea-level) and Oogiyama hill (295 m above sea-level). Numerous valleys (both small and large) are found throughout the range, dividing it into two areas, the Komatsu and Oogi areas, which are similar in size, and topographical and ecological characteristics. These hills are covered with various (kinds of) native grasses, and other areas of the range are mostly occupied by 'artificial' forests with Japanese cedars and a variety of copses (Kaseda and Ogawa, 1982).

The climate is moderate, with temperatures ranging from 4°C to 15°C in winter and from 24°C to 31°C in summer. June and July are rainy periods. Fresh water ponds are plentiful in the Misaki range. Generally, the warm climate and abundant rain provide lush vegetation in the summer.

2.2. Study animals and population characteristics

Misaki horses have been living freely in the range since 1697. Management practices are minimal and a small amount of supplementary grass is fed only during severe winters. Since 1972, the range has been patrolled daily in order to record any births, deaths or accidents, and the population dynamics of the horses and individual reproductive success and home range of each animal have also been recorded (Kaseda, 1981). This study was conducted from January 1988 to March 1997 and 12 young Misaki males were observed during this time. The number of horses ranged from 88 (mature males, 13; mature females, 43; young males, 9; young females, 6; colt foals, 5; filly foals, 5; and geldings, 7) in 1988 to 99 (mature males, 22; mature females, 41; young males, 11; young females, 7; colt foals, 5; filly foals, 10; and geldings, 3) in 1997, when the present study ended. In other words, Misaki female horses outnumbered males as adults and the differences of the sex ratio at birth were not significant when compared to the adult sex ratio which skewed more towards females (Table 1). Before 1980, almost all males other than males-to-be stallions had been castrated in their third autumn and left together with other horses on the pasture (Kaseda, 1981). Such geldings survived longer than intact males and had totalled 14 (60% of mature males) in 1980 and decreased gradually to 3 (14%) in 1997. In Misaki feral horses, almost all mature mares were found to have a stable consort relation with their harem stallions. However, some mares had no stable consort relations with any particular stallion and were observed to wander alone or with their offsprings, remaining with particular stallions in order to mate during estrus only transiently for a few hours or days (Kaseda et al., 1995). In the present study, every young male has been recorded individually on sketch maps since

Table 1
Sex ratio at birth (filly/colt) and adult sex ratio (mares[a]/stallion[b]) from 1988 to 1997

Sex ratio	Year

[b]Age 4 years and older.
There was no significance at the birth sex ratio ($P > 0.05$), but a significant correlation was found in adult sex ratio ($P < 0.05$).

1988. Almost all the horses spent a majority of their time on the grasslands from early April to late September. During the other seasons, they lived in the forests or in the weedy grasslands that face south (Kaseda and Ogawa, 1982). Individual horses were identified by their unique markings, such as coat color, sex, body size, marking, age [recorded as foal, yearling, immature (2 to 3 years old) and adult; each animal was considered to be in only one age class throughout a particular calendar year, and the age of all animals of the population is known through a birth date certificate] and the numbers branded on their hips. Because the horses were accustomed to the presence of people, they could be observed on foot from a distance of 5–15 m without affecting their normal behavior.

2.3. Field observation of social behavior

Observations of every animal had been recorded individually in the stud book since 1972. Field observations were made once a week or more during the study period. During the breeding season (from the end of March until the end of August), most of the males were found on top of the hill. Detailed observations were made on the social behavior of each group when the young males were allowed to remain within the group and to determine whether they would remain or enter any other particular group. During the non-breeding season (from September until the beginning of March), locating and observing the horses were not as easy because most of the groups had separated into small groups and then moved into the forests. Data on the behavior and movements of the young males were gathered by traversing routes through the study area on foot and by car. So when the known young males were sighted in the field, the location and branded number of the animal and its behavior were recorded on field maps. In this way, data on members of social groups were collected throughout the study period. The following behavioral categories were recorded on hand-held maps for each sighting: (1) the stability of the group and the amount of time each horse stayed in a particular group were recorded by observing their branded numbers during the association; (2) each time horses were observed associating with a particular group, the members of that group were checked to see if they were the same or different than at the last time of observation; (3) observing the stability (consort relationship) of the joining between the young stallion and the mare or mares during the breeding season. If this stability were

established, then the pre-harem formation stage was considered to have been completed from the first sighting of the joining between them. Young males which are known to have died before completing this stage were excluded from the data.

2.4. Definition of the stability of the consort relationship between the harem stallions and the mares

A consort relationship between a harem stallion and a mare was defined as stable if a particular mare was seen with the same stallion at least eight times in the breeding season of 1 year from early April to late August (at least once in April and August, and at least twice in May, June and July). Consort relationships were defined as unstable if a mare was found to change stallions or if she was seen to live solitary or with her offspring on every observation. Some mares were named wandering mares because they lived very often solitarily or with their offspring (Kaseda et al., 1995).

2.5. Demarcation of the commencement and completion of the pre-harem formation stage

The criteria used to decide whether the pre-harem formation stage had begun are as follows. Preliminary observations on the social organization of the males were made during their stay with their mothers or inside their natal band. Follow-up observations were made after their separation to make sure that separation was final (i.e., that they did not rejoin their mothers or natal band). From our investigation, the period between this separation and formation of new harems by the young males could be divided into two stages: the developmental stage and the pre-harem formation stage (Khalil and Kaseda, 1998). The developmental stage begins just after the separation of the young males from their natal band or mother. At the beginning of the development stage, according to the social groups in which they lived before they separated, the young males associated with three types of social groups. These were bachelor groups, harem groups and wandering female groups. During this period, males joined the three groups, mixed sex groups and sometimes were solitary. It was considered that these associations provided a good opportunity for males to acquire different behavioral patterns and experiences before they entered the next stage. At the end of the developmental stage, all young males become solitary for a time, suggesting the existence of a distinct phase between the developmental stage and the pre-harem formation stage, (3) the pre-harem formation stage, which starts after the males complete their transition period, and finishes when they form their own stable harems with their new mares.

2.6. Statistical analysis

The non-parametric Spearman rank correlation coefficient test was used for the correlation between the separation age and the number of days spent by the young males for the period between separation from the natal band and harem formation. Fisher's Protected LSD was used to evaluate differences in birth sex ratio and adult sex ratio,

average duration of the pre-harem formation stage in the breeding and non-breeding season. The significance of the test was established at $P < 0.05$.

3. Results

3.1. Starting season of pre-harem formation stage

As shown in Table 2, among all males, the duration of the pre-harem formation stage varied between 0.08 and 3.0 years. This variation was attributed to the season in which this stage commenced. Hence, of the 12 male horses living in the Misaki range, the period being from 1988 to 1997, seven started this stage in the non-breeding season, which began in late August and lasted until late March. Their pre-harem formation stage was characterized by a short duration which ranged between 0.08 and 0.6 years, with an average of 0.3 years. The other five male stallions commenced this stage in the breeding season, and their pre-harem stage was characterized by a long duration of time which ranged between 0.01 and 3 years, with an average of 1.3 years. The difference between the average duration of the pre-harem stages of the two season was significant ($P < 0.05$).

3.2. Social grouping association

In the pre-harem formation stage, the male horses associated with different social groups which were recognized as follows. (1) Bachelor groups which consist of two or three horses. The largest of these bachelor groups was composed of six horses. These

groups were formed by young males that had been separated from their natal band or their mothers, and/or by older males that had lost their harem members. (2) A harem group that consisted of a stallion and his harem. A harem consists of mares, juveniles and foals. (3) A wandering female group that is formed by young females separated from their natal band at adolescence and adult mares who had separated from their harem bands after their stallion had died. (4) A mixed sex group that consists of one or more young males, one or more young females and adult mares and their offspring. During the pre-harem formation stage, the number of days that the male horses spent associating with different social groups differed from male to male. In addition, these associations changed randomly from time to time. Furthermore, the young males associated with the same social group many times throughout this stage. Members of the same social group either remained unchanged, or were different at every observation time. The most time that young males spent during this stage was with wandering female groups, 1557 days (50.8%). The next was for associations with mixed sex groups, 843 days (27.5), then associations with other harem groups, 368 days (12%), and the shortest being the association with bachelor groups, 298 days (9.7%) (as shown in the Fig. 1).

3.3. Effects of natal separation on the reproductive strategy

The separation age among the 12 males studied here ranged between 0.7 and 3.9 years. After they separated, they began their developmental stage which was followed by the pre-harem formation stage which lasted until the males could form their own stable harems. In the present study, we found that the age of separation was correlated negatively but not significantly with the duration of the period between natal emigration and harem formation among all young stallions (Spearman $r_s = -0.492$, $n = 12$, NS). For example, the young males, M67, M16, M20 and M61, separated from their natal band at less than 2 years old and they formed their own harems at the average of 3.8 years after their separation. Other young males, M36, M74 and M42 separated at between 2 and 3 years old but the average duration spent until they had their harem formation was 2.9 years. The last five young males, M12, M57, M2, M6 and M23,

separated at more than 3 years old and formed their harems at an earlier average age of 2 years. Also, after separation, we find that regardless of age of separation and other variables, 7 of 12 stallions formed harems at about the same age (Table 3). Moreover, during our study period from 1988 to 1997, we found that more than 70% of the young stallions formed their harems at the age of 5 years old (Table 4).

4. Discussion

4.1. Starting season of pre-harem formation stage

Some researchers report that some harem groups become unstable and break into smaller units during the late fall and winter (Keiper, 1976; Miller, 1979). Furthermore, in the Misaki area, since the grass becomes poor in both quality and quantity and the grazing capacity tends to decrease after September, most horses are forced to transfer from the grasslands to other areas where there is enough food for the winter, in addition to water and shelter. Therefore, Misaki horses are usually forced to separate into numerous small groups and then move to their winter habitats (Kaseda, 1983; Kaseda and Khalil, 1996). Moreover, some mares have different winter habitats from their harem stallions, and live alone or with their offspring in their winter home range (Kaseda et al., 1995). So, 7 of 12 young Misaki feral stallions observed in the present study began their pre-harem formation stage in the non-breeding season which began in early fall and ended in late spring. During this time, there were many wandering females who had become separated from their harems, and joined mixed sex and wandering female groups, thus giving the young stallions a good chance to associate with a wandering mares to begin their own harems. Consequently, these young stallions spent only a short time in this stage, with the average time being 0.3 years for acquiring mares as the nucleus of a new breeding herd. These new herds established a stable consort relationship between the young stallions and their mares during the following breeding season. By contrast, the other five young stallions began this stage in the breeding season. During the breeding season, these young stallions tried to establish their own harems by stealing females from neighboring harems and mating with them, regardless of whether the females were in estrus or not, or of whether they were associated with other mares. However, these types of newly formed breeding bands are often unstable and the young stallions were displaced after only a few weeks or months. These young males spent a long time in the pre-harem formation stage, with the average being 1.3 years until they were successful in forming their own new harems.

4.2. Social grouping associations

During the pre-harem formation stage, the young stallions had many social associations with the different basic types of social groups (see Section 3), and they joined and then separated from these groups several times. Sometimes, the group consisted of the same members and sometimes of different members, giving each stallion a good chance to have various experiences that may have allowed him to bluff his way through fights and control his harem in future. Moreover, among these associations, the most frequently observed throughout this stage was that between the young male and the wandering female groups and the lowest one with the bachelor groups. Otherwise, in the developmental stage which starts just after separation, the young males have neither the prowess nor fighting skills needed to dominate stallions and achieve successful mating. So, they join bachelor groups more than other social groups to develop skills. However, in the pre-harem formation stage and after the young stallions have completed their

previous stage, they usually attempt to herd various mares before eventually succeeding in establishing a herd of their own through joining wandering female groups. In addition, throughout this stage, mutual recognition may have contributed to the attraction between two animals because the males were seen with the same groups with the same members many times during this stage.

4.3. Effects of natal separation on the reproductive strategy

Parental care of foals is basically given by the mother. Quickly after birth, the mother develops a close association with her foal and then provides it with its nutritional and productive needs (Waring, 1983). Moreover, the mare has a uniquely close relationship with the newborn, refusing to leave it from the moment of birth (Fraser, 1992). Our observations indicated that the duration of the period between emigration of the young males from the natal groups or mothers and harem formation is affected by the age of separation. For example, the males who leave their natal groups at less than 2 years of age are obviously not yet adult (Berger, 1983). Thus, they had less experience as to how prepare themselves to acquire mares by short and easy ways and spent a longer time until they successfully established their own harems than other males that separated later. Commonly, after weaning, the mares and her offspring maintain some degree of companionship that may last into adulthood or only until the offspring becomes sexually mature. Therefore, the young stallions acquire many essential ingredients for normal development such as, survival, play fighting, engagement in mutual grooming, mounting attempts, skills they will need to be successful adults, and were able to exhibit a strong attraction to any available mares (Tyler, 1972; Waring, 1983; Kiley-Worthington, 1987). Furthermore, remaining with the mother for a prolonged period is a good opportunity to play more with numerous peers in the same natal band. These results are also consistent with the proximate hypothesis of Bekoff (1977) that young animals with the least interaction with peers develop the weakest ties to the group, and disperse earliest, suggesting that peer interactions may be an essential component to the development of fighting skill and hence, the achievement of a harem after short time. In addition, in Misaki area, the young stallions formed harem groups between 4 and 6 years of age (Kaseda and Khalil, 1996), and the population of Misaki horses is highly female-biased sex ratio, suggesting that the skewed sex ratio may make it easier for all stallions to obtain harems at the same age. Hence, we found that the relationship between mares and their colts before separation had a great effect on the reproductive strategies in males after separation which leads to shortening of the period until they acquire their own new harems.

Relashionship between Plasma Testosterone Concentrations and Age, Breeding Season and Harem Size in Misaki Feral Horses

Ashraf M. KHALIL, Noboru MURAKAMI[1)] and Yujiro KASEDA

Laboratories of Animal Behavioral Science and [1)]Veterinary Physiology, Faculty of Agriculture, Miyazaki University, Miyazaki 889–2100, Japan

(Received 21 October 1997/Accepted 9 January 1998)

ABSTRACT. Jugular vein blood samples were collected from 23 young and sexual mature feral stallions to examine the relationship between plasma testosterone concentration and age, breeding season or harem size. Testosterone concentration increased with the age of the stallions until they formed their own harems, at about 4 to 6 years old. Seasonal variations in testosterone concentrations were observed, and found to be significantly higher ($P<0.001$) throughout the breeding season than non-breeding season, from 3 years of age. Testosterone levels were correlated with harem size for individual stallions. It can be inferred from these results that there is a relationship between plasma testosterone concentration and age, breeding season and harem size. — KEY WORDS: equine (wild), harem, testosterone.

J. Vet. Med. Sci. 60(5): 643–645, 1998

Testosterone is the hormone responsible for libido in mature stallions. Domestic stallions are sexually mature at about 16 months or older [6], while wild horses take at least 3 years [10]. It has been demonstrated, in domestic horses, that immature stallions have lower testosterone concentrations than the mature stallions, and that blood testosterone levels are higher during the breeding season than non-breeding season when they are mature [1, 4, 15]. These finding have also been observed in the wild and feral horses [9, 10, 15]. High testosterone levels during the breeding season leads to seasonal changes in libido [1], followed by a marked increase in the sperm and seminal fluid production rate for increased copulation and mating in the breeding season [1, 7]. When they have formed a successful harem, changes or individual differences in harem size between stallions may possibly be influenced by some factors which affect their reproductive success such as age [9], body weight and fighting abilities [2], or dominance and aggressiveness behavior [13]. Previous studies have concentrated on seasonal changes in the testosterone levels of domestic and wild stallions, but there have been no investigations into its role in harem formation and consequent effect on changes in harem size. In this study, therefore, we at first measured testosterone concentrations before and after sexual maturation or beginning of harem formation. Then we compared levels between breeding and non-breeding season in Misaki feral horses and examined the relationship between plasma testosterone levels and harem size in individual stud horses, by sampling over two consecutive years.

The study area is located on the Misaki range (about 500 ha) where the horses live in natural conditions, without human management, throughout the year. The Misaki range is divided into two areas: the Komatsugaoka area (287 m above sea-level) and the Ogiyama area (295 m above sea-level), and numerous small and large valleys that run down in all directions from them. The climate is moderate with the temperature ranging from 4°C to 15°C in winter and 24°C to 31°C in summer. June and July is the rainy season. Fresh water ponds are plentiful in the range. The grasslands are restricted to the upper area (about 40 ha) half way up the two hills (about 290 m above sea level) which are located in the center of the range and covered with various kinds of native grasses. Other areas of the range are mostly occupied by artificial forests with Japanese cedars and a variety of copses [8]. Generally, the warm climate and abundant rain provide a lot of vegetation in summer. In the first experiment, twenty-three feral male horses, ranging from 1 to 6 years of age, were used to determine the relationship between testosterone levels and age, or breeding season. All animals were in good physical conditions during the experiment. Individual horses were readily identified by the number branded on the hip. Almost Misaki horses were individually recorded the birth date and parents (identified by DNA analysis). Blood samples were collected four times every two weeks from 23 individual horses in May and June of 1994, and mean values of testosterone for each were obtained. These data was used to relate testosterone concentrations to age for the breeding season. Similarly blood samples were collected four times every two weeks in October and November of 1994, to provide data for the non-breeding season.

In the second experiment, we randomly selected 7 males at different ages (4–9 years old) with or without a harem, and examined the change of harem size and testosterone levels during two Breeding seasons from 1993 to 1995, in order to investigate their relationship. Blood samples were collected from the 7 individual males in May of both 1994 and 1995 and harem formation was observed. The horses were extremely dangerous to handle and were restrained with Xylazine as recommended by Dodman [5]. A dose of 4 mg/kg body weight was injected using a special syringe, fired from a blowgun at a few meters from the horse (hind quarter), for accuracy. Some of the horses never adjusted to the restraint procedures and so we tried again on other days. Blood samples were taken by jugular vene puncture into heparinised tubes and placed on ice, plasma was obtained by centrifugation and was stored at −20°C until

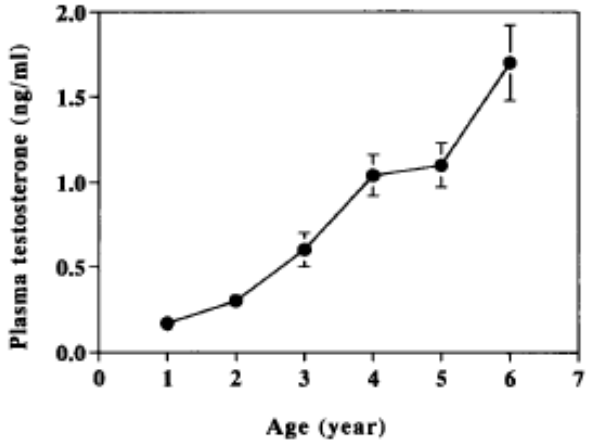

Fig. 1. Plasma testosterone concentrations at different ages in Misaki feral horses. The symbols and vertical bars represent mean ± SEM (n=4: 1, 2, 3, 4, 6, 7 years old; n=3: 5 years old). Blood samples were collected four times every two weeks in May and June from 23 individual horses and mean values were obtained, for each. Harem formation was observed in horses over 4 years old. Testosterone levels increased linearly except for in 5 years old. No significant differences were observed in analysis of values of 1 vs 2 years old, 4 vs 5 years old.

analysis.

Plasma testosterone concentration was measured by modified radioimmunoassay [14]. The specific antibody to testosterone was a gift from Dr. Etoh (Miyazaki Univ., Japan). Androstenedion (3.1%) was the only steroids, other than testosterone, with any significant reactivity. The ^{3}H-testosterone was purchased from New England Nuclear (England). The free and antibody-bound testosterone were separated by the dextran coated charcoal method. The lower and upper detection limits of the assay were 3.15 and 2,000 *n*g/tube, respectively. The intra-and inter -assay coefficients of variation for plasma testosterone were 14.5% and 5.9%, respectively. Data was evaluated by analysis of variance (Anova) and tested for significance with Duncan's new multiple range test.

The plasma testosterone of 23 young and sexually mature males in the middle of the breeding season had increased as a result of an increase in age from 1 to 6 years old (Fig. 1). These data included all samples from stallions with or without harems. However, stallions at 3 years old and younger did not appear to form harems. There were significant differences in testosterone concentration between the age groups ($p<0.001$). The testosterone levels were very low for 1 and 2 years old, and thereafter rapidly increased for 3, 4 and 6 years.

Figure 2 shows testosterone concentrations in the non-breeding and breeding season among different ages of male horses from 1 to 6 years old. Although no significant seasonal differences were observed in stallions of 1, 2 years old, all plasma testosterone levels were higher in the breeding season than non-breeding season, over 3 years of age. These differences were significant ($p<0.01$).

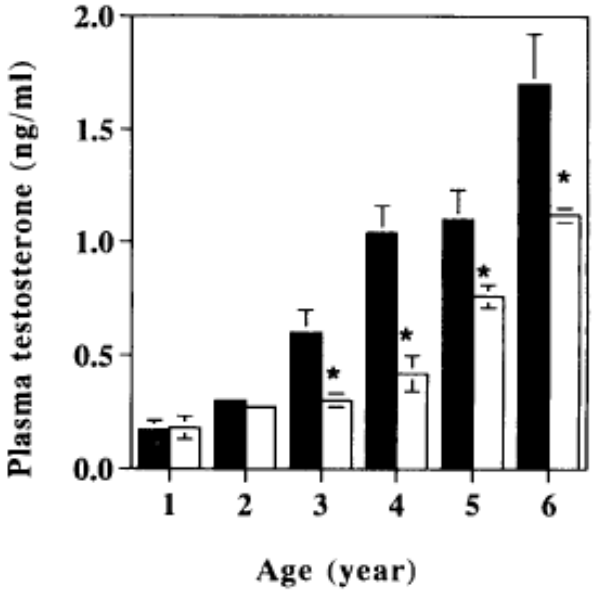

Fig. 2. Comparison of plasma testosterone levels between breeding and non-breeding season in Misaki feral horses. The black and white bars represent the mean value of breeding season and non-breeding season, respectively. The vertical bars represent the standard error. All samples were collected from the same horses as shown in Fig. 1. The blood samples for non-breeding season were collected four times every weeks in October and November. The asterisks represent the significant differences vs those of breeding season.

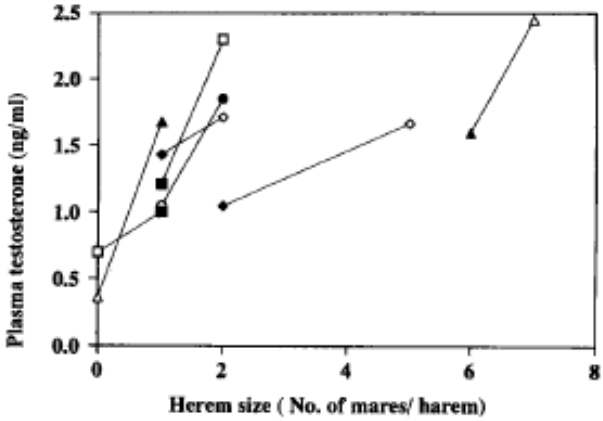

Fig. 3. Relationship between plasma testosterone levels and harem size (number of mares/ harem). Blood samples were collected from 7 individual males over 4 years old in May of both 1994 and 1995. The white and black symbols represent the testosterone value of the first and second year, respectively.

In the second experiment, 2 out of the 7 males were bachelor in the first breeding season, but acquired mares in the next season. A further 4 out of the 7 males decreased the number of mares in their harems in the second breeding season. The remaining males increased its mares from 6 to 7. In theses cases, as shown in Fig. 3, plasma testosterone concentrations increased and decreased in parallel with the

increase and decrease in the number of mares.

Generally, domestic stallions attained their sexual maturity after 16 months old [6], while the wild stallions became sexually mature at 3 years or older [11]. In both cases the testosterone concentrations in immature stallions were minimal compared to mature stallions. This is consistent with our results from feral horses which were mature at 3 years, because the young male horses had significantly lower testosterone concentrations than the mature horses ($p<0.05$). Also, the plasma testosterone concentration increased steadily with advancing age, suggesting a relationship between its concentration and the age of males up to harem formation, which generally starts from 4 to 6 years in Misaki feral stallions [9].

The finding of the present study is that the 1 and 2 year-old males had a lower serum level of testosterone and a similar level in the non-breeding and breeding season. These males were still immature with a reduced libido, which is consistent with the results of Chaudhuri and Ginsberg [3] who noted that males that have access to females, excrete more androgen than non-breeding males. Whereas, mature stallions (3 years or older), have a seasonal pattern of testosterone concentrations which were significantly higher in the breeding than the non-breeding season ($p<0.01$). These results are consistent with the hypothesis that seasonal changes in plasma testosterone can be correlated with seasonal frequencies of mating, copulation and seasonal variations in libido. It may therefore be suggested that this behavior, displayed in feral horses, may be an androgenic effect [16].

Testosterone concentrations can be shown to be closely associated with harem size, from our results. Plasma testosterone concentrations increased and decreased in parallel with an increase and decrease in the number of mares. Although there were few data, plasma testosterone was at very low levels in bachelors ($n=2$). These observations are in agreement with the data reported by Kirkpatric, *et al.* [10] who showed that testosterone concentration of bachelor stallions was significantly lower than of stud stallions. These results are consistent with the hypotheses that the presence of females may be a social stimulus influencing testosterone secretion [3], and that individual differences in harem size among feral stallions may be influenced by testosterone concentration, which affect the reproductive success of stallions. However, there may be many complex factors involved in determining harem size, such as avoidance of the parent-child relationship, strength of aggression of males, mental factor of mares. Therefore, although the testosterone levels may be associated with harem size, it is not known whether they are a predominant factor for harem size.

In this study, we used chemical immobilization to collect the blood samples for determination of the net testosterone value. However, their significance may not justify the chemical immobilization of wild creatures. We are now trying to carry the study non-invasively by means of fecal hormone measurements.

Habitat use and spatial dynamics of takhi introduced to Hustai National Park, Mongolia

Sarah R.B. King [1], John Gurnell *

School of Biological Sciences, Queen Mary, University of London, Mile End Road, London E1 4NS, UK

Received 27 August 2004

Abstract

The successful introduction of captive bred takhi or Przewalski's horse, *Equus ferus przewalskii*, into Mongolia in the 1990s is a good example of the benefits of ex situ conservation and one of the few examples of the recovery of an animal after it became extinct in the wild. This is also particularly interesting because virtually nothing was known about how takhi lived before they died out, and the introductions have enabled us to study how they have settled, and their ecology and behaviour within their former natural range. In this paper, we describe the movement, home range size and shape, and habitat use of takhi at one of the release areas, the 570 km^2 Hustai National Park in Mongolia. Harem home ranges varied between 129 and 2399 ha, with 80% core areas of between 61 and 1196 ha. There was no relationship between range size and harem size, or length of time since release. Initially, harems stayed near their release enclosures, but over time they established home ranges further away. There was little overlap between home ranges of different harems, but neither was there evidence of exclusive range use. The more nutritious vegetation at lower elevations was preferentially selected. Thus the present situation looks good, but, as the population continues to grow, we anticipate that there will be potential problems related to intraspecific competition for water and vegetation resources, and the potential for hybridisation with domestic horses belonging to the local people. We consider the time it may take for takhi to reach carrying capacity within Hustai National Park and emphasise that continual monitoring of the population is essential because interventional management is likely to be required in the future.

1. Introduction

Collections of animals and plants are increasingly being seen as opportunities for ex situ conservation, notably with respect to captive breeding programmes and subsequent release of captive-bred animals back in to the wild. However, to date there have been few successful examples of such a strategy; approximately 27% of the 116 reintroductions considered by Fischer and Lindenmayer (2000) were classified as failures, with the success of a further 47% not known. Moreover, the respective roles of ex situ and in situ conservation strategies are open to debate (e.g. Balmford, 2000; Entwistle and Dunstone, 2000). Captive breeding and reintroductions are lengthy, complex and expensive processes (IUCN, 1995; Balmford, 2000) but may be vital for the survival of a species in the wild (e.g. Spalton et al., 1999; Kleiman and Rylands, 2002).

Before reintroduction of captive bred takhi or Przewalski horses, *Equus ferus przewalskii*, into Mongolia in the 1990s, the last authenticated sighting of a takhi in the wild was in 1969, near the Tachyn-shar mountains

doi:10.1016/j.biocon.2005.01.034

in the western Gobi desert (Bouman and Bouman, 1994). The captive population of takhi in European and North American animal collections is descended from animals captured at the beginning of the 20th Century. In 1945, only 31 horses remained in captivity, and only nine of these bred. A species survival plan was set up in the USA in 1979, followed in 1986 by a European breeding programme (Europaisches Erhaltungzucht-Programm or EEP; Bouman and Bouman, 1994). By the start of the 1990s, there were more than 1500 horses in captivity. In 1992, reintroductions began to Tachyn Tal, by the German Christian Oswald Foundation and the Mongolian government, and to Hustai National Park, by the Dutch Foundation Reserves Przewalski Horse in association with the Mongolian Association for the Conservation of Nature and the Environment (Bouman, 1998).

For animals kept in captivity for many generations, there is a potential for loss of genetic variability (Foose, 1986; Ryder, 1986; May, 1991) or attenuation in survival skills (Box, 1991; Brock et al., 1994; Shepherdson, 1994; McPhee, 2003; Mathews et al., 2005). Thus there was concern that released takhi would not be able to survive after being bred in captivity for 13 generations (Klimov and Orlov, 1982). Moreover, there was no knowledge about the ecology of takhi in the wild before they became extinct, and so it was not clear how the released animals would cope in their new surroundings.

Between 1995 and 2000, we carried out a series of studies on the behaviour and ecology of released takhi in Hustai National Park. In this paper, we report on the spatial dynamics and habitat use of the horses. Against the background of changes in population size during the study period, we consider the establishment of home ranges by the harems in relation to their release point, size, interrelationship between the ranges of different harems, and utilisation of the habitat within these ranges. Finally, we consider what might happen in the future as the population continues to increase. By examining these factors we hope to be able to provide information on a reintroduction that currently appears successful, with an aim to helping future reintroduction projects.

1.1. Study site

Hustai National Park is 150 km south west of Ulaan Baatar, the capital city of Mongolia. It covers 570 km^2 along a southwestern spur of the Khentei range of mountains (47° 41′ N, 105° 54′ E). It was made a reserve in 1993 and designated a National Park in 1999. Hustai National Park borders the Tuul River, with an altitude of between 1100 and 1842 m and a continental climate (mean annual temperature = 0.2 °C and yearly rainfall = 270 mm, most of which falls in the summer; Wallis de Vries et al., 1996). During the study, horses were observed in temperatures of between −14 and +34 °C. Hustai National Park has a mountain forest steppe habitat that consists of steppe, meadow, grassland, shrub and woodland communities (Wallis de Vries et al., 1996). Water flows down most of the major valleys as streams, which are permafrost fed and covered by gravel at places along their length.

1.2. Study animals

Between 1992 and 2000, 84 horses were brought to Hustai National Park from reserves in Europe, where they had been kept in large (over 40 ha) grassy enclosures. The horses were released as a harem into acclimatisation enclosures of 40–45 ha; these enclosures were a minimum of 4 km apart and visually separated from each other. Although most of the horses had been kept together in Europe and were released together, others were introduced on arrival in Mongolia. Harems are referred to by the name of the dominant stallion (see Table 1). One harem was given a hard release (Turgen's harem), but other releases followed a 6–24 month acclimatisation period. Up to four harems other than the ones studied were also present towards the end of the study period (see Table 1).

2. Methods

Mongolian rangers and biologists gathered positional data of the harems at Hustai National Park for the full year from 1995 to 1997, and for the winter months (December to March) from 1998 to 2000. Detailed observations were carried out by the first author between June 1998 and July 2000, totalling 860 h. The standard procedure was to find a harem at dawn and follow it until 1400 h. The same harem was located at 1400 h the next day and followed until dusk. Every 10 min during an observation session the position of the harem was recorded with a Global Positioning System and marked on a large-scale map, together with weather details. Once accustomed to the presence of the observer, the horses were watched on foot from a distance of about 15 m and their behaviour recorded; these results will be considered elsewhere (see King, 2002).

The per capita growth rate per year for harems with more than three years of census data have been estimated using the formula $r = [\ln(N_t/N_0)]/t$, where N_t is the number of animals alive t years after reintroduction, and N_0 is the number of animals released (Komers and Curman, 2000). Where mares changed harems, for the purposes of this calculation they were included in the harem with which they were released. However, because mares move between harems, and the number of horses per harem is likely to decrease over time as the number

Harem range area = 95% kernel estimates, core area = 80% kernel estimates. a = wild born bachelor stallion acquired mares. b = harem hard released from travelling crates near release enclosure 1. There was no difference in mean home range size or mean core area among years, irrespective of harem (home range: $F_{5,\ 15} = 0.56$, $P = 726$; core area: $F_{5,\ 15} = 0.78$, $P = 0.578$; these include the data for Ares). Mongolian rangers collected data prior to 1998. * = data collected by SRBK; † = no data.

of stallions competing for mares increases (Linklater and Cameron, 2000; Linklater et al., 2000), changes in numbers of individuals within harems do not reflect overall population growth. Thus, we also consider population growth based on changes in population numbers between 2002 and 2004 (see Anonymous, 2004); no further introductions took place after 2001.

Home range and habitat use data were analysed using Arcview 3.2. One hundred per cent and 95% kernel harem range areas were calculated (see Worton, 1989; Seaman and Powell, 1996; Hooge and Eichenlaub, 1997), the latter excluded occasional forays outside the areas. Utilisation curves were used to estimate core areas; in all cases these were 80% of the total range area (King, 2002).

ANOVA was used to test whether the yearly range areas since release changed in a systematic way. Paramatric or non-paramatric correlation techniques were used as appropriate to compare the area overlap of each yearly harem range with the range in its previous year, and the movement of range centres from one year to the next. Harem range use was examined according to season and temperature using Kruskal–Wallis tests, because the data were not normal. For analyses of seasonal and altitudinal effects on activity, movement, and range size, the yearly range or core areas for particular harems have been treated as independent.

Eleven vegetation categories or habitat types were distinguished within Hustai National Park (Wallis de Vries et al., 1996). The areas covered by the different habitat types within each home range, and those that were grazed or used for shelter or water, were measured, and habitat selection indices (Manly et al., 1993) calculated. Preferences were formulated using χ^2 tests. The seasonal (spring – March to May, summer – June to August, autumn – September to November, and winter – December to February) use of vegetation was based on data from all years and this was compared with the vegetation available to them within their total range area over all years.

3. Results

3.1. Numbers and density of horses

Of 115 foals born between 1994 and 2001 (Table 1), 57% were still alive at the end of the study reported here (see Anonymous, 2004, for an update of population numbers). Twenty-six per cent of deaths were caused by babesiosis (piroplasmosis), which particularly affected newly released horses (three died from this in 1998 and nine in 1999; previous deaths from this disease are also possible, but were not diagnosed). Most other deaths were foals (63% of all deaths). In each year (1995–2000), on average, foals made up 25% of the population, and 12% of the population died. The increase in births in 1998 was mostly produced by three free-ranging harems (19 of the 25 births). Predation by wolves, *Canis lupus*, was low with a mean of 2.8 horses taken each year, all one year old or less (16% of all foals born between 1994 and 1999). It appears unlikely that predation affected population growth at the time of the study.

In July 2000 there were 91 free ranging horses, a density of 0.2 horses km^{-2} over the entire Park. The yearly mean density of horses within a harem between 1995 and 2000 was 1.8 horses km^{-2} ($N = 24$ harems, SD = 1.3 horses km^{-2}, range from 0.5 horses km^{-2} for Patron in 1995 to 5.4 horses km^{-2} for Margad in 2000). In 1995, 1996 and 1998 the home range and size of every harem was known. The density of horses over the area covered by these harems was 0.8 horses km^{-2} in 1995, 1.2 horses km^{-2} in 1996 and 1.8 horses km^{-2} in 1998. In 1999, density of harems within Hustai National Park was 0.01 harems km^{-2} ($N = 7$).

The per capita growth rates (r) of three reintroduced harems with census data spanning more than three years were: Paritet 0.69 – 1995 to 2000, Patron 0.65 – 1994 to 2000, and Khaan 0.79 – 1994 to 1998. Thus, these harems were very successful and doubled in size over these time periods. However, Khaan lost half his harem in 1999 to Margad when numbers dropped from 22 to 11 (Table 1), and he subsequently lost the rest of his harem the year after. A more realistic indication of population growth rate can be obtained by considering population numbers after 2001, when no further introductions took place. In 2002 there were 142 horses in Hustai National Park, and this increased to 162 horses by June 2004, of which 84 were reintroduced (Anonymous, 2004). This gives an overall per capita growth rate (r) of 0.066 per year. This growth rate must be treated with caution since it is based on only three years of data.

3.2. Harem range and core areas

Between 1995 and 2000, 95% kernel harem range areas ranged from 1.3 to 24.0 km^2 and 80% core use areas from 61 to 499 ha (Table 1, Fig. 1). There was no difference in range area among years ($F_{5,15} = 0.56$, $P = 0.726$; note, horses were observed for different periods of time within each year). Both mean range and core areas were significantly different among harems (range area: $F_{5,14} = 6.61$, $P = 0.002$; core area: $F_{5,14} = 7.65$, $P = 0.001$, these exclude the single home range estimate for Ares, Table 1); mainly because Patron's mean range and core areas were significantly larger than those of the other harems (Table 1).

There was no correlation between number of fixes and size of harem range or core areas (Table 1; range area: $r_s = 0.035$, $N = 21$, $P = 0.881$; core area: $r_s = 0.092$, $N = 21$, $P = 0.691$). In addition, there was

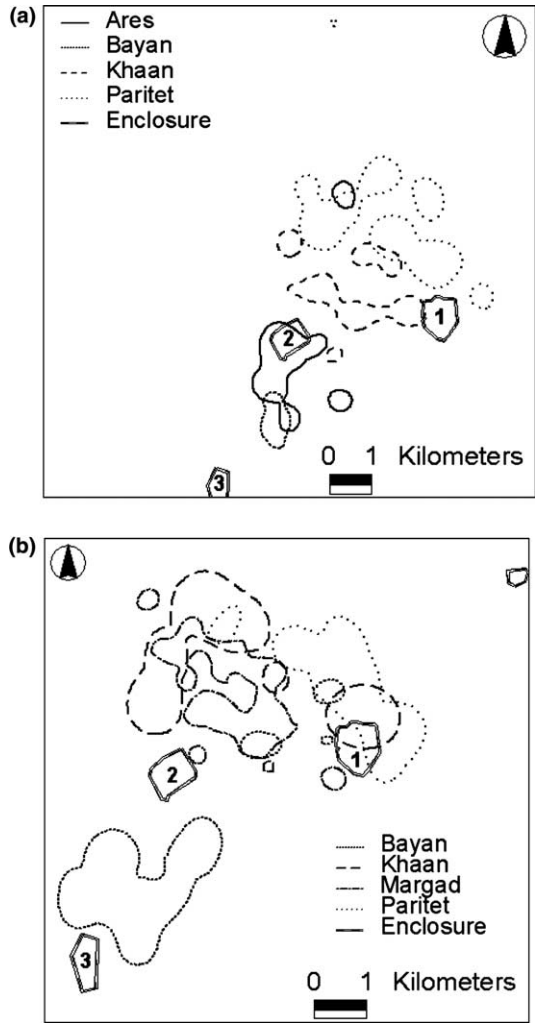

Fig. 1. Eighty percent core areas of the study harems in (a) 1998 and (b) 1999. Ranges show the core area of the entire harem, but the names of the dominant stallions are used. Paritet, Khaan and Bayan's harems were all released from enclosure 1 (in 1994, 1995 and 1998, respectively). Ares' harem was released from enclosure 2, and Margad acquired Khaan's mares in 1999.

no correlation between number of months since release and harem range ($r = 0.22$, $N = 31$, $P = 0.235$) and core area ($r = -0.01$, $N = 31$, $P = 0.976$), or between the number of adults and juveniles in each harem and range ($r_s = 0.220$, $N = 21$, $P = 0.337$) or core area ($r_s = 0.346$, $n = 21$, $P = 0.124$). Despite the small sample sizes, we tested for a year effect, but there was no significant difference in range or core area among years (range area: $H_5 = 3.56$, $P = 0.615$; core area: $H_5 = 5.09$, $P = 0.404$).

3.3. Harem range shifts between years

Overlap of individual harem ranges between years varied between 31% and 100% (mean = 59%, $N = 11$, SD = 26%) (Table 2). Overlap of yearly core areas varied between 11% and 100% (mean = 45%, $N = 11$, SD = 27%; Table 2). There was no significant correlation between the number of years since release and the degree of overlap (range area $r_s = -0.34$, $N = 11$, $P = 0.313$; core area $r_s = -0.40$, $N = 11$, $P = 0.255$;). In general the trend was for a decrease in range overlap over the years (Table 2).

The harem range centres did not move very far from one year to the next, with a minimum movement of 0.4 km and a maximum of 1.8 km (Table 3). However, distance from initial range centre after release to range centres the following years appear to show a movement away from the release enclosure. The harems tended to stay close to their acclimatisation enclosures in the year after release, then move further away to settle in a nearby valley.

3.4. Overlap between the ranges of different harems

Paritet, Bayan and Khaan were released from enclosure 1, Turgen from outside enclosure 1, and Ares and Patron were released from enclosure 2. Margad's was a naturally formed harem (Table 1). Overlap between yearly harem ranges was analysed to see whether harems moved to the same areas of Hustai National Park after release. The degree of range overlap between harems varied from 0% to 89% (mean = 39%, $N = 21$, SD = 30%); core areas overlapped 0% to 66% (mean = 18%, $N = 21$, SD = 21%) (Table 4). There was no correlation between number of years since release and amount of overlap between harem ranges ($r = -0.26$, $N = 21$, $P = 0.253$) or core areas ($r = -0.17$, $N = 21$, $P = 0.459$).

In 1995, when Paritet's harem was first released and Khaan's and Patron's had been free ranging for one year, there was no overlap between any of the core areas. Core areas overlapped in 1996 after Turgen's harem was released. Turgen's core area in 1996 and 1997 was overlapped more than any other harem except Ares' in 1998 (Table 4b). Patron's core area did not overlap with any other harem between 1995 and 1997, and did not do so during the rest of this study (SRBK, pers. obs.). The bachelor group moved among the home ranges of all (SRBK, pers. obs.).

Changes in overlap among core areas indicate range shifts and/or a change in area used. For example, Bayan overlapped with Ares in 1998, but in 1999 he used a larger area and his harem overlapped with all the other harems. The bachelor stallion Margad took most of Khaan's mares in 1999, and although they were using the same valley, their core areas only overlapped by 23%. By mid-summer, Khaan's remaining mares were taken over by another stallion and they moved to a different valley. Thereafter Margad's harem increasingly used Khaan's previous range; in 2000, 50% of Margad's core area overlapped with Khaan's 1998 core area and 57% with Khaan's 1999 core area.

* = no data for Khaan harem in 1997.

In 1999 and 2000 there were four other harems in Hustai National Park (Table 1). Although there were no data for these harems, it is possible that total overlap was larger than shown in Table 4. The harems appeared to distance themselves from each other but there was no evidence of exclusive use of an area by any harem. The harems appeared to select a home range in a valley where there were no previous horses, and where the harems were separated by ridges. However, Bayan broke this trend by tending to use the same valley as Margad in 2000. Moreover, observations by the Mongolian rangers indicate that all harems sometimes use the same valley during the winter.

3.5. Habitat use within the home range

Habitat use within the home range was influenced by several factors including temperature, season, time of day and the presence of flies. Although ranges were slightly larger in winter, there was no significant difference in the size of the ranges or core areas in different seasons (range areas: $F_{3,39} = 0.49$, $P = 0.693$; core areas: $F_{3,39} = 0.62$, $P = 0.605$).

In core areas, horses were found more often at a higher altitude during the summer than in spring or autumn (there were too few data for winter; median in summer = 1500 m, spring = 1425 m and autumn = 1400 m; Kruskall–Wallis $H_2 = 613.31$, $P < 0.0001$). There was also a diurnal trend in the horses movements (Fig. 2). In the morning, when it was cool, the horses spent most of their time grazing in the valleys. As the temperature increased, the horses moved to higher elevations where they could avoid flies and direct solar radiation by standing near rocky outcrops or in forest until the weather cooled enough for them to come down to graze again. This pattern was less marked in spring

Table 3

and autumn when the weather was cooler and the horses spent more time at lower elevations.

3.6. Vegetation use within the home range

Habitat composition of the different harems' ranges varied slightly, but all 11 vegetation classes described by Wallis de Vries et al. (1996) were grazed at some time (Table 5). However, all harems in all years did not randomly select vegetation classes (all χ^2 statistics, $P < 0.05$; Fig. 3). They most frequently selected vegetation classes from lower elevations (i.e., Meadow I, Tussock grassland and Lowland steppe; Fig. 3). Meadow I (dominated by bentgrass, sedge and *Iris lactea*) was preferred by Bayan in 1999 and 2000, and by Khaan in 1998. Although most preferred, Meadow I was not used by Khaan in 1999, and little by Margad.

Paritet's range did not include Meadow I vegetation and they preferred Tussock grassland (Fig. 3). Tussock grassland contains the needlegrass species *Achnatherum splendens* and *Stipa krylovii* which have high levels of crude protein and crude fibre (van Dierendonck and Wallis de Vries, 1993). Tussock grassland was not found in Khaan/Margad's home range.

Lowland steppe was selected significantly more than most other vegetation classes, and had a high selection index for all harems except Bayan in 1999 and Khaan in 1998 (Fig. 3). This vegetation class includes the wheatgrass *Agropyron cristatum*, which featured largely in the diets of feral horses, and is dominated by the needlegrass *Stipa krylovii*.

Both Mountain steppe vegetation classes were found in every home range, and one or both were significantly selected by the harems (Fig. 3). These were dominated by *Festuca lenensis* in Mountain steppe I and *Festuca sibirica* in Mountain steppe II. Although these species did not have the high crude protein content of needlegrass they had a higher crude fibre content (van Dierendonck and Wallis de Vries, 1993).

Grazing was observed in Woodland by most harems in most years (Fig. 3) and understorey vegetation such as *Spiraea media* and *Cotoneaster melanocarpa* was eaten rather than trees. The area covered by other vegetation classes (Upland steppe, Shrubland I, Shrubland II, Meadow II and Scrub) was small.

3.7. Seasonal use of the vegetation

The harems selected more vegetation classes in spring and autumn than in summer, and few classes were selected in winter (Fig. 4). From spring to autumn vegetation classes at mid to low elevations were used, with the exception of using woodland in the spring. In winter, vegetation at mid elevations was used. Lowland steppe was selected in every season of the year, and Shrubland I and Mountain steppes I and II were selected in every season except winter. Harems observed in winter preferred Lowland steppe. Woodland was not used at all in the autumn and winter, and Tussock grassland and Upland steppe were selected by at least two of the three harems in spring and autumn, but not in summer.

4. Discussion

4.1. Numbers

The reintroduced population of takhi increased in size during the study period, and continues to grow (Anonymous, 2004). This was despite loss of half the

Columns overlap rows. There was no difference among the harems in the overlap of home ranges ($F_{6,14} = 1.66$, $P = 0.204$), but there was a difference among the overlap of core areas ($F_{6,14} = 3.53$, $P = 0.024$).

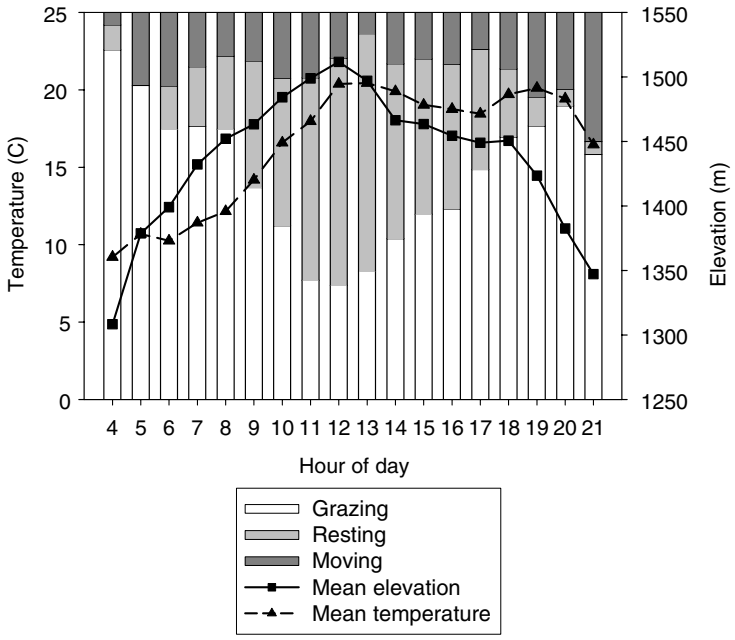

Fig. 2. Diurnal activity of the horses (% of total) according to mean elevation and temperature (SDs not included). The horses were observed in different activities at different times of day ($H = 17.38$, d.f. = 4, $P < 0.002$), and at different temperatures ($H = 577.12$, d.f. = 4, $P < 0.0001$) and different elevations ($H = 630.21$, d.f. = 4, $P < 0.0001$). The horses were found at higher elevations in the middle of the day ($H = 120.35$, d.f. = 15, $P < 0.0001$) and at higher temperatures ($H = 1279.18$, d.f. = 15, $P < 0.0001$).

Table 5
Habitat classes at Hustai National Park according to landscape features and dominant plant species (based on Wallis de Vries et al., 1996)

Habitat class	Dominant species		Landscape	Altitude	Slope
	Scientific name	Common name			
Meadow I	*Iris lactea*	Dwarf iris	Streamside	1100–1400	
Tussock grassland	*Achnatherum splendens*	Needlegrass	Valley terrace	1100–1400	
Lowland steppe	*Artemisia adamsii* *Stipa krylovii*	Wormwood Needlegrass	Footslope	1100–1400	South
Upland steppe	*Thermopsis lanceolatus* *Stipa krylovii*	False lupin Needlegrass	Footslope	1300–1500	South
Shrubland I	*Caryopteris mongholica* *Amygdalus pedunculata*	Bluebeard Sweet almond	Rocky slope	1300–1600	South
Mountain steppe I	*Festuca lenensis*	Tundra fescue	Ridge & topslope	>1300	
Mountain steppe	*Festuca siberica*	Siberian fescue	Mountain slope	>1400	North
Shrubland II	*Spiraea aquilegifolia*	Spiraea	Gully	1100–1600	
Meadow II	*Geranium pratense*	Meadow cranesbill	Combe	>1300	
Woodland	*Betula platyphylla*	Asian white birch	Mountain slope	>1400	North
Scrub	*Betula fusca*	Birch	Topslope	>1400	North

horses released in 1998 to babesiosis. *Babesia equi* and *B. caballi* are endemic to Mongolia and transmitted by the tick *Dermacentor nutalli*. Unless treated, between 25% and 100% of cases are fatal (West, 1992). However, animals can acquire immunity during the course of an infection, and mortality depends on the general immune status of the animal, and the virulence of the piroplasm (Schein, 1988). Foals can be infected during pregnancy, but gain protection from maternal antibodies (Donnelly et al., 1982). Thus local domestic horses and takhi born in Mongolia do not appear affected by the disease. In contrast, newly introduced animals with no immunity and that may become stressed for reasons such as transport, release, or poor body condition in early spring, are likely to be susceptible. In particular there is a high mortality rate during the initial infection of older animals

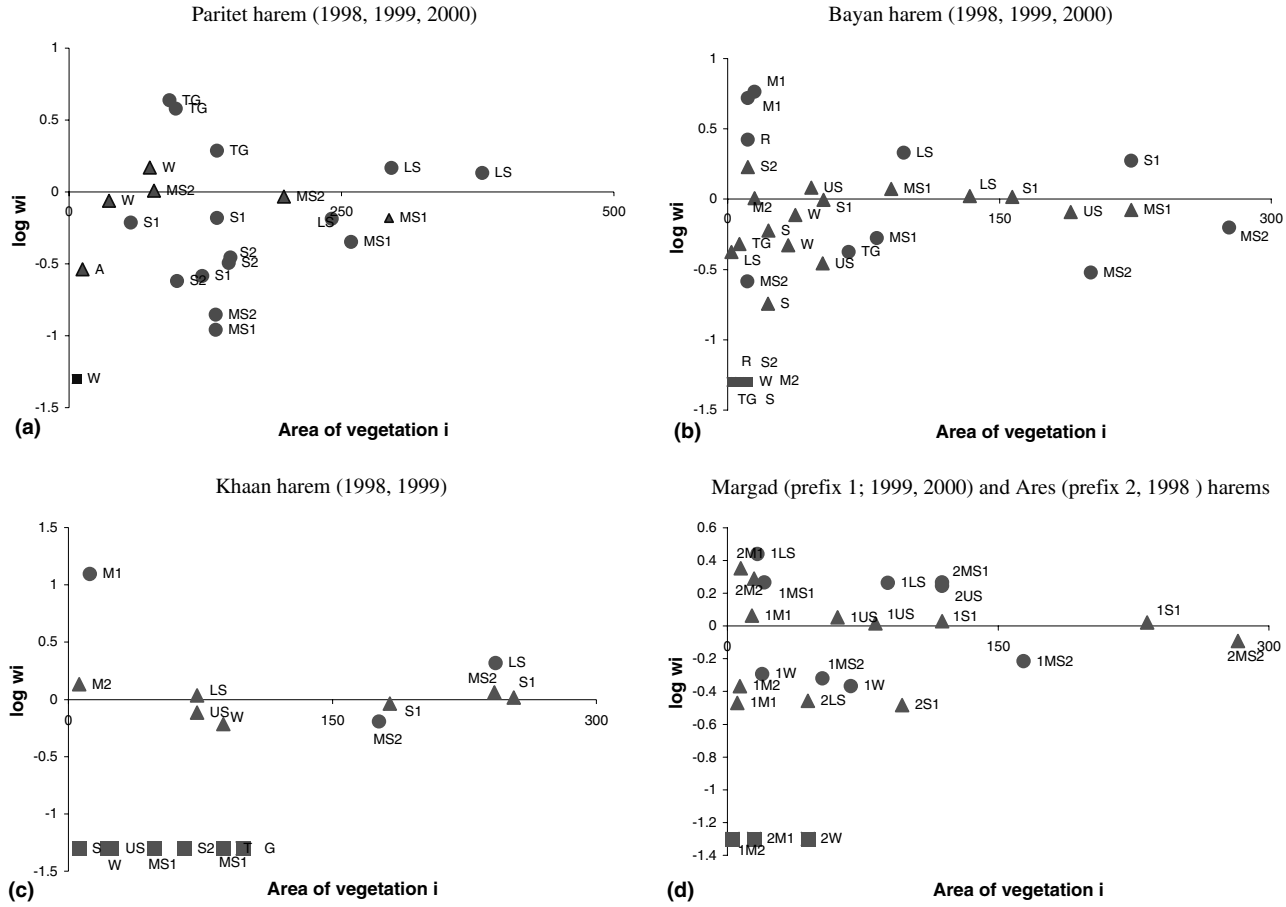

Fig. 3. Habitat selection indices (w_i, logged for presentational purposes) plotted against area of each vegetation type (i). M1 = Meadow I, M2 = Meadow II, TG = Tussock Grassland, LS = Lower Steppe, US = Upper Steppe, S1 = Shrubland 1, S2 = Shrubland 2, MS1 = Mountain Steppe I, MS2 = Mountain Steppe II, W = Woodland, S = Scrub, A = Agricultural Area, R = Rock and Stones. Habitat classification based on Wallis de Vries et al. (1996). A value of log $w_i > 0$ represents positive selection, = 0 represents no selection, <0 represents avoidance. Squares indicate habitats were not selected at all, but were arbitrarily assigned a value of 0.05 so that they appear on the figure, circles indicate w_i values significantly different to zero (χ^2 $P < 0.05$), triangles indicate insignificant w_i values or where expected values <5.

when brought from a country, such as Holland, where *B. equi* is not endemic (Schein, 1988).

Most losses to the population resulted from the death of foals. Diseases such as strangles (infection by *Streptococcus equi*) accounted for some of these deaths, as well as predation and the harshness of the Mongolian winter.

4.2. Home range use

Harem range sizes varied between 1 and 24 km^2 (mean 9.2 km^2, $N = 21$, SD = 5.64 km^2) and are similar in range to feral horse populations in Alberta, Canada (2.6–14 km^2; Salter and Hudson, 1982) and in New Zealand (1–18 km^2; Linklater et al., 2000), but smaller than those in North America (8–48 km^2; Pellegrini, 1971; Feist and McCullough, 1976; Berger, 1977, 1986; Miller, 1983a). Home ranges of horses in England (2.5–3.2 km^2; Tyler, 1972; Gates, 1979), and barrier islands (3–6 km^2; Keiper, 1976; Zervanos and Keiper, 1979; Rubenstein, 1981) were generally smaller than at Hustai National Park. In general, differences in home range size are related to vegetation quality and distribution of resources such as water and shelter (Leuthold, 1977). No trends in harem range size with time after release were found, or with harem size (cf. Zervanos and Keiper, 1979; Berger, 1986; Linklater et al., 2000), and there was no suggestion that forage was limiting. However, Mongolia suffers from periodic droughts and severe winters and these will affect the vegetation growth. It is possible that harem ranges will be smaller when forage quality is good; this was found in reintroduced Arabian oryx, *Oryx leucoryx*, whose ranges became smaller in areas where rain had fallen (Corp et al., 1998).

Similarity in size of reintroduced takhi home ranges and feral horses under similar circumstances implies not only that feral horse management techniques could potentially be applied to this population, but that they are using similar survival strategies. Thus takhi did not

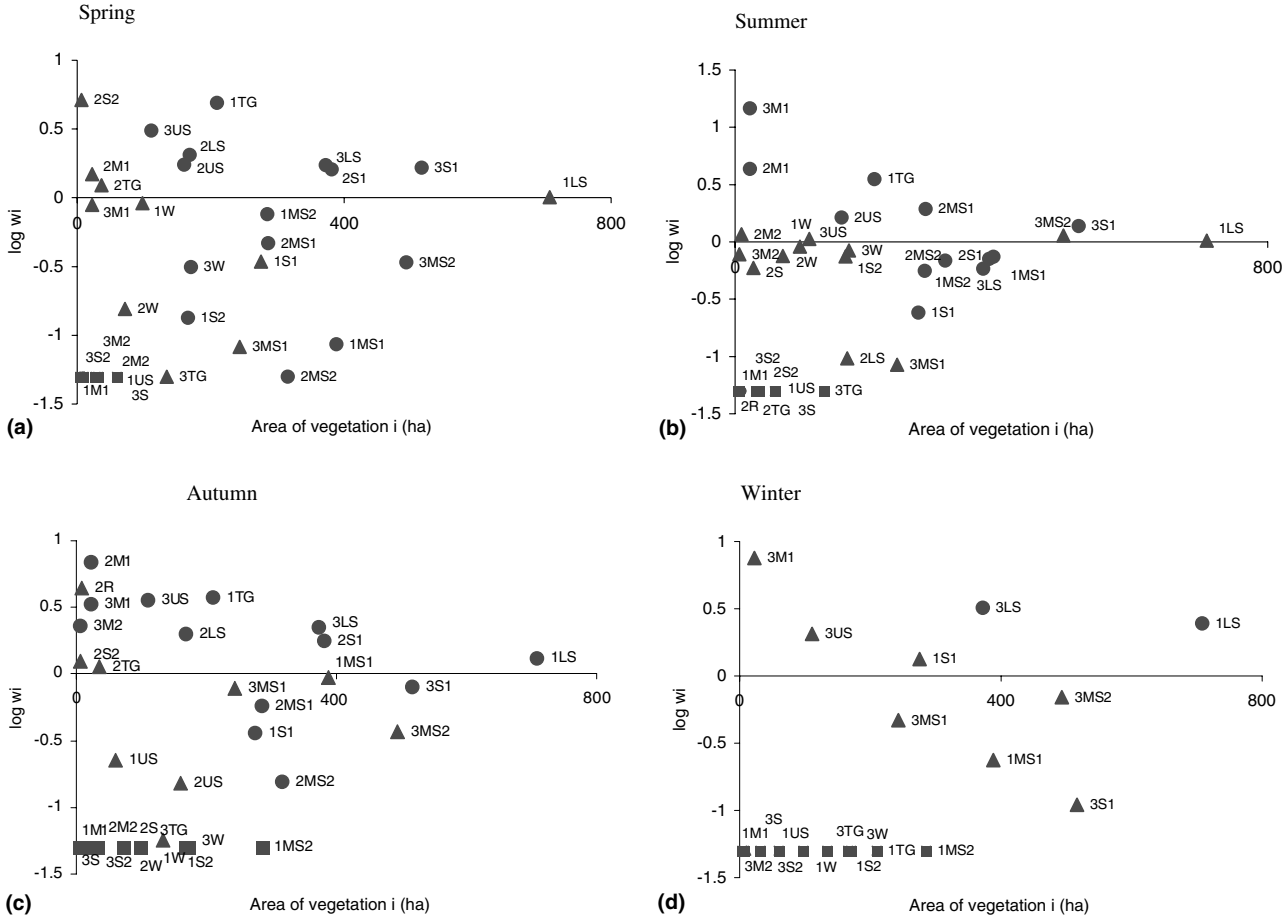

Fig. 4. Habitat selection indices (w_i, logged for presentational purposes) plotted against area of each vegetation type (i). (a) = spring, (b) = summer, (c) = autumn and (d) = winter. First number 1 = Paritet, 2 = Bayan, 3 = Khaan/Margad. M1 = Meadow I, M2 = Meadow II, TG = Tussock Grassland, LS = Lower Steppe, US = Upper Steppe, S1 = Shrubland 1, S2 = Shrubland 2, MS1 = Mountain Steppe I, MS2 = Mountain Steppe II, *W* = Woodland, *S* = Scrub, *A* = Agricultural Area, *R* = Rock and Stones. Habitat classification based on Wallis de Vries et al. (1996). A value of log $w_i > 0$ represents positive selection, = 0 represents no selection, <0 represents avoidance. Squares indicate habitats were not selected at all, but were arbitrarily assigned a value of 0.05 so that they appear on the figure, circles indicate w_i values significantly different to zero (χ^2 $P < 0.05$), triangles indicate insignificant w_i values or where expected values <5.

lose an ability to adapt to the wild despite 13 generations in captivity, just as this trait has not been bred out of horses despite 5000 years of domestication.

Characteristics of the ranges of all harems were that they included a permanent water source, an area of rocky outcrops near a ridge, and patches of forest that were used in the summer. The harems of Ares, Bayan, Khaan and Margad all overlapped at one particular place along the stream where pools were formed and the banks had been eroded to form a salt lick. However, in the main, the home ranges occupied separate valleys, defined by ridges which peaked at about 1600 m, but which also joined at passes and along watercourses.

As the size and number of harems change through time at Hustai National Park, competition for resources may increase. For example, larger harems have been shown to have priority of access to water holes (Miller and Deniston, 1979), and also tend to be found in areas of better vegetation (Miller and Deniston, 1979; Berger, 1977, 1986). Most studies on feral horses show extensive spatial overlap between ranges (Keiper, 1976; Miller, 1983a; Linklater et al., 2000), although horses appear to avoid each other temporally, as they did at Hustai National Park (King, 2002). After release, harems stayed near the release enclosure in the first year, then moved a little further away to settle in a valley. The harems selected valleys that were visually separated from each other, but as the population increases and more overlap occurs, more valleys will be colonised and smaller ridges within a valley may separate the harems. In winter harems seemed more tolerant of close proximity to each other (Mongolian rangers, pers. comm.), implying that at this time being near other harems is more important than having exclusive access to a food source. More work needs to be done in this season to examine if lack of spatial segregation between harems is for thermal reasons, or for greater protection against predation.

4.3. Vegetation use

Plants change in nutrition and palatability through the year (Novellie and Winkler, 1993), and in Hustai National Park the takhi preferred some species in their early development stages, and avoided others after they had flowered (Salter and Hudson, 1979; Duncan, 1983; Miller, 1983b; Putman et al., 1987; Enkhee, 1998). The takhi selected vegetation classes dominated by grasses and fescues which have a high fibre and crude protein content (van Dierendonck and Wallis de Vries, 1993). Although grazing was observed on all vegetation classes overall, takhi did not select all vegetation classes in every year, nor graze on all vegetation classes present.

Vegetation available to takhi affected their altitudinal movements through the year. They spent more time at low to mid elevations to shelter from inclement weather, and to feed on the most nutritious vegetation that was found in the Lowland steppe (Salter and Hudson, 1978). All the takhi had good condition throughout the year, and in the spring tended to have retained more body fat than local domestic horses (SRBK, unpubl.). As the takhi population grows there is potential for overgrazing to occur, especially on vegetation classes in the valleys that are preferred. Thus management will be needed in the future to ensure that this is kept under control.

5. Conclusions and the future of takhi at Hustai National Park

So far, the introduction of takhi to Hustai National Park seems to have been successful, although this assessment is based on a time period that only approximates one generation (see Gross, 2000). Despite this, there is little evidence that takhi have lost any ability to survive in the wild through many generations in captivity. All harems bar one were given a soft release, and maintained in acclimatisation enclosures for at least six months, thus allowing animals to get used to both the climate and disease vectors. The importance of a sufficient acclimatisation period is shown by the greater success of harems, such as Patron's, Paritet's and Khaan's, which were acclimatised for two years, compared to the those that had a hard release (Turgen's harem) or were acclimatised for only six months (Mark and Bohemian's harems). These harems suffered greater mortality, with only two horses from Turgen and Bohemian's harem surviving a year after release, and only one from Mark's. Local diseases were the main cause of mortality, suggesting knowledge of potential diseases should be obtained before animals are brought to the release site, and continuous monitoring post-release with immediate veterinary attention is desirable. Although target release sites should be surveyed for potential predators, in this case predation was not a major cause of mortality. However this is not true for all introductions (e.g., Matson et al., 2004).

The horses in this study tended to remain near their acclimatisation enclosure upon release, although they did move further away over time. Thus repeated use of a release enclosure could lead to intraspecific conflict and overexploitation of the nearby habitat. However, this does not seem to have occurred at Hustai National Park (enclosure 1 was used in 1994, 1995 and 1998, and enclosure 2 in 1994 and 1998; enclosures 4 and 5 were only used once); there was little overlap between ranges of different harems, although exclusive range use did not occur. All harem ranges at Hustai National Park contained access to a water source, and this has also been seen in feral horse studies. Releases should therefore be near a permanent water source, and this could be used to encourage animals to move further from a release enclosure. In addition shade areas and access to minerals seemed necessary for each harem. In comparison with feral horse studies, it appears that range size depends on habitat quality, and this should be taken into account in assessing target release sites. Importantly, takhi appear to use their habitat in a similar way to feral horses, so management techniques of feral populations could be applied.

It has been suggested that Hustai National Park (area 570 km^2) should be able to support a population of 400–500 horses (Bouman, 1998), equivalent to a density of 0.9 horses km^{-2} or 42 harems with the currently observed 12 horses $harem^{-1}$. However, because of the topography and availability of water, Hustai National Park may not support 500 horses. For example, in the western section of Hustai National Park there are streams in most valleys, but in the east (c. 144 km^2) there are only three ephemeral streams. Horses require a reliable water source, along with the presence of good quality vegetation and places for resting both by rocks near ridges and among trees. At present, the takhi population appears well below carrying capacity. Taking the rather tentative 2002–2004 estimate of per capita growth rate per year of 0.066, it will take 15.5 years for the population to reach a carrying capacity of 450 horses.

A future problem is the likelihood of hybridisation with domestic horses as the takhi expand beyond the Park boundary. Local people value hybrid offspring. Hybrids will need to be identified and either controlled, neutered or prevented from re-joining the population. Contraception may be a better way of limiting the population than removing animals (e.g., Gross, 2000). Future studies at Hustai National Park will provide insights into dispersal, harem formation, and the effects of intraspecific competition as the population increases. In addition studies of the horses over the winter may provide more insights into the habitat use and any

changes in social structure during this critical season. Takhi born in Hustai National Park could be used for future reintroductions in other parts of Mongolia as they will already have immunity to babesiosis and will have acquired the skills necessary to survive the varied seasons.

Acknowledgements

We thank the Foundation Reserves Przewalski Horse for their financial support and the opportunity of studying the horses at Hustai National Park, as well as access to past data. Thanks to the Mongolian Association for the Conservation of Nature and the Environment and the staff at Hustai National Park for all their help during the study, and thanks especially to the Hustai National Park biologists and rangers for collecting invaluable data, to Tessa Roos, and to Marc Hoogerwerf for advice on using ArcView. Funding for this study also came from IFAW, Queen Mary Expeditions Committee and Marwell Preservation Trust.

Abstract

Scent marking is a common form of intraspecific communication in mammal species, and using faeces or urine is a cost-effective way of signalling competitive ability and resource holding power. Marking is ritually performed by male equids, and here we assess the function of male scent-marking behaviour in a recently introduced population of Przewalski horses *Equus ferus przewalskii* in Mongolia. Two forms of scent marking were observed: defecation on stud piles formed from repeated dunging in the same place, and overmarking of faeces and urine of mares. Stud piles were marked with dung by the harem holder and sniffed before and after dung was deposited. They were not found specifically at the periphery of harem ranges but occurred for the most part along routes used by the horses, and were more common in the core parts of harem ranges or where harem ranges overlapped. Thus, rather than being used to defend range boundaries, stud piles were placed predominantly where they would be encountered by male intruders. Mare excreta were covered with urine by the stallion, but were only sniffed before they were marked, not after. These marks appear to advertise to the mare and other, intruding stallions that the harem holder was the mare's consort and that the interloper should not risk trying to steal the mare or sneak a mating. Thus, the two forms of marking by harem holders appear to combine as first and second lines of defence of paternity rights in male intrasexual competition.

Introduction

Scent marking via the urine, faeces or scent glands (Gorman & Trowbridge, 1989) is a common form of communication in mammals (e.g. Eisenberg & Kleiman, 1972; Brashares & Arcese, 1999*a*,*b*; Begg *et al*., 2003). It is often associated with competitive ability and resource holding power (RHP) in males, but may also enable females to assess mate quality (Ralls, 1971; Trivers, 1972; Gosling & Roberts, 2001). Faecal material is particularly good for scent marking as it is relatively persistent in the environment, it has a minimal energetic cost to the signaller, and it forms a substrate for glandular secretions (Brashares & Arcese, 1999*a*). Urine is a similar cost-effective substance that can be used as a marker. Nevertheless, urine and faecal marks degrade through time and signallers must reinforce the message present by re-marking at intervals (Gosling & Roberts, 2001).

In general, scent marking occurs commonly, but not exclusively, at socially important or well-used areas, it is most often carried out by high-ranking animals, and frequently occurs during agonistic encounters (Leuthold, 1977). Marking of stud piles has been recorded in all equid populations studied (Linklater, 2000) and is normally carried out by stallions. Dung piles, also known as stud piles, are produced by repeatedly defecating at one place over a period of time. Stud piles can get quite large and it has been suggested that they act as visual signposts, especially in open areas where no other landmarks are available (Salter & Hudson, 1978). Stud piles are sniffed and marked in a ritualized manner (Turner, Perkins & Kirkpatrick, 1981): typically the stallion will sniff faeces or urine, step over it with an arched neck, deposit some dung, and then turn and sniff the excreta again. Stallions also urinate or defecate on mare eliminations, the marking of which possibly has a different function to stud pile marking. The idea that overmarking is used to eliminate the odour of a female, as suggested by Tyler (1972) and Kimura (2001), has been disputed because not all eliminations are marked (Salter & Hudson, 1982).

Other hypotheses to explain male scent marking in horses have been proposed, including the fact that it is related to male intrasexual competition (Feist & McCullough, 1976) and that it is a relict behaviour from territorial ancestors (Klingel, 1972). Although scent marking is commonly related to territoriality (Burt, 1943; Ralls, 1971; Brashares & Arcese, 1999*a*), feral horses are not strictly territorial, *sensu*

an individual or group of individuals defending an area for exclusive use (Davies & Houston, 1984; Linklater, 2000; although see Rubenstein, 1981). However, horses exhibit female defence polygyny in the form of a harem-based social system. Each stallion dominates a group of mares or harem (multi-stallion harems have been observed; Linklater, 2000) and must defend these for exclusive mating rights; thus, similar principles to territoriality can be applied to female resource defence (Gosling, 1990; Gosling & Roberts, 2001).

Scent marks may transmit information about status and competitive ability of the resource holder (Gosling, 1982, 1990; Gosling & Roberts, 2001). It has been shown that animals have the ability to associate marks with individuals (Keverne & Kaba, 1990; Rich & Hurst, 1998; Lawson, Putman & Fielding, 2000, 2001), and this has also been observed in horses (Rubenstein & Hack, 1992). Thus, the most likely function of scent marking in stallions is a form of female resource defence, although the role of marking stud piles and marking female eliminations has not been adequately explained. We assess the function of these two types of male scent marking by studying the occurrence of scent marks in a population of Przewalski horses *Equus ferus przewalskii* reintroduced into Hustai National Park (HNP), Mongolia (van Dierendonck & Wallis de Vries, 1996; King & Gurnell, 2005). Stimuli causing scent marking are expected to alter through the year and provide information on the relative importance of female defence. By examining the spatial distribution, we aim to show the pattern of marking behaviour and whether it is used as a defensive mechanism against intruding stallions.

Methods

Study area

Studies were carried out at HNP, Mongolia between June 1998 and July 2000. HNP is situated about 150 km southwest of Ulaanbaatar, the capital city of Mongolia. It covers 570 km^2 along a south-western spur of the Khentii range of mountains (around the geographical coordinates: 47°41′N, 105°54′E). The area was made a reserve in 1993 in preparation for the first release of Przewalski horses in 1994 (Bouman, 1998) and designated a National Park in 1999. The park borders the Tuul river and has an altitude between 1100 and 1842 m. The climate is continental with a mean annual temperature of +0.2 °C and a yearly precipitation of 270 mm, most of which falls as rain in July and August (Wallis de Vries, Manibazar & Dugerlham, 1996). HNP has a mountain forest steppe habitat and water flows down most of the major valleys as streams (Wallis de Vries *et al.*, 1996).

Field observations and data analysis

Five harems were observed for a total of 860 h over three field seasons between June 1998 and July 2000. Horses were observed in temperatures of between −14 and +34 °C, but no observations were conducted between December and March. During the study period there were up to nine free-ranging harems in HNP. Harems consisted of a stallion and a group of mares, released as a unit, although the harem holder and composition of the groups changed through time. Stallions were identified individually by differences in markings and pelage.

Observations of the horses were carried out on foot from a distance of at least 15 m. We defined marking behaviour as occurring when a horse sniffed a non-food item and then proceeded to flehmen, urinate or defecate, or when excreta was placed on a known stud pile or mare excreta. All occurrences of marking behaviour were recorded on a voice recorder as they happened, even if the full ritualized sequence did not occur. The time when the marking took place, the identity of the animal carrying out the behaviour and the sequence of behaviours (e.g. whether the stimulus was sniffed before marking, after marking or both, and what form the marking took) were recorded, together with the stimulus marked and the terrain where the marking occurred. Marking during or after a confrontation with another horse was also recorded. To delineate home ranges and range use, and construct time budgets, the location and behaviour of the harem were recorded every 10 min during observation periods. Location data were entered into Arcview GIS for further analysis.

Stud piles were surveyed whenever they were encountered. A stud pile was defined as where at least two dungings had occurred on the same spot. The maximum width, length and height of the stud pile were measured and its relative age and composition were subjectively described as fresh (green and wet – just done, usually seen), new (recent – turning black and drying), old (dry, grey/brown and breaking up), new on old, fresh on old or fresh on new. The location of the stud pile was recorded as for marking events.

We combined the data from all field seasons for analyses. The frequency of marking in different months, as well as the location of marks, the type of stimulus when it could be identified, the terrain and the form of the marks were analysed using contingency tests. The sequence of events in the ritual of marking was also analysed in relation to the

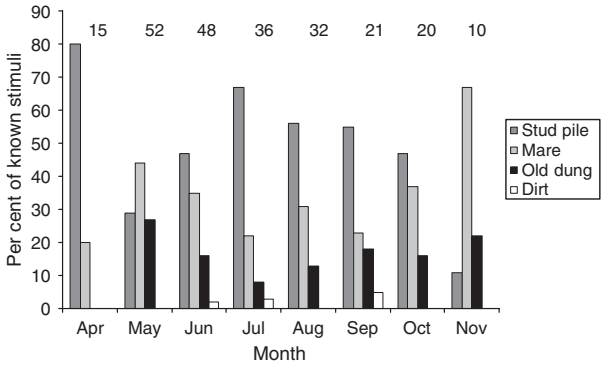

Figure 1 Per cent of stimuli marked according to month (numbers above bars = sample sizes for each month). Stimulus and month were significantly associated, excluding 'dirt' category ($\chi^2_{14} = 28.32$, $P = 0.013$).

stimulus. The sizes of stud piles of different age and form were analysed using non-parametric ANOVA. Ninety-five per cent kernel harem range areas were calculated in Arcview from the location data gathered; these excluded occasional forays outside the areas. Utilization curves were used to estimate core areas and, in all cases, these were 80% of the total range area (King, 2002; King & Gurnell, 2005). The distribution of stud piles within the ranges of the harems was examined by comparing their position within the home ranges and core areas of the harems using χ^2 goodness-of-fit tests, after first testing for heterogeneity in the data.

Results

Marking behaviour

We observed 343 marking events: 94% carried out by stallions, 6% by juvenile males (<3 years old, still within the natal harem) and 1% by mares sniffing either a stud pile or old dung. Only 11% of observed marking behaviour occurred during a confrontation between stallions; all others occurred during the course of the horses' daily movements. There was no evidence that the horses avoided eating near dung or latrine areas being formed. Excluding the very small

Table 1 Frequency of behaviours observed at each type of stimulus

	Behaviour				
	Flehmen	Flehmen and urinate	Sniff	Urinate	Defecate
Mare elimination	2 (6.5)*	3 (1.4)	15 (5.1)*	47 (20.6)*	7 (40.4)*
Old dung	8 (3.2)*	0 (0.7)	0 (2.5)	8 (10)	20 (19.7)
Stud pile	9 (9.3)	1 (2)	0 (7.4)*	5 (29.4)*	91 (57.9)*

*Significant cell χ^2 values, $P<0.05$.
Expected values in parentheses. Behaviour and stimulus were significantly associated ($\chi^2_8=143.6$, $P<0.0001$).

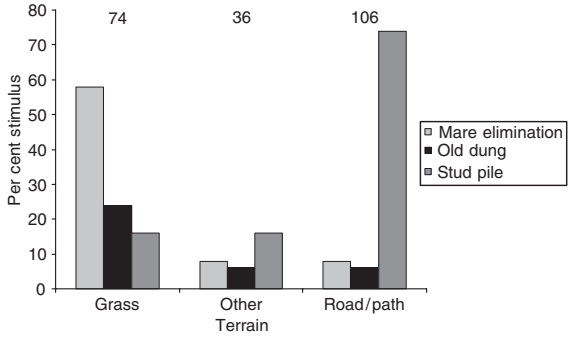

Figure 3 Per cent of stimuli on different terrains. Stimulus and terrain were significantly associated ($\chi^2_4=86.98$, $P<0.0001$).

Table 2 Frequency of behaviours observed marking each type of stimulus

	Behaviour				
Stimulus	Sniff before	Sniff after	Sniff before and after	No sniffing	Total
Stud pile	23 (49.3)*	1 (2)	82 (54.7)*	0 (0)	106
Mare elimination	62 (34)*	1 (1.4)	10 (37.7)*	1 (0)	74
Old dung	15 (16.7)	2 (0.7)	19 (18.6)	0 (0)	36
Dirt	2 (0)	0 (0)	1 (0)	0 (0)	3

*Significant cell χ^2 values, $P<0.05$.
Expected values in parentheses. Stimulus and behaviour were significantly associated ($\chi^2_4=74.54$, $P<0.0001$, excluding 'no sniffing' and 'dirt').

number of marking events on bare ground ('dirt'), there was a significant association between stimulus and month (Fig. 1). Stud pile marking was proportionally high in April before the breeding season in May and June. This dropped in May, but increased again in July. Significantly more than expected marking of mare eliminations occurred in November.

Most of the marking behaviour observed that could not be assigned to a particular stimulus occurred on grass (74%, $n=124$). The 'unknown' stimulus category has been omitted from the analyses below. Marking behaviour for known stimuli (except 'dirt', which only occurred three times) is summarized in Fig. 2. There was a significant difference in the frequency of different behaviours observed during marking events ($\chi^2_4=203.6$, $P<0.001$); defecation was the most frequent behaviour seen (55%), followed by urination (28%) and flehmen (9%). Stud piles were marked most (49%) followed by mare eliminations (34%) and old dung (16%). There was a significant association between the type of stimulus and the behaviour seen ($\chi^2_8=143.6$, $P<0.0001$; Table 1): defecation occurred more frequently on stud piles and urination on mare eliminations. Not all mare eliminations were marked, but we were not able to assess the relative frequency of this. The different stimuli also tended to be found on different terrains ($\chi^2_4=86.98$, $P<0.0001$; Fig. 3), with stud piles tending to occur on paths and mare eliminations on grass.

A sequence of behaviours was observed when the stallions marked. They would sniff the stimulus before marking, and/or afterwards, in a characteristic posture. The sequence of sniffing tended to vary with the stimulus ($\chi^2_4=74.54$, $P<0.0001$, excluding the 'no sniffing' behaviour and 'dirt' stimulus because of very low frequencies; Table 2). We observed that the stallions tended to sniff before marking on mare eliminations, but not after, and would sniff both before and after marking stud piles. Sniffing without marking occurred at 18% of mare eliminations.

Table 3 Median dimensions of stud piles of different ages and form that were mapped (interquartile ranges are shown in parentheses)

Age and form of stud pile	Length (cm)	Width (cm)	Height (cm)
New	85 (70.0–137.5)	65 (52.5–77.5)	10 (5.0–13.8)
Fresh on new	70 (55.0–85.0)	40 (37.5–102.5)	10 (5.0–16.3)
Fresh on old	140 (130.0–250.0)	90 (60.0–120.0)	10 (5.0–20.0)
New on old	200 (135.0–280.0)	110 (75.0–140.0)	10 (5.0–12.5)
Old	140 (102.5–182.5)	85 (70.0–125.0)	5 (5.0–5.0)

Size and position of stud piles

Stud piles tended to spread out and be long and wide rather than high, partly as a result of drying, weathering and insect activity, and partly because the stallions did not necessarily deposit faeces on the highest part of the stud pile. The median length of mapped stud piles was 145 cm [$n=114$, inter-quartile range (IQR) = 100–210 cm], the median width was 90 cm (IQR = 60–130 cm) and the median height was 5 cm (IQR = 5–10 cm). We found that stud piles that were used most frequently, i.e. new dung on old, were also longer (Table 3; Kruskal–Wallis $H_4=30.89$, $P<0.0001$), wider ($H_4=18.16$, $P=0.0011$) and higher ($H_4=22.23$, $P=0.0002$) than other ages and forms of stud piles.

Table 4 Area and perimeter length of home ranges of the harems (the name of the stallion is given), and position of stud piles relative to the home ranges

	80% core		95% range			Position relative to home range (%)			Position within home range (%)	
Home range of stallion	Area (ha)	Perimeter (km)	Area (ha)	Perimeter (km)	No. of stud piles	Core area	Periphery	Outside	Area of non-overlap	Area of overlap
Paritet	674	20.23	1693	33.46	21	71	24	5	45	55
Bayan	525	15.53	1117	23.74	14	79	7	14	42	58
Khaan	726	24.58	1460	19.7	25	68	8	24	5	95
Ares	240	11.02	744	32.15	21	57	38	5	45	55
Margad	345	17.62	684	32.15	7	57	43	0	14	86

Paritet, Bayan and Khaan overlapped each other in 1998 and 1999, Ares only in 1998 and Margad only in 1999.

Most stud piles were found within known home ranges (Table 4). Of those within ranges, significantly more were found in the core area (76%) compared with the peripheral area, after testing for heterogeneity among the five harem ranges studied (heterogeneity $\chi^2_3 = 5.99$, $P = 0.1118$; pooled $\chi^2_1 = 20.51$, $P < 0.0001$). The density of stud piles was also higher within core areas compared to the periphery (mean density core area = 0.025 stud piles ha^{-1}, SD = 0.010; mean density periphery = 0.004 stud piles ha^{-1}, SD = 0.004; $t_8 = 4.45$, $P = 0.007$). The data were not homogeneous to test for overall differences in the frequency of stud piles in areas of home range overlap and non-overlap (heterogeneity $\chi^2_3 = 70.68$, $P < 0.0001$). This was because most stud piles were in areas of overlap for Margad's and Khaan's ranges; these were in the valley that all other harems used, indicating that Margad and Khaan concentrated their marking in the areas of their ranges where they came across signs of other harems. However, there was no significant difference between areas of overlap and non-overlap for the other three harems (Table 4).

Twenty-five per cent of stud piles were found on ridges or saddles within the landscape and most of the rest were found on paths or tracks as described before (see also King, 2002). It therefore appears that stud piles were placed where other stallions were most likely to come across them. There was a noticeable increase in the number of stud piles along a path used by Khaan's harem after Ares' harem was released in the vicinity (S. R. B. King, unpubl. obs.), although data were not collected to quantify this.

Discussion

The stallions at HNP marked mare eliminations and formed dung piles as in most other equid populations (Turner *et al*., 1981), and adopted typical postures (Feist & McCullough, 1976; Turner *et al*., 1981; Salter & Hudson, 1982; Rubenstein & Hack, 1992). Although the same ritualized postures were observed when both stud piles and mare eliminations were marked, they were marked in different ways, suggesting different functions. Stud piles were marked with dung, and were sniffed both before and after they were marked, whereas mare eliminations were marked with urine and sniffed only before marking. The two stimuli were also found in different places, suggesting a different impact on another animal encountering the mark. Mare eliminations were normally on grass, where the mares spent most of their time feeding. This supports Lamoot *et al*.'s (2004) observations that mares do not perform latrine behaviour but defecate where they graze. However, stud piles were situated on paths or ridges and stallions would travel to a stud pile to mark it, in addition to marking them as they passed during their normal daily movements. Ridges often separated the home ranges of harems (King & Gurnell, 2005), but were also used as refugia from flies and were crossed as part of the daily movements of horses in summer.

There was no evidence that stud piles were used to mark the boundaries or peripheral areas of the home ranges. Rubenstein & Hack (1992) found that dung contained information on the identity of a stallion, and thus stud piles provide information about the horses that have passed over ridges or along paths. In addition to identifying occupancy of a range, these stud piles may provide way-points for a stallion and his consorts, and produce a familiar odour within the harem range (Gosling, 1982; Gosling & Roberts, 2001); this is possibly why stud piles are sniffed after marking as well as before. Stud piles are unlikely to be visual signposts (Salter & Hudson, 1978) due to their low profile.

Although marking stud piles during confrontations was relatively rare in this study, such marking provides an opportunity to communicate individual identity (Rubenstein & Hack, 1992; Lawson *et al*., 2000) and may also act as a release for aggressive behaviour (Turner *et al*., 1981). In other studies the order in which the stud pile is marked has been reported to indicate dominance hierarchy within the males (Miller, 1981; Turner *et al*., 1981; Redman, 1996). Conflicts between stallions can be costly (Berger, 1981), and it is expected that they should be avoided when possible. If stud piles relate to the harem's spatial position within the landscape and result in a reduction in conflict between harem holders, then their function is much more than the relict territorial behaviour hypothesized by Klingel (1975). It would be impossible to produce a line of marks sufficiently close that they would always be encountered by intruders along the boundaries of large ranges sited within a rugged, heterogeneous terrain (Gosling & Roberts, 2001). Instead stallions appear to mark in the areas they most

frequently use or in areas of spatial overlap among adjacent harems in a form of hinterland marking (Gorman & Mills, 1984). As the number of harems within the study area was relatively low when we carried out the study, there was little overlap between ranges and low encounter rates between stallions. It did not therefore appear that the number of stud piles was related to the number of stallions using an area. It is likely that as the population increases through time there will be greater competition among harems, and areas of overlap among harems would increase. It will be interesting to examine how the pattern of stud piles changes in the future.

Marking of mare eliminations most likely demonstrates the association between a stallion and a mare (Turner *et al*., 1981; Roberts & Dunbar, 2000). Most of this marking occurred during the breeding season, when comparatively fewer stud piles, but more unknown stimuli, were marked. Although not included in most of the analyses, we believe that most unknown stimuli were probably mare eliminations that were not observed being deposited. Turner *et al*. (1981) also observed more marking of mare eliminations during the breeding season than the winter. The anomalous marking of mare excreta in November is possibly due to the short time in the wild experienced by these horses; some mares may not yet have adapted to only coming into oestrus in the spring, as illustrated by foals occasionally being born in early winter in this population. The seasonal change in marking behaviour could be caused by changes in the pheromones present in mare urine and dung as they come into oestrus (Turner *et al*., 1981). Stimuli contained in female excreta, especially when detected by flehmen, have the potential to affect the sexual behaviour of animals (Eisenberg & Kleiman, 1972). The stallions behaved in a similar way to mare eliminations and unknown stimuli. Kimura's (2001) results suggest that pungent cresols within the urine of stallions may attenuate the chemical information in mare faeces, thus masking the difference between oestrous and non-oestrous mares. This might explain why mare eliminations were not sniffed after marking. However, even in the breeding season not all mare eliminations were marked, so whether there is an attempt to hide the scent of oestrous mares remains to be determined. Thus the most likely reason for marking of mare eliminations, especially when the mare is in season, is to provide information to all the other horses that this stallion is her consort, whether or not the sexual state of the mare is disguised, as was also observed in klipspringer *Oreotragus oreotragus* by Roberts & Dunbar (2000). In addition, marking may provide a sexual stimulus for the stallion and alert him to the receptiveness of the mare.

It is likely that all stallions within the small population at HNP were familiar with each other, and could connect a scent with a stallion's RHP (Smith & Parker, 1976). Thus, if an interloper can link the smell of a known stallion from a stud pile with the scent of the stallion's urine on an oestrous mare's urine, they benefit by assessing the risks involved in attempting to steal the mare or sneak a mating (Gosling, 1990; Gosling & Roberts, 2001). Marking of mare eliminations may have evolved with harem defence polygyny to benefit both the harem holder and the mare. If the stallion is in good physical condition he will be less likely to be confronted and lose the mare, and the mare will not be harassed by a large number of stallions attempting to mate with her. It is also possible that females may use the information in the scent marks to be 'reassured' that they match those of the harem holder with which they are familiar (see Gosling & Roberts, 2001).

Some studies that have dealt with marking behaviour in horses have combined both the marking of stud piles and the marking of mare eliminations (Klingel, 1972; Salter & Hudson, 1982). We believe that stud pile marking and overmarking mare eliminations have a similar but discrete function linked to intrasexual selection (Gosling & Roberts, 2001). Stud pile marking throughout the home range advertises site-specific dominance by the stallion (*sensu* Linklater, 2000) in a cost-effective manner and the fact that he is the resource holder. If interlopers enter the range of a harem holder, then overmarking of mare eliminations could advertise to intruding stallions, and the mare, that the harem holder is the mare's consort. This information can be combined with previous knowledge of the stallion's competitive ability, so that the interloper can judge the risk of trying to steal the mare or sneak a mating. Thus, we propose that the two forms of marking by harem holders combine as first and second lines of defence of paternity rights in intrasexual competition with other stallions.

Acknowledgements

We thank the Foundation Reserves Przewalski Horse for their financial support and the opportunity of studying the horses at Hustai National Park. Thanks to the Mongolian Association for the Conservation of Nature and the Environment and the staff at HNP for all their help during the study. Additional funding for this study was provided by IFAW, Queen Mary Expeditions Committee and Marwell Preservation Trust.

ABSTRACT

Castration is commonly used to control the behavior of companion animals and livestock, yet there have been few longitudinal studies of its effects. Despite the ubiquity of this surgery in ridden horses, the effects of castration (termed gelding in horses) have rarely been examined in a reproductive population. We tested effects of gelding on maintenance and social behaviors of individuals pre- and post-gelding, and in comparison to intact control adult males (2 to >16 years old) in both harem and bachelor status, we then tested how gelding affected association with mares (i.e., maintenance of a harem group) compared to intact controls, and any effects on bachelor social associations. We further explored any effects on foaling rate to assess potential impacts on population growth rate. We conducted this study over four years (2017–2020) at two Herd Management Areas (HMAs) in western Utah, USA: Conger and Frisco. We conducted demographic observations year round at both HMAs to record survival and foaling rate. We additionally recorded behavioral observations at Conger HMA. In December 2017, 27 adult males from Conger (42% of adult males in the population) were gelded and returned to the range with their social groups. Due to pre-treatment observations we were able to compare stallions of known status pre- and post-treatment (harem or bachelor), as well as gelded and intact males. We had no morbidity or mortality related to the gelding surgery and all males maintained good body condition throughout the study. There was no effect of gelding on maintenance behaviors (feeding, moving, and standing). There was no effect of gelding on frequency of agonistic behavior, and a non-significant tendency for less reproductive behavior in geldings; geldings showed more affiliative and less marking behavior. Age class and/or social status were better predictors of behavior than gelding. Over time fewer geldings maintained a harem, and their harem size declined during the study. Horses that were bachelors when gelded tended to remain as bachelors, whereas intact bachelors of the same cohort mostly attained a harem. Foaling rate at Conger was reduced in the year following treatment, but then returned to pre-treatment levels. From a welfare perspective gelding is safe to use in feral horses and has minimal effects on horse behavior and social interactions in a reproductive herd. Effectiveness for population growth control would likely require a larger proportion of males in the population to be castrated for longer-term effects on foaling rate.

1. Introduction

Castration has been used as a tool to control male behavior for millennia. It has been used to prevent reproduction and make males more tractable in all domestic mammal species, and even in humans (Zumpe et al., 1992). Sterilizing companion animals is considered the norm in many countries, with only 14% of dogs (*Canis familiaris*) remaining intact in the United States (Houlihan, 2017). Similarly the majority of domestic horses (*Equus caballus*) are castrated (Schumacher, 1996; Searle et al., 1999). This is referred to as gelding in horses, with castrates termed geldings. Despite the ubiquity of this surgery there has been surprisingly little longitudinal research on behavioral effects of castration, and even fewer studies on how castration affects free-roaming animals living in a population with intact congeners (Garde et al., 2016). In domestic dogs research has only recently started to focus on longer term effects of castration, with most studies examining health effects of castration at different ages rather than behavioral outcomes (Hart et al., 2014, 2019; McGreevy et al., 2018).

Despite castration generally being applied to modify behavior, there is surprisingly little evidence that it affects it. Castration is expected to affect behavior through removing testicular production of androgens such as testosterone, and subsequent effects on other endocrine glands (Thompson et al., 1980; Taravat et al., 2017). The two main behaviors that are expected to be controlled by testicular removal are aggression and reproductive behaviors. Although aggression was reduced in pet domestic dogs (Maarschalkerweerd et al., 1997), there was no difference in aggression post-castration of free-ranging dogs (Garde et al., 2016). Across other species, aggression was reduced in castrates compared to intact males in rodents and Japanese macaques (*Macaca fuscata*; Christie and Barfield, 1979; Hume and Wynne-Edwards, 2005; Lofgren et al., 2012; Takeshita et al., 2017; Gale et al., 2019), but not in prairie voles (*Microtus ochrogaster*) and some other non-human primates (Wilson and Vessey, 1968; Epple, 1978; Demas et al., 1999). Effects on horse aggression have rarely been studied and are confounded by aggression sometimes being the reason for castration; one study found aggression was controlled by gelding (Smith, 1974), whereas others found it continued to be problematic (Line et al., 1985; i Rios et al., 1995; Schumacher, 1996). Studies that have examined the effect of castration on reproductive behavior in a variety of species have found that it is rarely extinguished but tends to be presented less over time after surgery (Wilson and Vessey, 1968; Phoenix, 1974). Reproductive behavior has been reported in geldings and was evident regardless of whether horses were castrated pre- or post-puberty (Smith, 1974; Line et al., 1985; Cox, 1986; i Rios et al., 1995).

Management of free-ranging feral cats (*Felis catus*) commonly uses surgery as a tool to slow population growth (Guttilla and Stapp, 2010), yet despite most male riding horses being gelded it has been little used for feral horse (henceforth "horse") management. In the American west there is currently an increasing population of approximately 90,000 horses and donkeys on public lands managed by the Department of Interior (BLM, 2020), which is considered almost three times larger than these arid rangelands can sustain (BLM, 2020). These animals are protected under the Wild Free-Roaming Horses and Burros Act, as amended (Public Law 92, 195, 1971), with management options available to management agencies currently limited to gathers and removals from public land and/or fertility control. Surgical options are allowed under the Act but have rarely been used due to public litigation when they have been proposed. Thus fertility control to date has largely consisted of immunocontraception of adult females (Kane, 2018).

Horses have a female defense polygyny social system, where typically one adult male (stallion) associates with a group of adult females (mares) and their juvenile offspring of both sexes, defending the mares from harassment by other stallions in order to maintain exclusive mating opportunities (Boyd et al., 2016; King et al., 2016). In some populations multi-male groups have been observed, although the function of additional stallions in these groups is disputed (Feh, 1999; Linklater and Cameron, 2000a, 2000b; Feh, 2001; Linklater et al., 2013). Social groups of a stallion and mares (hereafter referred to as a harem) tend to have stable adult membership over periods of months to years (Ransom et al., 2016). Equids are unusual in polygynous ungulates in that both male and female offspring disperse from their natal group around puberty (Linklater and Cameron, 2009; Debeffe et al., 2015). Dispersed males live alone or in fission-fusion groups with other males until they form a more permanent association with adult females (i.e., become harem stallions). Some males never achieve harem stallion status and thus remain as bachelor stallions (Boyd et al., 2016). While the social network of horses is underpinned by long-term relationships between mares (Sigurjónsdóttir et al., 2003; Stanley et al., 2017), stallions also have a rich social life. In a natural population it is likely that most males know each other and their relative fighting ability (Rubenstein and Hack, 1992), resulting in most stallion interactions being non-violent due to ritualized behaviors (Sigurjónsdóttir et al., 2012) or play (Feh, 2005).

Only three previous field studies have examined effects of controlling male fertility on population growth of feral horses (using microcapsulated testosterone propionate (Kirkpatrick et al., 1982; Turner and Kirkpatrick, 1982), vasectomy (Eagle et al., 1993), and gelding and vasectomy (Collins and Kasbohm, 2017)). All found reduced foaling rates in harems of treated stallions in the first year after treatment or reduced female fecundity, but none examined any behavioral effects of the treatment, or longer-term effects. Modeling approaches indicated that male-based fertility control would only be effective if 90% of males were sterilized, as one male has the potential to fertilize many females (Garrott and Siniff, 1992). However it is unknown whether this would be true in practice due to female mate choice (Pickerel et al., 1993) and the strong social bonds formed within horse groups (Cameron et al., 2009). There is little published on how geldings may behave in a reproductive herd. When in a large pasture or free-roaming with mares and their offspring, geldings have been reported to form their own groups both in the presence and absence of intact stallions (Kaseda, 1981; Kaseda et al., 1997; Sigurjónsdóttir et al., 2003; Van Dierendonck et al., 2004).

Feral horses on public lands in the western United States are managed by the agency responsible for those lands: the United States Department of Interior's Bureau of Land Management (BLM) or U.S. Department of Agriculture, Forest Service (USFS). There is intense public scrutiny on management of feral horses, with broad interest in welfare implications of any action (Scasta et al., 2018). We conducted research to address questions of interest to both management and the wider public related to castrating a proportion of males in a free-roaming horse population. Management interest relates to the utility of gelding as a potential tool for controlling population growth, either due to reduced foaling rate of females, or replacing reproductive individuals with geldings. Managers are further concerned about welfare impacts of surgery, potential behavioral impacts on individuals and the social structure of the population, with the public also being concerned about how gelding may affect perceived 'wildness' of feral horses (Bureau of Land Management, 2016). We conducted our study on two horse populations, in which 42% of males in one population were gelded and all males in the other population were untreated (intact) controls. The social status (harem or bachelor) of all males was known prior to gelding, and tracked subsequently. We tested whether there was any effect of gelding on welfare of the males, in terms of survival and body condition in comparison with intact controls. We examined behavioral effects of gelding by comparing intact and gelded males, and behavior pre- and post-treatment. We hypothesized that gelded males would quickly lose interest in females, reflected in more time spent feeding and less time moving as they would not be seeking mating opportunities, and in lower frequencies of reproductive behavior and aggression due to lack of endogenous testosterone. In harem stallions we expected those gelded (hereafter referred to as harem geldings) to quickly lose their harems due to lack of interest in reproduction. In bachelors we expected there to be little difference in behavior between gelded and intact males as both are non-reproductive. We hypothesized that gelding would reduce foaling rate as there would be fewer reproductive males and the polygynous social system would reduce pregnancy in females with a gelded harem stallion.

2. Methods

2.1. Study areas and individuals

We conducted research on horses at Conger Herd Management Area (HMA; 69,198 ha) and Frisco HMA (24,430 ha) in western Utah, USA. Both have similar habitat of valleys with sagebrush (*Artemisia* spp.) meadows and pinyon (*Pinus edulis*)-juniper (*Juniperus* spp.) covered mountain ridges, although Frisco has both more sagebrush covered flat areas and more mountainous forest. The BLM conducted management gathers at both HMAs prior to our study and all horses captured were taken to holding facilities. A randomly selected 100 of the gathered horses (50 male, 50 female) across all age classes were returned to the

range at each site. Horses were returned to Conger HMA in August 2016, and to Frisco HMA in February 2017. All individuals returned to the range were marked with a numeric freeze brand on the left hip; other individuals and those born subsequently were identified by pelage color and markings. A total of 38 adult females at Conger and 30 at Frisco were fitted with radio collars (Lotek Wireless Iridium, and Sirtrack Ltd. very high frequency collars) following methods in Schoenecker et al. (2020); we fitted telemetry tail tags (Biotrack Ltd., and American Wildlife Enterprises) on 49 adult males at Conger and 35 adult males and yearlings of both sexes at Frisco (King and Schoenecker, 2022). Between November 28 and December 1, 2017 the BLM conducted a second gather at Conger only to treat males. This gather focused on maintaining horses in their social groups: 111 horses of both sexes and all ages were captured out of an estimated population size of 157. They were kept at the BLM Delta Wild Horse and Burro Facility in their known social groups (obtained from field observations), and released in these groups post-treatment. This research was approved under Colorado State University (CSU) Institutional Animal Care and Use Committee protocol 15–6058 A, U.S. Geological Survey (USGS) FORT IACUC 2015–10, and an inter-institutional agreement between CSU and USGS. All work was conducted on wild horses managed by the Bureau of Land Management and animal handling followed their protocols (Bureau of Land Management et al., 2015) and National Environmental Policy Act (NEPA) analyses (DOI-BLM-UT-W020–2015–0017-EA).

2.2. Treatment

In 2017 there were 64 adult males at Conger (i.e., born in 2015 or before) of which 34 were captured during the treatment gather (53%). We castrated all captured males $\geq$ 2 years old (n = 27) except for 7 controls: 3 harem stallions (i.e., associating with mares and exhibiting harem tending and reproductive behaviors) and 4 bachelors (i.e., not associated with mares), identified from field observations. The 27 males gelded represented 42% of adult males on Conger, and 79% of males that were captured (Table 1). Half of the harem stallions present in 2017 (50%) and 39% of bachelors were gelded. All adult ages were represented in samples of gelded and intact stallions (Fig. 1). Castration surgery was conducted on December 6, 2017 by a BLM-contracted veterinarian at the BLM Delta Wild Horse and Burro Facility. All horses receiving surgery were first given a sedative, then anesthetized with ketamine and succinyl choline, plus given a testicular block of lidocaine. After surgery they were administered tetanus vaccine, antibiotics, and analgesics. Anesthetized horses were recumbent for 6–25 min before regaining their feet and being moved to a recovery pen. Within hours of the surgery harem stallions were put back in a pen with their social group. There was no morbidity or mortality as a result of surgery. Harem groups in which the stallion was not gelded (i.e., remained intact) were returned to the range as a group after 6–11 days at the holding facility (between December 6 and 8); harem geldings and their groups, and gelded and intact bachelor stallions were returned to the range after 14–15 days at the holding facility (5–6 days post-surgery; December 11–12). All gelded males were located in the field to confirm recovery between December 12–19, 2017, and then at least monthly thereafter for the duration of the study.

2.3. Field observations

All telemetered individuals were located at least monthly between September 2016 and September 2020 at Conger (treatment population) and between March 2017 and September 2020 at Frisco (control) so that we could determine survival, social associates, and body condition of males (using the Henneke et al., 1983 scoring system), and population foaling rate. At Conger we targeted behavioral observations before and after treatment on a focal subset of telemetered individuals (16 males: 8 who were harem stallions and 8 who were bachelors in 2017; 4 mares); no behavioral observations were conducted at Frisco. We increased our sample size of individuals in behavioral observations by recording behavior of focal horses plus any social associates at the time of the observation. In this way we were able to collect data on the focal individual plus its social group, enabling us to track behavior of focal individuals moving into a new social group, or track behavior of new individuals joining a focal individual's group. For behavioral observations we aimed to locate each focal individual in each of three time periods (0700–1100, 1100–1600, 1600–2000) twice per month between April and September each year. Observations were conducted in teams of two trained people; interobserver reliability checks were conducted periodically. We located radio marked animals using telemetry tracking by ground observers, or opportunistically. We conducted observations through binoculars (10 ×40, various manufacturers) or with a scope (Bushnell 20–60 ×80) from a sufficient distance that caused no disturbance (mean = 324 m ± 430 SD). Every 5 min during an observation hour we used scan sampling (Altmann, 1974) to record the maintenance behavior of each individual in the group (feeding, moving, lying down, standing, other, or out of sight). We used all occurrence sampling (Altmann, 1974) to record social behaviors such as agonistic, affiliative, reproductive, and marking behaviors, based on author experience (King, 2002) and ethograms from Ransom and Cade (2009) and McDonnell (2003). We recorded the actor and start time of all occurrence behaviors.

2.4. Analyses

Behavior was examined in a before-after treatment design at Conger HMA, and only data on males are presented here (Schoenecker and King, 2022). We censored data to only include males that were observed for at least 1 h in any year of the study: out of 35 males that we gathered behavioral data on, 31 (including 15 who were gelded) had sufficient data in at least one of the study years to be included in analyses (SI Table 1). Analyses were conducted on 1004 h of observations collected on these 31 males between April 2017 and September 2020 (total was 1527 animal-hours of observations). Counts of the most common maintenance behaviors (feeding, moving, and standing) collected every 5 min during the observation hour was divided by 12 to conduct analyses on rate per hour. For analyses of all occurrence behaviors we combined observations of specific behaviors to a category. Agonistic behavior consisted of bump/push, bite, kick, chase, strike, box, arched neck threat, parallel walk, head toss, naso-nasal, and herding. Affiliative behaviors were:

Table 1
Status of stallions (male horses born in 2015 or before) at Conger and Frisco Herd Management Areas in Utah, USA in 2017: harem stallions were primarily associated with mares and exhibited tending behaviors, bachelors were associated with other stallions or alone. Not gathered and gathered indicates the number of horses that were captured in a gather in November 2017, which was followed by gelding of some stallions at Conger; gelded and intact indicates whether captured horses were castrated or not. There was no 2017 gather at Frisco.

		Conger			Frisco		
		Harem	Bachelor	Total	Harem	Bachelor	Total
Not gathered		6	24	30	No gather		
Gathered	Gelded	9	18	27			
	Intact	3	4	7			
Total number of stallions		18	46	64	16	33	49

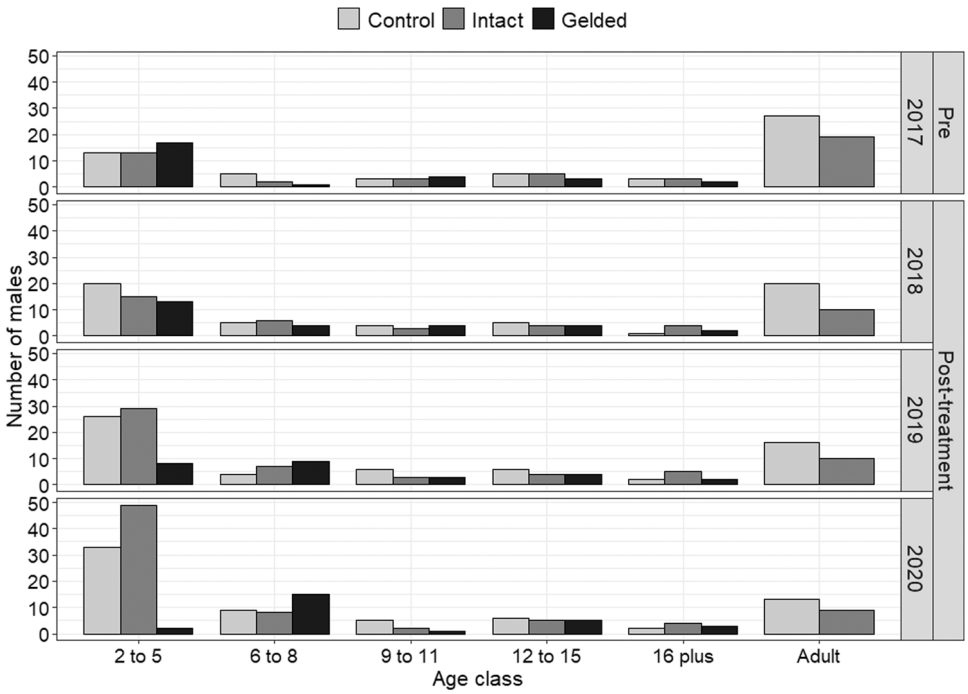

Fig. 1. Age structure of the adult male population at Conger and Frisco Herd Management Areas (HMAs), Utah, USA. Horses with no known age class (i.e., horses are those that were first seen as adults and do not have a known age) are described as "Adult". Control males were those at Frisco HMA; intact and gelded males were at Conger HMA. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year.

mutual grooming (where two individuals groomed each other simultaneously), allogrooming (where one individual groomed another without reciprocity), touch, and play. Reproductive behaviors were: sniff genitals, mounting (with or without an erection, or an erection was unknown), copulation (with or without successful intromission), and masturbation. Marking behaviors were: flehmen, sniffing feces and urine, and using feces and urine to overmark. We used all observations collected over the 1004 h of observation where one of the 31 males included in the behavioral analyses was the actor (n = 2508 events), using rate per observation hour for analyses.

All analyses were conducted in R software (R Core Team, 2017). To examine potential effect of gelding on maintenance behavior we used generalized linear mixed models with study individual as a random variable to account for repeated sampling. We used data from 2017 as the intercept in order to examine effects in relation to pre-treatment. For each model we used the behavior of interest (feeding, moving, or standing) as the response variable, year of the study, whether gelded, status (harem or bachelor), and age class as fixed variables. Prior to running models we assessed multicollinearity by fitting a global linear model for each response variable and using the package 'olsrr' (Hebbali, 2020) to calculate variance inflation factors of the fixed variables. Variance inflations factors were low (<2.2), therefore we concluded that multicollinearity was not an issue and thus using model-averaged regression coefficients to assess significance was appropriate (Cade, 2015). We used package 'MuMIn' (Bartoń, 2020) to rank models by Akaike's information criterion corrected for small sample sizes (AICc; Burnham and Anderson, 2010) and produce average coefficients of models within the top model set of delta $AIC_c < 2$. We considered parameters useful for inference if their model-averaged 95% confidence intervals (CI) did not overlap zero (Burnham and Anderson, 2010), however all parameters were additionally tested at 85% CI (Arnold, 2010); we report these results if they indicate biological significance that is not revealed with 95% CI. The nature of social behavior means that we had a zero inflated data set of all occurrence behaviors. We therefore used package 'glmmTMB' (Magnusson et al., 2021) for all models. We built models using the same factors as for maintenance behaviors, and ran them using Poisson, Conway-Maxwell Poisson and negative binomial with quadratic parameterization distributions, and hurdle models using truncated Poisson and truncated negative binomial distributions to test for the best distribution fit to the data. We determined the model with the best fit as being that with the lowest AIC using the function AICtab in package 'bbmle' (Bolker and R Core Team, 2020); for each tested behavior this was truncated negative binomial (truncated_nbinom2). We then ran all permutations of the model, using AICtab to rank models by AIC_c, and averaging models with delta $AIC_c < 2$. For all models we obtained estimated marginal means (package 'emmeans', Lenth et al., 2021) and reported odds ratio and significance level of the effect of gelding averaged over levels of other factors in the model.

To examine effects of gelding on stallion status we compiled all demographic data gathered at both Conger and Frisco between March 20, 2016 and September 23, 2020. In our populations multi-male groups manifested both as bachelors following a harem group from a distance but not integrating ("tag males"), and adult males that participated in group defense and were more integrated in the harem group but did not hold harem stallion status ("lieutenant males"; harem stallions had closer and longer association with the mares). On each occasion they were seen we determined whether a male was a harem stallion, bachelor, or a tag/lieutenant male. Tag/lieutenant males were considered bachelors for most analyses because they did not maintain a harem and most were transient members of a group. For analyses we censored the dataset to remove any males that had no known birth year, and any born in 2016 or later (i.e., horses that were foals or yearlings at the time of treatment, or not yet born). We also excluded any horse seen < 5 times in two or more years of the study. This resulted in a dataset of 49 males from Conger (25 gelded, 24 intact) and 24 males from the control population, Frisco.

We evaluated the effect of gelding on survival of males at Conger. We examined factors affecting body condition of adult males at Conger and Frisco using a generalized linear mixed model after checking for colinearity of variables: we used body condition score on each demographic observation as the response variable, with study area, year, age class, season (winter: December to February; spring: March to May; summer:

June to August; fall: September to November), harem status in the year of behavioral observation (harem stallion or bachelor), and whether the male was a Frisco control, Conger gelded or Conger intact as fixed variables, and study individual as a random variable. We ranked models by AIC_c, produced average coefficients of models within the top model set of delta $AIC_c < 2$, and considered parameters useful for inference if their model-averaged 95% confidence intervals did not overlap zero.

For analyses on harem stallions we included any horse that fulfilled those criteria (associating with mares and exhibiting harem tending and reproductive behaviors) at any period during the four years of the study. Using observations within a calendar year we classified whether stallions maintained association with mares the whole time ("kept mares"), became a bachelor and did not return to associating with mares ("lost mares"), whether they went from being a bachelor to associating with mares ("gained mares"), or whether they moved between harem and bachelor status several times during the year ("gained/lost mares") and provided these results descriptively. After testing for colinearity we used a generalized linear model to examine factors affecting the proportion of observations that an individual was the primary male seen with mares each year (Table 1). Factors included in the model were: proportion of observations stallion was with mares in a year as the response variable, and year of the study, age class, and whether a stallion was gelded, intact, or a control as fixed variables. We ranked models by AIC_c to produce average coefficients of models within the top model set of delta $AIC_c < 2$, and considered parameters useful for inference if their model-averaged 95% confidence intervals did not overlap zero. We repeated this process iteratively using each age class as the intercept to determine effect of age class. Harem size was assessed as the number of mares in the group each time a male was seen; we used linear regression to examine the relationship of harem size over time for each group of males (gelded, intact, or control), and then used Fisher's r-to-z comparison to detect any difference in slope among these groups.

For analyses, we classified bachelors as males that were not harem stallions for more than half demographic observations each year. We used a Kruskal-Wallis test to examine differences in number of bachelors in each of the three stallion groups (geldings, intact, and control males) across the years of the study. We used Wilcoxon signed rank tests to examine whether harem geldings were more likely to have tags or lieutenants, and whether the tag or lieutenant males joining the groups were more likely to be geldings.

Gestation length of horses is 11 months with most foals conceived around the summer solstice (Ransom et al., 2013), therefore most foals are born a calendar year after conception. Consequently, we assessed how gelding affected foaling rate > 1 year post-treatment. Foaling rate was calculated as the number of adult females (≥2 years old) divided by the number of foals born. Confidence intervals at 95% for foaling rate in

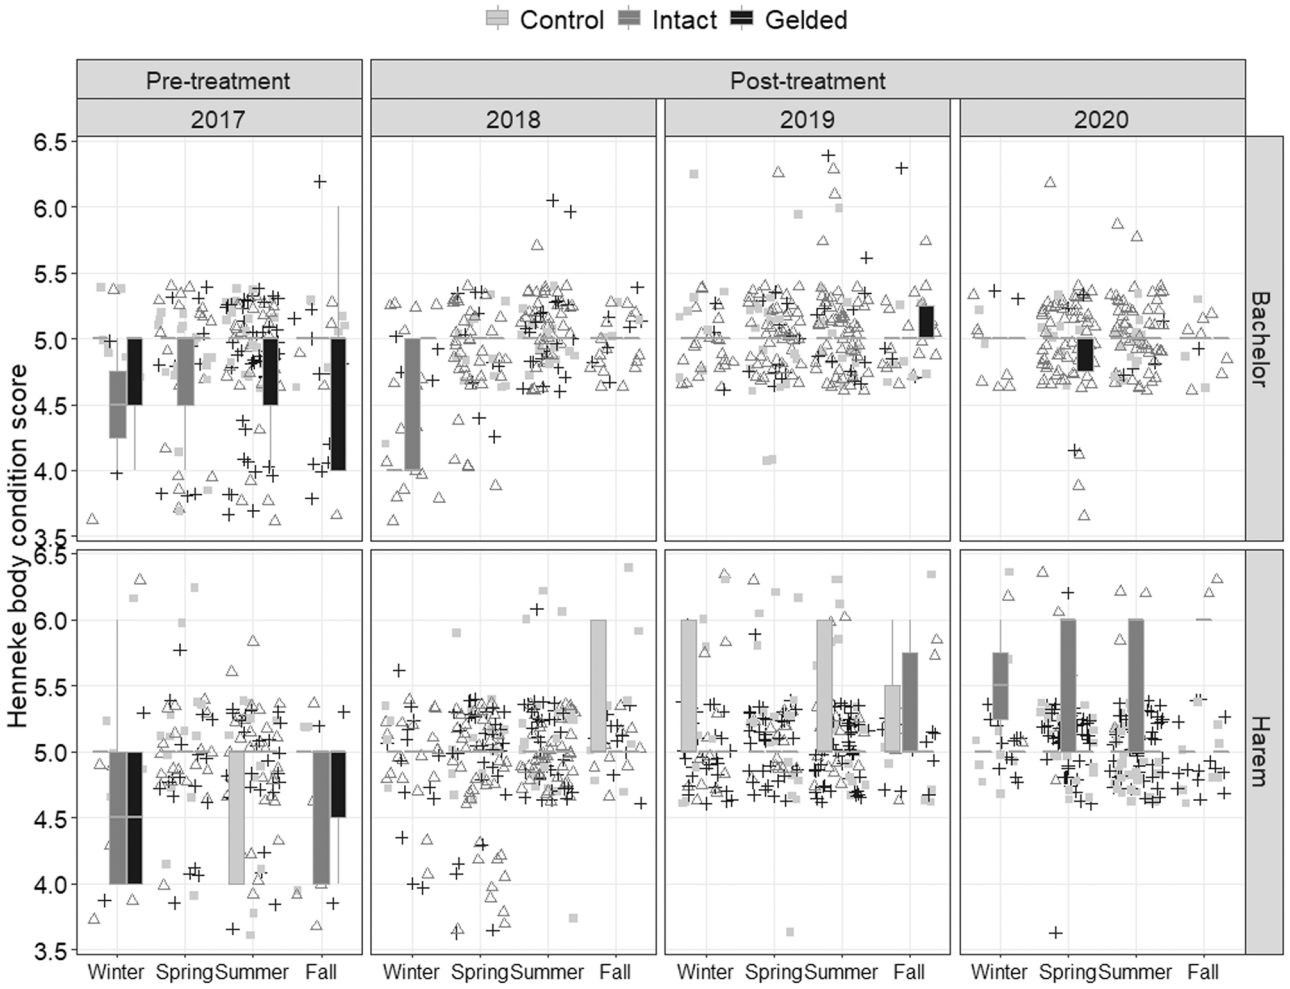

Fig. 2. Body condition score of males at Frisco (control stallions) and Conger (intact and gelded stallions) Herd Management Areas, Utah, USA across seasons between 2017 and 2020. Body condition score follows Henneke et al. (1983) on a scale of 1 = emaciated to 8 = obese. Boxplots show median values (horizontal lines), with the box limits indicating 25th and 75th percentile of the interquartile range and whiskers showing values 1.5 times the interquartile range above or below these percentiles. In most seasons median body condition was 5, meaning that no bar is displayed. Jittered data points are shown: controls in pale grey squares, intact in mid -grey triangles, and gelded in dark grey crosses. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year; they are shown separated in 2017 for comparison with post-treatment.

each year were calculated using an exact binomial test.

3. Results

3.1. Survival and body condition

Survival was not affected by being gelded. During the 4 year study the only mortality of an adult male at Conger was a 22 year old horse in 2017, the pre-treatment year, with no subsequent mortalities of gelded or intact males. Two adult males died at Frisco during the study. All males maintained good body condition throughout the study (Frisco controls: mean Henneke body condition score = 5.05 ± 0.38 SD; Conger intact: mean = 4.94 ± 0.33 SD; Conger gelded: mean = 4.96 ± 0.33 SD; Fig. 2). Body condition was not affected by being gelded: as a factor it was not included in any of the top models. Year, study area, and status were included in top models, but only year had a significant effect (0.001 – 0.033 95% confidence intervals (CI)).

3.2. Behavior

There was no effect of being gelded in models of factors affecting frequency of maintenance behaviors (feeding: model averaged odds ratio = 1.18, P = 0.2019; moving: odds ratio = 0.669, P = 0.1143; standing: odds ratio = 1.22, P = 0.730). The top models for feeding and moving only included whether a male was gelded and status (whether harem or bachelor male). For both behaviors the null model had the greatest support and neither factor was significant, indicating that they did not influence time spent feeding or moving (Fig. 3 A, B; SI Table 2a, b). The model for standing included all factors: standing was significantly affected by year, increasing after the pre-treatment year of 2017 (particularly 2019: 0.05–0.65 95% CI; Fig. 3 C; SI Table 2c), and by age class, with older males tending to spend more time standing (>16 years old: 0.08–0.85 95%CI). For both moving and standing, being gelded was significant at the 85% CI level (moving: 0.02–0.72 85% CI; standing: −0.35 to −0.05 85% CI) indicating a small effect.

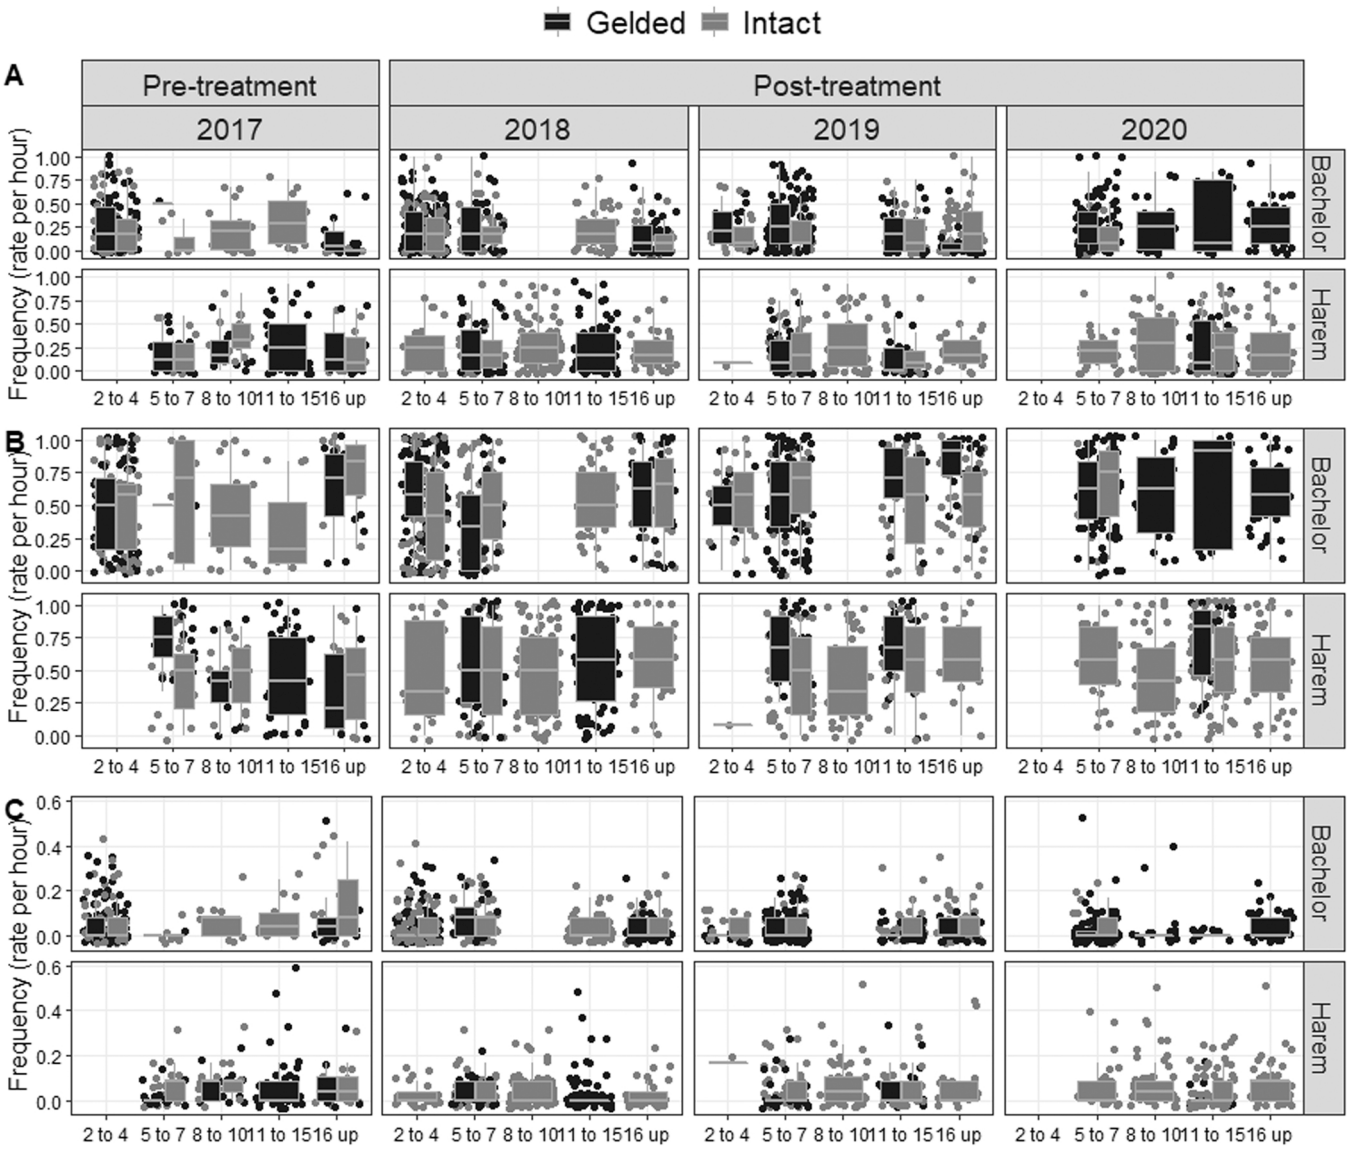

Fig. 3. Maintenance behaviors of gelded and intact males at Conger Herd Management Area, Utah, USA shown by harem status (bachelor or harem stallion) and age class in each year of the study. All data points are shown to give an idea of data spread. Maintenance behaviors presented are feeding (A), standing (B), and moving (C). Boxplots show median values (horizontal lines), with the box limits indicating 25th and 75th percentile of the interquartile range and whiskers showing values 1.5 times the interquartile range above or below these percentiles. Jittered data points are shown to give an idea of data spread: intact in paler grey, gelded in dark grey. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year; they are shown separated in 2017 for comparison with post-treatment.

Gelding was among factors in the top models for all social behaviors, but was only significant for marking and affiliative behaviors (gelded males showed more affiliative behaviors and marked less than intact males; affiliative: odds ratio = 1.74, P = 0.0254; marking: model averaged odds ratio = 0.539, P = 0.0019; Fig. 4 A, B SI Table 3a, b; Table 2), with no significant effect on agonistic or reproductive behaviors (agonistic: odds ratio = 0.838, P = 0.4769; reproductive: odds ratio = 0.524, P = 0.2009; Fig. 4 C, D; Table 2; SI Table 3c, d). Although not significant at 95% CI, gelding had biological significance at 85% CI in the model for reproductive behavior (0.42 – 1.37 85% CI; Table 2). Models for reproductive behavior and marking included status, with harem stallions having a significantly higher frequency of reproductive behavior than bachelors (Fig. 4 D; SI Table 3d). Age class was in the top models for agonistic and affiliative behaviors: 5- to 7-year-olds had a lower frequency of aggression than other age classes (Fig. 4 C SI Table 3c). Year was in the top models for all social behaviors but was not significant at 95% CI for any behavior (with the exception of reproductive behavior in 2020; SI Table 3).

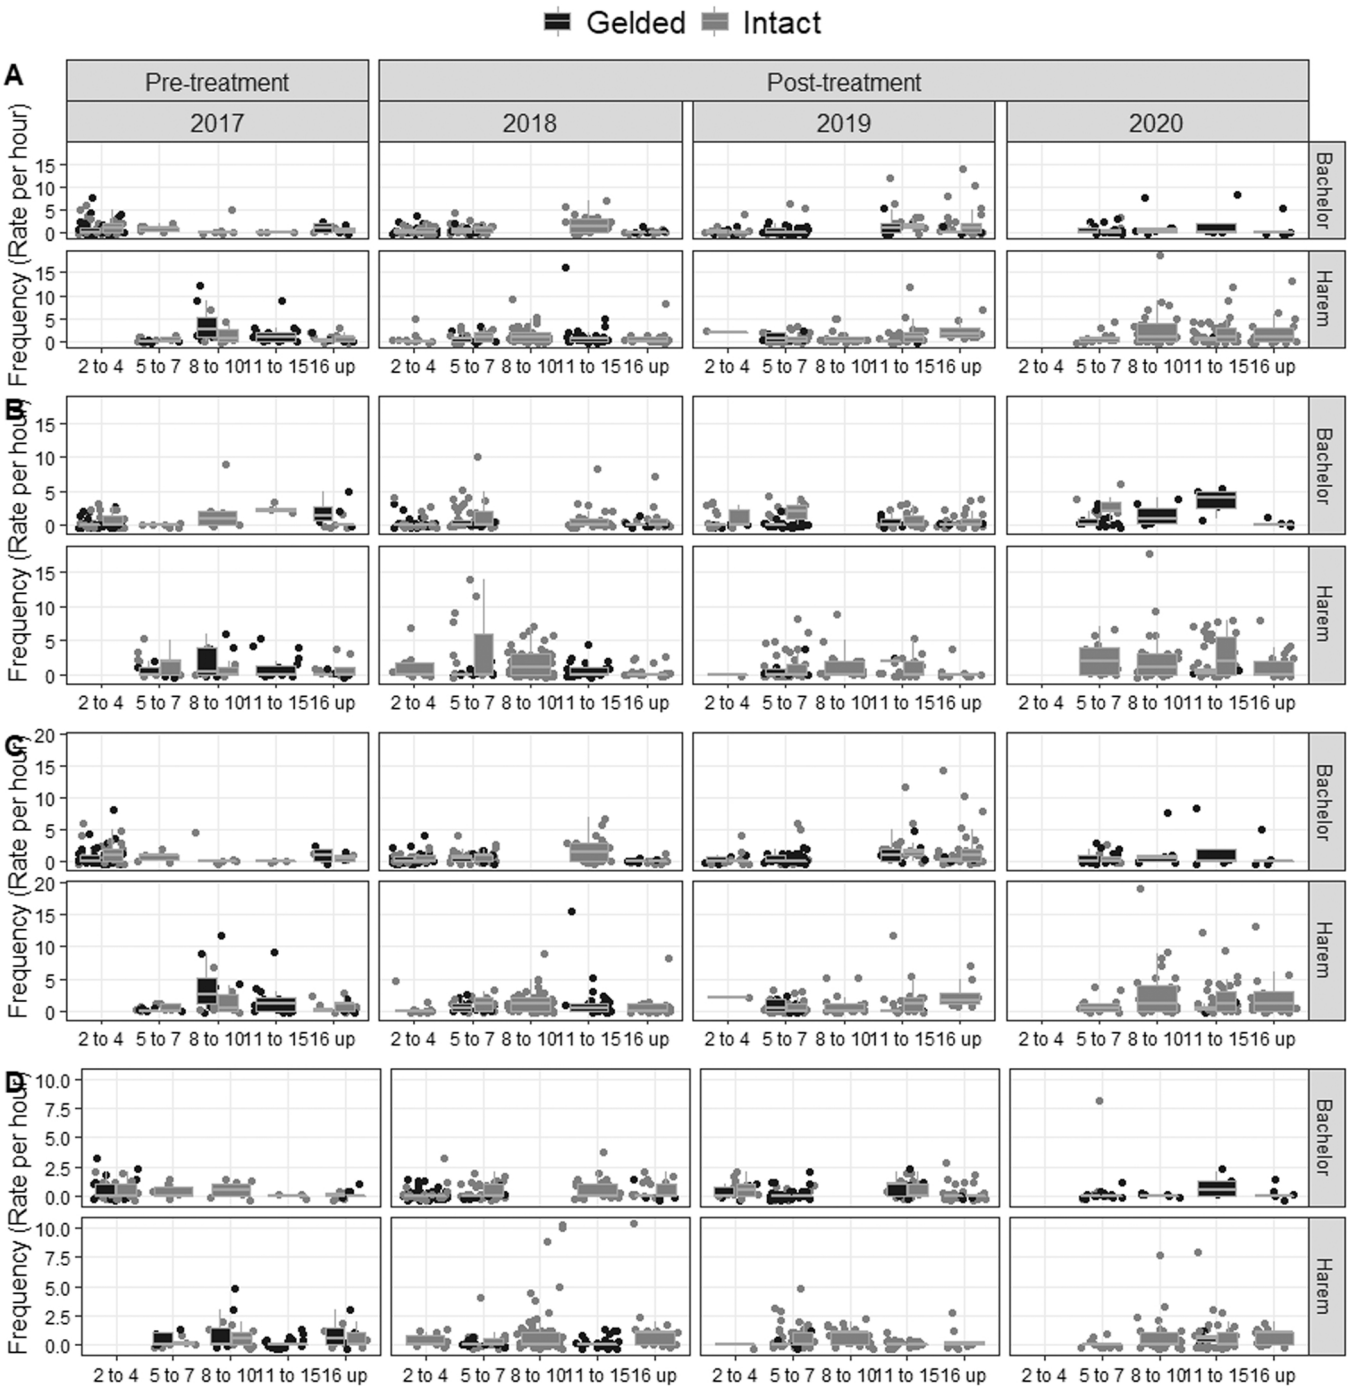

Fig. 4. Social behaviors of gelded and intact males at Conger Herd Management Area, Utah, USA shown by harem status (bachelor or harem stallion) and age class in each year of the study. All data points are shown to give an idea of data spread. Behaviors represented are affiliative (A), marking (B), agonistic (C), and reproductive (D). Boxplots show median values (horizontal lines), with the box limits indicating 25th and 75th percentile of the interquartile range and whiskers showing values 1.5 times the interquartile range above or below these percentiles. Jittered data points are shown: intact in paler grey, gelded in dark grey. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year; they are shown separated in 2017 for comparison with post-treatment.

Table 2
Frequency of social behavior per hour of male horses at Conger Herd Management Area, Utah, USA. Data were collected between April and September annually between 2017 and 2020 and summarized to show mean ± standard deviation for each behavior across all years. All males include both gelded and intact males; gelded males were intact in 2017 but data from all years is summarized.

Behavior	All males	Gelded males	Intact males
Agonistic	1.10 ± 2.04	0.86 ± 1.87	1.22 ± 2.11
Reproductive	0.53 ± 1.17	0.28 ± 0.65	0.64 ± 1.33
Marking	1.07 ± 1.89	0.54 ± 1.16	1.32 ± 2.10
Affiliative	0.77 ± 1.54	1.18 ± 2.05	0.58 ± 1.17

3.3. Harem stallions

In the pre-treatment year (2017) there was little difference in associations of harem stallions with mares between control stallions at Frisco and those at Conger (Fig. 5 A). In the first year after treatment (2018) one gelding gained a harem and 3 gained-and-lost, in 2019 no harem geldings gained mares, and 3 harem geldings gained-and-lost their harems in 2020. The number of harem geldings that kept their harem over a calendar year steadily diminished during the study, whereas the number of control stallions at Frisco and intact harem stallions at Conger that kept harems increased (Fig. 5 A).

When examining factors affecting proportion of observations harem stallions associated with mares (including data from Frisco controls; Fig. 5B), study site was not included as a factor in the averaged model, and there was no difference between intact stallions at Conger and control stallions at Frisco (0.69 to −1.59 95% CI). We ran the model a second time using only data from Conger and found gelding negatively affected the proportion of time spent with mares (Fig. 5B; −4.77 to −1.67 95% CI), but proportion of time spent with mares was also affected by age class (Table 3), with 2–4 year olds having less association with mares than all older age classes, and 5–7 year olds having less association than 8–10 year olds. There was no difference among age classes over 8 years old, and a model including an interaction term between proportion of time seen with mares and age did not converge. Year was not included as a factor in top models for time spent in association with mares. However there was a significant interaction of year and gelded status on harem size (Fig. 5 C; $F_{2,1303}$ = 13.3084, P = <0.0001), with a Fisher's r to z comparison indicating that the Pearson correlation for harem geldings (r = −0.37) was significantly different both from males at Conger that were intact (r = 0.08; z = 10.08, P = <0.0001) and controls at Frisco (r = -−0.08; z = 5.4, P = <0.0001; Fig. 5 C).

3.4. Bachelors

Bachelors in 2017 that were gelded were more likely to remain bachelors than those who were intact (Kruskal-Wallis K = 6.326, df = 2, P = 0.0423; Fig. 6A). Control males in Frisco and intact males in Conger who were bachelors in 2017 acquired harems over the years of the study. By 2020 fewer than a third remained as bachelors. There was no effect of gelded status on harem stallions that had lieutenants or tags associating with their group (intact: Wilcoxon W = 14, P = 0.1059; control: W = 6.5, P = 0.766; Fig. 6B), and there was no effect of gelded status on whether a bachelor became a lieutenant or tag (intact: W = 14, P = 0.1081; control: W = 7.5, P = 1.0).

3.5. Foaling rate

Over the 4-year study populations grew to an estimated size of 311 and 217 horses at Conger and Frisco, respectively, by September 2020. Foaling rate at Conger was reduced during the first year post-treatment

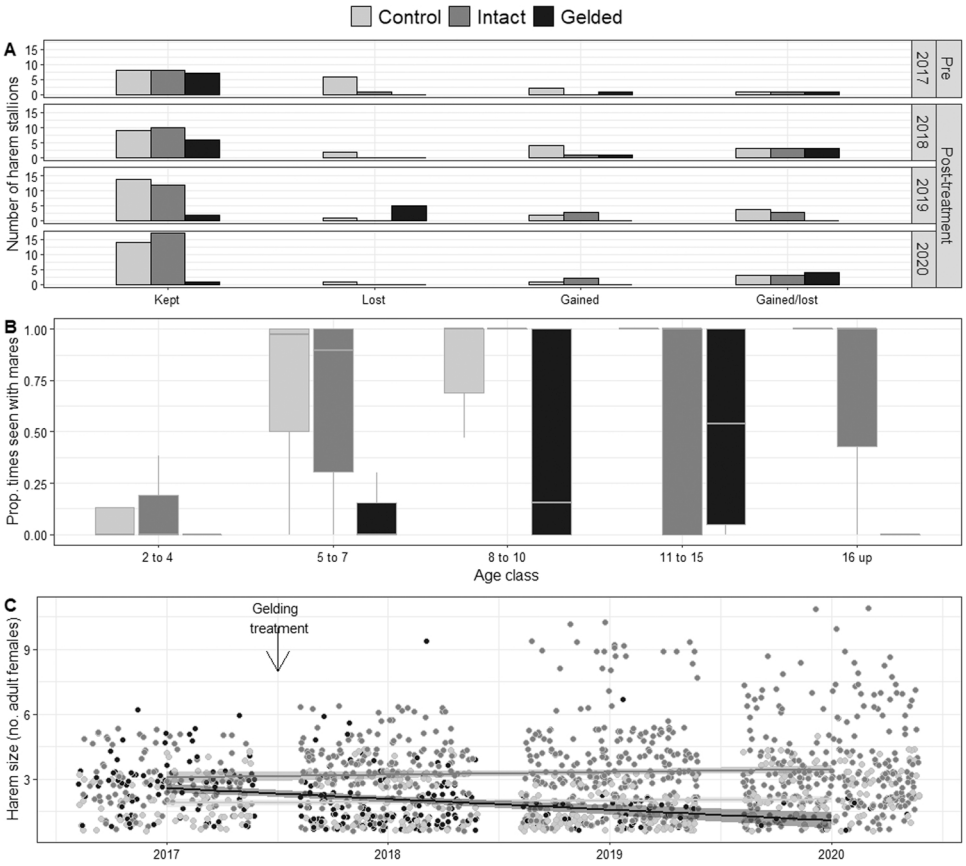

Fig. 5. Data on harem stallions at Frisco (intact controls) and Conger (gelded and intact males) Herd Management Areas, Utah, between 2017 and 2020. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year; they are shown separated in 2017 for comparison with post-treatment. A) The number of feral horse harem stallions in each year that kept their harem (i.e., were associated with mares on each observation), that lost their harem (i.e., were consistently seen with mares then were not seen with them again the rest of the year), that gained a harem (i.e., were seen alone or with bachelors, then consistently seen with mares), or that repeatedly gained or lost a harem during the year. B) Proportion of observations that males were seen with mares as harem stallions by age class. Boxplots show median values (horizontal lines), with the box limits indicating 25th and 75th percentile of the interquartile range and whiskers showing values 1.5 times the interquartile range above or below these percentiles. Instances where there is just a line at 1 or 0 indicate all observations were either of males with mares or without mares. C) Harem size over time. Regression lines with standard error are shown, together with all data points.

Table 3
Matrix of generalized mixed model estimates (beta values) and 95% confidence intervals showing the effect of age class and gelding on proportion of observations stallions were seen with mares at Conger Herd Management Area, Utah, USA. Significant effects are shown in bold.

Age class	Gelded	2–4	5–7	8–10	11–15	16 +
2–4	**-2.95 (−4.77 to −1.67)**		**2.54 (1.05–4.41)**	**4.13 (2.25–6.41)**	**3.11 (1.34–5.20)**	**2.82 (0.65–5.36)**
5–7		**-2.54 (−4.41 – −1.05)**		**1.59 (0.17–3.16)**	0.57 (−0.90 – 2.00)	0.28 (−1.65 – 2.24)
8–10		**-4.13 (−6.41 – −2.25)**	**-1.59 (−3.16 – −0.17)**		-1.03 (−2.70 – 0.51)	-1.32 (−3.49 – 0.80)
11–15		**-3.11 (−5.20 – −1.34)**	-0.57 (−2.00 – 0.90)	1.03 (−0.51 – 2.70)		-0.29 (−2.17 – 1.62)
16 +		**-2.82 (−5.36 – −0.65)**	-0.28 (−2.24 – 1.65)	1.32 (−0.80 – 3.49)	0.29 (−1.62 – 2.17)	

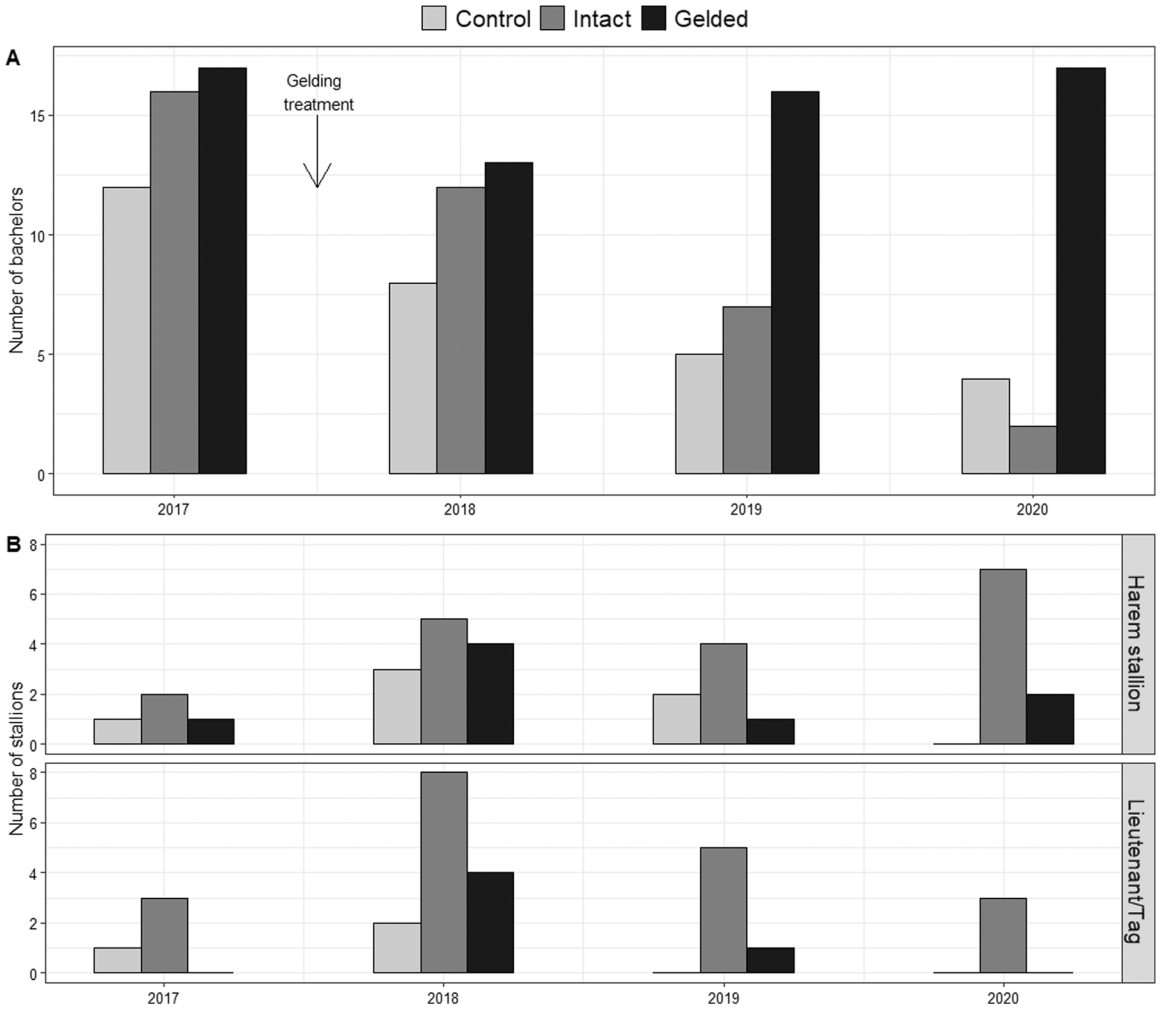

Fig. 6. Details of bachelors and multi-male groups at Frisco (intact control stallions) and Conger (intact and gelded males) Herd Management Areas, Utah, between 2017 and 2020. Twenty-seven males were gelded at Conger in December 2017 thus were intact during the pre-treatment year; they are shown separated in 2017 for comparison with post-treatment. A) Fate of males that were bachelors (i.e., not associated with mares) in 2017 across subsequent years of the study. B) Number of males that held harem status (i.e. were closely associated with mares) and that had a lieutenant or tag stallion following the harem (top panel), and number of bachelor stallions that were lieutenants or tags, following a harem (bottom panel).

Table 4
Foaling rate of feral horses at Conger (intact and gelded males present) and Frisco (only intact males present) Herd Management Areas in Utah, USA. Gestation length of horses is 11 months, thus foals are born approximately a calendar year after they are conceived. Foaling rate was calculated as the number of adult females (≥2 years old) divided by the number of foals born. 95% confidence intervals (CI) are provided. Treatment refers to castration (gelding), which occurred in December 2017.

Calendar year of birth	Conception year	Conger			Frisco		
		Females	Foals	Foaling rate (CI)	Females	Foals	Foaling rate (CI)
2018	Pre-treatment	57	44	0.77 (0.64–0.87)	42	29	0.69 (0.53–0.82)
2019	1 year post-treatment	69	40	0.58 (0.45–0.70)	46	32	0.70 (0.54–0.82)
2020	2 years post-treatment	86	61	0.71 (0.60–0.80)	57	33	0.58 (0.44–0.71)

but returned to pre-treatment levels by the second year post-treatment (Table 4). Confidence intervals were overlapping across all years for the control population at Frisco indicating there was no year effect.

4. Discussion

Our study showed that gelding is a safe potential management tool for feral horses: we had no mortality of gelded males, and no morbidity was observed. Gelded horses neither suffered loss of body condition following gelding, nor gained noticeable weight. Instead their body condition fluctuated similarly to other males on the range across seasons and years. Due to geldings' reduced testosterone (Thompson et al., 1980) we hypothesized that they would lose interest in mares and therefore devote more time to feeding and standing and less to moving. However, similar to observations on goats (*Capra hircus*; Silva et al., 2019), we found little effect of gelding on these behaviors. Instead standing was affected more by age class, with a year effect indicating environmental variables also play a role in this behavior. Our results indicated little biological impact of gelding: body condition did not differ between gelded and intact males.

No previous research has examined behavior of geldings in the presence of intact stallions. We expected gelding to reduce agonistic and reproductive behaviors due to lack of testosterone (Takeshita et al., 2017), and although there was a tendency for these behaviors to be shown less by gelded males, it was not statistically significant. Geldings have been observed to retain the full suite of equine behaviors, including reproductive behaviors (Sigurjónsdóttir and Haraldsson, 2019). We found low frequencies of agonistic behavior amongst males in our study populations, similar to those seen in other free-roaming horse populations (Fureix et al., 2012). Low levels of aggression can be simply related to space available for individuals to avoid each other (King et al., 2016), and agonistic interactions between males are moderated by ritualized displays and threat signals (Miller, 1981; Fureix et al., 2012; Sigurjónsdóttir et al., 2012). In our study age class was a major determinant of agonistic behaviors, with younger males exhibiting less agonistic behavior, and a clear shift in behavior trends once they passed 8 years old. This is considered prime of life for a stallion, when they would be most motivated to compete for a harem. Despite a lack of testicular testosterone production, geldings were still motivated to fight for access to mares, similar to free-roaming dogs that had no association between serum testosterone concentration and aggression whether castrated or not (Garde et al., 2016).

As would be expected, reproductive behavior was influenced by status, with harem stallions exhibiting more reproductive behavior than bachelors regardless of whether they were gelded or not. The persistence of reproductive behaviors in geldings likely influenced their drive to continue to seek a harem, although their ability to hold a harem decreased over time. Reproductive behaviors including herding, penile erection, mounting, and copulation have been observed in domestic geldings, and were seen whether the horse was castrated pre- or post-puberty (Line et al., 1985; Cox, 1986; i Rios et al., 1995). These behaviors were shown across age classes and harem statuses in our study, reducing the likelihood they were associated with prior sexual experience or time since castration. Bachelor males have lower levels of testosterone than harem stallions (McDonnell and Murray, 1995), so it was not surprising that they exhibited less reproductive behavior. However, demonstration of reproductive behaviors by bachelors may explain the short-term effect of gelding on foaling rate, as it is evidence of their motivation to mate. Extra-pair copulations (i.e., sneak mating by a male other than the harem stallion) have been documented in feral horse populations (reviewed in Boyd et al., 2016). Most sneak matings are considered to be done by other harem stallions or tag/lieutenant males; only one study specifically reported that sneak matings were conducted by bachelors (Ashley, 2000).

Gelding significantly affected marking behavior and affiliative behavior of males. Marking is conducted by males in response to mare eliminations, and as part of agonistic rituals when encountering other males (Rubenstein and Hack, 1992; King and Gurnell, 2007; Sigurjónsdóttir et al., 2012). Thus marking is likely affected by testosterone similar to reproductive behaviors; we saw a similar pattern of significance of status in addition to gelding affecting marking behavior, with harem stallions performing this behavior more than bachelors. Feces encodes information about familiarity, and stallions are undoubtedly aware of relative fighting ability with familiar males (Rubenstein and Hack, 1992). Thus geldings marking less may be related to loss of their harems.

While crucial for forming strong social bonds (Cameron et al., 2009), affiliative behavior has rarely been quantified in feral horses, particularly in relation to males (Costa et al., 2019). This is probably both because it is relatively rare and is often less obvious than agonistic interactions, however there is evidence that affiliative behavior is important for the cohesion and stability of horse social groups (Heitor et al., 2006; Costa et al., 2019; Sigurjónsdóttir and Haraldsson, 2019). Affiliative rates among males in our study were lower than those seen in Icelandic ponies of both sexes (including geldings) in a large pasture (Granquist et al., 2012; Sigurjónsdóttir and Haraldsson, 2019), but higher than those observed in a Przewalski's horse population (King and Gurnell, 2019), although generally consistent with rates in the literature (summarized in King et al., 2016). Notably, our results were only for males and included several behaviors, including play. As in Feh (2005), we observed play by both harem stallions and bachelors. We found that affiliative behavior was more frequent in both geldings and in younger horses, meaning that although geldings did not show any less agonistic behavior, they were possibly more inclined to reconcile or calm intense interactions (Feh and de Mazières, 1993).

We are confident that any differences in social associations observed post-treatment are a result of gelding, due to our field observations that social groups were maintained during and after the gather. As indicated by continued reproductive behavior and contrary to our expectations, not only did harem geldings not lose interest in mares but many continued to fight for and attain a harem throughout the study. By the end of the study only one gelding maintained a harem (a 14 year old who had a harem throughout the study), although four others gained and lost a harem during the final year. Harems of gelded stallions did become smaller over time, but geldings maintained similar aggression levels to intact stallions suggesting smaller harems were unlikely due to lack of fighting ability, but possibly a greater inclination for mares to change groups. In populations where mares are administered the fertility control immunocontraceptive porcine zona pellucida (PZP), mares continue to come into estrus but do not conceive; these treated mares change groups at a higher rate than untreated mares (Nuñez et al., 2009, 2017). A similar mechanism in which mares repeatedly come into estrus without conceiving could be also causing mares with harem geldings to change groups. It is notable that harem stallions did not immediately lose their harems after gelding, indicating that mares did not detect any changes that affected their social bond.

The biggest difference between geldings and intact males was among bachelors. Of the cohort of males who were bachelors in the pre-treatment year, all gelded individuals were bachelors in the final year of the study, compared to only a few intact males. As these gelded bachelors did not associate with mares prior to castration, this suggests that social or sexual experience may play a role in the drive to attain or maintain a harem, which could additionally be affected by lower testosterone levels in bachelors (McDonnell and Murray, 1995). We do not know whether bachelors who were older at the start of the study had a harem prior to our observations. Gelding treatment did not affect likelihood of a harem having multiple males. Both geldings and intact harem stallions were joined by lieutenants and tags, and both geldings and intact bachelors became lieutenants or tags. Formation of multi-male groups therefore seems independent of the presence of geldings in the population and is more likely due to other reasons beyond the scope of this study.

As a population growth management tool, gelding stallions had limited efficacy. At the levels applied in our study, it only reduced foaling rate in the first season after treatment. Statistical modeling of a horse population predicted that more than 90% of the male population would need to be sterilized in order to achieve meaningful population growth suppression (assuming that mares would be bred by any male; Garrott and Siniff, 1992). A higher proportion of males gelded would therefore be expected to show different outcomes for population control. Previous studies examining male fertility control also found short-term reductions in foaling rate, with treated stallions continuing to maintain a harem (Kirkpatrick et al., 1982; Eagle et al., 1993). In stable horse populations, most foals are sired by the harem stallion due to mare fidelity (Feh, 1990; Kaseda and Khalil, 1996; Gray et al., 2011) and the risk of infanticide and harassment (Cameron et al., 2003; Gray et al., 2011), but where group instability is high due to disturbance or other factors more extra-pair copulations are likely (Nelson, 1980). Both gelding and two gathers in two years likely contributed to some group instability at Conger, which combined with a cohort of males who were too young to geld in 2017 reaching maturity during the study likely resulted in increased sneak mating. A forthcoming study examining paternity of foals in this population will address this question. Gathering free-roaming horses over large areas is difficult. In our study population of known individuals in which groups could be located due to the presence of radio collared individuals it was still only possible to capture 53% of the males. This limits the ability to sterilize high percentages of males, and suggests gelding may be most effective when used in conjunction with other population control tools.

5. Conclusions

This study can allay public concern about welfare of gelded stallions – we found no difference in body condition or mortality, and geldings continued to exhibit the same suite of behaviors as pre-treatment, maintaining similar levels of aggression, and with ability to maintain a harem only slowly diminishing over time. In our study age class and/or harem status were often bigger predictors of behavior than gelding, and the lack of larger or longer impact on population growth may have been due to an insufficient proportion of males being gelded and due to young horses of both sexes achieving maturity during the study. Gelding has the potential to be effective as a management tool that reduces mare fertility rates only if a large proportion of males can be gathered and castrated, and is likely to be most effective for this when used together with other population control strategies.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Acknowledgements

Many thanks to our field crews who collected data with enthusiasm, especially Chrissy Barton, Brianna Brodowski, and Roslyn Wallace who observed horses over several seasons. We thank the Bureau of Land Management staff for handling assistance at facilities and for their success at maintaining social groups of horses during the 2017 gather, which added considerable time and cost to the gather. We are grateful to the BLM Wild Horse and Burro Program for project input and financial support through interagency agreements 4500065781 and L19PG00052, and to USGS for funding through cooperative agreements G14AC00138, G16AC00425, G17AC00417, and G18AC00312. Funding for this study was also provided by the CSU VPR's office and Warner College of Natural Resources. We are grateful to Jacob Hennig for constructive comments and assistance with analyses. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government. Data generated during this study are available as a USGS data release (Schoenecker and King, 2022).

Sworn Statement of Dr. Jay Kirkpatrick

1. I hold a B.S. in Biology from East Stroudsburg State College, and a Ph.D. in Reproductive Physiology from The College of Veterinary Medicine at Cornell University.

2. I currently work as the Director of The Science and Conservation Center in Billings, Montana. Prior to this position, I was an Associate Adjunct Professor in the Department of Population Health and Reproduction within the School of Veterinary Medicine at University of California, Davis. Concurrently, I was a Senior Staff Scientist for the Deaconess Research Institute in Billings, Montana. I also spent more than two decades working as an Associate Professor of Physiology in the Department of Biology at Montana State University-Billings, Montana. I also spent thirty years working with the U.S. Department of Interior, National Park Service, Bureau of Land Management (BLM), researching reproductive biology and chemical fertility control in wild horses.

3. For the past forty years I have dedicated my work as research scientist to studying wildlife fertility control. I have conducted research in a variety of areas including: reversible contraception in free-roaming herds, ovarian function in mares chronically treated with porcine zonae pellucidae (PZP), long-term effects immunocontraception of wildlife, and mechanisms of reproductive self-regulation in free-roaming ungulates. I was also integrally involved in the construction of a laboratory for wildlife immunocontraception research. In addition to this work, I have published more than seventy peer reviewed articles and peer reviewed book chapters on these topics.

4. Throughout my career I have been actively involved in many professional organizations. Since 1999, I have served as a Professional Fellow for the Association of Zoos and Aquariums (AZA), and for the past twenty years I have been a Member of the AZA

Contraceptive Advisory Group and the American Association of Zoo Veterinarians. In addition to these positions, I was a long-time member of the Society for Experimental Biology and Medicine and the Society for Study of Reproduction. A copy of my curriculum vita is attached, as Attachment A.

5. I have spent considerable time living, recreating, and working on the public lands in the Western United States, including six years working as a Park Ranger at Rocky Mountain National Park in Estes Park, Colorado. The wild horses that roam public lands are an integral part of the landscape and the ecological systems that comprise these areas.

6. I am familiar with the proposed BLM roundup in the Jackson Mountains Herd Management Area ("HMA"), which includes a proposal to return 44 geldings (castrated male horses) to the HMA. Based on my review of the pertinent scientific literature, I oppose this approach to herd management. It is extremely intrusive for the individual horses and not viable for the herds as a whole.

7. If stallions are sterilized as proposed by BLM, there will be massive changes in social organization and behavior. As a research scientist, current collaborator with the National Park Service with regard to wild horse management, and former BLM contractor who worked extensively on chemical fertility control in wild horses, I believe capturing and castrating – a non-reversible sterilization technique – wild male horses, and then releasing them back into the herds, is incompatible with the BLM's mandate to protect and retain the free-roaming nature of wild horses. This is true anywhere that BLM manages wild horses, meaning that geography plays no role in the level impact that would occur to horses and their herds as a result of this irreversible approach, because the impacts would be uniform across their range.

8. The very essence of the wild horse, that is, what makes it a wild horse, is the social organization and social behaviors that differ significant from domesticated horses. Geldings (castrated male horses) no longer exhibit the natural behaviors of non-castrated stallions. We know this to be true from hundreds of years' experience with gelded domestic horses. Furthermore, gelded stallions will not keep their bands together, which is an integral part of a viable herd. These social dynamics were molded by millions of years of evolution, and will be destroyed if the BLM returns castrated horses to the Jackson Mountains HMA.

9. Reproduction in male horses is a complex cycle that moves from the horse's brain to the testes and back again. Reproductive steroids, such as testosterone [T], affect the higher levels of the brain and cause a variety of a stallion's behaviors. These higher levels of the brain also send neural messages to the hypothalamus. The hypothalamus, in turn, stimulates the production and release of a protein hormone known as gonadotropin releasing hormone (GnRH). The GnRH, in turn, stimulates the anterior pituitary to produce and release follicle stimulating hormone (FSH) and luteinizing hormone (LH). The protein hormones stimulate the testes. Testosterone causes the aggressive behavior associated with successful stallions. These higher levels of the brain signal the hypothalamus to release GnRH, which in turn signals the pituitary to secrete FSH and LH. The FSH causes sperm production and the LH causes the testes to produce testosterone, which then feeds back to the brain, and on and on. This is a serious and significant alteration of normal physiological and behavioral functions for horses so treated and again, inconsistent with the law.

10. A major flaw in the plan to geld stallions and return them to the range both generally and at the Jackson Mountains HMA, is the fact that this will have absolutely no effect on reproductive rates of mares on the same range. As long as the harem band is intact and a

fertile stallion is at the head of it, mares will get pregnant regardless of the number of gelded stallions on the range. Indeed, the proposed action calls for 78 stallions (in addition to 44 geldings) – which is many more than is necessary to impregnate the 52 mares that will remain in the HMA. Further, gelded male horses will not become harem stallions, affecting social dynamics and behavior. But, beyond that, as explained above, the gelded stallions no longer even represent wild horses; they will quickly become the biologic anomaly that domestic horses have become. Finally, an emphasis on male fertility control to attempt to limit reproduction and "manage" any population of wildlife (deer, elk, horses) is superfluous; females have offspring – not males. Thus, as BLM has long recognized, population growth suppression must focus primarily, if not only, on limiting female reproduction. Since gelding does not further that goal, there is no scientific basis for returning geldings to the Jackson Mountains HMA under the circumstances.

11. The age priority given in the EA for removal actually runs counter to the objective of slowing reproduction. The removal of young animals from mares simply increases reproductive performance of those mares, a phenomenon known as compensatory reproduction (see Kirkpatrick and Turner 1991, *Compensatory reproduction among feral horses*. J. Wildlife Manage. 55:649-652). This action simply exacerbates the situation. Instead removal should focus on mares in the primary reproductive age class of five to ten years.

12. Castrating horses will effectively remove the biological and physiological controls that prompt these stallions to behave like wild horses. This will negatively impact the place of the horse in the social order of the band and the herd. For this reason, I oppose the BLM's proposed method of managing the Jackson Mountains HMA. There are less intrusive, more humane, and more sustainable forms of fertility control available to the BLM, which find

much more support in the scientific literature, and which comport with BLM's past understanding and handling of these issues with respect to wild horse population control.

Pursuant to 28 U.S.C.§ 1746, I hereby declare under penalty of perjury that the foregoing is true and correct to the best of my knowledge and belief.

Achieving population goals in a long-lived wildlife species (*Equus caballus*) with contraception

Jay F. Kirkpatrick[A,C] *and Allison Turner*[B]

[C]Corresponding author. Email: zoolab@wtp.net

Abstract. The ultimate goal of any wildlife contraceptive effort is some alteration of the target population, either through a slowing of growth, or stabilisation or reduction of the population. Early population models suggested that short-term contraceptive agents applied to long-lived species would not achieve significant population changes. Native porcine zona pellucida antigen (PZP), a short-term contraceptive vaccine, was applied to a herd of wild horses inhabiting Assateague Island National Seashore, MD, USA, over a 13-year period, with an immediate goal of achieving zero population growth, a secondary goal of reducing the population from 175 to 150 and a tertiary goal of reaching 120 individuals, all without the physical removal of animals. Contraceptive efficacy ranged from 92 to 100% on an annual basis (96.28 ± 2.49%), and the percentage of adult females that was treated on any given year ranged from 42 to 76% (67.78 ± 18.21%). The goal of zero population growth was achieved in 2 years, an initial decline in the population became apparent in 8 years and by Year 11, the population declined to 135, a decrease of 22.8%. The lengthy period required for achieving a population decline was caused by increasing body condition scores, reduced mortality and significantly increased longevity among treated females.

Additional keywords: equids, fertility control, horses, immunocontraception, population, zona pellucida.

Introduction

Contraceptive research aimed at managing populations of wild horses did not begin until the late 1970s (Kirkpatrick *et al*. 1982; Turner and Kirkpatrick 1983). These early and subsequent studies (Plotka *et al*. 1988; Kirkpatrick *et al*. 1990, 1991; Eagle *et al*. 1992; Willis *et al*. 1994; Daels and Hughes 1995; Goodloe *et al*. 1997; Turner *et al*. 1996; Turner *et al*. 1997, 2001, 2002; Cameron *et al*. 2001; Stafford *et al*. 2001; Killian *et al*. 2004) were all directed at testing the efficacy and safety of various antifertility compounds, vaccines, devices and delivery systems and/or the effects on social behaviour.

The actual management of wild horse populations by means of fertility control was initiated in 1995, on Assateague Island National Seashore (ASIS), MD, and represented the first attempt at actually altering an entire population and attempting to achieve a discrete population goal exclusively with fertility control. Shortly thereafter, additional attempts at managing entire populations were initiated on Carrot Island, NC, for the Rachel Carson National Estuarine Reserve, on the Shakleford Banks of Cape Lookout National Seashore, NC, and Return-to-Freedom Wild Horse Sanctuary, CA, and are ongoing. Two smaller and limited trials for the contraceptive management of wild horse populations were initiated in 2001 and 2002, on the Pryor Mountain National Wild Horse Range, MT and the Little Book Cliff National Wild Horse Range, CO respectively. The antifertility agent of choice for these initial attempts at population management was porcine zona pellucida (PZP) vaccine, first described as an inhibitor of fertility in horses by Shivers and Liu (1981) and Liu *et al*. (1989) and first applied to free-ranging wild horses by Kirkpatrick *et al*. (1990).

The onset of serious wildlife contraceptive efforts, in the early 1980s prompted the growth of population modelling with which to assess the theoretical effectiveness of contraceptive efforts. Several models were developed with which to determine the various levels of effort and the concomitant effects of contraceptive management on entire populations of large ungulates, and specifically, wild horses (Garrott 1991; Garrott and Siniff 1992; Hobbs *et al*. 2000). These various models examined possibilities within the parameters of (1) duration of contraceptive effect, (2) reproductive rates, (3) mortality rates and (4) contraceptive efficacy. The early predictions, although interesting, lacked a sound empirical database derived from actual population management trials, yet provided some direction for researchers in the field (McCullough 1997). For example, before the late 1990s, most models suggested that contraception would only be effective in species with short life spans and high reproductive rates (Hone 1992). Other models suggested that only contraceptives with multi-year life spans (Garrott 1991*a*) or actual sterilising agents (Garrott 1995) would be effective in population management. Still other complicating factors in early models included reproductive and growth rates of herds. Garrott (1997) suggested that only herds with less than 15% growth rates and the application of contraceptives with pharmacological life spans of 3–10 years

© CSIRO 2008
10.1071/WR07106 1035-3712/08/060513

would lend themselves to successful contraception. Almost all, however, made it clear that generalisations based on data that were not site specific with regard to herd age class profile, reproductive and mortality rates were fraught with risk.

The purpose of this research report is to provide empirical data regarding the management of a wild horse population exclusively by means of contraception, from which even more accurate models might be developed, and for other ungulate species that are candidates for contraceptive management. The hypotheses put forth at the beginning of this study were, that contraceptive management of a herd of barrier island wild horses, using a remotely-delivered short-term fertility control agent, could (1) stabilise the population rapidly and (2) reduce the herd size from ~175 animals to 150 over a longer period of time, and in a second phase, further reduce the population to 120, without the need to remove animals. The time elements necessary to achieve these goals were undefined at the initiation of the study.

Methods

Population

The study population consisted of wild horses inhabiting ASIS. The species has inhabited the island for 330 years and originated from 28 wild horses inhabiting the Maryland portion of the island (16 085 ha) at the time of the creation of the national seashore, in 1968. This population expanded to a high of 175 in March of 2001. The nature and circumstances surrounding this population, and the need for managing it in a manner ensuring acceptable ecological impacts and the maintenance of a healthy and viable herd have been described in detail elsewhere (Kirkpatrick 1995; Kirkpatrick and Turner 2007).

In 1988, the managing authority for horses, the National Park Service (NPS), authorised research aimed at evaluating the use of immunocontraception as a potential population management tool, and from 1988 through 1993, 46 different mares were intermittently treated with PZP vaccine (Kirkpatrick *et al*. 1990). Research during this period showed that the vaccine was effective and safe (Kirkpatrick *et al*. 1990, 1991, 1992, 1995). Beginning in 1994, with the herd size at 166, the NPS authorised actual management of the ASIS herd through PZP contraception. In phase I, and under the provisions of a written management plan and required environmental assessment, every untreated mare 2 years or older and which had never been treated before was given a single 'primer' dose of PZP. The purpose of this phase was to cause antigen recognition in the herd and thereby create a 'one-inoculation' population that would only require a single booster inoculation in subsequent years. In 1995, with the March herd size at 166 and the environmental assessment completed, phase II of the management plan was initiated, with an immediate goal of stabilising the population, a secondary goal of reducing the population to 150 animals and a tertiary and subsequent goal of reaching 120. For the first 3 years, the management plan allowed the inoculation of all 2-year old mares and booster inoculations with PZP at ages 3 and 4, followed by withdrawal of treatment until the mare produced three living offspring or a second generation, after which the mare would be treated with the PZP annually until her death. The underlying philosophy behind this plan provided for a delay in the reproductive age of mares, but a continuous contribution of genes from all mares on the island. This plan was modified in 1998 to allow only two foals after withdrawal from treatment, and again in 2000 to allow only a single foal, largely because there was no apparent decrease in the population as a result of contraception. This plan was maintained through 2007.

Vaccine application

The vaccine was prepared according to the modified method of Dunbar *et al*. (1980) at the University of California, Davis from 1988 through 1997 and at the Science and Conservation Center thereafter. Delivery of the vaccine was by 1.0 cc Pneu-Darts, at doses of 100 μg, along with an appropriate adjuvant, as described by Kirkpatrick *et al*. (1990, 1991), at ranges of 10–55 m and authorised under the Food and Drug Administration Investigational New Animal Drug Exemption File 8857-G0002. From 1994 to 2001 the adjuvant used for all initial inoculations was Freund's complete adjuvant (FCA), and since 2002, Freund's modified adjuvant has replaced the use of FCA. All booster inoculations for the entire duration of this study utilised Freund's incomplete adjuvant. No horses were captured or handled during the course of this study.

Data collection

All animals in the Assateague population are monitored every 2 months by an ASIS employee (AT) and data collected include: (1) identification of individual animals by unique markings; (2) band affiliation; (3) band location; (4) band habitat; and (5) dates of births and deaths. Numbers presented in this study are not estimates, but actual numbers based on bi-monthly data collection.

Results

The ASIS wild horse population profile is illustrated in Fig. 1. Systematic and regular population counts were initiated in 1975 and the period between then and 1987 indicates a growth curve that represents an approximate 8% annual increase. The dramatic drop between 1987 and 1990 was associated with the initiation of contraceptive research, which removed 26 mares from the reproductive pool, and an epidemic of eastern equine encephalitis (EEE) that caused, at a minimum, the death of at least another 14 horses. By 1997, 2 years after the initiation of management-level contraceptive control, the population was stabilised and continued within a range of nine animals over the ensuing 7 years. The March population began a decline to 158 animals in 2005, 138 in 2006 and 135 in 2007. During the 11 years following the initiation of management-level contraception, foaling rates dropped to $6.9 \pm 2.30\%$ annually (an approximate 88% reduction) for mares 3 years or older. Thus, the first two population goals of stabilisation and a reduction to 150 were achieved and significant progress has been made towards the goal of 120.

The age profile of the herd changed coincident with the intensive contraceptive control and is illustrated in Fig. 2, which provides a comparative view from 1990, before management, to April 2007. This change in age profile is characterised by (1) fewer young animals, (2) an increase of animals in older age classes and (3) the appearance of entirely new older age classes, primarily among mares. Sex ratio also changed

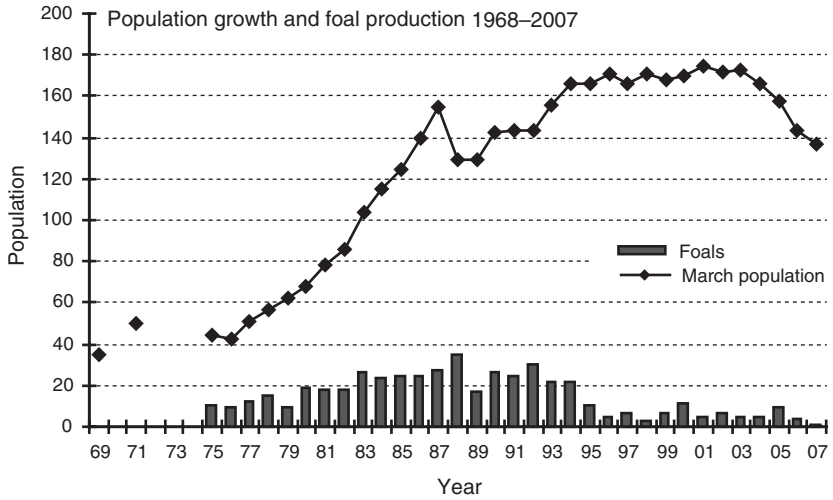

Fig. 1. Population changes of the Assateague Island National Seashore (ASIS) wild horse herd over a 38-year period. Contraceptive management began in 1995.

during the contraceptive management of the herd. Historically, the ASIS sex ratio has been ~1 : 1, but after 12 years of contraceptive management, the ratio has changed to 51 stallions : 84 mares, or 1 : 1.68 (Keiper and Houpt 1984).

The effort required, and the contraceptive efficacy necessary to bring about this level of population change, in this particular herd, is shown in Table 1. The percentage of adult mares treated annually ranged from a low of 52% to a high of 95% (67.78 ± 18.21). The latter high figure represents an effort in 1994, the year before the actual management effort went into effect, to treat all previously untreated mares with a 'primer' inoculation, not for purposes of contraception that year, but rather to establish the population as a 'one-inoculation' herd thereafter. The annual efficacy of the contraceptive vaccine ranged from a low of 92% to a high of 100% (96.28 ± 2.49). As time increased, so did the amount of time necessary to dart the target mares. Table 2 indicates this trend.

Discussion

The application of a short-acting immunocontraceptive to certain wild horse herds has the potential to reduce populations of long-lived wild horses given sufficient time; however, the application must be fairly intense over time. The change in population associated with contraceptive management provides some cause for optimism with regard to wider applications elsewhere. Mortality, outside of episodic disease and weather catastrophes, has been historically low in this population, yet the attainment of near-zero population growth was possible in only a few years.

At the outset of this research, historic data for population dynamics of this herd included a $57.1 \pm 3.9\%$ foaling rate (among adult mares), an annual 5% mortality rate and an overall annual 8% population growth rate (Keiper and Houpt 1984). The average age of a mare in 1994, before management-level contraception, was 8.19 ± 5.6 (s.d.) years. The 88% reduction in foaling rate during the 11 years following the initiation of management-level contraception, for mares 3 years or older, was expected; however, mortality rates also dropped until recently. From the onset of contraceptive management, in 1995, to 2003, the annual mortality rate was $3.3 \pm 1.0\%$ and the average age of mares increased to 14.8 ± 6.4 years. This was a period of population stabilisation characterised by an ever-increasing longevity among treated mares (Kirkpatrick and Turner 2002, 2007). As treated mares reached a new 'age of mortality', from 2004 to 2006, the mortality rate increased to $9.0 \pm 1.0\%$. The increased longevity has previously been shown to be directly related to contraceptive treatment (Kirkpatrick and Turner 2007), with the average age at death reaching >20 years for mares treated for 3 years or more.

In a recent critique of immunocontraception in wildlife, Cooper and Larsen (2006) suggested that it may be impossible to evoke a strong enough immune response against the contraceptive antigen to cause contraception in a large enough proportion of the target animals for effective population control. Much earlier, Seal (1991) suggested that any effort to successfully manage free-ranging populations would require an agent with 100% efficacy. The concept embedded in that concern confuses two elements of wildlife contraception. Virtually all contraceptives have differing efficacies (see Asa 2005; Frank *et al*. 2005), but the more important question of relevance in wildlife contraception is to what proportion of the target population the contraceptive can be delivered. It is intuitive that a contraceptive with an overall efficacy of 92–100%, as in the case of PZP and wild horses, or any contraceptive for that matter, would not be acceptable for human contraception. However, if a 92% effective contraceptive was applied to 48 to 76% of the human population, as it has been in the ASIS horses, there would be a significant decrease in fertility rates of humans. Obviously, the more effective the contraceptive, the more effective is the population control that can be achieved, but efficacy alone is not the determining factor in achieving success with wildlife.

The dramatic increase in the average age of the female population would be expected as a result of fewer young animals; however, those average ages alone mask the more significant trend of a shift to older age classes. In 1994, the

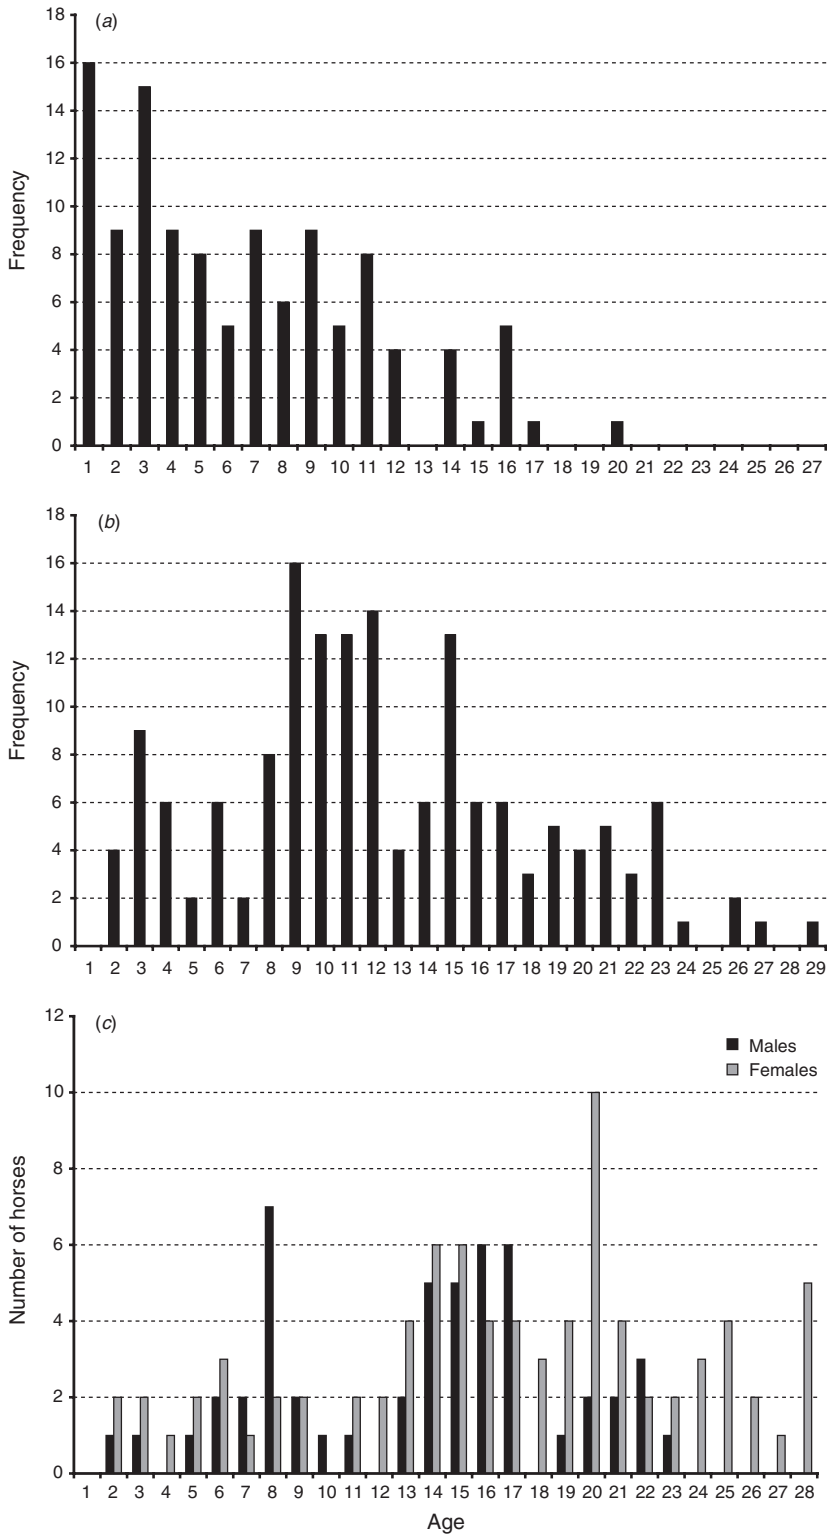

Fig. 2. Age-class structure for the Assateague Island National Seashore (ASIS) wild horse herd in (*a*) 1990, (*b*) 2002 and (*c*) 2007. Part (*a*) describes the age-class structure before contraceptive management, and it reflects a 'typical' structure profile for most wild horse herds. Part (*b*) indicates a shift in the structure after 7 years of management-level contraception, with increasing longevity being the major feature. Part (*c*) gives the structure for both males and females after 12 years of contraceptive management, reflecting the major increase in longevity among females.

Table 1. Percentage of mares treated and contraceptive efficacy, 1993–2006

Year	Spring population	Mares treated (%)	Foals	Foals from treated mares	Foals from untreated mares	Efficacy
1993	156	15 (20)	22	4	18	94%
1994	166	76 (95)	22	0	22	100%
1995	166	68 (83)	10	1	9	99%
1996	171	72 (84)	5	2	3	97%
1997	166	54 (59)	7	2	5	97%
1998	171	49 (52)	3	1	2	98%
1999	168	48 (52)	7	3	4	94%
2000	170	64 (68)	11	1	10	98%
2001	175	75 (79)	5	0	5	100%
2002	172	66 (69)	7	5	2	93%
2003	173	66 (70)	5	4	1	94%
2004	166	74 (76)	5	3	2	95%
2005	158	69 (71)	9	5	4	93%
2006	143	65 (71)	4	3	1	96%

Table 2. Number of days spent darting, 1994–2007

Year	No. of mares treated	Total days darting
1994	76	15
1995	68	14
1996	72	12
1997	54	17
1998	49	16
1999	48	17
2000	64	20
2001	75	25
2002	66	25
2003	66	28
2004	74	26
2005	69	34
2006	65	29
2007	55	25

percentage of mares between the ages of 15 and 19 years and >20 years were $9.8 \pm 1.8\%$ and $3.7 \pm 0.9\%$ respectively. By 2006, those same age-class cohorts had increased to $26.1 \pm 2.7\%$ and $23.8 \pm 2.5\%$ respectively. Thus, historic population dynamic data alone will not provide the necessary information to develop a sound and effective contraceptive management plan. Normally, 20 years represents an extreme old age among wild horse herds. Eberhardt *et al*. (1982) considered 20 years the maximum age for wild horses inhabiting ranges in Oregon, and Garrott *et al*. (1991) found that among 14 788 wild horses across Nevada, only 115 (0.007%) were older than 20 years. Linklater *et al*. (2004) found that among New Zealand's Kaimanawa wild horses, only an average of 1.0% would reach 20 years. Thus, the dramatic departure from these age restrictions among the ASIS horses represents a new understanding of the effects of contraception.

A major effect of the shift to older age classes among mares on ASIS is the change in the sex ratio from the historic 1 : 1 (male female) to 1 : 1.67, post-contraception. This change is clearly the result of mares living longer than before contraceptive management. There is no expectation that this change will widen in favour of mares, as mortality rates have now increased, once the mares reach a new 'age of mortality'. Normally, sex ratios for foals among most wild horse herds is near parity but in some cases it changes in favour of males in older age classes (Garrott 1991*b*), but this is not a hard and fast rule. The male : female sex ratio for a Nevada wild horse herd was 0.78 : 1.0 (Greger and Romney 1999). Indeed, a National Academy of Sciences study found a wide range of sex ratios among wild horses (NAS 1982). Other management options that involve removal of animals may also skew sex ratios. In the Pryor Mountains of Montana, the adult sex ratio in 1970 was close to 1 : 1 (48 males : 52 females) (Feist and McCullough 1975), but within the ensuing 8 years, the ratio changed to 1 : 2, largely because of the bias in removing males through removal programs (Perkins *et al*. 1979). Given the stabilisation of the sex ratio on ASIS, as a result of more mares dying now, the current sex ratio should pose no serious problem and should shift back towards parity.

Used to slow or stabilise population growth among a long-lived species such as the horse, rather than to decrease numbers, PZP immunocontraception can have a rapid and significant effect. A reduction in growth rates and stabilisation of the population can occur in as little as 2 years if the intensity of the treatment is high enough. Indeed, such stabilisation of population growth has even been reported for African elephants treated with PZP (Delsink *et al*. 2006, 2007). If the management goal is reduction in herd size, on the basis of contraception alone the time necessary will be significantly longer and, it is now clear, even longer than historic models predicted, based on historic foaling and mortality rates. Both of the latter parameters, foaling and mortality rates, will change as the length of treatment time for individual animals increases, as a result of significantly lower mortality, increased body condition and increased longevity. Thus, population models will have to account for these changes in population dynamics, or contraceptive management must be flexible and adaptive.

Some concern might arise over the genetic effects of intense contraception. Studies were conducted on the genetic diversity of

the ASIS population (Eggert *et al*. 2005) using faecal mtDNA haplotypes and nuclear genotypes at eight polymorphic loci. The results indicated that the relative genetic contributions of the founder animals were well represented and consistent with a high level of nuclear genetic diversity. Even at numbers as low as 100 horses, the population will not accumulate significant loss of genetic diversity sufficient to result in any inbreeding depression effects, nor will kinship increase, over time, and lead to line breeding potential (CBSG 2006).

Despite these empirical data, concerns about genetic effects of wildlife immunocontraception persist in some quarters (Nettles 1997; Cooper and Larsen 2006). In the case of the ASIS population, contraception has eliminated the use of gathers and removals for population control. As conducted by other agencies, for other wild horse herds, gathers and removals most often focus on young horses that are popular for adoption by the public. These removed animals have never bred or entered the gene pool, thus it is intuitive that the potential for genetic effects of the alternative management approach is far greater than from a simple delaying of reproduction and decreasing the number of foals produced by each mare.

It is now clear that contraception is associated with significant downward population trends and changes in long-lived wildlife species. The requirements for achieving these changes are both species specific and site specific, but careful analysis of all demographic and contraceptive parameters for any given species and agent, based on the data derived from the Assateague studies, suggests that this approach is viable and can be effective.

DIRECTOR'S REPORT

Advancing Science within the Bureau of Land Management

February 2012

DIRECTOR'S REPORT

ADVANCING SCIENCE WITHIN THE BUREAU OF LAND MANAGEMENT

INTRODUCTION

The Bureau of Land Management (BLM) has a critical and compelling mission: *to sustain the health, diversity, and productivity of America's public lands for the use and enjoyment of present and future generations.* Distinctive to its mission within the Department of the Interior (DOI) are the BLM's core purposes of multiple use and sustained yield. Resource development, restoration, and conservation are all essential activities of the BLM.

Fulfilling its mission requires leadership and field managers to make important decisions about natural and cultural resources under BLM's management. These decisions often impact adjacent lands, waters, and communities. They often impact other federal and state resource management agencies. They take place within a broad and complex environmental, legal, socioeconomic, scientific, and political context. Hence, effective BLM decision-making must reflect best available sound science, accurate fidelity to the law, and long-term public interest.

The BLM must be a "science-informed" bureau. Science for the BLM includes the full range of disciplines within the biophysical and socioeconomic sciences relevant to the multiple-use mission of the BLM. It includes monitoring, research, syntheses of existing science, and application of findings to meet BLM resource management needs. BLM science (science conducted by the BLM and/or for the BLM) should be mission-oriented, place-based, high-quality, objective, and result in usable knowledge for BLM managers and stakeholders.

Given the extent of current and future environmental and socioeconomic change—including energy development, demographic trends, climate change, and water demands—the scientific needs of the BLM are necessarily increasing. Like other federal land management agencies, the BLM must employ science as it "manages for change".

To prepare the BLM to effectively manage now and in the future, the science it uses must be expanded, improved, and more deeply integrated into the bureau's culture and decision-making

processes. In May 2012, BLM Director Abbey commissioned a Director's Report that would assist in advancing science within the BLM. Director Abbey asked that the BLM's National Landscape Conservation System (NLCS) serve as a pilot in this effort.

The BLM has produced several strategic plans for science. These documents include detailed objectives, research agendas, processes for priority setting, and implementation actions. The development of an additional strategic plan or an update of existing on-the-shelf plans is unlikely to have significant impact on the bureau's approach to and use of science. Rather, this Director's Report focuses on specific recommendations for: a) advancing science within the BLM, b) integrating science into BLM decision making, and c) accelerating the progress of advancement and integration of science for the BLM.

How this Director's Report was Prepared

BLM Director Bob Abbey requested that Dr. Gary Machlis, Science Advisor to the Director of the National Park Service, prepare the report. Dr. Machlis co-leads the DOI Strategic Sciences Group, and is a professor of conservation at the University of Idaho. Dr. Machlis formed a core group that included Dr. Matt Preston, NLCS National Science Coordinator, and Dr. Healy Hamilton, an independent scientist with experience working with BLM managers. An executive committee of BLM field and national leadership was formed to provide guidance, assistance, and review of the Director's Report.

The core group conducted a detailed review of over 75 laws, regulations, policies, and plans related to science within the BLM. In addition, they conducted over 40 detailed interviews with a range of individuals including: a) BLM leaders and managers at the national, state, and field levels, b) BLM scientists and professionals, and c) external scientists with knowledge of BLM science, such as USGS scientists and university faculty. These interviews were not a formal representative sample, but did provide a range of insights regarding advancing science in the BLM. The core group met with BLM managers within the NLCS at their 2012 management conference in Albuquerque, NM. They traveled to the BLM National Operations Center (NOC) in Lakewood, CO and met with a range of group leaders and staff. A draft of this report was reviewed by the executive committee and comments were provided to the core group. A final

draft was completed, reviewed by the executive committee, and prepared by Dr. Machlis and other members of the core group for delivery to the BLM Director.

BACKGROUND

Authorities and Mandates

The BLM has legal, regulatory, and policy authorities and mandates to conduct science. The Federal Land Policy and Management Act of 1976 (FLPMA) provides the BLM explicit authority to conduct management-related science and requires the systematic consideration of scientific information when developing land use plans. Other authorities require scientific investigation and consultation before BLM actions (e.g. NEPA, Endangered Species Act), while some legislation requires scientific tasks on specific topics (e.g. inventory and monitoring of archaeological resources). More generally, the DOI policy manual (e.g. §305 DM 2) describes how science shall be integrated and used in management practices and decisions. Similar mandates for incorporating science into management are in several other DOI and BLM policy documents (e.g. BLM Manual §1601), including those related to the NLCS (e.g. Secretarial Order 3308; BLM Manual §6100).

The bureau also has an obligation to ensure that BLM lands remain a resource for the scientific community. FLPMA, the NLCS' Organic Act, and several individual laws creating NLCS units call for the protection of the scientific values of BLM lands, i.e. the protection of resources deemed to be of importance to scientific research.

Organizational Support for BLM Science

BLM scientific expertise is spread throughout the bureau. In the Washington Office there are several individuals tasked with providing scientific advice and/or coordination; most do not work full-time on science projects or policies. Many are affiliated with specific programs and focus on applying relevant science to these programs. There are also scientists assigned to multi-state zones who provide expertise to BLM offices.

In State and Field Offices, many resource staff members have scientific backgrounds. The majority of BLM's field-level scientific expertise is focused on interpretation and application of available science, rather than the conduct of scientific research as part of their workload.

The NOC's Division of Resource Service houses a group of BLM's senior technical specialists, including some who conduct scientific research. The Washington Office uses their expertise to conduct and support national-level projects. Some State and Field Offices utilize NOC technical expertise as well.

The BLM has outsourced substantial scientific work to partners that include local, tribal, state and federal governments, academic institutions, professional societies, industry groups, entities under land use authorizations, non-governmental organizations, citizen groups, and contractors.

Scientific funding is spread throughout the bureau. In FY11 about $15 million was spent on applied research projects across the BLM States. Some scientific activities, such as monitoring, are not included in this amount. Funding does not come from a centralized pool and is spent on an *ad hoc*, office-by-office basis.

The BLM chartered an external Science Advisory Board under the Federal Advisory Committee Act (FACA) in the late 1990s and early 2000s to provide scientific advice to the BLM Director. It is no longer active. Various versions of an internal National Science Committee have been formed to coordinate, prioritize, and communicate scientific endeavors. At times the Director has had a science advisor. Current and developing science-related committees include the BLM Science Committee/Core Science Team (the most recent version of a National Science Committee), the NLCS Science Advisory Team, the Data Advisory Committee/Working Group, and the Socio-economic Oversight Committee.

BLM Science Strategies

The BLM has prepared several overarching science strategies, including versions in 1991, 1996, 2000, and 2008. A science strategy for the NLCS was prepared in 2007. These strategies share several themes and goals. Each of the science strategies recognize the need to: a) systematically identify research needs; b) engage with science partners; and c) transfer research results to

managers and to the public. Implementation plans, or draft implementation plans, have been written for several of the strategies.

Other currently available science-related strategies include a socioeconomic strategic plan, a geo-spatial strategic plan, the joint fire science plan, and NLCS unit science strategies. The latter has been completed in a few NLCS units and a new template for unit strategies was recently developed that includes the unit's scientific background, scientific needs, engagement with partners, and more.

While not a formal "science strategy", the BLM's recent adoption of a landscape approach is a framework for science-informed management, with scientific data, assessments, and projections forming the base from which to develop management direction and decisions. It builds upon previous BLM field applications, such as the Northwest Forest Plan and the Interior Columbia Basin Ecosystem Management Project. This approach connects regional and local decisions to landscape-scale understanding (e.g. BLM's rapid ecoregional assessments, REAs). The landscape approach requires standardization of assessment, inventory, and monitoring (AIM) efforts by instituting common indicators, statistically-valid data collection, and centralized data storage (i.e. BLM's AIM Strategy).

Results of Interviews with BLM Staff and Partners

Amongst interviewees there was widespread but not universal agreement that the primary obstacle to integrating science into BLM decision making is organizational culture. The BLM is viewed as a decentralized agency with inconsistent direction from leaders at multiple levels concerning the integration of scientific information into decision making. Pressure to incorporate available science in the planning and use authorization processes is often viewed as arising from external forces, such as litigation. There was general recognition that the need for science to become a more ingrained component of BLM decision-making has never been greater, as the multiple, complex, and interacting forces of environmental and socioeconomic change (e.g. intensified fire regimes, resource development, invasive species, and climate change) erase the concept of "business-as-usual" for the BLM.

Interviewees felt that the range of disciplines that provide information potentially useful to BLM decisions is broad and diverse, including life, earth, and socioeconomic sciences, and the pace of discovery and advancement is fast and increasing. There was recognition that it is impractical for BLM to maintain internal scientific expertise in all these fields with responsibilities to conduct research, assist managers in translating data to decisions, and keep abreast of the latest advances in their respective fields. Those interviewed frequently mentioned the resulting emphasis on the essential role of science partners. A recurring theme emerged that existing partnerships are often underperforming relative to their potential. For example, perception of the quality, timeliness, and accountability of science requested and funded by the BLM and conducted by USGS greatly varied. While some interviewees were satisfied, the majority of BLM-USGS interactions were not regarded as a productive return on investment or as an effective agency-wide strategy for injecting usable science into management decisions. The Cooperative Ecosystems Studies Units were repeatedly mentioned as logical partners to more actively cultivate as science providers to the BLM. Establishing closer ties to relevant professional societies (e.g. Society for Range Management) was consistently mentioned as another potential underutilized avenue.

The interviews highlighted specific scientific needs required to support BLM activities at different scales. The most consistent need involved the translation of available scientific data into usable knowledge that managers can easily and rapidly incorporate in the process of decision making. In addition to science translation, there was a recognized need to organize and increase accessibility to existing data. Another science need identified by interviewees was better understanding of the implications of the forces of global change at multiple scales, from the project up to the landscape, and the incorporation of this understanding into decisions across these scales.

Finally, the NLCS was widely regarded by interviewees as a valuable locale for advancing BLM science, though it was often viewed as being isolated from the rest of the bureau's activities and core mission. Many interviewees saw the NLCS as a reference point for understanding the impacts of change drivers in the relative (but not complete) absence of extractive practices, as well as a location to conduct science in support of adaptive management. The NLCS was often

viewed as a system that could be utilized for experimental testing of alternative methods for achieving desired conditions. The degree of public visitation on the NLCS was recognized as an opportunity for increased application of social science research on recreation impacts, cultural and historic values, citizen science, and community engagement.

FINDINGS ON THE CHALLENGES FACING SCIENCE IN THE BLM

Like all federal land management agencies, the BLM faces challenges (real and perceived) in meeting the ambitious goal of becoming a "science-informed" organization. Some challenges are inherent to the bureau's complex mission; other challenges stem from organizational structure and culture. Additional challenges are related to work processes and the delivery of science to managers and decision makers. In addition, there are specific challenges to advancing science within the NLCS.

A key challenge facing the BLM is that its mandate for science is fragmented and sometimes not clearly understood or consistently applied by BLM managers. Flowing from this key challenge are several other organizational barriers to advancing science within the BLM: a lack of integration of science across BLM programs and directorates, inconsistent integration of science into BLM decision-making, and lack of consistent policies concerning science. Morale amongst BLM science professionals varies, as does the degree of scientific training of BLM managers.

There are also challenges with BLM work processes related to science. A major issue is improving the scientific foundation of environmental impact statements and assessments (EIS and EA). BLM analyses are often single-dimensional and species-specific, rather than integrative and systems-based. Similarly, the temporal and spatial scales of analyses are often too narrow; e.g. Field Offices' geographic boundaries are typically not the appropriate scale for addressing cumulative impacts and future scenarios. The BLM's reliance on *ad hoc* and reactive scientific efforts limits scientific integration. In addition, there are significant time and resource constraints that hinder the ability of BLM professionals to conduct and apply best available sound science.

Another key challenge is an often slow and less than adequate information transfer—including slow delivery of research results, presentation of results in formats that are of limited used to managers, limited access to data and relevant scientific literature, and lack of advanced

information technology. Inadequate information transfer may in part stem from BLM's often disconnected relationships with science partners, in which BLM lacks clear communication of needs and has limited engagement. The BLM's lack of a workable and consistent system of scientific peer-review for conducted and sponsored research limits the assurance of the scientific quality of products and affects manager's trust in using the scientific products in decisions.

There are also science challenges specific to the National Landscape Conservation System. While conserving "scientific values" is part of the NLCS mission, this mandate is ill-defined and hence not yet fully implemented. Science has a low profile with many NLCS managers and stakeholders. Often, NLCS science is perceived as "marginalized" or separate from broader BLM needs. There is significant lack of awareness of the NLCS value and opportunity amongst the general scientific community.

These challenges, while substantial, are tractable and create opportunities to advance the role of science within the BLM.

RECOMMENDATIONS FOR ADVANCING SCIENCE WITHIN THE BLM

The following recommendations are derived from the review of written documents, the interviews and site visits, and the core team's experience with advancing scientific programs. The recommendations are organized around three categories: a) organizational structure and culture, b) work processes and delivery, and c) distinctive challenges and opportunities for NLCS science.

Organizational Structure and Culture

1. *The BLM should revise appropriate sections of the BLM Manual and/or consider adding a new section in order to explicitly recognize and require that BLM resource decisions should be based on best available sound science, accurate fidelity to the law, and long-term public interest.* This policy will advance science as an essential input into decision-making. The manual should make clear that "science-informed" decision-making is the required standard for managers, and the BLM should invest in the necessary training and preparation of managers to enable this standard to be met.

2. *The BLM should establish a chief scientist position (at the ST level), reporting to the Deputy Director for Operations.* The chief scientist would provide critical science leadership. The BLM chief scientist would lead the development and implementation of science-related policies, processes, and priorities. Additionally, the chief scientist would provide advice, coordinate science across BLM states and directorates, and represent BLM science to other federal land management agencies, the broader scientific community, and stakeholders. The chief scientist should be a member of the Executive Leadership Team (ELT). The chief scientist would lead the implementation of several of the recommendations identified in this report. Line authority over individual scientists should remain within existing structures.

3. *The BLM should re-establish an external national BLM Science Advisory Board.* The board would provide necessary, independent advice on science and science policy to the Director. The board should operate under a FACA charter. It should include outstanding scientists from the external scientific community representing a broad range of relevant disciplines. The chief scientist should serve as liaison to the group.

4. *The BLM should eliminate the multiple and overlapping science committees and replace them with a single internal Science Coordinating Group (SCG).* A single coordinating group would increase efficiency, reduce overlap and unnecessary administrative burden, improve internal communication of science priorities, and focus responsibility for advancing science. The SCG would work with the chief scientist to develop BLM's science-related policies, processes, and priorities. It would include senior scientists and managers from Field Offices, State Offices, Centers, and Washington Office directorates, and be chaired by the Chief Scientist. Identified science leaders from each of BLM's three key work areas (conservation, development, and restoration) should be represented on the SCG. The Chief Scientist would be responsible for gaining support and approval for SCG outputs from the ELT and the Deputy Director. Technical work groups could be temporarily established for specific tasks (e.g. standardizing data, calculating ecosystem services).

5. *The BLM should clarify and communicate the scientific roles and responsibilities of the National Operations Center's Division of Resource Services*. This would improve the effectiveness of the division, clearly connect its work to the BLM mission, and increase awareness of its

services throughout the BLM. The role of the division should be developed collaboratively with BLM offices. Annual or multi-annual scientific responsibilities should be developed in consultation with the Science Coordinating Group.

6. *The BLM should institute ecoregion-based teams of scientists to facilitate and/or conduct scientific efforts for and with BLM State Offices, Field Offices, and NLCS units within that ecoregion.* With limited resources, ecoregion-based teams would enable efficient, coordinated, and relevant science to be proactively identified, conducted, and delivered to decision-makers. Collaboration with other DOI bureaus should be encouraged. Five-to-ten year work plans should be developed for these teams in collaboration with regional BLM leadership and the Science Coordinating Group.

7. *The BLM should accelerate development of a diverse set of qualified scientific partners, and reduce administrative hurdles associated with science partnerships.* Connection to the external scientific community is vital to ensure the application of modern scientific practices for BLM resource management. Collaboration with other DOI bureaus should be encouraged and supported with resources. Staff time needs to be allocated to developing quality partnerships and to working closely with partners before, during, and after projects.

8. *The BLM should invest in maintaining and improving the understanding of science and its application by BLM professionals*. To ensure that scientific understanding is a core tenet of BLM's work, BLM professionals need to be conversant in science and its application to BLM decision-making. Options include increased scientific training, scientist/manager meetings, and the publication of a quarterly science magazine for BLM professionals.

Work Processes and Science Delivery

9. *The BLM should examine each of its work processes and establish specific policies to ensure that science is integrated at relevant junctures*. This is a necessary and essential step to provide clear guidance on the practical actions that can advance science within the BLM. This effort should be the Science Coordination Group's first assignment, with draft policy statements submitted to the Deputy Director. For example, the SCG should develop a set of policies and procedures for the scientific activities required of permittees for each type of land use

authorization. More broadly, the SCG should consider policies that promote integrative, systems-based, multi-scale analyses of resources and impacts to resources; promote communication of uncertainty surrounding data or forecasts used in analyses; and for NLCS units, require the consideration of impacts to designated NLCS values.

10. *The BLM should establish and implement a scientific peer-review policy that applies to BLM funded science products, both internal and external.* Peer-review increases the quality of scientific products, and makes science-informed decisions defensible. The peer review policy should be consistent with OMB requirements currently in place and with the DOI peer review policy now in development. Implementing the policy should be based on producing best available sound science, meeting DOI information quality standards, and operating a peer review system that is efficient, cost-effective, and practical.

11. *The BLM should periodically and systematically identify and prioritize scientific needs, with a focus on supporting future management decisions*. In a period of limited resources, such assessments focus effort, increase effectiveness, and reduce unnecessary costs. Scientific needs should be identified at all levels of the organization, with input from the Science Advisory Board. For example, every NLCS unit should identify its scientific needs. The Science Coordinating Group should propose priorities for these scientific needs and then communicate them internally and externally. In addition, bureau-wide scientific needs that could be best answered in the NLCS should be identified (e.g. experimental testing of best management practices in a limited use environment).

12. *The BLM should provide operational support for rapid adoption of the Assessment, Inventory & Monitoring (AIM) Strategy protocols on all BLM lands.* This will allow systematic assessment of resource conditions at multiple scales and improve the quality of data for decision-making. Bureau-wide adoption of this standardized, quantitative approach should occur as soon as possible. The value of the AIM Strategy protocols should be enhanced by continued development of explicit, consistent, measurable standards for describing resource trends and conditions. Funds from across the bureau that have been historically used for ad hoc assessment, inventory, and monitoring efforts should be redirected towards this standardized approach.

13. *The BLM should ensure that geospatial data is properly collected, curated, analyzed, and distributed in order to support the systematic use of spatial data in decision-making, especially at local levels.* The availability of high quality geospatial data allows for large amounts of disparate information to be incorporated in the decision-making process, as well as communicated to diverse, non-technical audiences. Such data increase the defensibility of BLM decisions and potentially reduce BLM's exposure to litigation. In some cases, interagency collaboration will be the most efficient and cost-effective way to make geospatial data available to BLM managers.

14. *The BLM should establish a centralized, online science permitting and tracking system for both BLM funded and external projects.* This system would ensure research activities are appropriate and maximize the utility of the scientific projects being conducted on BLM lands. The NLCS would be an appropriate pilot location for this system. To properly permit research projects, the BLM should establish guidelines for appropriate scientific use, with specific and distinctive consideration for NLCS units (e.g. ensuring the preservation of NLCS units as benchmark sites). Guidelines should include reporting requirements, such as a brief manager's summary and a full scientific report.

15. *The BLM should enhance delivery of scientific information via a searchable, web-based, data and report portal.* This portal would greatly increase the communication of scientific information. The National Operations Center should develop this portal in consultation with State and Field Offices; the NLCS could pilot its use. Full potential of a web-based data and report portal would be realized if coupled with a modernization of the bureau's information technology infrastructure and policy (e.g. data sharing technology and policy).

Distinctive NLCS Recommendations

16. *The BLM should collaborate in the integration of the NLCS into a landscape-scale conservation network in partnership with the other federal land management agencies*. This network would help to ensure protection for all US ecosystem types, provide a venue to increase collaboration between and amongst agencies, and increase public understanding of federal conservation efforts.

17. *The BLM should systematically identify the "scientific values" of each NLCS unit and ensure the protection, conservation, and restoration of these values.* This would be an important step toward fulfilling the legislative mandate to protect, conserve, and restore scientific values in the NLCS. The BLM should issue guidance directed at NLCS units for identifying scientific values and ensuring their conservation (e.g. via management prescriptions provided in land use plans). Following the identification of NLCS scientific values, the BLM should communicate them to the internal and external scientific communities.

18. *The BLM should establish a standardized framework for periodically assessing how well NLCS units' designated values are protected, conserved, and restored.* Periodic assessment of conditions will improve the NLCS' management and funding effectiveness at both the unit and system level. In addition, these assessments can contribute to increasing public awareness and gaining public support. The assessments should be based on scientific data, collected at both the landscape-scale and the local-scale. Results from these assessments will aid in determining how compatible certain uses are with the NLCS' conservation mandate.

19. *The BLM should invest in a strategic NLCS communications campaign that brands the NLCS as "America's Outdoor Laboratory"*. A communications campaign would expand the scientific community's recognition of the NLCS as a well-known, respected, and useful place for conducting science. Communication techniques could include participation in appropriate scientific meetings, modern web-based communication efforts that describe priority NLCS research topics, and incorporation of scientific findings into outreach materials.

CONCLUSION

The BLM has a critical role in the future of American energy development, resource management, restoration of lands and waters, and conservation. Science is essential to fulfilling these responsibilities. The BLM must advance the role of science within the bureau, improve the integration of science into BLM decision-making, and accelerate the process of accomplishing both these goals. The NLCS, as a valuable national resource and laboratory for science, is a strategic and appropriate element of the BLM to pilot several of this report's recommendations.

BLM-relevant applied science and the usable knowledge that it creates has significant potential return on investment. It can improve decision-making, empower managers at the field, state, and national levels, engage citizens and communities, and increase the efficiency and effectiveness of the bureau. Hence, the need for action is also an opportunity for the BLM to manage its future.

Confronted with heightened resource demands and unprecedented and increasing environmental and socioeconomic change, there is great urgency in BLM acting boldly and decisively. The recommendations in this Director's Report, if implemented, will accelerate the advance of science within and for the BLM.

A Review of Equine Standing Laparoscopic Ovariectomy

Monika Lee and Dean A. Hendrickson, DVM, MS

INTRODUCTION

Equine ovariectomies are performed for various reasons. The most common indications are to prepare a mount mare for semen collection, eliminate estrus behavior and colic signs associated with estrus,[1,2] sterilize the mare for registration purposes, and to prepare recipient mares for embryo transfer.[2] Other reasons are associated with removing pathologically abnormal ovaries in the form of granulosa–theca cell tumors.[2] Regardless of the reasons for performing the surgery, it has developed into a regularly requested procedure.

Different surgical approaches and amputation techniques have been developed to remove equine ovaries. Horses can be operated on while in a standing or dorsally recumbent position. The standing technique can be performed using sedation and local anesthesia,[3] whereas dorsally recumbent procedures require administration of general anesthesia.[2] General anesthesia has been shown to cause hypoxemia and hypoventilation that may necessitate a ventilator.[1] The surgery can be done as a ventral midline celiotomy, flank laparotomy, or colpotomy.[1,2] Colpotomy complications include unidentified and potentially fatal hemorrhage of the mesovarium caused by poor hemostasis, intestinal and mesenteric trauma, peritonitis, adhesions, and possibly death.[2] The flank approach is favorable because visibility is improved, but it is still difficult to exteriorize the ovary without making large incisions.[2] Consequently, standing laparoscopic ovariectomy has become a more common technique to remove ovaries in mares.

Advantages of laparoscopic techniques include the reduction of complications through full observation of the operative field, minimal invasiveness, a shortened convalescent time with fewer postsurgical complications,[1,2] and improved cosmetics after surgery.[1] It also allows for tension-free ligation of vessels in the mesovarium.[2] Concerns and limitations associated with laparoscopic techniques include the necessity and cost of specialized equipment, technical difficulty of the procedures and required training to conduct them, and the fact that a lack of familiarity with procedures can dramatically increase operating time.[2,3]

Performing laparoscopy in standing horses adds the advantage of avoiding the risk and expense of general anesthesia while providing easier access to the ovaries because of the location of the reproductive anatomy.[3] Limitations of standing procedures include horses with unsuitable temperaments for standing sedation surgery, the size of the horse, and the availability of appropriate facilities for restraint.[3]

MATERIALS AND METHODS

Patient Preparation

Feed but not water is withheld from the horses for 18 to 24 hours to reduce bulk in the peritoneal cavity and improve the working space. The use of prophylactic antibiotics is left to the surgeon's discretion; however, at most only perioperative antibiotics should be used. Preoperative nonsteroidal anti-inflammatory drugs should be given to reduce pain and inflammation associated with surgery. The horses are sedated, a catheter is placed, and surgical sedation can be obtained with intravenous boluses of detomidine, epidural detomidine (40 μg/kg brought to a total volume of 10–12 mL with sterile saline), or titrated to effect intravenous infusion of detomidine (20 mg/L liter saline or polyionic replacement fluids). Both flanks for bilateral ovariectomy, and the ipsilateral flank for unilateral ovariectomy, should be clipped and aseptically prepared for surgery. The surgical sites can be anesthetized with local anesthesia in either an inverted "L" block, a line block, or, as the authors prefer, individual portal blocks (Fig. 1). The first portal is placed at the level of the base of the tuber coxae, midway between the tuber coxae and the last rib. A 10- to 12-mm-diameter, 15- to 20-cm-long cannula with a blunt trocar is advanced through a 12-mm incision in the skin and external abdominal oblique fascia and the rest of the abdominal musculature into the peritoneal space. The trocar is then replaced by a laparoscope connected to a 300-watt xenon light source and laparoscopic camera, which is used to confirm penetration through the parietal peritoneum. Abdominal insufflation with carbon dioxide is to an intra-abdominal pressure of 8 to 12 mmHg initially. The second portal is made just cranial and 10 cm proximal to the first cannula, and the third portal is made 10 cm ventral to the first cannula[3] (Fig. 2).

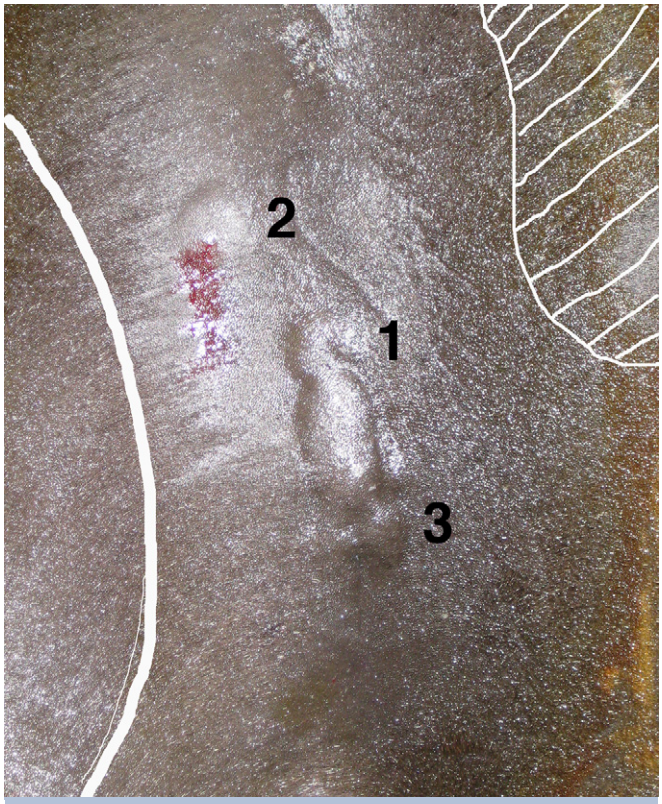

Figure 1. Photograph of left flank showing portal sites: 1, first portal; 2, second portal; 3, third portal. Note the local anesthetic between portals 1 and 3 to facilitate enlargement of portals for ovary removal. White line on left corresponds to last rib. White line with crosshatches on right corresponds to tuber coxae.

Throughout the procedure, all laparoscopic instruments are inserted through the instrument portals as required. The mesovarium should be infiltrated with 10 to 15 mL 2% lidocaine before resection.[4] If a single ovary is removed, the ventral incision is enlarged for removal of the ovary. For bilateral ovariectomy, both are resected; the right ovary is passed under the descending colon to the left side of the abdomen and removal is via the left flank. Only the skin is closed in the small incisions using size 2–0 nylon in a cruciate or simple interrupted pattern. The external abdominal oblique muscle and fascia are closed in the single enlarged incision using size 0 polyglyconate (Maxon, Covidien) in a simple continuous pattern and size 2–0 nylon in the skin in a simple continuous pattern. The horses are generally kept in a stall for 1 week and a stall/run for 1 week, and then they are returned to work.

Various techniques have been used to amputate the ovary in standing laparoscopic ovariectomy. The main variations are the methods with which hemostasis is achieved. Reported methods include hand-tied ligating loops, pre-tied ligating loops, bipolar and monopolar electrosurgical forceps, ultrasonic cutting/coagulating devices, radiofrequency devices, surgical staples, and lasers. The ultimate objective in ovariectomy experiments is to find a method that facilitates the ovarian resection and removal with minimal hemorrhage and ovarian manipulation.[5]

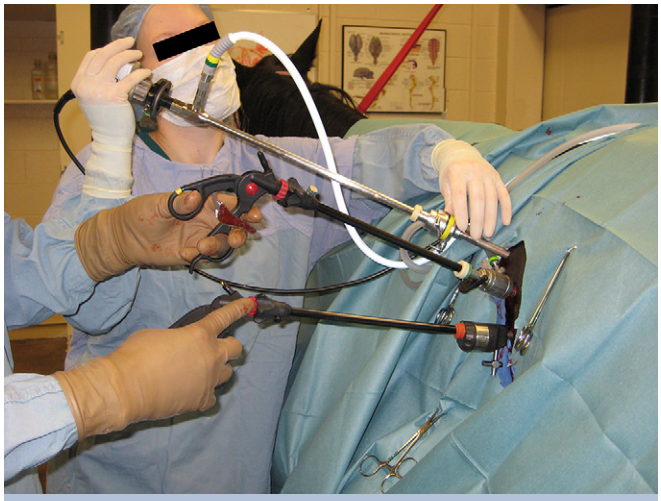

Figure 2. Portal placement in left flank.

Ligating Loops

Intracorporeal suturing in laparoscopic surgery requires extensive skill and practice. Consequently, other suture techniques have been developed to provide a simpler ligation technique using loop sutures. The most common suture combinations are size 2 or 3 polyglactin 910 (Vicryl, Ethicon) in a modified Roeder knot,[1] size 1 polyglyconate (Maxon, Covidien) using a 4-S modified Roeder knot,[3,6] or the pre-tied Endoloop (size 0 polyglactin 910 or polydioxinone, Ethicon Endosurgery). All of these knots are designed to slip while advancing but to lock into place when tightened. In the study by Shettko et al,[6] the combination of the 4-S modified Roeder knot, and size 1 Maxon was significantly stronger than all other suture and knot combinations tested.

The caudal pole of the ovary is sharply dissected to reduce the pedicle size (Fig. 3), and two ligating loops are placed on the ovarian pedicle (Fig. 4). The ovary is grasped with forceps through the ligature loop and then manipulated to tease the loop around the newly created ovarian pedicle. It is generally effective to twist the ovary through the loop. Once the pedicle is snared, the loop is tightened by advancing the knot pusher while pulling the tail end of the ligature. The knot pusher is then exchanged for scissors, and the tail of the ligature is cut and removed; this is repeated. The ovarian pedicle is then carefully transected with laparoscopic scissors between the ovary and ligature and checked for bleeding (Fig. 5). Specific equipment for this technique

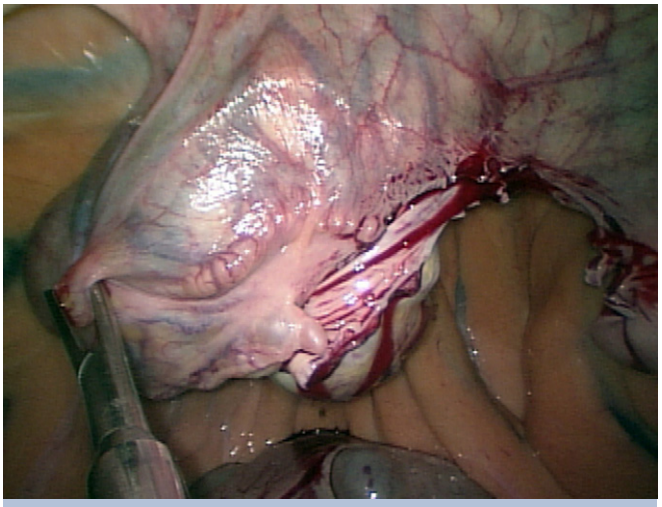

Figure 3. Photo showing dissection of the caudal pole of the left ovary.

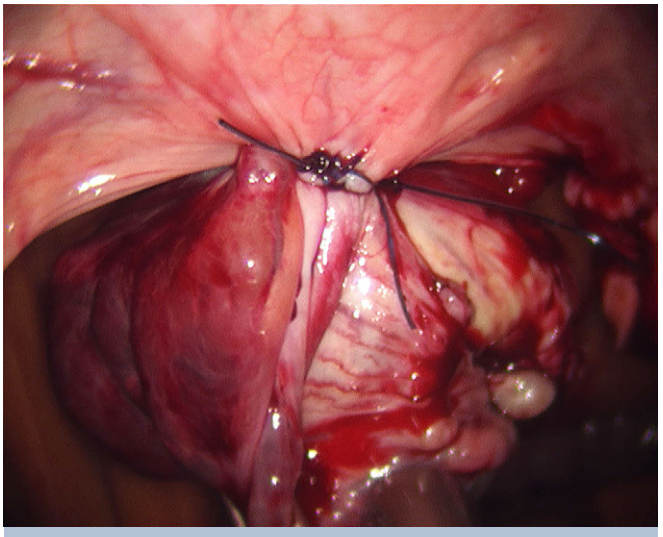

Figure 4. Photo showing two ligating loops on the left ovarian pedicle.

includes a knot pusher, a 5-mm reducer, a suture scissors, and a tissue scissors.

No major complications have been associated with this technique. In a few circumstances, incomplete hemostasis occurs, which is very easily resolved with an additional ligature or by placement of a ligating clip. Hemostasis also can be achieved without ovarian pedicle dissection, but it often results in reduced ligature security. Limits to this technique occur when the ovaries are larger than 15 to 18 cm in diameter, because it is difficult to control such a large loop in the abdomen.

Polyamide Tie-Rap

Another technique used to perform mesovarian ligation is through the use of a white-colored, commercially available polyamide tie-rap, more commonly known as a zip-tie.[7] The tie used is 500 mm long, 4.8 mm wide, and 1.2 mm thick. Sterilization of the tie-rap can be done using gas plasma sterilization, steam, ethylene oxide (which minimizes elongation of the material), and autoclave techniques. The tie is manually marked every 20 mm before initiation of the surgery to ensure that the tie-rap tightens adequately during surgery. The polyamide tie-rap is prepared by creating a loop and connecting it to a hooked metal bar. The metal bar tie-rap unit is inserted in the metal tube, and cervical forceps are inserted to grasp the ovary and provide tension on the mesovarium. Curved Metzenbaum scissors are inserted through the second portal and are used to slightly transect the mesovarium, on the caudal and cranial ends. The scissors are then removed, replaced by tie-rap unit, and the loop is set horizontally and under the ovary. The loop typically slides quite easily over the ovary due to the stiffness of the polyamide tie. With the traction from the cervical forceps on the ovary, the loop

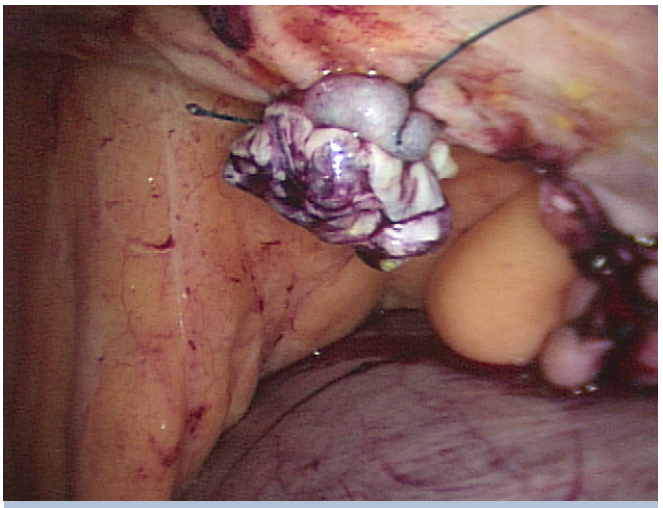

Figure 5. Photo showing transected stump after amputation of left ovary.

is positioned as high as possible on the pedicle and then tightened by pushing up on the buckle of the tie rap with the metal tube while pulling on the end of the tie-rap with the hooked metal bar. The tie-rap is tightened until the surgeon sees the buckle rest between marks 3 and 4. The metal bar is then removed and replaced by tissue forceps, which is used to completely tighten the loop. The cutter–sleeve unit is inserted to cut off the end of the tie rap, and the ovary is then completely transected from the mesovarium with laparoscopic scissors.

Few complications were noted in this report. Mesovarial hemorrhage can occur if the vessels are not entirely occluded, which is easily fixed with the application of a second

tie-rap proximal to the first. Two weeks after surgery, the tie-rap and mesovarial stump is partially encapsulated with yellowish fibrovascular tissue, at 4 weeks encapsulation is complete, and at 12 weeks, the stump is entirely encapsulated with organized fibrous tissue.

The polyamide tie is inexpensive and widely available at any hardware store. Because the polyamide polymer is a nylon monofilament material, it is biologically inert and noncapillary. Its melting point is 250°C, which is important to remember when sterilizing. The suture material is nonabsorbable and can elicit an inflammatory reaction but typically does not cause problems. The major advantage of using the polyamide tie-rap is that the loop to be placed around the ovary is rigid and is therefore easier to apply in comparison with a ligature. The 14-cm-diameter loop can be a limitation when it is insufficient to allow passage of a large ovary. Larger tie-raps are available, however, which minimize this problem.

Electrocoagulation

Bipolar cautery can be used to provide hemostasis of the ovarian pedicle.[2] This procedure involves the use of basic laparoscopic tools and bipolar forceps to provide hemostasis of the mesovarium. Bipolar cautery provides a safer environment than monopolar cautery, because there is a reduced likelihood of collateral damage from aberrant currents.

Laparoscopic grasping forceps are inserted through one instrument portal to provide traction on the ovary. The bipolar electrosurgical instrument is inserted through either the most cranial or the most dorsal instrument portal. Pedicle dissection is initiated when the electrosurgical forceps are placed across the cranial aspect of the mesovarium approximately 1 cm proximal to the ovary. The cranial mesovarium is coagulated until blanching and shrinkage are observed. The laparoscopic scissors then replace the atraumatic grasping forceps, and coagulation and transaction is repeated caudally until the ovary is only suspended by the tubal membrane, oviduct, and proper ligament of the ovary. The electrosurgical instrument is replaced with grasping forceps to grab the ovary. Laparoscopic scissors are used to transect the remaining mesovarium, which now lacks any major blood vessels. Once the ovary is transected, the mesovarium is observed for bleeding before laparoscope removal.

The advantages of electrosurgery are that it is less technically demanding than ligature placement; however, it does require more equipment to purchase and maintain. It can generally provide adequate hemostasis of the mesovarium and consequently a dry surgical field. However, it is generally limited to coagulating vessels of 3 mm in diameter or less. Thermal injury to bowel from stray currents can lead to perforation and subsequent life-threatening postoperative peritonitis. This can occur because of insulation failure in the active electrode, direct coupling, or capacitive coupling. These complications can be reduced by avoiding the use of high-power settings, energizing the active electrode only when it is in contact with the target tissue, keeping the active electrode in the field of view, not inserting metal cannulas through plastic devices, avoiding touching the active electrode to other metal instruments, and avoiding long activation of the active electrode. The standing position helps minimize injury because the ovary and mesovarium are located dorsal to abdominal viscera; however, distention of the bowel can cause problems, which emphasizes the importance of withholding feed before surgery.

Ultrasonic Cutting and Coagulating Devices

Ultrasonic energy is delivered to the ovarian pedicle to coagulate vessels and cut the tissue of the pedicle.[8,9] Standard laparoscopic instrumentation along with a device for providing the ultrasonic energy are required for this procedure. Two main devices are available, the Harmonic Scalpel (Ethicon Endosurgery) and the Autosonix (US Surgical, Covidien). The units consist of a generator, a foot pedal, and hand piece with a connecting cable, and a blade system. A transducer in the hand piece converts electrical energy from the generator into ultrasonic vibration, 55,000 Hz, which is transmitted along an extending rod to the active blade tip. This energy is sufficient to cause protein disorganization and denaturation, resulting in a sticky protein coagulum capable of sealing vessels up to 3 to 5 mm in diameter. The devices use multiple power settings to empower a blade system that allows a surgeon to control the balance between cutting and coagulation by varying power settings, changing blade configurations, and varying the grip force.

The ovary is stabilized by grasping the infundibulum with laparoscopic claw forceps while the shears are inserted. When using the Harmonic Scalpel (Ethicon Endosurgery), the coagulating shears transect the mesosalpinx, uterine tube, and proper ligament with a sharp blade and the number 5 setting while simultaneously coagulating blood vessels. The vertical part of the ovarian pedicle is transected using the blunt blade and number 3 setting, and the first cuts are made on the most cranial part. The shears are exchanged for laparoscopic scissors, and the remainder of the ovarian pedicle is separated into medial and lateral components by blunt dissection. The laparosonic coagulating shears are reintroduced into the craniodorsal portal, and the lateral aspect of ovarian pedicle is transected followed by the medial aspect.[8] A similar technique is performed using the Autosonix (US Surgical, Covidien) except that a single pair of shears is used[9] (Fig. 6).

The advantages of using an ultrasonic device are that it is simple to use and it is capable of grasping, coagulating, and cutting tissue simultaneously. It minimizes the number of

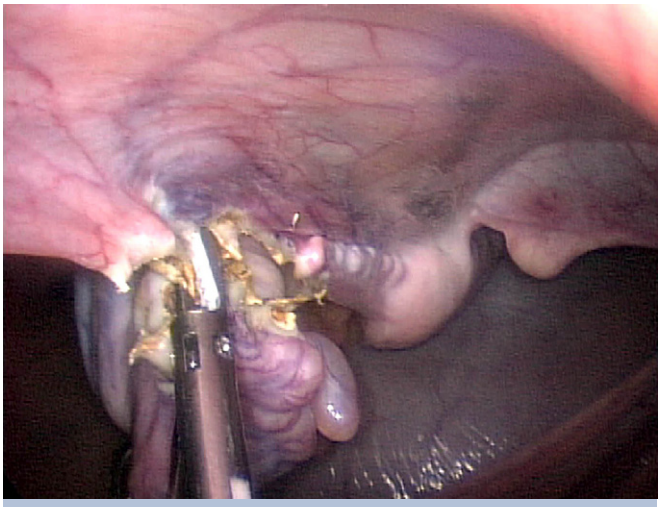

Figure 6. Intra-abdominal view of cauterization and amputation of the left ovary using the ultrasonic cutting/coagulating shears (Autosonix, US Surgical, Covidien).

Figure 7. Intraabdominal view of cauterization and amputation of the left ovary using a radiofrequency wand (LigaSure, Covidien).

instrument exchanges needed to complete the procedure, and the surgeon can control the balance of coagulation and cutting by varying the power setting, blade configuration, and tissue pressure. The shears are easy to use and achieve reasonable hemostasis of the ovarian pedicles. In the report by Alldredge and Hendrickson,[9] many of the pedicles required further treatment in the form of ligating clips for hemostasis. The shears can be used to offer further hemostasis. The equipment can be expensive, and the shears are designed to be single use.

Radiofrequency

Radiofrequency can be used to cauterize the ovarian pedicle.[10] The LigaSure (Covidien) device is a feedback-controlled bipolar vessel sealing device used to establish hemostasis. The feedback-controlled electrothermal scaler applies the precise amount of energy to produce a seal of the vessel walls in the form of partially denatured protein. The integrity of the seal is independent of a proximal thrombus and resists dislodgment because the seal is inside the vessel wall structure. Unlike electrocoagulation device, the LigaSure minimizes thermal spread to adjacent tissue and reduces sticking or charring at the seal sites.

The use of the LigaSure does not require the dissection of the mesovarium to create a smaller ovarian pedicle. The instrument is inserted through the appropriate portal and is positioned to begin from either the caudal or the cranial pole of the ovary. The Atlas wand incorporates a cutting blade so that the tissue can be coagulated and cut sequentially without changing instruments. This process is repeated until the ovary is removed, which takes approximately five to seven applications of the LigaSure (Fig. 7).

A technical problem of spark emittance has been reported with mechanical operation of the device when discharging it across tissue. This could be attributable in part to too much tissue forced into the instrument's jaws, or sterilizing and re-using a device designed for single use. The LigaSure is advantageous to use because it does not require dissection of the mesovarium, there is no likelihood of ligature slippage, and no foreign-body reaction occurs because of the suture material. The instrument is effective for vessels up to 7 mm in diameter, and the translucent appearance of the seal indicates a complete lack of blood flow to the cut edge of the pedicle. Although designed to be a single-use instrument, the wand can be sterilized for cost-effectiveness in a hydrogen peroxide/plasma sterilizer.

Endoscopic Stapling

Stapling devices have been part of equine surgery since the 1970s. Recently they have been adapted for endoscopic procedures. The endoscopic stapling devices generally require a 12- or 15-mm-diameter cannula. The Endo-GIA II (US Surgical, Covidien) stapling device is designed to seal ovarian vessels and transect the mesovarium all in a single application. It also is possible to use a disposable specimen pouch for removal of the ovaries from the abdomen.[5]

The mesovarium is dissected to isolate ovarian vessels, creating a pedicle capable of containment within the stapling device. The ovary is manipulated with grasping forceps to incorporate the entire pedicle into both arms of the stapler. The distal aspect of the stapler is typically the most common site of incomplete occlusion, which is

important to consider when performing this procedure. Once the pedicle is completely encased in both arms of the stapler, the blade within the stapler is advanced, causing release of the staples and subsequent severing of the pedicle. Any residual attachment of the pedicle that is not incised is transected using laparoscopic tissue scissors. It is critical that the transected pedicle be evaluated for bleeding before removal of the ovary. The detached ovary can then be placed in the EndoCatch II (US Surgical, Covidien) disposable specimen pouch, previously inserted into abdomen through the dorsal instrument portal. In the report reviewed, the right ovary was placed into the bag and then the left ovary directed toward the caudal aspect of the right abdomen by passing it between the bladder and the body of the uterus. To perform this step more carefully, the camera is moved to the left flank for better visualization and then moved to the right flank for removal. Once both ovaries are in the pouch, it is closed with a drawstring and pulled tightly against the flank. The right abdominal incision is then enlarged to pull the bag through the body wall, and all incisions are closed.

Bleeding from the pedicle can occur when the initial dissection is too close to the ovary. The advantages of using this technique are the simultaneous hemostasis of the ovarian vessels and transection of the ovary. The disadvantage is the cost of the staple cartridge and bag if used. The main advantages of using a laparoscopic stapling device technique compared with a suture are the shorter surgical time, that the ovary is resected from the mesovarium immediately without the need for transaction after individually ligating vessels, and that there is no risk of inadvertently cutting the suture or displacing the knot during amputation. The primary advantage of using the EndoCatch II device is the avoidance of losing the ovary during transfer to another grasping instrument, given there is sufficient space in the bag for both ovaries. The disadvantage associated with this technique is the increased surgical time needed to control bleeding when ovarian vessels are inadvertently transected, which can be corrected with electrocautery or laparoscopic clips.

CONCLUSIONS

The primary advantages of standing laparoscopic surgeries are excellent intraoperative visibility, secure hemostasis, reduced surgical and postoperative morbidity, decreased postoperative discomfort, rapid and uncomplicated healing, reduced quantity of medication needed, shorter postoperative management, and less expense than for ovariectomies performed under general anesthesia.[3]

There have been few reported significant complications associated with standing laparoscopic ovariectomy. Choosing the appropriate animals to undergo standing surgery under sedation is the most important first step. If the mare is not amenable to a standing surgical procedure performed in the stocks, it should be anesthetized. Bleeding from the pedicle can be managed immediately because the procedure allows direct visualization of the surgical site. It is possible to drop the ovary into the abdomen after amputation; it is generally considered important to find the ovary and remove it from the abdomen. In most cases, this can be done using laparoscopic instruments. In some cases, it requires an enlarged incision and identifying the ovary manually for removal.[2] Sometimes ovaries with large follicles are difficult to exteriorize and are incised and drained in the abdomen to decrease ovarian size and avoid slippage during removal.[7] Most mares are clinically normal immediately after surgery. The tension-free amputation is believed to be less painful than traditional techniques. There are reports of mares that have a slight decrease in appetite and increase in temperature for the first 12 hours postoperatively or that experience mild incisional edema and subcutaneous emphysema, which often resolves in 3 to 5 days.[1] Mares often show mild signs of colic and are given a single dose of flunixin meglumine, which has been shown to be useful.[2]

All of the reported techniques are useful in equine ovariectomy. Of the techniques discussed in this review, the ligating loop is the least expensive but requires the most skill. The LigaSure device requires the least skill and is similar in cost to the other techniques. The authors recommend using the ligating loops for normal-sized ovaries and the LigaSure device for ovaries larger than 15 to 18 cm. In a recent retrospective study evaluating the clients' perspective on standing laparoscopic ovariectomy, behavioral improvement was seen in 83% (19/23) of mares treated for behavior-related problems, aggression problems improved in 86% (12/14) of cases, general disagreeable demeanor improved in 81% (17/21), and excitability improved in 75% (12/16) of cases where these behaviors had been previously observed. Kicking and biting improved in 73% (8/11), problems in training improved in 72% (13/18), and frequent urination and problems with other horses improved in 64% (7/11 and 9/14, respectively) of cases.[11]

Laser Ablation of Endometrial and Lymphatic Cysts

William B. Ley, DVM, MS, Russell G. Higbee, PhD, DVM, and G. Reed Holyoak, DVM, PhD

This article discusses uterine cysts (endometrial and lymphatic), their diagnosis, and therapeutic management using neodymium: yttrium-aluminum-garnet laser ablation as directed by hysteroscopic visualization. The technique used in our clinical setting is described along with a discussion of the follow-up results in mares treated by the Sarkey's Surgical Laser Laboratory at Oklahoma State University, Stillwater, OK, over the past 7 years.
Key Words: Cyst, cysts, endometrium, uterus, laser, neodymium:yttrium-aluminum-garnet, hysteroscopy, mare, equine.

UTERINE CYSTS are of 1 of 2 types: endometrial (glandular) or lymphatic. Endometrial cysts are typically smaller in dimension (1-10 mm) and are dispersed multifocally throughout 1 or more areas of the uterus. They result most commonly from chronic degenerative changes in the endometrium leading to periglandular fibrosis and glandular lumen restriction with dilatation of the glandular lumen resulting in its cystic distension. Lymphatic cysts are typically larger (>10 mm) and usually are isolated to 1 to 3 locations. These result from lymphatic outflow stasis; surrounding endometrial tissues may have chronic inflammatory infiltrates or may be normal histologically. Either condition requires use of either ultrasonography or hysteroscopy for identification; however, the larger lymphatic cysts may be identified by careful rectal palpation. The relationship between presence of cysts and fertility is still as yet unclear.

Most clinicians believe that large cysts influence early embryonic mobility in the uterine lumen (after day 7 or 8 and before day 15 or 16), thus threatening maternal recognition of pregnancy, if not jeopardizing embryonic nutritional support because of restriction of uterine histotroph absorption. There are also exceptions to this, in that many clinicians have also observed normal embryonic development and pregnancy maintenance in the presence of 1 or more large uterine cysts. Despite their potential indication of significant underlying endometrial pathology, their presence also confuses the naive diagnostician, as well as many of the most experienced clinicians, at the time of initial pregnancy diagnosis. Mistaken identity of an embryo for a cyst, and vice versa, is a common challenge. Most cysts are also observed in older brood mares. One report[1] found most cysts in 11 of 73 mares whose mean age was 13.4 years, whereas 62 of 73 mares without cysts were of a mean age of 6.9 years. A Swiss study[2] in thoroughbred mares reported that pregnancy rates at days 14 and 40 were significantly ($P < .01$) lower in mares with cysts (77.6% and 71.4%) compared with mares without cysts (91.5% and 88.0%). This would suggest that the presence of uterine cysts may play an important role in the reduction of fertility. However, in this study when all mares were assigned to 3 age groups, less than 7 years (n = 116), 7 to 14 years (n = 117), and older than 14 years (n = 26), a significant ($P < .01$) increase in the number of endometrial cysts was observed with advancing age (4.3%, 29.1%, and 73.1%, respectively). In a postmortem examination of the genital tracts of 104 mares in Germany, endometrial cysts were identified in 13% of cases.[3] In clinical examination of 82 mares, endometrial cysts were recorded in 13.4% of mares of various breeds.[4] These investigators found no evidence of cysts in mares less than 10 years of age, and mares in their study that had cysts in the endometrium had a 10% higher incidence of disturbed fertility. They reported that 7 of 9 mares having evidence of endometrial cysts became pregnant and continued their gestation without complication. Therefore, the true relationship between presence of cysts and age-related reduction in pregnancy maintenance is difficult to sort out.

For these reasons, and the general lack of truly successful treatment options, most clinicians will recommend breeding the mare with uterine cysts on 1 or more cycles in an attempt to see if she will carry her pregnancy in spite of them. If this approach is taken, it is very prudent to record and map on a uterine chart the presence and size of all endometrial or lymphatic cysts identified before each attempted breeding. Cysts will appear and disappear occasionally throughout an estrous cycle or between an ovulation and an initial pregnancy diagnosis at 14 to 15 days postovulation. When several attempts to induce a successful pregnancy have failed, it would be advised then to obtain an endometrial biopsy (or biopsies) to determine the histomorphologic status of the endometrium in general. Treatment plans directed solely at the elimination of a cyst or many cysts will not be fruitful should the uterus in general have significant endometrial fibrosis. In many mares with uterine cysts, there may also be intraluminal adhesions present that cannot be detected by any means short of direct intrauterine palpation or visualization by hysteroscopy.

Treatment options have included electrocoagulation, direct puncture by biopsy forceps, manual rupture, and various intrauterine infusions with saline, hypertonic saline, and magnesium sulfate. Cysts often have either failed to be removed by these attempts, or when successfully resolved, have returned in 1 or 2 cycles. Electrocautery for cyst removal has been used via hysteroscopy.[5,6] Results were similar in these 2 reports in that 3 of 5 treated mares became pregnant in the subsequent estrous period after cyst removal,[5] and 3 of 6 mares in the other report either produced a live foal or became pregnant.[6] Cyst ablation by hysteroscopic neodymium:yttrium aluminum garnet (Nd:

YAG) laser irradiation has been reported previously[7]; 3 of 6 treated mares had positive outcomes after these photoablative treatments. The following is a description of the methodology developed and a report of some of the outcomes associated with laser ablation of equine uterine cysts at the Sarkey's Surgical Laser Laboratory, College of Veterinary Medicine, Oklahoma State University. This work represents the clinical research effort and experience of multiple clinicians as well as these authors over the past 7 years.

Diagnosis and Case Selection

Clinical cases with uterine cysts were identified or diagnosed by referring practitioners and confirmed at the Oklahoma State University Teaching Hospital, Equine Clinic, by using palpation and ultrasound examination (Fig 1). The cysts' exact location and number were determined by ultrasonography before treatment. Mares with cysts greater than 20 mm in diameter or those with multiple cysts less than 20 mm, which were cylindrical and covered more surface area, were considered candidates for laser ablation. Mares received a complete breeding soundness examination including endometrial biopsy to evaluate the presence and degree of endometrosis and to provide some prognostic value to the mare owner with respect to the value of the laser ablation procedure.

Surgical Procedure

Horses were tranquilized with 20 to 40 μg/kg detomidine HCl administered intravenously (Pfizer, Exton, PA). Restraint was by use of examination stocks, and the room or area in which the laser ablation was performed had its access restricted. The mare was prepared with a full tail wrap; tail tied to the side; and given a perineal scrub using water, cotton, and a nondisinfectant, mild soap or chlorhexidine scrub; thoroughly rinsed again with clean water; and then dried with clean paper towel. The operator wore a sterile shoulder length plastic obstetrical sleeve, and a sterile, nonbacteriostatic obstetrical lubricant was placed on the back of the gloved hand. Before the introduction of the endoscope, a thorough vaginal and cervical examination was performed digitally to evaluate the cervix for patency, absence of fibrotic scars, adhesions, or other damage.

Examination of the vaginal mucosa, cervix, uterine endometrium, and visualization of the cysts was accomplished with a Welch Allen laser-safe flexible endoscope (model 81201; Welch Allen, Skaneateles Falls, NY) attached to a Welch Allen video processor (model 86000; Welch Allen, Skaneateles Falls, NY). A commercially available RCA (Thomson Multimedia, Indianapolis, IN) 4-head VHS video tape recorder was used to document the procedure. The tip of the endoscope was guarded by the sterile gloved hand and guided through the vulva, into the vagina, avoiding the urethral opening ventrally, and advanced cranially until the cervix was identified. The external cervical os was gently invaded and the full length of 1 or 2 fingers were inserted through the cervix stopping at the body of the uterus. The endoscope (1 cm × 1 meter) was then carefully guided between the fingers and placed into the uterus, the lumen of which was then insufflated with air. Once the uterus was properly insufflated, large lymphatic cysts were easily identified (Fig 2). The laser fiber was then advanced through the biopsy channel of the endoscope until the tip was visualized. A suction apparatus was attached to facilitate the removal of carbonized tissues and released cyst contents as needed.

A Sharplan model 2100 Nd:YAG laser (Sun Medical, Inc, Arlington, TX) with peak energy at 1064-nm wavelength was operated at a power setting of 25 to 30 W and a pulse duration of 7 seconds. Energy was delivered through a Sharplase (Sun

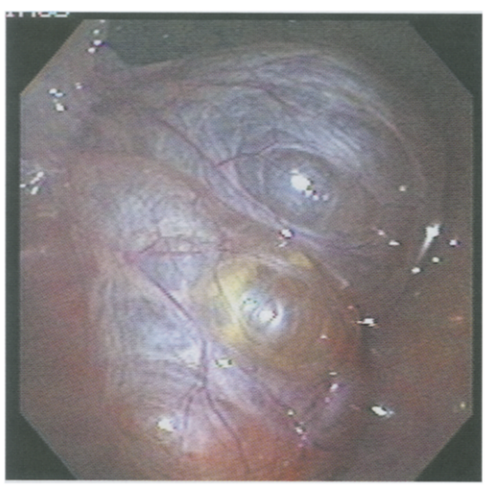

Fig 2. Hysteroscopic view of a large, thin-walled, multiloculed lymphatic cyst. Once adequate insufflation of the uterus has been achieved, these cysts are easily identifiable. (Courtesy of S. Palmer.)

Medical Inc, Arlington, TX) frosted conical 600-μm diameter fiber (model 25581) producing approximately 175 to 210 J of energy per pulse (Fig 3). This conical fiber provided a higher degree of localized energy dispersion than did a flat-ended fiber. This allowed the cyst wall to encompass the fiber and keep the laser energy localized to the cyst wall. Protective eyewear appropriate for use with the Nd:Yag laser was used by all persons in the vicinity of the operating laser. Smoke evacuation was accomplished by a filtered house vacuum attached to the endoscope. The typical total energy delivered ranged from approximately 1,500 J to over 5,000 J. This variability was dependent on the number of cysts present and their type. The energy required to rupture a cyst was quite variable and depended greatly on the nature of the cyst wall. Thin, friable cysts usually ruptured at 25-W energy levels and fibrous walled cysts ruptured around 30 W (Fig 4).

Postoperative Therapy

After laser ablation of the cysts, the uterus was flushed with a large volume of sterile lactated ringers solution (1-3 L). Follow-up uterine examinations were performed by using transrectal ultrasound at days 1, 3, 14, and 21 to 30. On rare instances, treated mares returned for ablation of additional cysts not treated on the first attempt or for ablation of additional cysts that developed after the first treatment was completed.

Discussion

On gross hysteroscopic examination of the mare's endometrium, large lymphatic cysts often occluded the uterine lumen until insufflation allowed uterine distention and greater visualization of the cyst's margins. On vaporization of the cyst's wall, the fluid contents poured into the uterine lumen and were subsequently aspirated, leaving the collapsed structure, which could be further reduced by vaporizing the remaining redundant tissue. Large lymphatic cysts were often pedunculated, and vaporization of these cysts at their base allowed quick drainage and tissue excision. This method appeared to be the most desirable approach for complete elimination of the structure. Cysts with large bases often required multiple passes for complete ablation (Fig 3). Cysts embedded deeper in the endometrium were usually small and were possibly cystic dilations of degenerated endometrial glands. These could be ablated by linear vaporization, thus allowing evacuation of the contents and dissolution after necrosis of the margins. The laser was fired when the quartz fiber was being drawn across the cysts or toward the endoscope channel and not while being pushed away. Perforation of the uterus will not occur if this rule is observed. Fluid-filled cysts absorbed more thermal energy than less or noncystic structures because the fluid acted as a transmitting medium that aids in dissipation of heat produced during the treatment. Because of this dissipation effect, multiple passes had to be performed so that less heat penetrated into the underlying endometrium and myometrium. It is our general impression that cysts containing fluid of higher viscosity required treatments of higher wattage for ablation. It was necessary to destroy the endometrial gland dilations within the stratum compactum or cause coagulation of the lymphatic lacuna to prevent recurrence of endometrial cysts and lymphatic cysts, respectively.

Fig 3. Hysteroscopic view of laser tip being applied to a lymphatic cyst. Below the tip of the laser fiber is a blackened or charred area in which photoablation has just occurred.

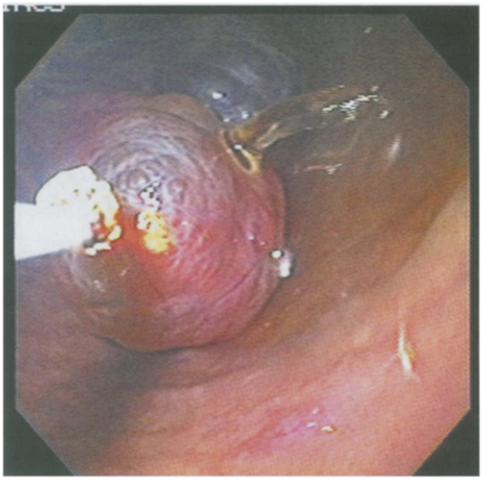

Fig 4. Hysteroscopic view of the laser being used to puncture the wall of a large, thin-walled, multilobular lymphatic cyst. Note the clear yellow fluid draining from the cyst onto the floor of the uterus. (Courtesy of S. Palmer.)

The Nd:YAG laser produced tissue coagulation necrosis for about 2 to 4 mm in all directions around the zone of vaporization. This caused localized destruction of the endometrium to the level of the superficial myometrium without threatening the integrity of the deeper myometrium. Immediately after laser ablation of large lymphatic cysts or detectable endometrial cysts, the target structure was reduced to a small area of carbonized or blanched tissue with a concomitant radius of erythematous tissue.

The endometrium possesses amazing powers of regeneration. Within 14 days of laser treatment, often the only marker remaining was a small (<2 mm) foci of carbon. By 28 days posttreatment, nothing more could be found other than a focal area of white scar tissue usually 1 to 2 mm in diameter. In some cases, no scar was present at all. When comparing histopathologic samples of endometrial biopsies taken 14 days and 28 days

posttreatment, preliminary results indicate no concomitant increase in endometrial fibrosis or glandular degeneration in the area of cyst ablation over that found in the uterus before laser surgery (W.B.L., R.G.H., and G.R.H., unpublished data, 2001). There was no indication of cyst redevelopment in the site of the previous cyst. However, some mares may develop both lymphatic and endometrial cysts in other areas of the uterus. The exact mechanism(s) behind this has not been elucidated.

Laser therapy involves invading the uterine lumen, the evacuation of cyst contents into the lumen, and the destruction of endometrial and lymphatic tissue. This will cause an acute inflammatory response that peaks within 24 to 48 hours. Immediately after laser surgery, the uterus was lavaged with 2 to 3 L of lactated ringers solution. Generally, 1 L was infused into the uterus through gravity flow and then siphoned off. A second liter was then infused in a similar manner; if the evacuated fluid returned clear, then a broad spectrum antibiotic was infused prophylactically. The subsequent inflammatory response probably helps to clear necrotic debris by forming a mucopurulent accumulation within the uterine lumen 2 to 3 days posttreatment. To clear the lumen of this material, the uterus was lavaged for 2 to 3 days posttreatment and reevaluated ultrasonographically to assess the need for further uterine treatment. To assist in uterine emptying, these mares can be administered oxytocin (10 units subcutaneously every 4 to 6 hours) or prostaglandin F_2 alpha to increase myometrial activity and tone. Uterine lavage was continued until there was no further fluid accumulation within the uterine lumen, usually 1 to 2 treatments 1 to 2 days apart were all that was needed.

Although we have ample anecdotal evidence of improved fertility after laser ablation of uterine cysts, until our current study is completed, we cannot say that pregnancy rates will be significantly increased. However, we have had mares come into our program with a history of being barren that have successfully become pregnant and carried foals to term after laser ablation of cystic structures in the uterine lumen. It would appear that larger cysts, greater than 20 to 25 mm in diameter, present a challenge for the embryo to circumnavigate during the prefixation mobility phase of its development. Location of these larger cysts is most commonly observed at the base of the uterine horns[8] and thus may affect proper fixation and embryonic orientation. Further study in this area is warranted.

Effect of prepubertal versus postpubertal castration on sexual and aggressive behavior in male horses

Scott W. Line, DVM; Benjamin L. Hart, DVM, PhD; Linda Sanders, BA, MA

SUMMARY

Male horses castrated prepubertally occasionally display stallion-like sexual and aggressive behavior as adults. A retrospective survey of 140 horse owners was undertaken to compare the effectiveness of prepubertal versus postpubertal castration on objectionable sexual and aggressive behavior. Of 94 geldings that had been castrated prepubertally (before 2 years of age), 20% to 30% displayed stallion-like sexual behavior and aggression toward horses, and 5% were aggressive toward people in a stallion-like manner. This occurrence of problem behavior was not significantly different from the occurrence of these behavioral patterns in 46 geldings that had been castrated as stallions (over 3 years of age). When castration was examined as a therapeutic measure to eliminate sexual and aggressive behavior in stallions in which the behavior had become objectionable, it was found that the operation was effective on sexual behavior and aggression toward people in 60% to 70% of horses and on aggression toward horses in 40% of horses.

MALE HORSES NOT intended for breeding usually are castrated before puberty in an attempt to prevent development of objectionable sexual libido and the aggressive temperament characteristic of stallions. Nevertheless, geldings occasionally display stallion-like sexual behavior or aggressiveness toward horses or people.[1,2] In 2 studies, stallion-like behavior in geldings was found not to be attributable to residual testosterone or the production of testosterone by nongonadal tissue.[3,4] Although castration of juveniles for behavioral purposes is common, its effectiveness in preventing objectionable sexual or aggressive behavior is unknown. A related question is whether castration before puberty is more effective in preventing objectionable behavior in adults than is castration after puberty. An answer to this question would be useful in advising clients who might wish to delay castration beyond puberty. Information about the effectiveness of castration on objectionable sexual and aggressive behavior, once it appears in stallions, would be useful in formulating prognoses in using castration therapeutically. The purpose of the study in this report was to obtain quantitative data on the aforementioned issues by interviewing a large number of owners whose horses had been castrated either prepubertally or postpubertally.

Methods

Selection of cases—Two groups of horses were selected from the January 1976 to June 1982 records of horses castrated at the Veterinary Medical Teaching Hospital, University of California at Davis. Those designated prepubertal (juvenile) castrates were less than 2 years old when castrated. Those designated as postpubertal (adult) castrates were older than 3 years at the time of castration. All horses were at least 5 years old and had been castrated for at least 1 year at the time of the study.

Interviews of horse owners—Telephone interviews of the owners were completed for 46 adult castrates and 94 juvenile castrates. Owners were told the study was being conducted to determine behavioral effects of castration on horses. Questions pertained to duration of ownership, type of housing, presence or absence of aggressive or sexual

behavior, and the main reason for castration. Specific questions were asked about biting, kicking, or rearing directed at people and horses, and about sexual interest in mares in estrus, which included displaying erection, mounting, and genital investigation during attempts at courtship, as well as copulation itself.

Statistical methods—A 2-sample binomial comparison (95% confidence intervals) was used to compare the occurrence of sexual and aggressive behavior in juvenile and adult castrates and the pre- and postcastration occurrence of sexual and aggressive behavior in adult castrates. A logit transformation was used to correct for distortion of the confidence interval for each proportion less than 0.20 or greater than 0.80.

Results

Of the 94 horses castrated prepubertally, 33% displayed stallion-like sexual interest (erection, mounting, genital investigation, or copulation), 25% were reported aggressive toward horses, and 5% were aggressive toward people in a stallion-like manner. When compared with the occurrence of these behavioral patterns in stallions castrated in adulthood, there was no statistical difference (Fig 1). When the behavior of stallions was examined before and after castration, it was found that sexual behavior and aggression toward people declined significantly ($P<0.01$), as did aggression toward horses ($P<0.05$; Fig 1). Combining the data for the adult and juvenile castrates, it was found that the prevalence in all castrates was 31%, 25%, and 8%, respectively, for objectionable sexual behavior, aggression toward horses, and aggression toward people.

The survey data for the effects of castration in stallions may be looked at in a different manner. If one is interested in the effectiveness of castration for stallions in which castration would be performed as a therapeutic measure for objectionable behavior, one would want to look at the alteration of behavior for just those stallions that displayed the problem behavior before castration. Of the 18 stallions reported to be aggressive toward people before castration, 6 still were aggressive after castration, and of these 6, 3 were reported to be less aggressive. Of the 21 stallions reported to be aggressive toward other horses before castration, 13 were still aggressive after castration, and 6 of these 13 were reported to be less aggressive. The analysis of the effects of castration on sexual behavior is more problematic because many male horses are not given an opportunity to express sexual interest toward mares in estrus after castration. In the survey, there were 30 stallions that copulated with mares before castration and also were observed in the presence of mares in estrus after castration. Of these horses, only 2 still copulated a year or later following castration and an additional 7 displayed some interest in the form of mounting, erection, or attempts to genitally investigate mares. Thus, the probability of eliminating sexual behavior or aggression toward people in stallions was found to be between 60% and 70%, and the probability of eliminating aggression toward horses was about 40% (Fig 2).

Discussion

It has been theorized that geldings with stallion-like behavior may have been castrated improperly, such that some androgen-producing tissue was left intact; these animals were often referred to as "proud cut." However, analyses of blood testosterone concentrations of geldings with stallion-like behavior revealed that testosterone concentrations were not different from those of more typically behaving geldings.[3] Our study indicates that about 20% to 30% of horses castrated at less than 2 years of age can be expected to display stallion-like sexual interest in

COLORADO STATE UNIVERSITY

mares and aggression toward horses and that about 5% can be expected to be aggressive toward people in a stallion-like manner. These percentages must be considered the normal prevalence of stallion-like behavior in geldings and not an abnormal occurrence due to factors such as hormonal imbalance or extragonadal production of testosterone.

The appearance of stallion-like behavior in geldings that had been castrated prepubertally is consistent with what is known about the effects of prepubertal castration on behavior in other mammalian species. Mounting by prepubertally castrated male cattle[5] and dogs[6] has been noted. Recently it has been documented that urine spraying and aggressive behavior in prepubertally castrated male cats[7] occurs at the same rate as the persistence of urine spraying and aggression in male cats that are castrated in adulthood after the behavior has appeared.[8]

The effectiveness of castration as a therapeutic measure in stallions to eliminate objectionable sexual behavior and aggressive behavior toward people was found to be between 60% to 70% and about 40% for aggression toward horses. This finding is along the lines reported for behavioral changes in adult males of other species. In adult male cats, castration is effective 80% to 90% of the time in reducing objectionable spraying, roaming, or fighting behavior.[8] In dogs, castration of adult males is 50% to 60% effective on mounting, aggression toward other dogs, and urine marking in the house.[9] Our results from this survey of stallions are therefore consistent with what has been reported in other species, and the percentages we present for the effectiveness of castration can be used as guidelines in giving clients prognoses. It should be noted that the percentages we report were for those cases in which the owners reported an elimination of the behavior rather than just a reduction. Since some clients may feel that a reduction in the objectionable behavior may be considered a favorable outcome of the castration, the effectiveness is probably underestimated.

An important result is that the data reveal no behavioral differences between male horses castrated as adults or juveniles. This information may be useful in advising clients who wish to delay castration of their males until they have obtained the more stallion-like morphologic characteristics. Presumably such a delay would not increase the chance of the animal retaining objectionable stallion-like behavior once it is castrated at a later age.

Cutaneous innervation of the thorax and abdomen of the dog

The anatomy of the cutaneous nerves innervating the canine thorax and abdomen was investigated by gross dissection of 38 dogs. Additionally, the cutaneous areas innervated by the thoracic and abdominal cutaneous nerves were mapped in a 2nd group of 33 barbituate-anesthetized male dogs, using electrophysiologic techniques. The skin of the thorax was innervated by dorsal cutaneous branches, lateral cutaneous branches, and ventral cutaneous branches of the spinal nerves. The dorsal cutaneous branches were branches of the dorsal primary branches of spinal nerves C6 and T2 through T11. The lateral cutaneous branches were branches of the ventral primary branches of spinal nerves T2 through T12. The ventral cutaneous branches were branches of the ventral primary branches of spinal nerves T2 through T10. The skin of the abdomen was innervated by dorsal and lateral cutaneous branches of spinal nerves T12 through L3 (and occasionally L4). The cutaneous areas of the dorsal cutaneous branches occupied the dorsal half of the scapular and thoracic regions and the dorsal 2/5 of the abdominal region. The cutaneous areas of the lateral cutaneous branches covered the major portion of the ventral half of the thorax and the ventral 3/5 of the abdomen. The cutaneous areas of the ventral cutaneous branches occupied the axilla and the ventral part of the thoracic wall.—*C. S. Bailey, R. L. Kitchell, S. S. Haghighi, et al in Am J Vet Res, 45 (Sept 1984): 1689.*

Tests for cooperative behaviour between stallions

WAYNE L. LINKLATER & ELISSA Z. CAMERON
Ecology Group, Institute of Natural Resources, Massey University

(Received 8 November 1999; initial acceptance 19 January 2000; final acceptance 8 June 2000; MS. number: 6399)

Breeding groups with multiple stallions occur sympatrically with single-stallion breeding groups in feral horse, *Equus caballus*, populations. Mutualism and reciprocal altruism between stallions have been proposed to explain the origin and functioning of multistallion bands. However, empirical support for these hypotheses is contradictory and incomplete. Furthermore, there are no explicit tests of the predictions that each hypothesis makes about stallion behaviour and social structure. We compared nine multistallion and 18 single-stallion bands in the Kaimanawa Ranges, New Zealand. Compared with agonistic behaviours, affiliative behaviours were relatively unimportant in the relationships between stallions within bands. The number of stallions in the band did not have a positive influence on mare group size, stability, home range quality or reproductive success in bands. Furthermore, there was a positive relationship between aggression ('intolerance') by the dominant towards subordinate stallions and the subordinates' effort in mare group defence ('helping') but a negative relationship between helping effort by subordinates and their proximity to, and mating with, the bands' mares. Therefore, the predictions of the mutualism and reciprocal altruism hypotheses were not supported. Indeed, for some of the predictions we found the opposite outcomes to be true. Multistallion bands had significantly poorer reproductive success, and dominant stallions were less tolerant of subordinates that helped most and reduced their access to mares. Nevertheless, in all other respects Kaimanawa stallions in multistallion bands behaved like those described elsewhere. Thus, we reject cooperative hypotheses for multimale breeding groups in horses and discuss the mate parasitism and consort hypotheses as better alternatives.

© *2000 The Association for the Study of Animal Behaviour*

Animal breeding groups sometimes contain individuals that appear superfluous to reproduction and whose behaviour may even be costly to the Darwinian fitness of other group members, if not their own. For example, the breeding groups or resource territories of polygynous ungulates sometimes contain more than one breeding male (e.g. waterbuck, *Kobus ellypsiprymnus*: Wirtz 1982; oribi, *Ourebia ourebi*: Arcese 1999; white rhinoceros, *Ceratotherium simum*: Owen-Smith 1975; horse, *Equus caballus*: Miller 1981; Linklater et al. 1999). The mating system of the feral horse is described in detail in Linklater et al. (1999) and Linklater (2000). Briefly, it is characterized by polygynous breeding groups, called bands, with 1–26 mares and one to five stallions with declining frequency. Males that are not part of a band live alone or in all-male (bachelor) groups with ephemeral membership. Both male and female offspring disperse from natal bands and so kinship relationships between band members are rare.

The presence of multimale breeding groups that are sympatric with the more common single-stallion bands have been hypothesized to result from cooperation between stallions for mutual benefit (Miller 1981; Rubenstein 1982; Berger 1986; Franke Stevens 1990; Feh 1999). However, there are flaws in the approach, data and logic that have been used to support cooperative hypotheses such as mutualism and reciprocal altruism between stallions in bands (Linklater & Cameron 2000). Also, Linklater et al. (1999) showed that multistallion breeding groups were actually deleterious for the body condition and fecundity of mares. In multistallion bands poorer foaling rates and higher offspring mortality (fetal to yearling) are attributed to greater harassment of mares by resident stallions (Linklater et al. 1999) and possibly infanticide (Cameron 1998; see also Duncan 1982; Berger 1983; Kaseda et al. 1995). Therefore, it seems unlikely that the relationship between stallions in multistallion bands is a cooperative adaptation.

Resolving the controversy requires explicit tests of the null model (that stallions do not cooperate) by testing for the predictions that each cooperative model makes about stallion behaviour and social structure. Such tests must measure differences in the rates of primary stallion

behaviours that are defined operationally, for example, kicking behaviour as a measure of aggression, mutual grooming for affiliation, or interindividual distance for association. Tests of the cooperative models must avoid seeking differences in derived or secondary behaviours (e.g. 'helping'), where the definition of the behaviour is conceptual and presupposes its cause (Linklater & Cameron 2000; see Tinbergen 1963 on 'neutral terminology').

We compared the behaviour and ecology of Kaimanawa feral horses in single- and multistallion breeding groups with those described elsewhere, and tested the following predictions made by authors invoking mutualism and reciprocal altruism hypotheses for multistallion bands. (1) Via mutualism, each stallion in a multistallion band receives a net fitness gain from their relationship by being able to maintain a larger and more stable mare group (Miller 1979; 1981; Franke Stevens 1990), dominating limiting resources and better-quality habitat (Miller 1981) and obtaining greater reproductive success (Feh 1999). (2) Stallions in a multistallion band have a relationship based on reciprocal altruism whereby inferior stallions trade their help in mare group defence with the dominant stallion for his tolerance and, therefore, band membership, greater access to mares, and more reproductive opportunities (Berger 1986; Feh 1999). In the light of our results we discuss the limitations of cooperative hypotheses for multistallion bands and alternatives such as the mate parasitism and consort hypotheses.

METHODS

Study Site and Population

The origins, range use and demography of Kaimanawa wild horses, and the extent, vegetation, topography and climate of their range, as well as the study area and focal population, are described by Linklater et al. (2000). Comparisons in Linklater (2000) show that the population structure, behaviour and ecology of Kaimanawa feral horses are identical to those of feral horses throughout the world. We noted the membership and locations of 27 bands that inhabited the central study area (listed in Table 1) in all 32 months from August 1994 to March 1997. The Four-male and Shoehorn bands are excluded from some analyses because of the difficulty of locating the former during winter and the formation of the latter less than 5 months before the end of the study. The majority of adults in all bands were identified by freeze brands. (Horse capture and marking are described in Cameron & Linklater 2000.) The remainder were identified by permanent and unique differences in their colour marks. Where necessary, observations of bands and individuals were made with binoculars (× 10–15) and field telescopes (× 15–60) but often we were able to approach marked individuals and bands to identify them without visual aids because they became habituated to us. The minimum age of branded individuals was estimated by tooth eruption and wear patterns (Hayes 1968; Fraser & Manolson 1979) and their front shoulder height measured (Cameron 1998; Linklater 1998).

Band Size, Structure and Membership Stability

We calculated average band size, and the number of mares and stallions in bands, from the monthly modal number of adults. We recorded the membership of bands often enough to estimate membership changes and foaling reliably (Linklater 1998; Cameron et al. 1999). All changes in band membership by mares moving into or out of bands, whether temporary or permanent, were termed join or leave events, respectively. A permanent change in band membership by a mare was termed a dispersal event. There was a positive correlation between the number of join and leave events per year and mare group size (Linklater et al. 2000). Therefore, we adjusted the rate of join and leave events for mare group size so we could compare bands. Measures of membership stability for each band are expressed as rates (i.e. number of dispersal or join and leave events per mare per year). A stable core membership group was defined by the individuals that were members of their bands from the beginning of observations or the band's formation to the end of observations or the mare's death.

Home Range Size, Structure and Quality

We recorded the locations of bands often enough to estimate home range size and structure reliably (Linklater 1998). We calculated band home range and core use areas from the coordinates derived by marking the location of the bands on 1:25 000 scale topographical and vegetation maps (Linklater et al. 2000). To determine home range, we used 95% minimum convex polygons (WildTrak software, Todd 1992). Core areas and core area fidelity were calculated from 50% adaptive kernels (Worton 1989) and the ratio of the 50 to 95% adaptive kernels, respectively (Home software, Taborsky & Taborsky 1992). Home range size per adult and core use area fidelity were considered coindicators of home range quality given that there was a significant positive relationship between band size and home range size (Linklater et al. 2000). Thus, we inferred that bands in poor-quality habitat would have larger home ranges per adult and show reduced fidelity to small core areas within their home range.

We selected seven single- and four multistallion bands with a representative range of mare group sizes from the existing population in spring 1994 (Table 1). The 11 bands were located in a random sequence at intervals between 3 and 21 days from 29 November 1994 to 4 December 1995 to provide 36–44 independent locations per band. The sites occupied by the 11 bands, when located, were described from the slope (degrees from flat), altitude (above sea level to nearest 10 m), and aspect (i.e. N, NE, E, SE, S, SW, W, NW), and from ground cover within the area enclosed by the spread of their adult members. Ground cover was described from vegetative (i.e. species or taxonomic group) or other (i.e. bare earth, mud, rock, scree, gravel, sand) items observed at the site.

*Each of the 11 focal bands located in a random sequence between November 1994 and December 1995 to determine ground cover categories and topographical variables that were selected or avoided by bands.

†Range refers to the range in the size of the mare or stallion membership of each band during the study period.

‡Core refers to the stable mare or stallion membership that was in the band at the beginning of the study or the band's formation and still in the band at the end of the study or the individual's death.

§All ages are minimum estimates and given as of summer 1996–1997 at the end of observations.

**The stallions are listed in order from dominant to most subordinate, left to right, from observations of the outcome of agonistic interactions. The ages and heights of stallions in bold type indicate the core stallion group.

††Bands were placed in the following age categories: 1: formed during 1996–1997 year (1 September to 31 August); 2: formed during 1995–1996 year; 3: formed during 1994–1995 year; and 4: were extant bands when observations began in August 1994.

‡‡These bands had only one stallion during brief periods when the stallions were separated either each with some of the mares or one with mares from other bands.

§§This band lost the first of its four stallions in spring 1995 and only one remained by spring 1996.

***These bands had more than one stallion during brief periods in which a bachelor successfully challenged the resident stallion and resulted in loss of mare(s) or the permanent displacement of the resident stallion from all resident mares.

	Bare ground	5.82	0.02	0.592
	Intercept	38.20	0.00	−6.183

We ranked the five that contributed most from 8 (most common) to 3; any other items that were judged common scored rank 2, all items present but not already scored ranked 1, and items not seen at the site but found elsewhere in other samples ranked 0 (see Scott 1989, for plotless vegetation description by the ordinal ranking of species). We combined data from all sites ($N=432$) to provide a sample of habitat selected by bands in the study area.

We drew 10 parallel lines running magnetic north to south on a 1:25 000 topographical map at 375-m intervals across the study area between the borders of the minimum convex polygon that contained all 11 bands' location coordinates. Points were prescribed at 250-m intervals along each line from one side of the polygon to the other. Using a compass and topographical map as guides, we visited the coordinates prescribed by each point. Once at a coordinate, we walked a random number of steps from 0 to 999 to the north or south to the sample site. At the resulting sample site we measured slope, altitude, aspect and ground cover as for the sites selected by the 11 bands. Data from all sample sites ($N=189$) were combined to provide a sample of the habitat available to the 11 bands.

The average score for the ranks of taxonomic or morphologically similar groups of ground cover species or items (Table 2) were obtained for all selected and available sites. We determined the selection or avoidance of topographical variables and ground cover categories by a logistic regression (logistic, backward selection procedure, SAS Institute 1990) of data from selected and available sites, as described in Manly et al. (1993). Variables whose coefficients of selection were least significant were sequentially removed until only significant variables ($P<0.05$) and their coefficient estimates remained. The estimates of significant coefficients of selection were used to construct a resource selection probability function (Manly et al. 1993).

We combined available sample sites that fell within the home range of each band to give average scores for the ranks of the ground cover categories within each band's home range that had significant selection coefficients. We then entered the average scores of these ground cover categories into the resource selection probability function to obtain a 'probability of selection' value for each home range. The probability of selection value was used as a relative index of home range quality with possible values that could range from 0 (extremely poor-quality home range) to 1 (an extremely good-quality home range).

Stallion Behaviour in Multistallion Bands

We conducted continuous focal behaviour samples on seven of the multistallion bands from November 1995 to March 1997. Samples ranged from 30 to 150 min during daylight hours to provide an average of 29 h per band (range 7–38 h). During samples, we recorded agonistic and affiliative interactions that involved the stallions

whenever observed. Agonistic interactions were defined as those that involved overt, threat, or display aggressive behaviours. Aggressive behaviours (e.g. overt and threatened bites, kicks, arched neck threats and head threats with ears laid back) and avoidance, retreat and chase behaviours were as described and defined by Feist & McCollough (1976) and McDonnell & Haviland (1995). An agonistic interaction was classified as a win if the other stallion retreated first. The stallion winning the most dyadic agonistic interactions was considered dominant. Defence events of mare groups are defined as those in which agonistic interactions occurred between resident stallions and other stallions or bachelor males when the latter approached the mare group. An affiliative behaviour was an approach between stallions that culminated in an attempt to groom or a mutual grooming event as defined by Feist & McCollough (1976) and McDonnell & Haviland (1995). We recorded all mounting of mares by stallions that included intromission whenever observed. We could not always determine if ejaculation also occurred with intromission. Every 4 min during focal behaviour samples we visually estimated the distance from each stallion to the centre of the mare group in adult body lengths. Average stallion distance to the mare group centre was calculated from averages of each sample. Focal behaviour sampling took precedence over 4-min samples of stallion distances if they occurred simultaneously.

Hypothesis Testing

We tested two hypotheses. First, we tested whether the number of stallions in a band had a positive influence on the reproductive success, size and stability of the mare group, and the band's home range quality, as predicted by the mutualism hypothesis. We used a multivariate analysis of variance (MANOVA, SAS Institute 1990) to test the influence of additional stallions on band and home range measures, and a chi-square test for differences in the foaling rate of mares in single- and multistallion bands. Second, we tested whether there was a negative relationship (regression, SAS Institute 1990) between the frequency of defence behaviours by subordinate stallions in mare groups (i.e. 'helping') and (1) the rate of agonistic interactions that the dominant stallion directed towards the subordinate stallion (dominant stallion 'intolerance') and (2) the distance of the subordinate stallion from the mare group ('reproductive opportunity') as predicted by the reciprocal altruism hypothesis.

RESULTS

Band Composition and Structure

Band stallions varied in age from 4 to 12 years (minimum estimate) at the completion of observations. The oldest known male was a bachelor aged at least 14 years. The average age and height of stallions in those bands already formed when the study began (i.e. band age category 4, Table 1) were not different between single- and multistallion bands (age: multistallion: $\bar{X} \pm \mathrm{SE} = 9.0 \pm 0.7$; single stallion: 9.7 ± 0.4; Mann–Whitney U test: $U=17.5$, $N_1=4$, $N_2=12$, $P=0.42$; height: multistallion: 145.3 ± 1.9 cm; single stallion: 146.2 ± 0.8 cm; Mann–Whitney U test: $U=21.5$, $N_1=4$, $N_2=12$, $P=0.76$). Core groups of mares were evident in both single- and multistallion bands (Table 1). Core group mares ranged in age from 4 to 12 years in those bands that had already formed when the study began (i.e. band age category 4). The average age of core group mares was not significantly different between single- and multistallion bands (multistallion: $\bar{X} \pm \mathrm{SE} = 8.0 \pm 1.1$; single stallion: 8.1 ± 0.4; Mann–Whitney U test: $U=75.5$, $N_1=6$, $N_2=27$, $P=0.79$; Table 1). In conclusion, the age and size of the members of single- and multistallion bands were similar.

Table 3. The percentage (with numbers in parentheses) of interactions won and lost by stallions in multistallion bands during dyadic agonistic interactions

	Won		
Lost	Alpha	Beta	Gamma
Beta	98.7 (154)	—	—
Gamma	95.7 (23)	68.2 (22)	—
Delta	100 (20)	100 (28)	92.3 (13)

Stallions are ranked from most dominant (alpha) to most subordinate (delta).

Affiliative behaviour between stallions was extremely rare. We observed only two mutual grooming events and both occurred between the alpha and gamma stallions of Punks band. In comparison, agonistic behaviours between stallions were frequent. We recorded 7–90 agonistic interactions between stallions in each multistallion band. From 13 to 71% of agonistic encounters between stallions in each band had no clear outcome because both stallions withdrew after an aggressive display sequence (see Feist & McCollough 1976; McDonnell & Haviland 1995). Of the remaining interactions for which we could determine a winner or loser, stallions showed a consistent dominance relationship with one of the stallions causing the retreat of the other in greater than 90% of encounters, with the exception of beta and gamma stallions in bands with three or four stallions (β won 68% of the time against γ, Table 3). Furthermore, in four of the seven multistallion bands, one of the stallions won all agonistic encounters. Therefore, there was a stable hierarchy between the stallions in multistallion bands: alpha (α)>beta (β)>gamma (γ)>delta (δ).

A stallion's rank determined his position relative to other stallions and the mare group in multistallion bands and the number of matings they obtained. Subordinate stallions were more likely to be further from the centre of the mare group than stallions dominant to them (paired t test: $t_{15}=3.16$, $P=0.01$) and dominant stallions mounted and achieved intromission with band mares more often than stallions subordinate to them (paired t test: $t_5=2.61$, $P=0.048$). Furthermore, of the subordinate stallions, we

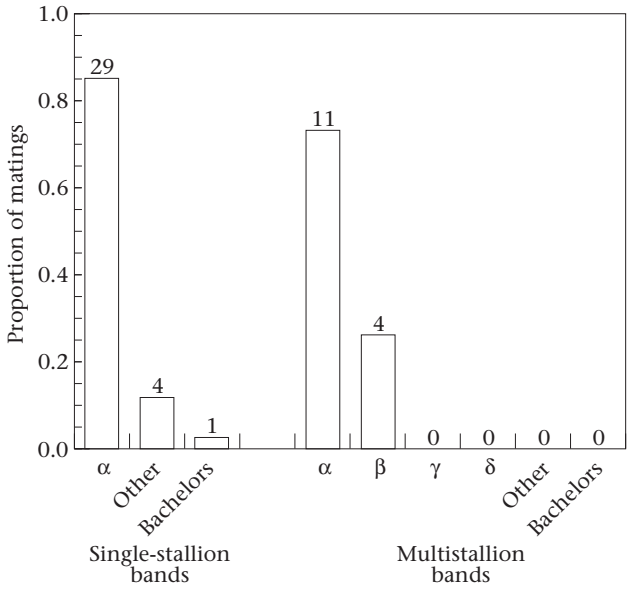

Figure 1. The distribution of observed matings between stallions (of different rank, i.e. α>β>γ>δ, from other bands and bachelors) and the mares in single- and multistallion bands. The numbers of matings are given above the bars.

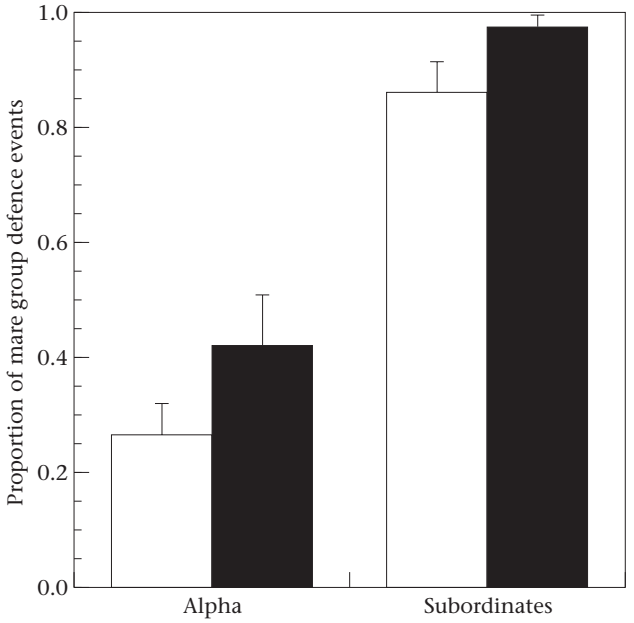

Figure 2. The average proportion of mare group defence events (N=88) that the alpha and subordinate stallions initiated (□) and contributed to (■) in multistallion bands. Vertical bars indicate 1 SE.

observed only beta stallions mating, never gamma and delta stallions. We observed 34 matings with mares in single-stallion bands and 15 with mares in multistallion bands. Mating of a band's mares by the stallions of other bands and bachelor males was observed only in single-stallion bands (Fig. 1).

Dominant stallions were significantly less likely to initiate and contribute to mare group defence events and subordinate stallions contributed to most mare defence (paired t test: initiated: t_6=5.73, P<0.001; contributed: t_6=6.06, P<0.001; Fig. 2).

Table 1 shows the age and height of member stallions in multistallion bands in their order of dominance. In multistallion bands where more than one of the stallions was aged and height measured, the dominant was not significantly younger, older, or taller than the subordinate stallion (paired t test: age: t_6=1.53, P=0.18; height: t_6=0.00, P=1.0; Table 1). Dominant stallions were on average only 1 year older (range 1 year younger to 3 years older) than the subordinate and there was no difference in the average height of member stallions (range dominant 8 cm shorter to 13 cm taller). Therefore, the age and size of stallions of different rank in multistallion bands were similar.

The Mutualism Hypothesis

The average size and range in size of multistallion and single-stallion bands were almost identical (multistallion: 2.9–9.0; single stallion: 2.0–8.4 adults), as was the number of mares in them (multistallion: 1.0–7.0; single stallion: 1.0–7.4 mares; Fig. 3a). The rate of join and leave and dispersal events by mares in single- and multistallion bands, were also indistinguishable (Fig. 3b, c). Furthermore, for mares that remained in the same band for each entire year (1 September to 31 August), those in multistallion bands had significantly poorer foaling rates than those in single-stallion bands (multistallion: 0.54; single stallion: 0.70 foals/mare; chi-square: χ^2_1=4.8, P<0.05). Therefore, stallions in multistallion bands did not each obtain a net fitness gain by increasing the size, stability or reproductive success of their mare group compared with stallions that defended a mare group alone.

Of the topographical variables and vegetation classes, only short green grasses, tussock grasses, leguminous herbs, other dicotyledonous herbs, mosses and lichens, and bare ground categories were significant indicators of site selection by the 11 bands for which it was measured. Therefore, we used estimates of these selection coefficients (Table 2) to construct the resource selection probability function.

Selection probability (home range quality)= exp(2.833 (short green grasses)+0.695(tussock grasses)+ 3.173 (leguminous herbs)+4.125(other dicotyledonous herbs)+0.587(moss and lichen)+0.592(bare ground)).

Of the 27 bands, 21 were observed for more than 1 year and had home ranges that were contained entirely within the area in which available habitat was measured. We calculated the values for the resource selection probability function for the home range of each of the 21 bands. They varied from 0.42 (relatively poor-quality home range) to 0.68 (relatively good-quality home range) and were almost identical for single- and multistallion bands (Fig. 3d). Furthermore, band home range size/adult and core area fidelity were similar for single and multistallion bands (Fig. 3e, f) and there was no relationship between band size and home range quality (Pearson correlation: r_{23}=0.354, P>0.05). Therefore, additional

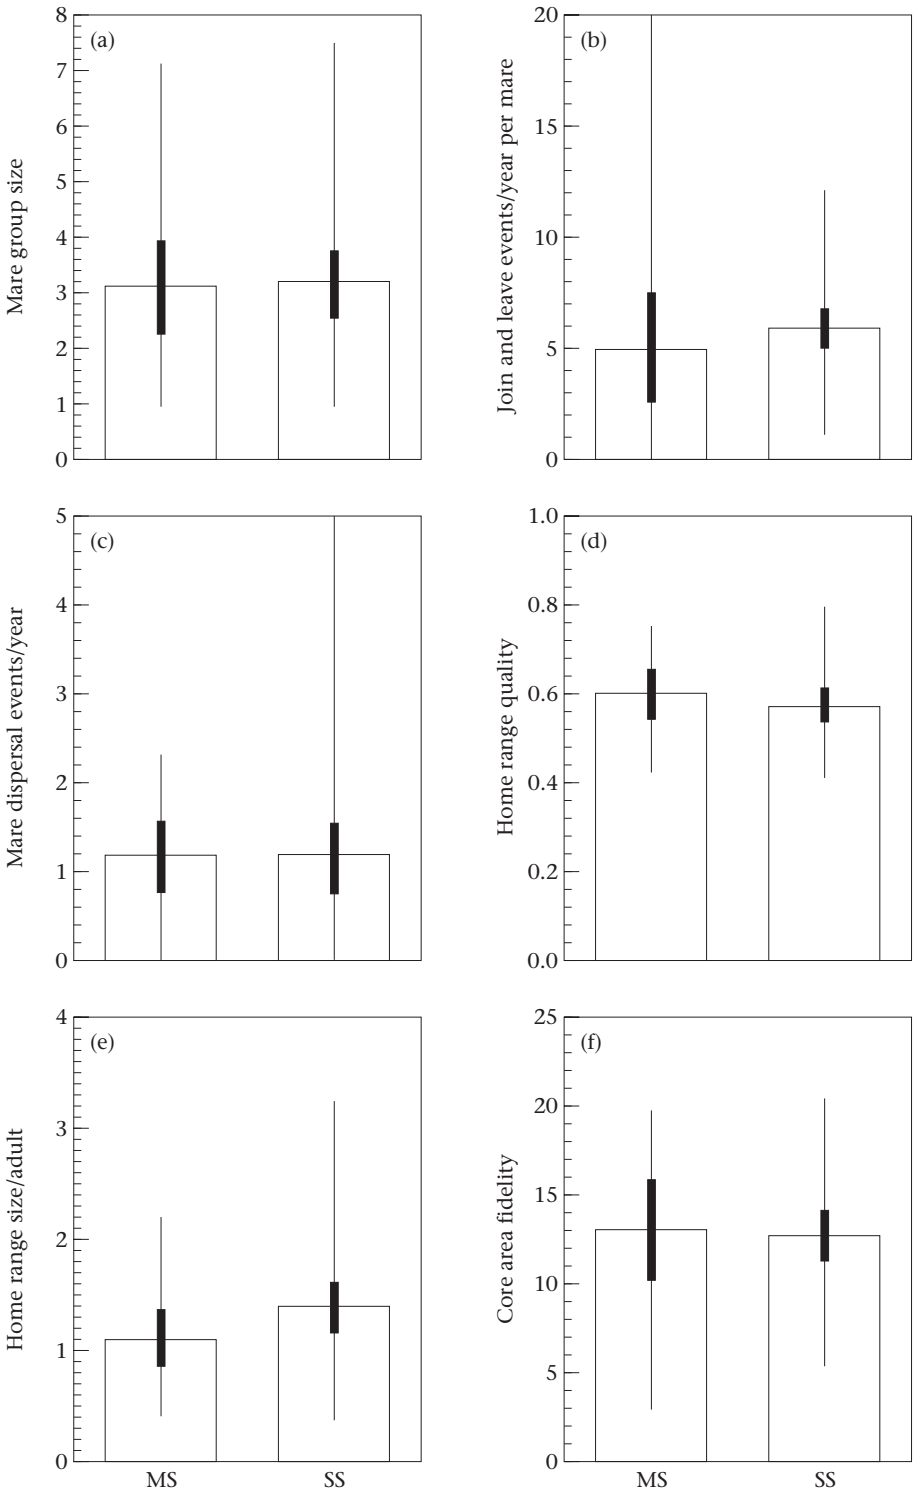

Figure 3. A comparison of (a) mare group size, (b) rate of mare join and leave events, (c) rate of mare dispersal, (d) home range quality, (e) home range size and (f) core area fidelity for single- (SS, *N*=18) and multistallion (MS, *N*=8) bands. The bar denotes the average figure, the black vertical rectangle denotes ± 1 SE, and the vertical line the range of values.

stallions in bands did not improve a band's access to better-quality habitat.

The two measures of band stability were significantly correlated with each other (Pearson correlation: r_{25}=0.53, P<0.01) and therefore only one, mare dispersal rate, was entered into the MANOVA. Additional stallions did not alter the size or stability of their mare groups, the size or quality of their home ranges, or their fidelity to core areas

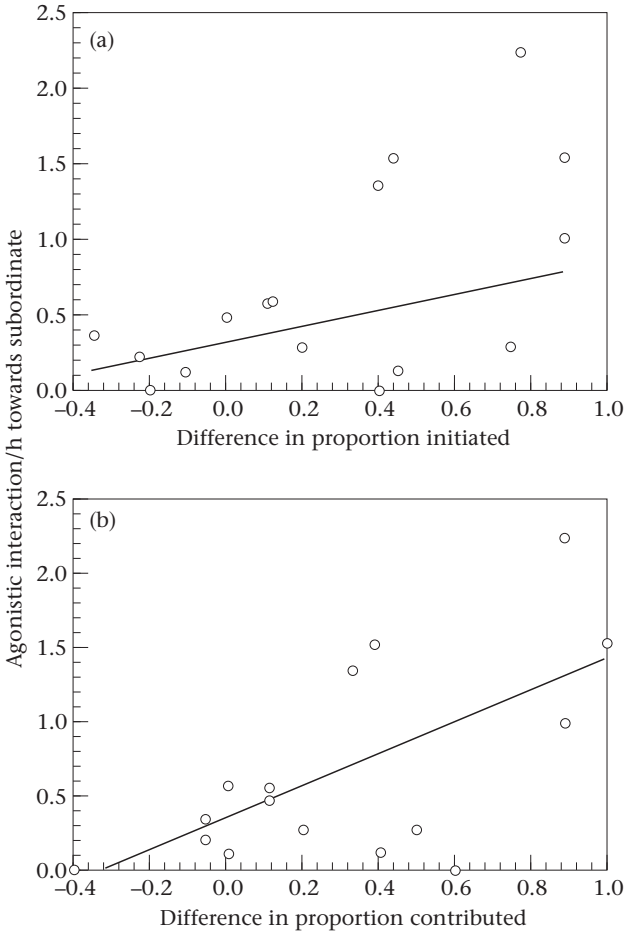

Figure 4. The relationship between the difference in the proportion of mare group defence events that stallions (a) initiated and (b) contributed to (subordinate's–dominant's proportion) and the rate of aggressive interactions by the dominant stallion that caused the subordinate to retreat.

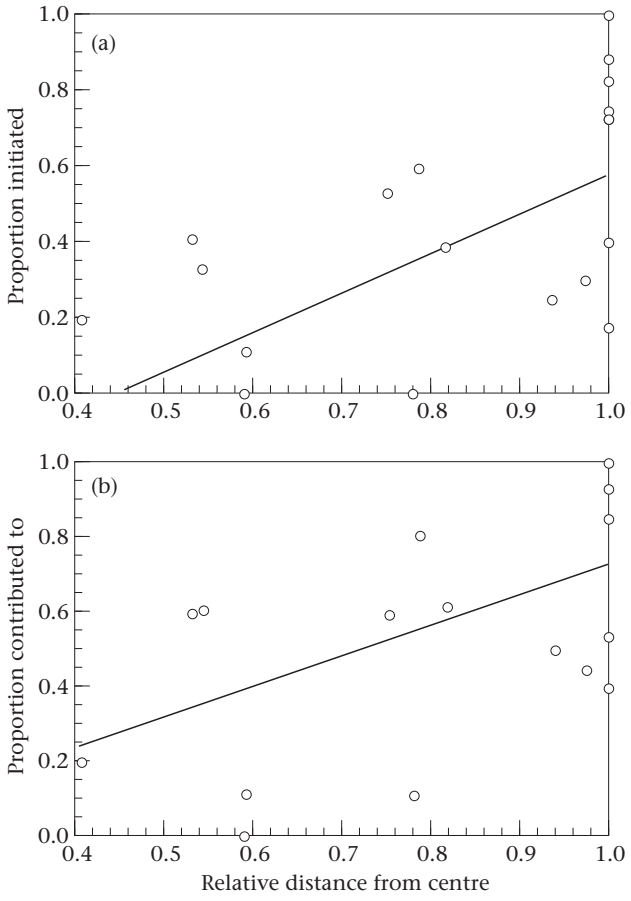

Figure 5. The relationship between the average distance of a stallion from the centre of the mare group relative to the average distance of the most peripheral stallion and the proportion of mare group defence events that they (a) initiated and (b) contributed to. A distance of 1.0 is equivalent to the distance of the most subordinate stallion from the mare group's centre.

within their home ranges (MANOVA: $F_{6,17}$=0.19, P=0.96; Fig. 3).

Reciprocal Altruism Hypothesis

There was a significant positive, not negative, relationship between the difference in the proportion of mare group defence events that subordinate and dominant stallions initiated and contributed to and the rate of aggressive interactions directed at the subordinate by the dominant stallion (regression: initiated: $F_{1,14}$=8.10, R^2=0.32, P=0.013; contributed: $F_{1,14}$=9.60, R^2=0.36, P=0.008; Fig. 4). Furthermore, there was a positive relationship between the relative distance each stallion was from the mare group's centre and the proportion of band defence events that he initiated and contributed to (regression: initiated: $F_{1,16}$=6.34, R^2=0.24, P=0.02; contributed: $F_{1,16}$=7.28, R^2=0.27, P=0.016; Fig. 5). Thus, dominant stallions were less, not more, tolerant of subordinate stallions that 'helped' most, therefore ensuring that subordinate 'helpers' were more, not less, peripheral to the mare group. The marginalization of subordinates from the mare group was reflected in the number of mating opportunities they obtained. Beta stallions obtained approximately a quarter of observed matings in multistallion bands while gamma and delta stallions obtained none (Fig. 1), even though they contributed most to mare defence in their respective bands. Therefore, subordinate 'help' was not reciprocated with dominant stallion tolerance or greater mare access and mating opportunities, contrary to the prediction of the reciprocal altruism hypothesis.

DISCUSSION

The stallions in multistallion bands had a strongly hierarchical relationship that was not subject to change in the medium term relative to a stallion's reproductive life. Agonistic encounters between stallions were frequent and affiliative behaviours rare. The dominant stallion maintained proximity with the mare group while successively subordinate stallions were increasingly peripheral to it. Consequently, more dominant stallions were on average

closer to the mares in a band and conducted the majority of matings even though more subordinate stallions contributed most to mare group defence. Similar observations have been reported in other populations (Miller 1981; Berger 1986; Feh 1990; Franke Stevens 1990). Furthermore, our observations of mating by stallions conform to expectations from previous comparative analyses of paternity in single- and multistallion bands (Bowling & Touchberry 1990; Eagle et al. 1993; Asa 1999; Feh 1999). The alpha stallions in multistallion bands obtained slightly fewer matings and less paternity in their bands than stallions in single-stallion bands because of some successful mating by the subordinate(s). Subordinate stallions in multistallion bands obtained few matings: the lower their rank the fewer they obtained. The gamma and delta stallions were not observed to mate. Also, approximately half of the matings and paternity gained by the beta stallion would have been lost by the alpha stallion to stallions from other bands or bachelors if he was the sole stallion in a single-stallion band anyway. Thus, the alpha stallions in multistallion bands are largely successful at limiting the paternity lost to subordinate(s) (see also discussion of comparative paternity analyses in Linklater & Cameron 2000).

Thus, our results confirm previous observations about the social and spatial structure of the relationships between stallions in multistallion bands. However, although Kaimanawa multistallion bands were outwardly identical in these ways to those in other populations (see also Linklater 2000), we found no indication that their structure or functioning could be explained by mutualism or reciprocal altruism as they have been applied previously to the problem of multistallion bands.

Mutualism?

Miller & Denniston (1979) found that large bands generally displaced smaller bands at water holes and Miller (1981) found multistallion bands to be larger than single-stallion bands in the Red Desert, Wyoming, U.S.A. Consequently, Miller (1981) suggested that multistallion bands gained better access to limited resources such as water in the Red Desert. He concluded that these factors meant that collaborating stallions had greater lifetime reproductive success than stallions in single-stallion bands. However, although band size was an indicator of dominance, Miller & Denniston (1979) found no correlation between the number of stallions in the band and its dominance relationship with other bands. Second, as we found in the Kaimanawa population, there was near complete overlap in the sizes of single- and multistallion bands (single stallion: 2–21, multistallion: 3–17 members, Miller 1979; single stallion: 1–16, multistallion: 6–16 members, Miller & Denniston 1979). Third, Berger (1986) suggested that it was single-stallion, not multistallion, bands that were more likely to occupy high-quality home ranges in the Great Basin. Lastly, Franke Stevens (1988, 1990) found no difference in the success of single- and multistallion bands defending access to a water hole and recorded no significant difference in mare group size between single- and multistallion bands. She found that the band occupying the water hole won agonistic encounters most often and independently of its size or number of stallions. Therefore, proposed relationships between the number of stallions in bands, mare group size and band dominance are at best weak, if they exist at all.

Miller (1979) found more stable mare membership in multistallion bands and concluded, without behavioural measures of the effort stallions took in maintaining the band, that 'the presence of subordinate males probably contributes to the greater stability and larger average size of multiple male bands' (Miller 1981, page 346). Furthermore, of the 10 mares Franke Stevens (1990) observed changing bands during 7 months of observation, all came from single-stallion bands. Franke Stevens (1990) showed that in winter the mare groups of single stallions spread further, and suggested that a single stallion may be less able to retain mares in winter than multiple stallions. Consequently, she suggested that the dominant stallion's lifetime reproductive success was improved if he was able to prevent mare loss by accepting a subordinate stallion's 'help', while the subordinate stallion(s) stood to inherit the mare group from the dominant stallion at the end of the latter's reproductive life. Unfortunately, Franke Stevens (1990), like Miller (1981), assumed that additional stallions contributed to mare group stability, even though her measures of band maintenance activities by stallions (e.g. herding) in winter were not significantly greater in multistallion bands than in single-stallion bands. In addition, she measured no increase in reproductive success in multistallion bands or inheritance of mare groups by subordinate stallions (Franke Stevens 1990), and Berger (1986) showed that it was bachelor males, not subordinate stallions, that were more likely to inherit mares. We found no relationship between the number of stallions and mare group stability in the Kaimanawa population. Therefore, while a relationship between the number of stallions in bands, mare group size and stability, and band dominance in preferred habitat makes an elegant hypothesis, there are clearly significant inconsistencies and contradictions in it.

Lastly, and most crucially, we must consider reproductive success directly. Mutualism predicts that individual stallions will make a net gain in reproductive success by cohabitating with other males in the same mare group. This prediction is best illustrated from the work on lions, *Panthera leo* (Bygott et al. 1979; Packer et al. 1988; Grinnell et al. 1995) where the reproductive success of males that live together is improved by better control of access to females. Prides with more male lions have more offspring. Feh (1999) showed that even the alpha stallions in multistallion bands do not obtain greater paternity than stallions who defend a mare group alone partly because they lose paternity to the subordinate stallions. Only if both the dominant and subordinate stallions in multistallion bands obtain even less paternity without their relationship can it be regarded as mutualistic. Without this evidence the pattern of paternity between stallions, as Feh (1999) presented it, is not evidence for

mutualism and is open to alternative explanation (see Linklater & Cameron 2000).

Therefore, there is still considerable work to be done here. In particular, paternity measures should be conducted in populations from which males are not artificially and selectively removed, and where multistallion bands include more than just two stallions. Adult sex ratio parity, large variation in male quality, and bands with as many as four, and sometimes five, stallions are typical of unmodified and free-roaming feral horse populations throughout the world (Linklater 2000) and are thus unlike the Camargue population of horses (Feh 1999). Consequently, the information available at this time is clearly not strong enough to invoke mutualism for the origin and functioning of multistallion bands in feral horse populations. This conclusion and recent work that suggests multistallion bands may be deleterious for the body condition and reproductive success of mares (Linklater et al. 1999) do not support the mutualism hypothesis, that stallions cohabit in the same band to gain a net reproductive advantage.

Reciprocal Altruism?

Subordinate stallions put disproportionately more effort into mare group defence than dominant stallions (Berger 1986; Feh 1999), despite having fewer matings (this study) and significantly less paternity (e.g. Bowling & Touchberry 1990; Eagle et al. 1993; Asa 1999; Feh 1999). Asymmetrical effort in mare group defence by resident stallions indicates that they do not reciprocate in kind for contributions to mare group defence. However, Berger (1986) and Feh (1999) suggested that by helping in mare group defence the subordinate stallion's membership in the band is tolerated by the dominant stallion. Thus, help from a subordinate is reciprocated with tolerance by the dominant and vice versa. The subordinate stallion gains greater access to mares and improved paternity but costs the dominant stallion some paternity. The dominant stallion benefits from the subordinate's assistance with mare defence and therefore longer tenure with the mare group. In this way both may gain fitness benefits (Feh 1999). This is a compelling idea that, until now, has not been tested by checking for a negative relationship between subordinate effort in mare defence (i.e. 'help') and aggression by the dominant towards the subordinate (i.e. 'intolerance').

If reciprocal altruism is occurring, then subordinate stallions that contribute more to mare group defence than the dominant stallion should receive less aggression from the dominant stallion, be more proximal to the band's mares, and obtain more matings. In the Kaimanawa population we observed the reverse to be true. Dominant stallions directed significantly more aggression at subordinates that helped most and subordinates that helped relatively more were significantly less proximal to the mare group. Furthermore, although the most subordinate and, therefore, peripheral stallions helped most, they obtained few matings and in bands with three or four stallions the gamma and delta stallions were never observed to mate.

In support of the reciprocal altruism hypothesis, Berger (1986) and Feh (1999) described a pattern in which the subordinate more often met an intruding stallion while the dominant more often herded the mares away, and where the dominant stallion came less to the aid of subordinates in band defence than vice versa. Berger (1986) and Feh (1999) attributed this pattern to subordinate stallions helping with mare defence in return for tolerance by the dominant stallion, subordinate band membership and access to mares. We suggest that this pattern is more simply explained by the competitive and spacing relationship between stallions, rather than reciprocity. The pattern may result from (1) the different probabilities with which dominant and subordinate stallions encounter foreign stallions and are near mares during these encounters, (2) the dominant stallions' reluctance to leave the mares with the subordinate stallion, and (3) the subordinate stallions being aggressively dissuaded, by the dominant stallion, from approaching the band's mares.

Subordinate stallions were more peripheral to the mare group and their marginalization increased with increased aggression from the dominant stallion. Consequently, when a multistallion band is approached by a foreign stallion, the subordinate is disinclined to respond by moving towards the mares to herd them away because he is aggressively deterred from approaching them by the dominant stallion. His only alternative course of action is to meet the foreign stallion to stem his approach. Furthermore, being peripheral means that the subordinate stallion is more likely than the dominant to identify and encounter foreign stallions first. If the dominant stallion is the first to identify an approaching foreign stallion, he will be disinclined to meet the intruder first because that would necessitate leaving his mares open to an approach by the subordinate stallion. When the subordinate stallion identifies and encounters the foreign stallion first then the dominant stallion, who is proximal to the mares and already recognizes the subordinate stallion as an intruder and persistent challenger, will be disinclined to meet with two competitors for his mares at the same time, and his best strategy is to retreat, taking his mares with him, if he responds at all. Therefore, the dominant stallion is more likely to respond to the intrusion of yet another stallion by herding his mares away. Dominant stallions use herding behaviour to move mares away from both the subordinate and foreign stallions who approach their mares (Linklater et al. 1999). Their herding response is, therefore, a generalized response to avoid potentially successful and/or multiple competitors, rather than a specific response made possible by a collaborating subordinate(s). In many cases the dominant stallion will not respond and contribute to the defence event because the foreign stallion does not proceed past the subordinate towards the mare group and so the interaction does not escalate. In conclusion, the disparities in mare defence and herding behaviours between dominant and subordinate stallions, and differences in the frequency with which they defend mares at the same time (i.e. 'come to each other's aid'), may be an artefact of their competitive and spacing relationship that results in the subordinate

being peripheral to the mare group, rather than a cooperative relationship between stallions based on reciprocity.

Future Directions

Clearly there are still gaps in our understanding of multistallion bands in horses. In particular, there is the need for experimental stallion removals from multistallion bands to test for a mutually dependent relationship between stallions that share a mare group (e.g. Linklater 1998; Linklater et al. 1998). The absence of experimental manipulations and the lack of well-designed comparative paternity data is the weakness of this and previous studies. Nevertheless, this study describes inconsistencies and contradictions in previous evidence for stallion cooperation. Furthermore, it provides results on the behavioural structure and functioning of single- and multistallion bands in the Kaimanawa population that are different enough from the expectations of mutualism and reciprocal altruism to suggest that cooperation hypotheses cannot be applied generally to explain variation in the number of stallions in feral horse bands. In addition, multistallion bands are found in all free-roaming populations despite extreme differences in their habitat, density and adult sex ratios (Linklater 2000). Only when people have removed so many stallions that some mare groups were without one, have multistallion bands not formed. Multistallion bands, therefore, cannot be explained as an adaptive behavioural response or as a behavioural adaptation to differences in the resource or social environment. In feral horses, valid explanations for variations in social and spatial organization should apply to unmodified populations throughout the world since extreme regional differences in environment and demography have a negligible influence on the social organization and mating system of horses (Linklater 2000). Cooperative and socioecological explanations for multistallion bands have poor cross-populational generality and so we hope that this analysis will stimulate effort towards new explanations for the multistallion band phenomenon.

One alternative hypothesis that may prove useful is mate parasitism (Taborsky 1997) or a best-of-a-bad-job strategy (Dunbar 1982) by subordinate stallions as also suggested by Berger (1986). Indeed, the positive relationship between aggression by dominant stallions and defence of the mare group by subordinate stallions may be interpreted as tentative support for this hypothesis. If subordinate stallions are mate parasites then dominant stallions should be less tolerant of the most capable subordinates (i.e. those that 'helped' more) as we observed in this study. Perhaps this relationship is evidence that dominant stallions are making greater efforts to oust the most effective mate parasites from their bands or maybe they are coercing the mate parasite to 'help'? Our record of matings indicates that although mate parasitism is likely to be a less successful strategy for gamma and delta stallions than remaining a bachelor male, the beta stallion does achieve matings, particularly those normally lost to stallions from other bands or bachelors when stallions defend a band alone. Feh (1999) also showed this pattern in bands from the Camargue that had two stallions. Therefore, the mate parasitism hypothesis appears prima facie to warrant further investigation.

There are, however, some problems with the mate parasitism hypothesis for multistallion bands. For example, multistallion bands may contain up to five successively subordinate stallions and sometimes with only one mare as in the population described here (Table 1). The selective advantage of mate parasitism by the most subordinate stallion in such circumstances appears negligible given the absence of mating by gamma and delta stallions and the success of alpha stallions in limiting even the beta stallions to a small fraction, and sometimes none, of the band's total paternity (Bowling & Touchberry 1990; Feh 1999). Even when the dominant stallion is vasectomized, he appears to control the paternity of subordinate stallions (Eagle et al. 1993; Asa 1999). Therefore, although mate parasitism may explain the behaviour of beta stallions it cannot account for additional subordinates that behave like the beta stallion. Furthermore, and perhaps most importantly, during this 32-month study we observed nine new bands form from bachelor males and dispersing mares, including four multistallion bands (Table 1). However, on no occasion did a multistallion band form by a bachelor male attaching himself permanently to an existing single-stallion band to become a subordinate stallion (mate parasite), as one would predict if mate parasitism is the route for the origin and functioning of multistallion bands.

Linklater et al. (1999) and Linklater & Cameron (2000) suggested that an alternative explanation for the existence of multistallion bands may be found in the ontogeny of breeding groups that involves variation in the frequency of critical events during the short period of band formation (i.e. the consort hypothesis). Where, during band formation, there are dominance reversals between stallions after courtship and mating, and courtship and mating stimulate mate loyalty by consorting stallions (mate loyalty or 'guarding' reduces harassment of mares and prevents infanticide, see Linklater et al. 1999; Berger 1983; Kaseda et al. 1995), then multistallion bands may result from mares soliciting more than one stallion. Thus, multistallion bands may be an unselected artefact of the process by which mates are chosen and breeding relationships form, which normally results in the formation of single-stallion bands, but occasionally in bands with from two to five stallions with increasing rarity. The number of stallions in a newly formed band is determined by the number of stallion dominance reversals and consort relationships formed with a receptive mare after she disperses from her previous band. Our preliminary data (Linklater 1998; unpublished) suggest that this is the route of band formation. This approach offers new ways of understanding the origins and structure of horse breeding groups and new predictions to test. Furthermore, it may have utility in many other species with breeding groups of multiple males and females in birds and mammals where, because of mate loyalty, events during the ontogeny of new breeding groups may have long-term implications for breeding group structure. We advocate a greater awareness of the

potential role of breeding group ontogeny in variation in mating systems.

Acknowledgments

We thank Ed Minot, Kevin Stafford and Clare Veltman who supervized our Ph.D.s, John Byers, Patrick Duncan, Peter Jarman, Euan Young, Charlotte Hemelijk and two anonymous referees for comments on the manuscript, and Jerry Wolff and Michael Ferkin for important discussion of the ideas presented. We also thank Operations Branch, HQ, Property Management Section, and Waiouru Support Company (4th Logistics Battalion) of the Army Training Group, Waiouru, New Zealand, for logistical support and permission to work in the Army Training Area. Special thanks to John Akurangi, Neil Bleasdale, Eru Brown, Bob Campbell, Phil Hughes, Jamie Jones, Chris Lawrence and John Mangos. Fond thanks to the Kaimanawa wild horses who 'cooperated' with us during this study and to those who worked to protect them. This study was supported by funds from the New Zealand Department of Conservation contract (No 1850) to Massey University and the Department of Ecology.

Surgical Approaches to Ovariectomy in Mares

University of Florida
Dawn A. Loesch, DVM, DACVS
Dwayne H. Rodgerson, DVM, MS, DACVS*

KEY FACTS

- When performing ovariectomy by a colpotomy (vaginal) approach, proper positioning of the vaginal incision is necessary to prevent fatal complications.
- A colpotomy approach should not be used to remove ovaries larger than 8 to 10 cm in diameter; ovaries up to 15 cm in diameter can be removed safely through a flank approach; and larger ovaries should be removed through a celiotomy incision.
- Laparoscopic ovariectomy techniques allow optimal visualization and tension-free ligation to maximize hemostatic security.
- A wide variety of complications of differing severity (from mild to fatal) can follow any ovariectomy technique.

ABSTRACT: The preoperative considerations, surgical techniques, postoperative care, and complications associated with the surgical techniques available to perform unilateral or bilateral ovariectomy in horses are described. Standing techniques described include the colpotomy (vaginal), flank laparotomy, and laparoscopic approaches. Procedures that require general anesthesia, including flank laparotomy, ventral midline celiotomy, paramedian celiotomy, diagonal (oblique) paramedian celiotomy, and laparoscopic approaches, are also discussed. Complications following surgery can range from mild incisional swelling and pain to fatal intraabdominal hemorrhage or eventration. Careful consideration of the advantages and disadvantages of each procedure allow equine surgeons to select the most appropriate approach for each patient.

Equine ovariectomy is a commonly performed elective surgical procedure. Various surgical approaches are used for unilateral or bilateral ovariectomy. The surgical approaches described include vaginal or colpotomy, flank, diagonal or oblique paramedian, ventral midline, caudal paramedian, and numerous laparoscopic techniques. The decision as to which approach to use for a particular case depends on the following factors:

- Specific indications for ovariectomy
- Size of the affected ovary
- Surgeon's preference
- Financial constraints imposed by the client
- Temperament of the mare
- Equipment available
- Client expectations

An understanding of the benefits and disadvantages of all approaches can aid the clinician in selecting the appropriate surgical approach for each patient. This article reviews the surgical approaches used to perform unilateral and bilateral ovariectomy in mares.

*Dr. Rodgerson is currently affiliated with Hagyard-Davidson-McGee Associates, Lexington, Kentucky.

PREOPERATIVE CONSIDERATIONS

Special preoperative preparation of the mare should be instituted before performing ovariectomy. Food should be withheld for 12 to 24 hours before surgery to help decrease the amount of ingesta and gas within the gastrointestinal tract, thereby making it easier to exteriorize the ovary and suture the abdominal wall incision. Depending on patient positioning, laparoscopic techniques require that food be withheld for 12 to 48 hours prior to surgery[1,2] to improve visualization of intraabdominal structures and to decrease the likelihood of penetrating a viscus when the laparoscopic instruments are introduced into the abdomen.[3–7]

Abdominal palpation per rectum (with or without ultrasonographic evaluation) is useful in detecting abnormalities associated with the reproductive tract and should be performed in all mares presenting for ovariectomy regardless of the reason. Results of this evaluation may help dictate the necessary surgical approach based on the palpable size of the ovary to be removed. In addition, identifying pathology, such as adhesions or abscessation associated with the reproductive tract, may provide valuable information regarding the optimal surgical approach.

The rationale for and use of antibiotics to treat horses undergoing ovariectomy vary among surgeons. If antibiotics are used, they should be administered preoperatively to ensure that adequate systemic concentrations are present at the time of surgery. Administration of broad-spectrum antibiotics should be continued postoperatively if a break in aseptic technique occurred during the procedure. Tetanus prophylaxis should be administered routinely when performing ovariectomy.

SURGICAL PROCEDURES

Vaginal Approach (Colpotomy)

In 1903, Williams first described a vaginal approach, or colpotomy, using an ecraseur to ovariectomize mares.[8] The vaginal approach is now commonly used to perform a bilateral ovariectomy in normal mares, but unilateral removal of a suspected granulosa–theca cell tumor less than 8 to 10 cm in diameter can also be performed using this approach.[9,10] There are several advantages to the colpotomy technique, including the fact that it is performed as a standing procedure, minimal instrumentation is required, the procedure can be performed quickly, excellent cosmetic results can be expected, and the convalescent period following surgery is relatively short.

Ideally, mares should be in diestrus or anestrus because ovarian vasculature is believed to be minimized at these times.[11] Mares are restrained in standing stocks and sedated. Sedation is most commonly accomplished with an α_2-agonist and butorphanol to provide analgesia as well as profound sedation. Acepromazine can be administered for tranquilization as well. Administration of caudal epidural anesthesia is unnecessary but is recommended by some surgeons to help prevent the mare from straining during the procedure.[12,13] The tail is wrapped and secured away from the perineal region, and all manure should be evacuated from the rectum to prevent contamination of the external genitalia. Routine aseptic preparation of the external genitalia and perineal region is performed, and the vagina is lavaged with sterile saline or dilute povidone–iodine solution. In some mares, catheterization of a large urinary bladder may facilitate the procedure and may help reduce the risk of inadvertent injury during the procedure.[14–16]

The location of the initial incision in the cranial fornix of the vagina is very important. The incision must be placed in either a craniodorsal (at the 2- or 10-o'clock) or a cranioventral (at the 4- or 8-o'clock) position. Potential complications of a misplaced incision include entering the rectum if the incision is placed too dorsal, injuring the urethra or bladder if placed too ventral, and incising the caudal uterine branch of the urogenital artery if too medial or lateral (at the 3- or 9-o'clock position).[11,17,18] The incision should be started 3 to 5 cm caudal to the os cervix to avoid disruption of the cervical musculature.[12,14,16] Using a scalpel blade, scissors, or mosquito hemostat, a small 1- to 3-cm vaginal incision is sharply/bluntly created. This initial incision should penetrate the full thickness of the vagina and peritoneum to prevent the peritoneum from lifting away from the underlying tissues during blunt dissection. The incision is then bluntly enlarged digitally, and the peritoneum is perforated to allow the surgeon's hand to enter the abdomen. The ovary and associated mesovarium are isolated by direct manual palpation. Anesthesia of the mesovarium can be attempted using gauze sponges soaked with local anesthetic, which are held around the mesovarium for 30 seconds to 2 minutes. To prevent loss of the sponges within the abdomen, a long suture or strand of umbilical tape should be secured to the sponges.[13,16,19]

To transect the ovary from the mesovarium, a chain ecraseur is used to slowly crush and cut the mesovarium. The chain ecraseur should be carefully placed around the mesovarium, ensuring that bowel, intestinal mesentery, or a portion of the uterine horn is not encircled by the chain.[12,17,18] Once the chain is properly positioned, it is tightened slowly (over 1 to 4 minutes) using the ratchet system of the ecraseur. Hemostasis of the mesovarium depends on crushing the vascular structures and the resulting vasospasm. While the ecraseur is being tightened around the ovary, the ovary

should be held within the surgeon's hand to prevent losing it within the abdomen. The contralateral ovary may be removed via the same vaginal incision if a bilateral procedure is to be performed. The vaginal incision is left open to heal by second intention. Optionally, an episioplasty (Caslick's procedure) may be performed to complete the surgery in an effort to decrease the risk of ascending infection.[11]

Tie stall restriction for 2 to 7 days postoperatively has been advocated to prevent recumbency and reduce the risk of evisceration.[13,19,20] However, some authors suggest that this is unnecessary and report no adverse effects with routine stall confinement.[11,17] Exercise restriction is employed for 1 to 3 weeks following surgery, depending on the rate of healing of the vaginal incision. During this time, limited hand walking or small paddock turnout is important to reduce the potential formation of adhesions to the ovarian stump.[11,15,18] Light riding and a slow return to normal work are allowed after this time.

The primary disadvantage to the colpotomy approach is the lack of visualization.[21] By palpation alone, the ovary must be differentiated and isolated from the omentum, local mesentery, loops of intestine, and fecal balls within the small colon.[12,22] Hemorrhage from the mesovarium may be difficult to determine and control due to the lack of visualization with this approach.[13,21] Postoperative administration of broad-spectrum antibiotics may be indicated in mares undergoing a vaginal approach because it is difficult to adequately prepare the vagina for aseptic surgery. This approach is not recommended in mares that pool urine or in mares with vaginal, cervical, or uterine infections.[14,18,22] Ecraseur transection of large ovaries (larger than 8 to 10 cm in diameter) should not be attempted due to the size of vaginal incision needed to remove the ovary, the possibility of dropping the ovary within the abdomen, and the enlarged vascular supply associated with larger ovaries.[10,11,13,18,23] Even with adequate restraint and heavy sedation, this approach poses a risk to the surgeon due to positioning behind the mare.[12,22] Thus only tractable mares are good candidates for this procedure.

Flank Approach

The flank ovariectomy approach can be performed with the mare in the standing or recumbent position. To perform a standing flank laparotomy, the mare's temperament must be amenable to standing surgery. When performing a standing flank laparotomy, the mare is sedated, restrained in standing stocks, and the tail is wrapped and secured away from the surgical site (as described for the colpotomy procedure). For the recumbent technique, mares are placed in lateral recumbency so that the ovary to be removed is uppermost. The recumbent flank technique requires general anesthesia, resulting in a slightly greater cost to the client and potentially increased risk to the mare. The recumbent flank technique is generally only used for unilateral ovariectomy, as it offers easy access to only one ovary.[14]

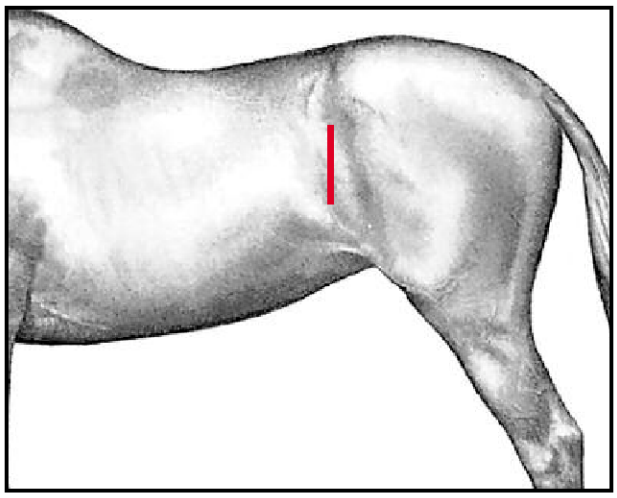

Figure 1—Position of paralumbar flank incision for ovariectomy between the 18th rib and tuber coxae. This incision position can be used in both standing and recumbent horses.

Compared with the colpotomy approach, both the standing and recumbent flank laparotomy approaches enable the surgeon to remove larger ovaries and give better exposure of the mesovarium, thus potentially providing superior hemostasis.[13,19,22] The ovary is normally situated beneath the paralumbar fossa. In horses, the limited size of the paralumbar fossa (compared with bovines) and the thickness of the body wall in the flank region may limit the ability to easily exteriorize large ovaries.[10,11,24] Ovaries up to 15 cm in diameter can be removed easily through a flank approach.[9,18,23] Bilateral ovariectomy typically requires a second incision through the opposite paralumbar fossa to remove the contralateral ovary. In the standing mare, bilateral ovariectomy can be achieved through a single flank incision, but the contralateral ovary must be excised blindly within the abdomen using a chain ecraseur.[12,14,19]

Regardless of positioning, the paralumbar fossa is clipped, aseptically prepared, and draped. Regional anesthesia in the form of an inverted L-block or local infiltration of the proposed incision site is required in standing mares.[11,12,24] The incision is started 5 cm ventral to the lumbar transverse processes between the 18th rib and the tuber coxae and is extended ventrally 10 to 15 cm as needed, depending on the size of the ovary to be

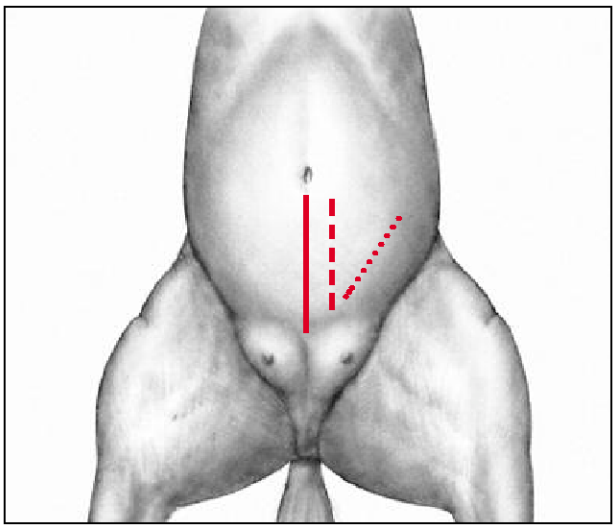

Figure 2—Position of traditional celiotomy incisions performed under general anesthesia with the horse in dorsal recumbency. *Solid red line* = ventral midline approach; *dashed line* = paramedian approach; *dotted line* = diagonal (oblique) paramedian approach.

removed (Figure 1). Following incision of the skin and subcutaneous tissues, a grid or modified grid approach may be used to incise the abdominal musculature. The grid approach creates a slightly smaller opening into the abdomen and should only be used for ovaries less than 10 cm in diameter; larger ovaries will necessitate use of the modified grid technique.[13,14,19] A grid approach involves separating the external abdominal oblique muscle along the direction of its fibers, whereas a modified grid technique involves incising this muscle along the line of the skin incision.[14] For both techniques, the internal abdominal oblique and transversus abdominis muscles are bluntly separated along the direction of their fibers or incised to expose the peritoneum. The peritoneum may be incised or bluntly perforated to allow access to the abdomen. The ovary is then identified and isolated. In standing mares, the mesovarium is anesthetized by topical administration of anesthetic, similar to that described for the colpotomy procedure, or by direct injection of anesthetic into the mesovarium, if visualization permits. The ovary may be transected within the abdomen or after exteriorization. Aspiration of cystic cavities within the ovary may reduce the overall ovarian size and facilitate exteriorization.[9,10,18] The means to achieve hemostasis and transection of the mesovarium depend on the ability to exteriorize or visualize the mesovarium through the flank incision. Possible choices include the use of a chain ecraseur, emasculator, surgical stapling device, or transfixing ligatures.[11,14,16,19,24] Following removal of the ovary, the mesovarium is observed for hemorrhage and oversewn if desired, when adequate visualization permits. Oversewing the mesovarium with 2-0 absorbable suture material may reduce possible intraabdominal adhesions of a segment of bowel to the transected mesovarium.[14,18] Closure of the laparotomy incision is routine.

Postoperative pain and discomfort may be observed in association with the flank incision. Incisional swelling and discharge may be noted 24 to 72 hours after surgery.[24,25] Incisions created in a more ventral position on the flank tend to develop more swelling and cause increased postoperative pain and discomfort.[24] Incisions in the flank have been associated with incisional discharge and partial dehiscence.[13,14,22] Occasionally, this approach results in a poor cosmetic outcome if scarring of the incision site occurs.[10-12] Exercise should be restricted to hand walking or turnout in a small paddock for 4 to 6 weeks following surgery, after which light riding and a slow return to normal work may be allowed, provided the incision has healed without complications.

Diagonal (Oblique) Paramedian Approach

The diagonal (oblique) paramedian approach has been reported to be superior to other approaches for ovariectomy, especially for the removal of ovaries up to 20 to 25 cm in diameter.[26,27] Because the incision is created so close to the intraabdominal position of the ovary, exteriorization through a diagonal paramedian incision generally results in less traction being placed on the mesovarium. In addition, the body wall is thinner at this location, as compared with other approaches, which allows greater flexibility in retracting the wound edges. Improved visualization of the ovary and mesovarium can often be achieved with this approach. Bilateral ovariectomy can be performed; however, two incisions are generally required. General anesthesia is necessary to perform an ovariectomy with this approach; therefore, the cost and risks associated with recumbency are also associated with this technique.

Perioperative preparation and care is similar to that for the previously described approaches. Following induction of general anesthesia, the mare is placed in dorsal recumbency. Slightly tilting the mare toward the side opposite the affected ovary helps minimize the tendency for bowel to protrude from the incision. Following routine aseptic preparation of the ventral abdomen, an incision is started approximately 5 to 10 cm cranial to the ipsilateral mammary gland and extended approximately 20 cm (or as needed, depending on the size of the affected ovary) cranially and laterally toward the fold of the flank[11,15,16] (Figure 2). The incision is extended through the underlying external rectus sheath,

parallel to the initial skin incision. The rectus abdominis, internal rectus sheath, and peritoneum are bluntly divided in the direction of their fibers or incised (depending on surgeon preference) to allow access to the abdomen.[13,18,26] The ovary is located and exteriorized. Local anesthesia of the mesovarium, either by topical application of anesthetic-soaked gauze sponges or direct injection of local anesthetic, may be used to diminish the pain response secondary to traction on the ovary.[16,28] Fluid within cystic cavities may be aspirated to reduce the size of the ovary and facilitate its removal from the abdomen.[16,23,27] Large suture material placed as stay sutures within the ovary and retraction on the incision edges may aid the surgeon in exteriorizing large ovaries. Overlapping transfixation ligatures of No. 2 absorbable suture material or application of a TA-90 stapler (US Surgical) may be used for hemostasis prior to transection of the mesovarium.[15,18,26,29] Ligatures should be tightened and staples should be applied to the mesovarium in a relaxed position; application under tension may result in failure to provide adequate hemostasis.[13,19,28] Following complete transection of the mesovarium, closure of the abdominal incision is routine. Due to the location of the incision on the ventrum, a good cosmetic outcome usually follows ovariectomy by the diagonal paramedian approach.[11]

Exercise restriction during the early postoperative period should consist of stall confinement with hand walking for the first 2 to 4 weeks following surgery.[11,27] After this time, small paddock turnout may be allowed for an additional 2 to 4 weeks of confinement,[11] the actual length of restriction depending on the individual patient's wound-healing progress. Return to a full exercise schedule and/or the allowance of natural service should not be allowed for at least 8 to 12 weeks postoperatively.[27] Mares may be bred by artificial insemination when the estrous cycle occurs following surgery.[15]

Ventral Midline Celiotomy Approach

A ventral midline celiotomy approach offers good exposure of the ovaries in the majority of mares.[14,15,28] The ventral midline incision can easily be extended as necessary, depending on the individual case, making it the technique of choice for removal of extremely large, tumorous ovaries.[13,19] The ventral midline approach is generally used to remove very large granulosa–theca cell tumors but can also be used to perform a bilateral ovariectomy.[11,15,16,23,25] A good cosmetic outcome is expected with this approach, provided no complications with incisional healing occur.

Perioperative preparation and care are similar to previously described approaches. For a ventral midline technique, general anesthesia is required and the mare is placed in dorsal recumbency. A caudal ventral midline linea incision is created, beginning at the mammary gland and extending cranially 25 to 35 cm as needed for adequate exposure[13,14,29] (Figure 2). The ovary is located by manual palpation and exteriorized. Local anesthesia of the mesovarium can be used if desired. Topical application of anesthetic-soaked gauze sponges or direct injection of the mesovarium with local anesthetic may decrease the pain response related to traction on the mesovarium.[16,28] Intraoperative hypotension believed to cause myopathies and neuropathies has been associated with excessive traction on the mesovarium, and these complications may be reduced by the application of local anesthetic.[28] Hemostasis and transection of the mesovarium are similar to what was described for the flank and diagonal paramedian approaches. Closure of the ventral midline incision is routine.

Postoperatively, care is similar to the other ovariectomy approaches. Stall confinement with hand walking should be enforced for the first 2 to 4 postoperative weeks, at which time sutures or staples used to close the ventral incision should be removed.[19] Small paddock turnout may be allowed after this, for an additional 2 to 4 weeks of confinement, after which light riding or pasture turnout may be allowed.[14] Full exercise should not be allowed for a minimum of 8 to 12 weeks after surgery, depending on the progress of incisional healing.[13,14]

Paramedian Approach

The paramedian approach can be used to remove large pathologic ovaries or to perform bilateral ovariectomy through one (contralateral ovary must be transected blindly) or two incisions.[18,19,23,25,28,30,31] The paramedian approach is similar to the ventral midline approach except for the location of the incision. The incision is made 4 to 8 cm lateral to midline and extends cranially from the level of the mammary gland for 25 to 35 cm or as needed for adequate exposure[16,19] (Figure 2). Methods to exteriorize the ovary and provide hemostasis of the mesovarium are similar to those described for other approaches. Postoperative care following a paramedian celiotomy is similar to the ventral midline and diagonal paramedian approaches.

Laparoscopic Techniques

In the past 10 years, laparoscopic ovariectomy techniques have been described for mares in the standing[3,4,32–34] and dorsally recumbent[2,4,5,21,34,35] positions. Laparoscopic techniques can greatly improve visualization of the ovary and mesovarium, potentially decrease postsurgical complications, and allow tension-free ligation of the vessels within the mesovarium.[2,3,21,32,33] How-

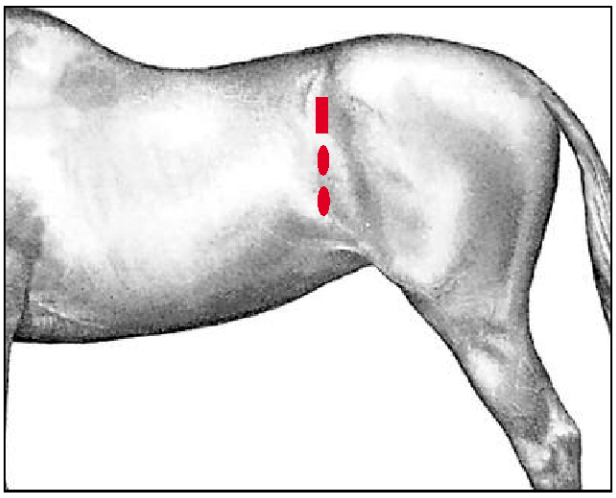

Figure 3—Position of the laparoscope *(rectangle)* and instrument portals *(ovals)* for laparoscopic ovariectomy in the standing horse. The laparoscope portal is positioned between the 18th rib and the tuber coxae, just dorsal to the crus of the internal abdominal oblique muscle. Instrument portals are created 4 to 8 cm ventral to the laparoscope portal.

ever, important considerations when performing equine laparoscopic ovariectomy include the requirement of specialized equipment, the technical difficulty of certain procedures, and the potential for anesthetic complications in horses placed in the Trendelenberg position.[4,21,33] Additionally, the use of laparoscopic equipment may be cost prohibitive in certain situations.[3,21]

Laparoscopic Ovariectomy in the Standing Mare

Laparoscopic ovariectomy in the standing mare avoids the need for general anesthesia, eliminates the cardiovascular derangements associated with the Trendelenberg position, and shortens the required preoperative fasting time (12 hours instead of 24 to 48 hours).[1,3,32] Mares are sedated using either xylazine hydrochloride or detomidine hydrochloride in combination with butorphanol tartrate. For bilateral ovariectomy, both paralumbar fossae are prepared for aseptic surgery and draped. The paralumbar fossa is desensitized using regional anesthesia or by direct infiltration of the proposed laparoscope and instrument portal sites.[4,5,36] The abdominal cavity can be insufflated with carbon dioxide through either a Verres-type needle inserted dorsally in the paralumbar fossa or a teat cannula inserted ventrally, as if performing abdominocentesis.[7,37] As an alternative (to avoid the potential complication of inadvertently insufflating the retroperitoneal space), the trocar–cannula can be inserted through the paralumbar fossa prior to insufflation of the abdominal cavity.[6,32,33,38]

A 15-mm skin incision is made at the dorsal border of the internal abdominal oblique muscle, and the sharp laparoscopic trocar–cannula is introduced into the abdominal cavity perpendicular to the paralumbar fossa[1,3,4,39] (Figure 3). The trocar is replaced by the laparoscope, and the caudal portion of the abdomen is examined to identify the ovary. The first instrument portal is made 4 to 8 cm ventral to the laparoscope portal, and a second instrument portal is made 4 to 8 cm ventral to the first[4] (Figure 3). Trocar–cannula units are passed through each instrument portal perpendicular to the flank musculature. Using a long spinal needle inserted separately through the flank musculature or a laparoscopic injection needle placed through a cannula, the mesovarium can be infiltrated with local anesthetic.[5,31,38] Hemostasis of the mesovarium can be achieved using suture ligatures, staples, laser energy, electrosurgical instrumentation, a vessel-sealing device, or a harmonic scalpel.[1,3,32,33,36,38–41] The ovary is transected using laparoscopic scissors distal to the site of ligation or coagulation. The ovary is removed by enlarging one of the instrument portals or by connecting the two instrument portals.[5,36] After removing the ovary, the abdomen is deflated through a laparoscopic cannula. The superficial abdominal fascia and skin at the portals are closed separately. The same procedure is then performed through the opposite paralumbar fossa to remove the contralateral ovary in bilateral procedures.

A hand-assisted laparoscopic ovariectomy technique in standing mares can be used to remove granulosa–theca cell tumors as well.[42] A standard flank approach is used, but the process of injecting local anesthetic into the mesovarium, application of a surgical stapling device, and transection of the mesovarium is performed intraabdominally with digital manipulation while using laparoscopic observation of the procedure.[42] After transecting the ovary from its mesovarium, the ovary is placed within a sterile plastic bag and sharply transected. Placing the ovary within the bag facilitates removal through a smaller incision and prevents abdominal and body wall contamination from the ovarian cystic fluid.[35,42] The standing, hand-assisted, laparoscopic ovariectomy technique is technically easy to perform, can be used for large pathologic ovaries (up to 30 cm in diameter), allows accurate placement of the staple line, and eliminates the potential risks and costs associated with general anesthesia.[42]

Laparoscopic Ovariectomy in the Anesthetized Mare

To perform unilateral or bilateral ovariectomy in an anesthetized mare using laparoscopy, the horse is anesthetized and positioned in dorsal recumbency, and the

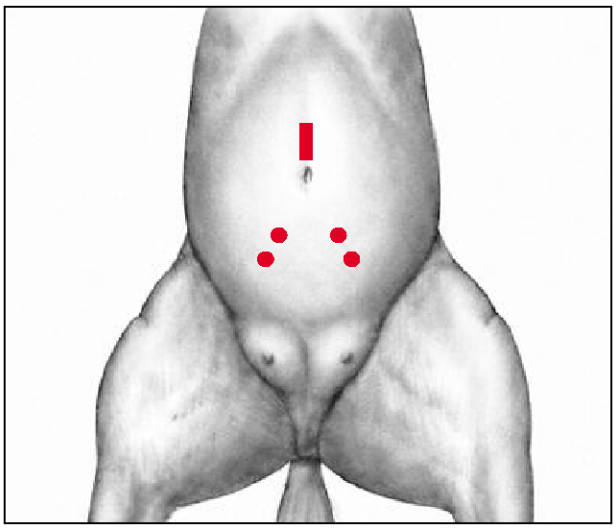

Figure 4—Position of the laparoscope and instrument portals for ovariectomy in the dorsally recumbent horse under general anesthesia. The laparoscope portal *(rectangle)* can be positioned just cranial to the umbilicus or just lateral to the umbilicus. Instrument portals *(dots)* are created between the laparoscope portal and the ipsilateral mammary gland.

tail is secured to the surgery table. The caudal abdomen is aseptically prepared and draped. To improve visualization of the caudal abdomen, a urinary catheter can be passed to decompress the urinary bladder.[35,43] A 10-mm skin incision is made just cranial or lateral to the umbilicus (Figure 4). The abdomen is insufflated with carbon dioxide through a teat cannula to a pressure of approximately 15 to 20 mm Hg.[2,4,39] A laparoscopic trocar–cannula unit is introduced into the abdomen, and the trocar is replaced with the laparoscope. In the recumbent technique, patient positioning becomes important for adequate visualization of the caudal abdomen. In routine dorsal recumbency, the female reproductive tract is obscured by intestinal viscera, so the surgical table must be elevated in such a way that the mare's head is lower than the hindquarters. For removing ovaries, an angle of inclination of approximately 30° from horizontal (Trendelenberg position) is generally required.[4,21] Two instrument portals (cranial and caudal) are created on both the left and right ventral abdomen (Figure 4). The cranial instrument portals are located midway between the ipsilateral mammary gland and the umbilicus. The caudal instrument portals are placed midway between the ipsilateral mammary gland and the cranial instrument portal.[35] After creating the four instrument portals, the ipsilateral uterine horn is elevated using a Chambers catheter (Jorgensen Laboratories) inserted through the contralateral caudal instrument portal. A knot push rod equipped with a modified Roeder knot or a commercial suture loop is inserted through the ipsilateral caudal instrument portal (left caudal instrument portal for removing a left ovary).[2] Sharp-toothed laparoscopic grasping forceps are passed through the cranial instrument portal on the same side as the suture loop. The jaws of the forceps are passed through the suture loop and used to grasp the ovary. The suture loop is passed over the ovary and tightened around the mesovarium. The mesovarium is then transected distal to the suture ligature.[21] The transected ovary is maintained in the jaws of the grasping forceps while the same series of steps are reversed to allow removal of the opposite ovary. The abdomen is deflated and the ovaries are removed by enlarging one of the cranial instrument portals. For the enlarged incision, the external fascia of the rectus abdominis, subcutaneous tissue, and skin are closed separately.[21] All remaining incisions are closed by simply apposing the skin.

Because most laparoscopic ovariectomy techniques can be accomplished through small incisions, the mare can be returned to exercise shortly after the procedure is performed. Postoperatively, mares should be confined to a stall for the first 24 hours followed by stall or small paddock confinement for 2 to 3 weeks before they are returned to unrestricted exercise.[33,35,38]

Laparoscopy can be used to remove large ovarian granulosa–theca cell tumors. One report described two mares that had a granulosa–theca cell tumor removed using a recumbent laparoscopic ovariectomy technique.[2] The mares were placed in Trendelenberg position, and the maximum diameter of the ovaries was estimated to be 20 cm in diameter.[2]

Complications that may occur following laparoscopic ovariectomy are similar to those seen with other approaches. Hemorrhage from the mesovarium has been reported following ligature slippage.[1,21] Subcutaneous emphysema may be observed postoperatively if the abdomen is not decompressed adequately prior to closure of the incisions.[32,43]

COMPLICATIONS

Although great advances have been made in the routine use of general anesthesia and surgical technique in horses, ovariectomy remains a procedure in which potential complications may occur, regardless of the approach used. In general, ovariectomy has been associated with greater postoperative morbidity and mortality than for other elective procedures.[10,13,15,22,25] Postoperative hemorrhage from the mesovarium can occur if hemostasis of the mesovarium fails.[3,22,23,44,45] Intraabdominal hemorrhage from branches of the ovarian artery is a serious and possibly fatal complication that

may go undetected at the time of surgery. Therefore, mares should be confined to a stall for the first 24 hours after surgery. Clinical signs associated with blood loss include tachycardia, pale mucous membranes, weakness or ataxia, weak thready pulse, and poor jugular distention.[13,18,22] Hemorrhage must be controlled, and initial medical therapy should be aimed at replacing the lost blood volume by intravenous administration of fluids and whole blood.

The vaginal approach also has the potential risk of inadvertently incising the caudal uterine branch of the urogenital artery when making the incision into the abdomen.[11,15] Care to avoid the 3- and 9-o'clock positions will help prevent this potentially fatal complication. Other potential complications reported when performing a vaginal approach include pain and discomfort; injuries to the cervix, bladder, or a segment of bowel; delayed vaginal healing; eventration of bowel, incisional site hematoma, or abscess; intraabdominal adhesions to the vagina; and chronic lumbar or bilateral hindlimb pain.[14,17,19,45]

Reported complications with the other celiotomy approaches vary depending on position. Intraoperative hypotension, myopathies, and neuropathies have been associated with traditional ovariectomy approaches performed under general anesthesia to remove granulosa–theca cell tumors.[13,22,25,45] Tension placed on the mesovarium during the process of exteriorizing an ovary is speculated to cause a decrease in arterial blood pressure and potentially lead to inadequate peripheral circulation.[25]

Cardiopulmonary derangements have been observed during laparoscopic procedures with horses placed in the Trendelenberg position.[21,32,39,46] This positioning exaggerates the force of abdominal insufflation and the weight of abdominal viscera on the diaphragm, decreasing the horse's ability to adequately ventilate without mechanical assistance and potentially compromising venous return to the heart.[21,32] Metabolic acid–base disturbances may also occur following prolonged abdominal insufflation with carbon dioxide, which diffuses easily into the systemic circulation.[39,46] As with traditional surgical approaches, myopathies and neuropathies can be a consequence of prolonged dorsal recumbency.[21] Therefore, proper anesthetic patient monitoring is required when performing laparoscopic ovariectomy with the mare in the dorsal recumbent position.

Regardless of whether the surgery is performed with the mare standing or recumbent, postoperative pain, anorexia, depression, incisional swelling, incisional infections, incisional dehiscence, eventration, peritonitis, intraabdominal adhesions, and death have been reported following ovariectomy in mares.[10,11,13,17,22,25,44,45] Incisional complications have been associated with ovariectomy techniques to remove granulosa–theca cell tumors.[25] A higher incidence of incisional complications have been observed with approaches through the paralumbar fossa.[14,24,47] This may be associated with the increased amount of dead space and possible muscle necrosis that may occur with the paralumbar approach.[47]

Proper aseptic techniques must be employed when performing ovariectomy procedures, or postoperative septic peritonitis may result.[12,24,25,44] This potential complication can be prevented by adhering to proper aseptic technique throughout the procedure and by the administration of perioperative antibiotics. Intraabdominal adhesions can develop after any abdominal procedure; however, the use of proper aseptic technique and ensuring minimal trauma to gastrointestinal serosal surfaces can help prevent formation of adhesions.[14,28]

Ovariectomized mares may continue to display signs of estrus after ovariectomy. It has been reported that 60% of ovariectomized mares will cease estrous behavior following surgery.[19] If previous hormonal therapy has been successful in altering the mare's behavior and/or performance favorably, then bilateral ovariectomy is likely to be successful at meeting the client's expectations. Prospective "jump" mares to be used for stallion collection should stand well during estrus as an intact mare; otherwise, the individual is not likely to be a good candidate for ovariectomy for this purpose.[48]

CONCLUSION

The equine surgeon presented with a mare requiring ovariectomy has numerous approaches available. The specific approach to be used should be chosen carefully to minimize traction on the pedicle yet allow adequate exposure and visualization of the ovarian pedicle for secure hemostasis. Standing techniques include colpotomy (vaginal), flank laparotomy, and laparoscopy. Traditional techniques that require general anesthesia are flank, paramedian, diagonal (oblique) paramedian, and ventral midline celiotomy approaches as well as laparoscopic procedures. Laparoscopic techniques are superior in providing visualization of the ovaries and tension-free ligation for maximal hemostatic security. However, laparoscopy requires specialized instrumentation and surgical knowledge, which may increase operative time, at least initially, until experience is gained. Each technique for equine ovariectomy has associated advantages and disadvantages, and as such, there is no single "proper" technique to be used for every case. When deciding which approach to use, clinicians should be intent on completing the procedure in the most efficient way, while at the same time minimizing patient discomfort and postoperative complications.

ARTICLE #5 CE TEST

The article you have read qualifies for 1.5 contact hours of Continuing Education Credit from the Auburn University College of Veterinary Medicine. *Choose the best answer* to each of the following questions; then mark your answers on the postage-paid envelope inserted in *Compendium.*

1. Mares undergoing ovariectomy by colpotomy should be in what stage of the estrous cycle?
   a. immediately after ovulation
   b. diestrus or anestrus
   c. actively cycling
   d. pregnant
   e. seasonal transition

2. The initial vaginal incision for the colpotomy approach to ovariectomy should be in which position?
   a. directly dorsal
   b. on the medial wall
   c. on the lateral wall
   d. cranioventral or craniodorsal
   e. directly ventral

3. Oversewing the mesovarium following transection is recommended for which of the following reasons?
   a. decrease adhesion formation
   b. prevent eventration
   c. provide analgesia
   d. ensure adequate hemostasis
   e. complete sterilization

4. Which of the following is considered the main advantage to the ventral midline celiotomy approach to ovariectomy?
   a. little interference from abdominal viscera
   b. ease of performing a bilateral procedure
   c. optimal visualization of ovaries on short pedicles
   d. most tension-free ligation
   e. the ability to extend the incision as needed

5. Which of the following is generally not used for hemostasis when performing laparoscopic ovariectomy?
   a. suture ligatures
   b. staples
   c. chain ecraseur
   d. laser energy
   e. electrosurgical instrumentation

6. What is the main theory for why intraoperative hypotension is associated with traditional ovariectomy procedures performed under general anesthesia?
   a. Tension on the mesovarium decreases arterial blood pressure.
   b. Blood loss from the surgical incision causes hypovolemia.
   c. Hypoventilation causes decreased arterial oxygen content.
   d. Anesthetic agents cause decreased systemic blood pressure.
   e. Abdominal viscera interfere with venous return to the heart.

7. Which incision location has been associated with a higher incidence of complications?
   a. ventral midline
   b. paramedian
   c. laparoscopic
   d. flank
   e. diagonal paramedian

8. What percentage of mares stop showing estrous behavior following bilateral ovariectomy?
   a. 100%
   b. 60%
   c. 75%
   d. 50%
   e. 30%

9. Which of the following are advantages to laparoscopic ovariectomy approaches compared with the traditional celiotomy approaches?
   a. smaller incisions for access to the abdomen
   b. visualization of the ovary and mesovarium
   c. tension-free ligation of the mesovarium
   d. shorter, less complicated postoperative recovery
   e. all of the above

10. Which of the following is not a reported complication following equine ovariectomy?
    a. septic peritonitis
    b. eventration
    c. neurologic deficits
    d. hemorrhage
    e. hindlimb pain

BONE AND MINERAL

The long-term effect of ovariectomy on the quality and quantity of cancellous bone in young macaques

K. Lundon, M. Dumitriu, M. Grynpas*

Department of Pathology, University of Toronto and Samuel Lunenfeld Research Institute of Mount Sinai Hospital, 600 University Ave., Suite 984, Toronto, Ontario M5G 1X5, Canada

(Received 12 March 1993; revision accepted 20 October 1993)

Abstract

The effect of ovariectomy on the quality and quantity of cancellous bone using the young cynomolgus monkey was evaluated after a 2-year period. The bodies of the second lumbar vertebrae were analyzed for changes in bone mineral quality using density fractionation, chemical analysis, and X-ray diffraction techniques. Changes in bone tissue quality and quantity were evaluated using bone histomorphometry and image analysis. The experimental group ($n = 14$) was made surgically menopausal (bilaterally ovariectomized), compared with intact controls ($n = 16$), and then sacrificed after a 2-year period. There was a non-significant shift in the mineralization profile towards less dense bone in the ovariectomized (OVX) vertebrae compared with controls. Physical characteristics of the bone mineral in terms of crystal size or strain were unaffected by OVX. There was a parallel increase in mineral content with fractions of increasing density, however there was no difference in mineral content or the Ca/P ratio in each fraction between treatment groups. Histomorphometric analysis for structural parameters demonstrated no difference in bone volume between control and OVX groups. There was no significant change in trabecular width in the OVX vertebrae compared with controls. There was a significant increase in both osteoid volume and osteoid surface in the OVX vertebrae ($P < 0.001$). Trabecular architecture as measured by image analysis was unchanged. There was a significant increase in eroded surface in the OVX vertebrae ($P < 0.03$) compared with the controls. In conclusion, young, ovariectomized female cynomolgus macaques do not appear to be a useful animal model for the study of postmenopausal bone loss, however they may be a useful model to evaluate skeletal pathology which might be observed after surgical ovariectomy in young human females.

1. Introduction

Understanding the mechanism by which the quality and/or quantity of bone is affected by surgical or physiologic cessation of ovarian function has challenged many in recent years. In spite of these efforts, the evidence for altered quality and distribution of mineral in bone is largely restricted in humans, at least, to non-invasive measurement findings, or at best, biopsy from bony sites such as the iliac crest which display inherent functional differences from the vertebrae where changes are so remarkable at the time of the menopause. The multifactorial nature of bone mass regulation in humans makes it difficult to study the relative contribution of a single factor and as a consequence, the changes that occur with ovariectomy are complicated and difficult to qualify. Results of studies in the acute phase post-ovariectomy are well documented across numerous animal models [1–4] as well as in humans [5]

It is generally accepted that in the human menopausal period of approximately 5–7 years duration, there is altered (increased) turnover and up to 2% annual loss of bone which predominantly affects trabecular bone of the vertebrae, with an eventual decline in bone loss occurring at the end of this period [6]. It has been argued that bone behaviour in premenopausal oophorectomized females is not qualitatively different from that occurring in postmenopausal females, and that any differences in bone loss between postmenopausal and ovariectomized premenopausal females are only quantitative [7]. In a study where premenopausal oophorectomized females were reviewed after a follow-up period of 9 years, both peripheral and axial bone mineral density measurements were decreased in a placebo treated group, while estrogen treatment was seen to prevent bone loss at both sites over this same time period [7].

In another study, the estrogen deficiency associated with both premenopausal OVX and the menopause determined that estrogen deprivation rather than the effects of aging was the most important determinant of bone loss at least in the axial compartment under both conditions [8]. Few studies assume an observation period that is of sufficient length to capture any true effort on the organism's behalf at achieving homeostasis over the long-term, as would be experienced over the natural course of events in a lifetime. In addition to the temporal limitations of studies, the species chosen for experimentation typically differs from the human in their response to or creation of a sex steroid hormone climate, making it less likely that the results are comparable with the human condition. Numerous short-term, cross-sectional studies have been conducted in ovariectomized rats, where increased bone turnover is detected within 2 weeks, and bone loss is demonstrable after 8 weeks [2,3,9] as well as in dogs of different ages [10–13]. Regardless of the model used, there is consistent agreement that a loss of bone and an increase in bone turnover occurs soon after cessation of ovarian function, however the long-term manifestations are heterogeneous or remain unexamined.

The early histomorphometric observations of cancellous bone loss following

ovariectomy (OVX) has been characterized in dogs by Faugère et al. [10] which has provided advanced information about the sequence of events following OVX within a 4-month period, however similar studies which might capture further processes beyond the acute phase in non-human primates or other animal models are few and contradictory. There are conflicting results in the literature characterizing the changes occurring in bone after ovariectomy using the non-human primate model. In this regard, findings by Miller et al. [14] revealed a significant loss (42%) in trabecular bone volume (TBV) in OVX cynomolgus monkeys after 22 months, while Jayo et al. [15] did not observe these changes in a similar model and over a period of similar duration. In baboons, increased bone turnover and bone loss were noted as early as 6 months [1]. A study by Thompson et al. [16] employed OVX adult female baboons and their data showed no actual difference in BMC of the radius or femoral neck regions between OVX and control groups after a 1-year period. Shaw et al. [17] found no significant difference in the TBV in the vertebrae of young OVX dogs compared with controls after 12 months. A recent 6-month study by Shen et al. [18] identified a lack of sizable responses in histomorphometric, bone mass and biochemical parameters which may serve to limit the utility of dogs for the study of cancellous bone loss in ovarian-dysfunction osteoporosis.

The purpose of this paper was to specifically examine the nature of both the quality and quantity of cancellous bone after ovariectomy in a young non-human primate. Techniques to study the quality of bone mineral, such as density fractionation (to obtain a profile of mineral of different maturities) can help to capture events involving turnover of bone [19]. Quantity of bone can be determined and its respective constituents further qualified using histomorphometric techniques, demarcating bone tissue remodelling activity. Trabecular architecture can be determined using image analysis of histological sections. Non-human primates have been used extensively in studies on reproductive biology, in part, because in the female the menstrual cycles are similar in length and control to those in human females. The dynamics of androgen and estrogen metabolism and production in the cynomolgus monkey show a pattern that is, in general, similar to those in humans, with minor variations in the interconversion of androgens and estrogen [20]. Additionally, 1 macaque year is equivalent to 3 human years in biological terms, making a 2-year study potentially useful for simulating conditions affecting the human skeleton involving a length of time such as the 5–7 year period of menopause. The goal of this study was to identify whether a 2-year period post-OVX allows sufficient time for bones to reach a new equilibrium. A young OVX adult primate model observed over a 2-year period, as well as specific and thorough examination using multiple techniques to determine quality and quantity of the cancellous bone in the vertebrae were employed to identify the events during and after high-turnover bone loss known to occur after ovariectomy.

2. Materials and methods

2.1. Animals

A group of 30 feral young adult female cynomolgus macaques (*M. fascicularis*) (mean age, 9.5 years as estimated by dentition: age range, 7–12 years) imported from

Jakarta, Indonesia were used in this study. All the animal experiments were conducted at the primate colony in the Department of Comparative Medicine, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC. The animals were randomly selected from a group of monkeys involved in a large 2-year experiment designed to study the inhibition of diet-induced coronary artery atherosclerosis by different hormonal therapies [21]. Fourteen animals were made surgically menopausal (bilateral ovariectomy) with sixteen left intact as controls, observed and cared for as outlined by Carlson et al. [22], and sacrificed after a 24-month period. At sacrifice, the second lumbar vertebrae were removed and cleaned of soft tissues, stored at −70°C, and sent to our laboratory for structural histomorphometric and chemical analysis of cancellous bone.

2.2. Bone histology

A 2-mm mid-coronal section was cut using the Isomet saw through the central body of the second lumbar vertebrate from each monkey. Sections were fixed in 10% buffered formalin, dehydrated through graded alcohols to acetone, infiltrated in increasing strengths of spurr/acetone solutions, and embedded undecalcified in polymerized plastic spurr blocks. Also, 5-μm thick coronal sections of the vertebrae were cut using the heavy duty Jung K microtome with a carbide type knife, oven-dried for 12 h, then stained undeplasticized using a modified Masson-Goldner trichrome technique which permits optimal discrimination between mineralized and non-mineralized (osteoid) bone [23].

Structural parameters of trabecular bone were analyzed by histomorphometric methods which complied with the nomenclature, and were calculated according to the ASBMR histomorphometric nomenclature committee [24]. Sections were viewed at 150 × magnification using a 100-point integrating eye piece and a semi-automatic image analyzer (Leitz ASM, Wetzlar, FR). The sections were examined quantitatively using an IBM-PC microcomputer and Bioquant image analysis software.

The structural parameters were measured by static analysis as dynamic labeling information was not available. These morphometric parameters included cancellous bone volume (BV/TV) (percentage of endosteal bone and marrow tissue occupied by osteoid and mineralized bone); the mineralized trabecular bone volume (percentage of endosteal bone and marrow tissue occupied by mineralized bone alone); the osteoid volume (OV/BV) (percentage of endosteal bone and marrow tissue occupied by osteoid); the osteoid surface (OS/BS) (percentage of total endosteal surface covered by an osteoid seam); the endosteal mean osteoid seam width (O.Wi.) was determined indirectly by surface/area measurements [25]; the eroded surface (ES) (percentage of mineralized endosteal bone surface displaying evidence of erosion); and trabecular width (Tb. Wi.) was determined indirectly by using the area and length method (Ar/0.5 Pm) [26]. In addition, we calculated trabecular separation and trabecular number using the formulae of Parfitt and co-workers [27] and Birkenhager-Frenkel et al. [28]:

Trabecular separation: Tb. Sp(μm) = 1000/Tb.N. − Tb. Wi.

Trabecular No. (No./mm) = % Trabecular Volume/Trabecular Width × 10

An average of 24 fields of pure cancellous bone was analyzed per sample at 150 × magnification, allowing an average area of 20×10^6 μm^2 to be examined per specimen. Each specimen was measured 5 mm down from the superior and lateral surfaces of the vertebral body, taking care to avoid the mid-central portion of the vertebrae known to be supplied by the nutrient arteries.

2.3. Image Analysis

Photographic images of the bone sections used for histomorphometry were scanned to obtain TIFF images files accessed by a Quantimet 570 (Leica) image processing and analysis system. Mathematical morphology operations [29] together with standard image processing tools were used to analyze the images. After thresholding the grey level images, we obtain binary images which were then skeletonized in order to obtain connectivity and orientation parameters [30]. The skeleton of the trabeculae obtained by the thinning transformation was pruned to remove parasitic branches. Using the multiple point function, the connection pixels between vertical and horizontal trabeculae were found. The end-point function was used to mark the free ends of the skeleton on the binary images. The images containing triple points and end points were used to obtain the connectivity parameters: average number of node/trabecula [30] and the parameters described by Mellish et al. [31] and Parisien et al. [32] in their trabecular strut analysis. The parameters used were: the number of nodes (No. Nd/mm^2), the number of terminus (No. Tm/mm^2), the total strut length (TSL/mm^2), and the node-to-node (Nd.Nd), node-to-terminus (Nd.Tm) and terminus-to-terminus (Tm.Tm) strut lengths. Finally, a rose of direction was obtained for each binary image and the ratio between the trabeculae in the 90° direction (vertical) and these in the 0° direction (horizontal) was called the anisotropy ratio [30].

2.4. Bone mineral studies

Density fractionation. The remainder of the vertebrae were crushed, tris-washed to rid them of bone marrow, lyophilized and then defatted in 2:1 v/v chloroform/methanol. The bone pieces were then pulverized in a percussion mill (Spex Freezer Mill, Meteuchen, NJ), cooled in liquid nitrogen, and sieved in a sonic sifter to separate bone particles less than 20 μm in size. The bone powder was then chemically 'fractionated' ($<1.8->2.2$ g/ml) in a bromoform-toluene mixture by the stepwise centrifugation method of Grynpas and Hunter [19]. Approximately 200 mg of sieved bone was added to a polyallomer centrifuge tube containing 35 ml of a 2.0 g/ml density solution (calibrated with sink floats). The tubes were sonicated to achieve a homogeneous suspension of the powder which subsequently was centrifuged at 10 000 RPM for 30 min. The density of the supernatant was adjusted to 1.9 g/ml via the addition of toluene, and the modified solution was re-centrifuged. In a similar way, each precipitate obtained from a solution of progressively decreasing density (at 0.1 g/ml steps) was collected. For a range of mineral densities greater than 2.0 g/ml, the precipitate obtained from the initial 2.0 g/ml density solution was resuspended in a solution with a density of 2.2 g/ml. Similarly, successive centrifugation of the precipitate at progressively decreasing densities (0.1 g/ml steps) determined the higher density fractions. Removal of organic solvents was achieved by a 'rinse'

centrifugation of the series of specific gravity fractions in 100% ethyl alcohol. The samples were then dried in a dessicator at room temperature. The contribution of each fraction relative to the original weight of unfractionated bone was calculated to determine a mineralization profile for each group.

X-Ray diffraction. Samples of bone powder from the unfractionated samples were analyzed with a Rigaku diffractometer using Cu-Kα radiation and a highly crystalline mineral fluorapatite as a standard. The values of $B½$ (002) and (130), the widths at 50% the maximum height of the hydroxyapatite reflections, were measured using a step-scanning procedure with 0.4° 2θ per step and 100 s of counting. Because the instrumental broadening was small compared with sample peak breadths, the measured half-widths were corrected for instrumental broadening by subtracting the square of $B(002)$ and $B(130)$ for the standard (fluorapatite) from the square of the bone value and taking the square root of the difference. D values, which are related to the crystal size\strain in the long dimension (002) and the cross section (130) of the apatite crystal, were calculated from the corrected $\beta½(002)$ and $\beta½(130)$ values using the Sherrer equation [33]:

$$D = \frac{K\lambda \text{ radian}}{\beta½ \cos \theta}$$

where λ is the X-ray wavelength, $\beta½$ the breadth at half the height of the 002 and 130 peaks, and θ the diffraction angle. K is a constant varying with crystal habit and chosen as 0.9 for the elongated crystallites of bone. Each measurement was repeated three times and the results averaged.

Chemical studies. Samples of bone powder (10 mg) from the three largest fractions as determined by the density fractionation technique were washed in a 4:1 v/v nitric/perchloric acid mixture in order to digest the organic matrix. A blank containing only acid mixture was used as a control for the procedure. Two external standards were used: 10 mg of phosphate rock (NBS Standard #1206) and 10 mg of animal bone from the IAEA (International Atomic Energy Association). The samples, contained in covered teflon beakers, were placed on low heat and then brought to a boil for approximately 1.5 h. The samples were then uncovered and allowed to evaporate (about 0.5 h) to a small volume (1 ml). The digested sample was then brought to a volume of 25 ml with double deionized water, brought to a pH range between 2.5 and 2.9 using 1 and 10 M NaOH or HCl stock solutions accordingly and transferred to a dust-free container. From each sample, a single 2-ml aspirate was drawn and analysed for calcium (Ca) and phosphorus (P) using the Beckman Synchron CX4 chemistry analyser [34]. Quantitation of the elements calcium (Ca) and phosphorus (P) using Arsenazo II dye and phosphomolybdate as reagents, respectively, was determined by timed end-point reactions and then expressed in mM. Final concentrations were expressed as %Ca and %P of the dry weight of bone. Additionally, the Ca/P molar ratio and the mineral content (Ca + PO_4) were calculated for each of the three largest fractions recovered from the density fractionation technique.

Data analysis. Results are expressed as the mean ± S.D., with the exception of the mineralization profiles and image analysis which are presented as means ± S.E.M. Comparison between means was performed using the Student's two-tailed t-test,

with a level of acceptance of $P < 0.05$. Most computations were performed using the PowerStat software package (PowerStat version 1.04, Analytical Engineering Corporation, Toronto, Canada).

3. Results

3.1. Bone histomorphometry

Table 1A gives the results of the measured structural parameters as evaluated by static morphometric analysis. There was no difference in trabecular bone volume (TBV) in the young ovariectomized non-human primate compared with controls. There was a significant increase in osteoid volume (OV/BV) compared with the controls ($P < 0.001$). In addition to an increased volume of osteoid, an increase in osteoid-covered endosteal surface (OS/BS) in the ovariectomized group was noted ($P < 0.001$). There was a significant increase in eroded surface (ES/BS) ($P < 0.03$) in the treatment group compared with controls. The control group demonstrated a normal eroded surface value of $\approx 4.76\%$, indicating a relatively active remodelling surface in the young cynomolgus monkey. Osteoid width (O.Wi.) indices were augmented, but remained non-significantly different in the experimental group compared with controls which was most likely a reflection of the increase in both osteoid surface and volume values. Interestingly, the contribution to osteoid volume in the OVX group was in part achieved by the occupation of large erosion pits by osteoid. There was no significant decrease in trabecular width (Tb. Wi.) in the OVX group compared with controls. There was no significant difference between trabecular separation and number values between the OVX group and controls.

3.2. Image analysis

Table 1B gives the results of the trabecular connectivity and orientation as evaluated by image analysis. There was no significant difference in the average number of nodes per trabecula or in the connectedness of the trabecular network as shown by strut analysis: node number, terminus member, total strut length, terminus-to-terminus strut length, terminus-to-node strut length and node-to-node strut length. Also, when we examined the ratio of vertical trabeculae to horizontal trabeculae (anisotropy ratio) we found no difference between the control and the ovariectomized group.

3.3. Bone mineral studies

Using a logit function [ln(proportion < 1.9 mg/ml per proportion ≥ 1.9 mg/ml)] we were able to compare shifts in the distribution of mineralization between the experimental and control vertebrae. The mineralization profile of the vertebrae of the OVX monkeys after the 2-year period demonstrated a shift to lower density fractions, which indicates a lower mineralization pattern compared with controls; however, this shift did not reach significance (Fig. 1). The X-ray diffraction data demonstrate no significant changes in crystal size/strain in the mineral of the vertebrae of the experimental group compared to controls (Table 2). There was a parallel increase in mineral content with fractions of increasing density in both groups, however, there was no significant difference in mineral content or in the Ca/P ratio in each fraction between treatment groups (Table 3).

4. Discussion

Our findings indicate that in the young non-human primate model (*M. fascicularis*) minimal changes in mineralization are evident 2 years after OVX in cancellous (trabecular) bone. There is no difference in trabecular bone volume of the OVX model versus controls, however, there are indices of persistent and increased formation and resorption activity in trabecular bone 2 years post-OVX. There have been few studies examining the long-term effects of ovarian dysfunction on the quality and quantity of bone mineral/tissue in non-human primates [1,14–16]. There is even less representation in the literature defining these events using a young non-human primate model, which would have the added advantage of avoiding confounding age-related variables known to affect the skeleton.

There is some disagreement about the effects of ovariectomy (OVX) or ovariohysterectomy (OVH) on cancellous bone across species of different ages and over different lengths of time. In the dog, a decreased [10,11] or unchanged [13,17,18] volume defect has been shown. It is of interest that those reporting no change in unqualified total bone volume are the long-term studies [17,18], while rapid loss of cancellous bone volume with evidence of a later initiation of formation indices is a reported feature of the short-term studies [10]. The observations of Danucci et al. [13] of increased osteoid surface, resorption surface, and bone formation rate after

Table 3
Chemistry: long-term effects on cancellous bone post-ovariectomy

Fraction	%Ca	%P	Ca/P	Ca% + PO_4%
A Control vertebrae				
1.8–1.9	18.7 ± 0.8	8.1 ± 0.4	1.8	43.4 ± 1.9
1.9–2.0	19.8 ± 1.7	8.4 ± 0.7	1.8	46.5 ± 2.2
2.0–2.1	22.4 ± 1.2	9.4 ± 0.6	1.8	51.3 ± 2.9
B Experimental vertebrae				
1.8–1.9	17.8 ± 0.8	8.2 ± 0.4	1.7	42.8 ± 1.7
1.9–2.0	19.6 ± 0.6	8.8 ± 0.2	1.7	46.5 ± 1.0
2.0–2.1	21.2 ± 0.9	9.6 ± 0.8	1.7	50.7 ± 1.9

a 6-month period post-OVX in the dog is in agreement with ongoing high remodelling activity. In concert with the failure to observe a significant decrease in cancellous bone volume, to which osteoid was reported to contribute at least in part as a surface phenomenon, may indicate a certain recovery effect has been initiated after acute loss of surface cancellous bone in the dog model.

Limited studies of cessation of ovarian function and the long-term effects on the skeleton have employed non-human primate species [1,14,15]. A non-human primate model (cynomolgus monkey) offers the advantage of being physiologically similar to the human especially in terms of reproductive cycles and endocrine profiles [20] making continued efforts at analyzing the quality and quantity of bone in this model worthwhile. A significantly decreased BMD was observed in the lumbar spine in a group of young ovariectomized adult monkeys, however, there was no report of increased incidence of crush fractures in this population [35,36].

In a study of the effects on bone of surgical menopause and hormone replacement therapy in adult cynomolgus monkeys, there was in fact no difference in trabecular bone volume between the monkeys that were oophorectomized and those that received either estrogen-replacement therapy alone, or estrogen replacement plus progesterone after 25 months. This was found despite a reported significant decrease in BMD between the oophorectomized and the estrogen-replacement therapy plus progesterone treated group [15]. The lack of a difference in cancellous bone volume between oophorectomized and the control group of monkeys is similar to that which was observed in the present study, and in fact does not support the use of this young cynomolgus monkey as a model for postmenopausal bone loss. Of great interest and support to our findings in the present study were the results of the effects of alendronate on the trabecular bone (iliac crest) in the OVX baboon [16]. After a 12-month period, a significant increase in osteoid surface and volume measurements was observed as early as 6 months in the OVX model compared with the controls, despite a significant decrease in mineralized trabecular bone volume compared with controls. An increase in resorption parameters (osteoclast number) was significantly elevated at 6 and 12 months, coincidental with the significantly increased values of formation indices (osteoid volume and surface measurements, as well as serum alkaline phosphatase levels). Bone mineral content of the radius and femoral neck regions as measured by DPA in this study reported a significant difference in BMC in the femoral neck region between the control and OVX group when compared relative to time 0, however, there is no significant difference between the effects of OVX and controls at the end of the 12-month period.

An interpretation made retrospectively, could be that the presence of decreased TBV followed shortly by evidence of bone manufacturing indices of increased osteoid volume and surface measurements suggest attempted recovery of some kind, providing mineralization ensues. If indeed an OB insufficiency is the explanatory variable for the decreased bone volume seen relatively soon after cessation of ovarian function, it would seem that this phenomenon is arrested at least in the young non-human primate model by some means thereafter (within the 2-year period, the equivalent of 6 human years). The fact that recovery of bone volume was achieved in this study through/by both osteoid volume and surface parameters is a novel finding, having been reported only as an initial effort in the short-term study by

Faugère et al. [10] and in the long-term by Thompson et al. [16]. Any kind of impressive bone loss must have occurred (and it must have, based on the amount of osteoid) well before the 2-year post-OVX period was terminated.

At some time during this time course a return to normal bone volume values was established and future sequential studies over a 2-year period are required to capture the temporal profile of these events, as are longer ones to observe whether this new bone mineralizes normally. Because of the significant amount of osteoid volume and surface characteristics in the OVX group indicating ongoing formation, a significantly increased eroded surface, and essentially intact mineral quality, there is a powerful suggestion of ongoing/persistent high turnover rate (HTR) changes rather than a mineralization deficit occurring in the experimental group even after a 2-year period. The image analysis results show that this remodelling did not affect the cancellous bone architecture as shown by strut analysis [31,32] or the orientation of the trabecula as shown by the anisotropy ratio [30]. Alternatively, because the monkeys used (human equivalent 20–30 years) endured surgical menopause, a climate was created that is not dissimilar to that created by amenorrhea or other ovulatory disturbances, where tolerance of decreased bone mass exists [37].

Of additional interest is that the mechanical properties measured in terms of elastic modulus and maximum stress in compression were not significantly different in cores of cancellous bone obtained from the femoral head in the same group of monkeys. Apparent density as measured by water displacement was not significantly different between OVX and control groups (Kasra, pers. commun.). It is not out of order to hypothesize that in the young female adult there may be other physiological compensatory mechanisms which may be more at play in younger organisms than in older ones, making this inherently a poor model for postmenopausal osteoporosis. This model may be an ideal one to study the long-term effects on the quality of cancellous bone of premenopausal females who have undergone OVX or suffer from acute ovulatory dysfunction, a population in whom only a quantitative decline in BMD affecting both cancellous [7,8] and cortical compartments [7] has been previously reported.

The bone mineral studies support lower mineralization occurring in the ovariectomized model vertebrae than controls reflected by a mineralization profile shifted to less dense mineral. Based on past findings using the density fractionation technique, bone that is less mineralized usually is less mature and has been formed more recently in comparison with bone that is more highly mineralized [19]. Our findings identified trabecular bone mineral that was slightly less dense in the experimental group compared with controls, and based on these principles most likely represented newly formed bone indicating recent turnover activity. The X-ray diffraction and chemical data determined that the physical characteristics of the mineral in the OVX vertebrae did not differ from the control group.

The results of the present study indicate that TBV is not different between experimental and control groups due to the contribution of substantial osteoid to this volume in the OVX group. This suggests that some strong effort at recovery has ensued beyond the acute stages post-OVX. This observation becomes particularly intriguing when a study involving similar bone mineral studies and histomorphometry addressing the effects of ovariectomy in the same monkey population identified the

cortical bone (femora) as being victim to this treatment in terms of having less dense bone and demonstrating active high turnover activity characteristics [38]. That bone tissue is targeted differentially by the same treatment, in the same population, and over the same course of time may bring us closer to understanding the pathophysiology of bone loss in trabecular bone compared with cortical bone, which to date has been classified as Type 1 and Type 2 osteoporosis.

This study provides novel quantitative and qualitative information about trabecular bone tissue and the status of the bone remodelling system as affected by a lack of ovarian derived female sex steroid hormones over a 2-year period (equivalent to 6 human years) in a young non-human primate. Characterization of the physical-chemical qualities of the mineral phase of trabecular bone, in addition to detailed histomorphometric findings shows that the trabecular bone in the vertebrae of the young, non-human primate is susceptible to the acute effects of ovariectomy but has demonstrated the potential to return to values similar to controls in terms of bone mineral quality and quantity.

5. Acknowledgements

We thank Doctor M. Adams and Doctor M. Jayo for providing the bones. This research was supported in part by NIH grants (HL 33492 and RR 00919), the MRC and the Arthritis Society of Canada, and The Royal Canadian Legion.

ABSTRACT

Background/aim: In a previous study we showed that mandibular alveolar (trabecular) bone appears to be less sensitive to estrogen deficiency than the proximal tibia spongiosa. We hypothesized that the mechanical loading of the alveolar process during mastication may protect the alveolar bone from the detrimental effects observed in other skeletal sites. To test this hypothesis we compared the effect of ovariectomy on the mandibular alveolar bone and the proximal tibia spongiosa of rats fed either a normal (hard) or a soft diet.
Methods: Forty six-month-old female Sprague–Dawley rats underwent trans-abdominal ovariectomy (OVX) or sham operation (SHAM). Half of the animals received their food in the usual form of pellets (hard consistency), while the other half received a soft, porridge-like, isocaloric diet of identical composition (soft consistency). Micro-computed tomographic histomorphometry was used to evaluate the trabecular micro-architecture. A two-factor analysis of variance was used to test for effects and interaction of ovariectomy and/or soft diet.
Results: OVX had a significantly negative effect on the proximal tibia spongiosa (all parameters under study except trabecular thickness; $p<0.001$) and on the mandibular alveolar bone (trabecular number and spacing; $p<0.05$). Soft diet led to a further decrease of mandibular BV/TV ($p<0.01$), trabecular thickness ($p<0.05$) and number ($p<0.05$), as well as increase of separation ($p<0.001$). A significant interaction was observed between OVX and soft diet concerning the mandibular BV/TV, as well as trabecular thickness and spacing ($p<0.05$).
Conclusion: Normal (hard) diet limited significantly the negative effects of estrogen deficiency on mandibular alveolar bone micro-architecture four months after ovariectomy.

1. Introduction

Ovariectomy (OVX) in the rat results in bone loss and micro-architecture deterioration at various skeletal sites containing trabecular bone (Ammann et al., 1996) and is the most commonly used animal model of post-menopausal osteoporosis (for a review see Turner et al., 2001). As far as mandibular bone is concerned, there are some studies that have demonstrated a negative effect of OVX on the mandibular body (Elovic et al., 1995), condyle (Tanaka et al., 2000; Sakakura et al., 2001), and the alveolar process (bone surrounding the teeth) (Hara et al., 2001; Tanaka et al., 2003). However, many studies have failed to detect any effect or concluded that the effect of OVX on the mandibular condyle (Fujita et al., 2001; Yamashiro and Takano-Yamamoto, 1998; Tanaka et al., 1999) or the alveolar process (Johnson et al., 2002; Jiang et al., 2003) was significantly weaker in comparison to the long bones. Rat strain and site of measurement might partially explain these discrepancies (DeMoss and Wright, 1998).

Mastication is the first step in the process of digestion and is meant to prepare the food for swallowing and further processing in the digestive system (Van der Bilt et al., 2006). During mastication the bite force is regulated by central control mechanisms and sensory feedback from peripheral mechanoreceptors according to the size and the texture of food (Woda et al., 2006; Kohyama et al., 2003; Van der Bilt, 2010) in order to produce a smooth and efficient break down of the bolus before swallowing (Peyron et al., 2004; Mishellany et al., 2006). Food hardness is sensed during mastication and affects the masticatory force (Kohyama et al., 2004), the jaw muscle activity (Agrawal et al., 1998), and the

mandibular functional movements (Peyron et al., 1997). Animal experimental studies have shown that changes of the masticatory muscle function induced by soft diet lead to a reduction of masticatory muscle strength and functional capacity (Kiliaridis and Shyu, 1988). The masticatory muscles have broadly distributed origins and insertions on the skull and mandible, while most muscle fibers attach to internal aponeuroses rather than to the bones directly (Herring, 2007). Masticatory hypofunction has been shown to result in changes of the mandibular morphology in both growing (Mavropoulos et al., 2004a, 2004b) and adult (Mavropoulos et al., 2004a, 2004b) rats.

There is significant evidence that the association between systemic and oral bone loss is very weak (Kribbs et al., 1989; Krall et al., 1996; Streckfus et al., 1997; Jeffcoat et al., 2000; Bollen et al., 2004; Wactawski-Wende et al., 2005; Ejiri et al., 2008). In a previous study we demonstrated that mandibular alveolar (trabecular) bone is less sensitive than the proximal tibia to estrogen-deficiency induced osteoporosis in the rat (Mavropoulos et al., 2007). We hypothesized that this might be due to the mechanical loading of the mandibular bone during mastication, which has been shown to influence the mandibular bone density and micro-architecture in the growing (Mavropoulos et al., 2004) and the adult rat (Mavropoulos et al., 2010). To test this hypothesis we compared the effect of estrogen depletion (ovariectomy) and reduced masticatory loading (soft diet), as well as their interaction, on the mandibular alveolar bone and the proximal tibia spongiosa in adult rats.

2. Materials and methods

2.1. Animals and protocol

Forty six-month-old female Sprague–Dawley rats (Novartis, Basel, Switzerland) underwent trans-abdominal ovariectomy (OVX) or sham operation (SHAM), and were pair-fed isocaloric hard or soft diet (Novartis Nutrition, Bern, Switzerland). For half of the animals the food was given in the usual form of pellets (hard consistency), while for the other half it had a soft, porridge-like, consistency. The experiment lasted 16 weeks. Body weight was recorded every week. Blood was collected at the tip of the tail and 12 hours urine collections were obtained at the end of the study in metabolic cages. The study received the approval of the Animal Ethics Committee of the Faculty of Medicine of the University of Geneva.

2.2. Microtomographic histomorphometry by microcomputed tomography (μCT)

Micro-computed tomographic histomorphometry of the secondary spongiosa of the proximal tibia and the mandibular alveolar process was performed with a high-resolution μCT system (μCT 40; Scanco Medical AG, Bassersdorf, Switzerland) as previously described (Muller et al., 1996; Mavropoulos et al., 2004a, 2004b). Three-dimensional images of each proximal tibia and hemi-mandible were acquired with a voxel size (nominal resolution) of 16 μm in all spatial directions. Samples were secured in a cylindrical sample holder in air. Resolution was set to medium (500 projections with 1024 samples each). The trabecular and cortical parts of the tibia were separated with semi-automatically drawn contours. For the rat hemi-mandible (Fig. 1A), the volume of interest (VOI) was drawn on a slice-based method starting from the first slice containing the crown of the first molar and moving dorsally one hundred slices in the area of the alveolar process between the roots of the molars and the root of the incisor. Trabecular bone was carefully contoured on the first and the last slice, while the intermediate slices were first interpolated by morphing (Fig. 1B). Each slice was subsequently visually inspected and the contour was modified where necessary.

Micro-tomographic histomorphometric indices were calculated directly from the binarized VOI. Total volume (TV) was the volume of the whole sample examined. Bone volume (BV) and surface (BS) were calculated using tetrahedrons corresponding to the enclosed volume of the triangulated surface. Mean trabecular thickness (Tb.Th.) was determined from the local thickness at each voxel representing bone. Trabecular number (Tb.N.) was calculated by taking the inverse of the mean distance between the middle axes of the structure. The complete acquiring procedure was repeated a further four times with four mandibles chosen at random to calculate the coefficient of variation (CV; range, 1.57–2.51% for Tb.Th and BV/TV, respectively).

2.3. Biochemical parameters

Plasma osteocalcin and IGF-I were measured using radioimmunoassay with reagents from Biomedical Technologies (Stoughton, MA, USA) for the former and with a kit from Nichols Institute (San Juan Capistrano, CA, USA) after extraction by acid-ethanol and cryoprecipitation for the latter. Total urinary deoxypyridinoline was determined after acid hydrolysis using a kit from Metra-Biosystems (Mountain View, CA, USA).

2.4. Statistical analysis

All data are presented as mean and standard error of the mean (in parentheses). A two-way analysis of variance was employed to investigate the main effects of both experimental factors (OVX and soft diet) as well as their interaction. All statistical analyses were performed using the SPSS statistical package (SPSS 19.0.0, SPSS Inc., IBM Corp., USA). A result was considered as statistically significant at $p < 0.05$.

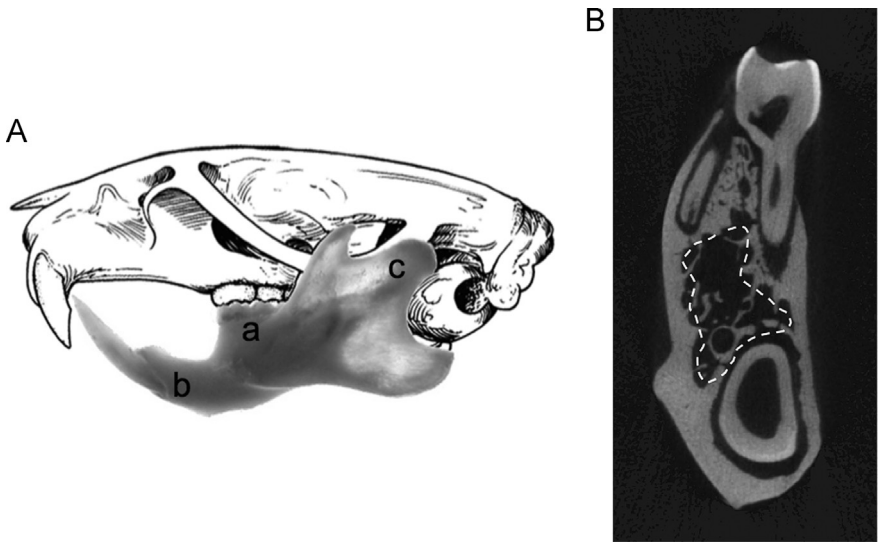

Fig. 1. (A) Lateral photograph of a rat mandible superimposed on a drawing of the skull (a) the alveolar process that houses the molars and is the equivalent of the alveolar process in humans; (b) not to be confused with the incisor alveolar process, which does not exist in the human mandible; and (c) the condylar process, which articulates with the skull, and (B) micro-CT scan (the dashed line represents the volume of interest (VOI) as it appears in one layer).

3. Results

3.1. Body weight and biochemical parameters (Table 1)

At the end of the experiment no weight difference was observed between the animals fed the normal (hard) and those fed the soft diet, indicating a similar nutrient absorption with both diets. OVX was associated with higher weight ($p=0.001$) at the end of the experiment despite a strict pair feeding, as expected.

Ovariectomy led to increased levels of serum IGF-I ($p<0.001$), serum osteocalcin ($p<0.01$), and urinary deoxypyridinoline ($p<0.001$). Soft diet was associated with lower levels of serum IGF-I ($p<0.05$) and serum osteocalcin ($p<0.01$). Plasma IGF-I at sacrifice was significantly correlated to the weight of the animals ($R^2=0.57$; $p<0.001$).

3.2. Micro-tomographic histomorphometry of the proximal tibia spongiosa (Table 2)

Ovariectomy led to a deterioration of all histomorphometric parameters of the proximal tibia spongiosa under study ($p<0.001$) with the exception of trabecular thickness that increased ($p<0.001$). Soft diet did not have any effect on the proximal tibia spongiosa.

3.3. Micro-tomographic histomorphometry of the mandibular alveolar bone (Tables 3 and 4)

Overall, ovariectomy had a negative effect on trabecular number ($p < 0.05$) and spacing ($p < 0.05$). Soft diet led to a deterioration of mandibular BV/TV ($p < 0.01$), as well as trabecular thickness ($p < 0.05$), number ($p < 0.05$) and spacing ($p < 0.001$).

A significant interaction (synergy) was observed between OVX and soft diet concerning the mandibular BV/TV ($p < 0.05$), as well as trabecular thickness and spacing ($p < 0.05$). The delta percentages of all histomorphometric parameters under study between the sham and the ovariectomized animals for both normal and soft diet are presented in Table 4. Ovariectomy led to a deterioration of BV/TV and trabecular thickness, number and spacing, only in those animals fed the soft diet.

4. Discussion

In the present study, we showed that normal (hard) diet protected (at least partially) the rat mandibular alveolar bone from estrogen-deficiency induced osteoporosis. Among the ovariectomized animals, those fed a soft diet (masticatory hypofunction) underwent a significant deterioration of the mandibular alveolar bone architecture, while those fed a normal (hard) diet preserved their mandibular alveolar bone almost completely four months after the operation.

During the same period of time the proximal tibia spongiosa in both groups of animals displayed a substantial and similar bone loss. As expected, there was no effect of the diet consistency at this skeletal site, which indirectly attests to the quality of pair feeding and nutrient absorption. Ovariectomized animals were found, as expected, to have higher body weight, serum IGF-I and osteocalcin, as well as urinary deoxypyridinoline. This IGF-I increase has been repeatedly observed after ovariectomy in both rodents (Ammann et al., 1996) and humans. The effect of ovariectomy on tibia bone microarchitecture and plasma IGF-I is fully in agreement with previous studies (for a review see Turner et al., 2001). These effects of ovariectomy observed at the level of the proximal tibia are in contrast with the moderate effects observed at the mandibular alveolar bone of the same animals.

In the present study, OVX provoked only a small reduction of alveolar trabecular thickness and a small increase of alveolar trabecular spacing. In the rat, the trabecular bone of the alveolar process is approximately three times thicker compared to the proximal tibia (Mavropoulos et al., 2007). This possibly means that further bone loss is needed before thinning of the trabeculae leads to structural deterioration of the mandibular alveolar bone. This experiment lasted 16 weeks. It is possible that a longer exposure to OVX might have had a greater impact on the alveolar bone. In humans, trabecular bone of the alveolar process is approximately two times thicker than that of the proximal tibia (Moon et al., 2004; Ding and Hvid, 2000). It is noteworthy that the mandibular bone arises from a different embryonic germ layer (neuroectoderm) compared to bone of the axial and appendicular skeleton, which arise from mesoderm.

The dentition is an integral part of the masticatory system, which prepares food for deglutition. The teeth form the occlusal area where the food particles are physically broken down into smaller particles to facilitate swallowing and digestion (Van der Bilt et al., 2006; Buschang, 2006). The number of processing cycles increases as foods become more difficult to chew. Adding fluid to a solid dry food has been shown to reduce both the muscle activity and the number of chewing cycles until deglutition (Van der Bilt et al., 2007). The teeth are subjected to the masticatory forces and they transmit them to the bone of the alveolar process through the periodontal ligament (PDL), which functions as a shock absorber. It is generally accepted that the PDL plays a crucial role in transferring occlusal forces from the teeth to the alveolar bone. In a recent study using finite element analysis it has been shown that the PDL affects not only the deformation and thus strain magnitudes of the alveolar bone around the teeth, but also the deformation of the whole mandible under masticatory stress (Groning et al., 2011). This unique biomechanical configuration is entirely different from any other skeletal site of the body. Of note, rat molars erupt normally, exactly like human molars, in contrast to rat incisors, which erupt continuously (Wise et al., 2001).

The alveolar bone, the bone process of the mandible housing the dentition, is subjected to heavy forces during mastication. The correlation between mandibular alveolar trabecular architecture, bone mineral density, and masticatory mechanical loading has been established in a previous study, where masticatory forces were modified through the alteration of food consistency in the adult rat (Mavropoulos et al., 2010). It was suggested that a reduction of the masticatory loading of the alveolar bone (soft food) leads to a reduction of bone mineral density, trabecular bone volume and thickness, as well as narrowing of the alveolar process itself. It seems that the mechanical loading during mastication directly influences the alveolar bone macro- and micro-architecture. In the present study, we clearly demonstrate that the mandibular alveolar bone resists more than the tibia spongiosa to estrogen deprivation, because of the anabolic effect of the mastication-induced bone strain. In a previous study on growing rats on a calcium deficient diet, it was concluded that normal masticatory function (hard diet) led to a higher bone apposition rate and better-organized trabecular system compared to animals fed a soft diet (Kiliaridis, 1989). The protective effect of exercise during estrogen deprivation has been demonstrated in a number of previous studies (for a review see Iwamoto et al., 2005).

In the rat, the forces developed during incision have been estimated to range from 2 to 25 N (but mainly below 8 N) depending on the hardness of the food, but are of relatively short duration (40–160 ms). During chewing (and swallowing), however, forces are of lower magnitude (4 N) but of a relatively long duration (160–680 ms) (Robins, 1977; Nies and Ro, 2004). In normal function the mechanical loading of the tibia is inferior to that of the alveolar bone during mastication. For most vertebrates, long bone peak functional strains range from less than 1000 microstrain (με) during walking to between 2000 and 3200 με for more vigorous activities (Ehrlich and Lanyon, 2002). Finite element data suggest that alveolar bone strain during mastication can reach up to 4000–6000 με depending on food consistency (Knoell, 1977; Daegling and Hylander, 1997).

Bone formation is influenced by strain rate, frequency, amplitude, duration, and interpolation of rest periods (Ehrlich and Lanyon, 2002). It is known, for example, that bone cells respond better to a mechanical environment dominated by high strains changing at fast rates and presented in unusual distributions (Mosley and Lanyon, 1998; Nordstrom et al., 1998; Skerry, 2008). During each chewing session that lasts a few minutes, alveolar bone strain goes from almost zero to 4000 με and back again to almost zero in 160–680 ms. When the food is available ad libitum, eating frequency has been estimated to be around 30 times per day in the rat (Konig et al., 1968).

A recent study on Sprague Dawley rats investigated the effect of estrogen deficiency (OVX) on the indentation viscosity of mandibular and vertebral bone tissue using nanoindentation (Kim et al., 2013). Indentation viscosity was higher for the mandibular bone compared to the vertebral bone. The OVX mandibular bone tissue had a greater viscosity than both the sham groups and the OVX vertebral bone. It has been suggested that bone tissue with high indentation viscosity can absorb more energy under loading (Isaksson et al., 2010). Ovariectomy has been shown to result in a reduction of mineralization and osteocyte density, in contrast to soft diet, which led to a significant increase of mineralization density in Sprague Dawley rat alveolar bone (Rawlinson et al., 2009; Kingsmill et al., 2010). Although one should be cautious interpreting these findings, they provide an insight into why estrogen deficiency has less effect on mandibular bone than on other load-bearing bones.

The reason why osteocalcin and IGF-I plasma levels were lower in those rats fed a soft diet is not clear. A different protein intake between the two groups is excluded since the rats were pair fed. One hypothesis is that mechanical stimulation of the mandible during mastication may induce a production of osteocalcin that influences its plasma levels. It has been demonstrated that mechanical loading results in both an increase of bone formation (Chambers et al., 1993) and of bone IGF-I mRNA expression (Lean et al., 1995). Another hypothesis is related to the fact that the duration of food consumption is longer to those animals fed the hard diet. Since IGF-I was measured only 4 hours after feeding the rats, its plasma levels might be differently influenced. It is possible that its plasma levels peaked earlier in the soft diet group.

In the present study, normal (hard) diet limited significantly the negative effects of estrogen deficiency on mandibular alveolar bone micro-architecture four months after ovariectomy. Combining this finding with the results of previous studies conducted by the same research group, it can be deduced that the alveolar bone is partially protected due to the anabolic effect of high bone strain during normal masticatory function. In those animals with a masticatory hypofunction (soft diet), ovariectomy provoked a significant amount of bone loss and micro-architecture deterioration. This study underlines the specificity of the alveolar bone behavior to classic bone loss stimuli and helps better understand the pathophysiology of mandibular osteoporosis.

Conflict of interest statement

The authors have no conflict of interest.

Acknowledgments

The authors express their warmest gratitude to Isabelle Badoud and Séverine Clément for their indispensable technical assistance in conducting this investigation.

Mare and Foal Behavior

Sue M. McDonnell, MA, PhD

Inadequate maternal behavior of mares and mare and foal bonding problems are rare in natural social environments. Management that best accommodates natural behavior can help avoid or overcome problems in domestically managed horses. Author's address: University of Pennsylvania School of Veterinary Medicine, New Bolton Center, 382 West Street Road, Kennett Square, PA 19348; e-mail: suemcd@vet.upenn.edu. © 2012 AAEP.

1. Introduction

A basic understanding of normal and problem mare and foal behavior under natural and domestic social conditions can be valuable to the veterinary practitioner for (1) education of clients to manage foaling to best support normal mare and foal bonding and foal development, for (2) providing professional assistance in instances of inadequate or aberrant maternal behavior or mare and foal bonding problems, as well as for (3) advising on common questions concerning normal and abnormal foal behavior during development, early intensive handling, and least-stress weaning of foals.

Parental Behavior in Horses

Studies of mare and foal behavior under natural social and environmental conditions as observed in various free-roaming and semiferal populations with original references have been summarized elsewhere.[1] In brief, care and protection of the neonate and developing foal involves principally the dam and her harem stallion but also includes some contributions as needed from other adults and even older juveniles within the natal band in the form of assisting with retrieval of a lost or stranded foal or directing a neonate to the dam, should it attempt to nurse a herd mate.

Normal maternal behavior includes attention to fetal fluids and membranes during and immediately after parturition and positive attention to the neonate, including olfactory investigation and Flehmen response, licking, nuzzling, avoiding walking on, keeping intruders from approaching or interacting, allowing and facilitating sucking, and standing guard near or with head and neck over the foal whenever it is recumbent. Attention to the fetal membranes and fluids is common, but ingestion of the afterbirth as is common in some species is rare.[2] Under natural conditions, the strategy of horses for dealing with the predator-attracting birth fluids and membranes is to move away from the birth site as soon as possible. The harem stallion can often be seen encouraging the foal and mare to move on to a fresh site as soon as the foal stands, even before nursing.

The foal's behavior appears to play a role in stimulating the dam's response and vice versa. In its first coordinated movements immediately after birth, even before standing, the foal appears to orient toward the dam, reaching for her head and appearing to seek nose-to-nose contact at first. Upon standing, the foal appears to be instinctively attracted visually to follow horizontal edges at nose height, which in nature is usually only the dam's

NOTES

abdomen. Along with assistance of the dam's reverse parallel orientation to the foal and likely olfactory cues as the foal approaches the udder, this instinctive behavior brings the foal's lips to the flank and udder.

Under domestic management, care of the foal is generally limited to the dam. Detailed descriptions of mare and foal behavior under domestic conditions can be found in publications of Dr. Katherine Houpt[3] and her student Dr. Sharon Crowell-Davis.[4] When isolated or when housed or pastured with unfamiliar horses, some individual dams appear hypervigilant and demonstrative in their role of protection of the neonate, perhaps due to lack of the social support for this role within a band under natural social conditions. In pasture groups of domestically managed horses, the behavior of other mares is typically either ambivalent or positive toward a dam and neonate. Gelding herd mates may show protective behavior of the dam and/or foal, as under natural social conditions a harem stallion would guard and protect his band. Most geldings, like stallions, are especially protective and tolerant of foals.

Mare and foal bonding problems have been detailed in Grogan and McDonnell.[5] Briefly, there are at least six distinct types of problem.

(1) Good maternal protectiveness misunderstood as aggression toward foal. Probably because of the domestic practices of isolation and confinement for foaling, some dams appear especially stressed concerning foal protection and care. When confined in small or "trapping" spaces with poor footing and obstacles, foals can easily be injured by a mare trying to position herself between her foal and a threat. For example, if her hay is fed at the rear of a stall, a dam with strong instantaneous reaction to threats may inadvertently trample or bump a foal into an object in the process of responding to a threat at the front of the stall. Adequate space and facilities with minimal provocation of protective behavior is recommended until protectiveness usually naturally wanes over the period of 3 days to 2 weeks.

(2) Ambivalence. Primiparous mares, as well as weak or painful mares, may have delayed interest and response to the foal. The onset of intensely protective behavior is typically not immediate and may be first seen as late as 18 to 36 hours after parturition. Under natural conditions, other adults, including the harem stallion, appear to assist such dams with protection of the foal and with keeping the foal with the dam. Support of the foal in staying near the dam and supervised nursing is recommended, with typically a good prognosis for onset of adequate to excellent maternal behavior and bonding with the foal within 2 to 5 days.

(3) Fear of the foal. Some mares, almost always primiparous, react to their neonate with fear behavior as some horses may react to species such as swine or camelids, with which they have not been exposed. Positive reinforcement–based systematic acclimation, similar to what is effective in helping a horse overcome fear of other new objects, procedures, or situations, is recommended, with typically a good prognosis for eventual acceptance of the foal adequate for maintenance of the pair.

(4) Nursing only avoidance or aggression toward foal. Most often this is judged to be due to sensitivity at the flank or udder, sometimes in association with obvious udder discomfort. Relief of udder discomfort and positive reinforcement–based acclimation to touch of the flank and udder as well as supervised nursing or milking and bottle-feeding at the udder are recommended until the foal is accepted.

(5) Savage attack. Just as some stallions intermittently attack people, some mares that show otherwise good maternal behavior, intermittently attack their foal. Attacks can involve biting, kicking, thrashing by the crest of the neck, and stomping in a sustained manner similar to that of a horse killing a small mammal. If the foal survives, the mare typically returns to good maternal behavior and then repeats at some later date. In confirmed cases of savage attack, immediate separation is recommended. It can be expected that the mare may repeat with subsequent foals.

(6) Foal stealing. A near-term pregnant mare may steal a neonate from a weaker mare. When the thief mare foals, she typically abandons the stolen foal in favor of her own. Foal stealing is rarely observed in horses, except under crowded conditions and synchronization of foaling, for example, induced parturition in feed-lot conditions.

Orphan Foals

Use of a foster mare is generally considered the best method for meeting the nutritional and behavioral needs of an orphaned foal. Foster mares can include local mares that have recently (within 24 hours) lost a foal or occasionally one that will accept a second foal, open mares hormonally prepared to lactate and to accept foals,[6] and professional "nurse" mares managed by farms with systems of hand-rearing the foals of the nurse mares. If a horse or pony mare is not available, nanny goats typically accept nursing of a foal (Fig. 1), and typically provide better for the nutri- F1
tional and behavioral needs better than hand-feeding. Most foals can be trained to drink from a bucket or tub (Fig. 2). Training can be accom- F2
plished by drawing the foal's muzzle into shallow pail of milk, with a finger or nipple in the foal's mouth. In healthy foals, withholding feedings for several hours before bucket feeding attempts may increase appetite and acceptance. Groups of foals have also been successfully fed using an automatic calf-feeding machine, which provides a constant supply of fresh milk replacer through a nipple mounted on the wall.[7] To avoid behavior problems in hand-reared foals, which can be generally described as overly bonded to people to the extent of sexual response to humans, it is recommended to

provide as much social interaction with horses (or other animal companions such as donkeys or goats) and as little human contact as possible. Particularly, to the extent possible, feeding should not be done in the presence of people. Therefore bucket-feeding is far superior to hand-held bottle-feeding. Orphans reared together and bucket-fed in a "kindergarten," as shown in Fig. 3, typically develop normal behavior. Older foals can be observed performing some of the protection and emotional sup- F3

COLOR

port responses typical of dams. Geldings or open mares without foals in nearby paddocks or within a kindergarten can provide additional social support for orphan foals.

Early Intensive Handling Protocols for Foals

A program of early organized positive handling of foals to introduce them to human contact and basic handling equipment and techniques, including transport, while they are young, is considered generally to be a wise practice. Considerable debate continues on the best timing and the most efficient and effective procedure with least likelihood of adverse effects due to "technique failures." In general, the younger and less strong the foal, the easier to safely confine and restrain it for organized and positive introduction to human handling and acclimation to restraint and specific procedures. There is evidence that the foal's experience as a bystander when its dam is handled in a positive manner can be a positive influence on its own acceptance of human handling (Henry et al[8]).

Normal Early Foal Behavioral Development

Based on observations of both semiferal and domestic foals, Grogan and McDonnell[5] proposed a scoring system for early foal development based on an expanded list of behaviors reflecting early development. Table 1 outlines their neonatal early development (NED) scoring system. Foals born in more natural environments such as at pasture and in semiferal social conditions generally score higher than foals born indoors, isolated from the stimulation of herd mates or on artificial surfaces that obviously delay the ability to stand and move. T1

Least-Stress Weaning

In recent decades, evidence has accumulated that early or abrupt weaning poses considerable risk to the foal of developing gastric ulcers, losing condition, and showing behavioral signs of stress that together can result in interruption of thriving and in some instances can predispose the foal to life-long behavior problems such as stereotypies and separation anxiety (Waran et al[9]). Current recommendations for least-stress weaning include separation from the dam no younger than 5 or 6 months of age, ensuring that the foal has developed behavioral signs of independence from the dam and social interest in other horses, and ensuring that the foal

Table 1. Neonatal Early Development (NED) Scoring Inventory

Behavior	Slower Than Usual = 0	Average to Low Normal = 0.5	High Normal = 1
Sternal righting	>5 min	3–5 min	<2 min
Shake response (head or body)	>10 min	3–10 min	<3 min
Attempts to stand begin	>30 min	10–30 min	<10 min
Stand successfully (with steps)	>60 min	30–60 min	<20 min
Standing udder-seeking	>10 min	3–10 min	<3 min
Suckle	>90 min	45–90 min	<45 min
Locomotor burst of speed	>2 h	1–2 h	<1 h
Circle dam at speed	>2 h	1.5–2 h	<1.5 h
Organized recumbency	>3 h	2–3 h	<2 h
Autogrooming	>3 h	2–3 h	<2 h
Organized gaits (walk, trot, plus)	>4 h	2–4 h	<2 h
Retreat from approaching human	>4 h	2–4 h	<2 h

From Grogan and McDonnell.[5]
Total score of greater than 10 is high normal, 4 to 6 is average to low normal, and less than 4 is slower than usual.

Orig. Op.	OPERATOR:	Session	PROOF:	PE's:	AA's:	4/Color Figure(s)	ARTNO:

is nutritionally independent from the dam before weaning. Methods that temporarily separate the foal from access to the udder while allowing direct contact or nearby visual contact with the dam for "emotional" support during moments of stress, typically appear least stressful to the foal. Udder covers or gradual introduction to separation from the dam at increasing distances and durations within sight and with known companions and/or some remaining adult mares is considered less stressful than abrupt permanent separation in isolation from known herd mates or from other horses.

The Equine Behavior Program at New Bolton Center is in its 25th year of support by the Dorothy Russell Havemeyer Foundation.

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

Acknowledgments

When asked by Juan and Jon to join them in editing this *Current Therapy* I accepted without much thought. The chance to work with authors, learn from reading and editing their manuscripts, and to publish a book with editors who were employed in private practice was a temptation too much to deny. Apart from the edification, it emphasized to me that specialization in private practice was so well accepted that authors and editors need not be restricted solely to those institutions of higher learning.

The *conception* and *gestation* of this *Current Therapy* was clearly Juan's domain. He decided on the necessity of this, *his progeny* to be introduced. He provided *the gametes* with the outline and list of authors and Jon and I were co-opted for the *fertilization* process. Early in gestation a problem with this *pregnancy* was identified wherein, after narrowly avoiding *early embryonic death*, it began to look like *elective termination or even abortion* was a possibility. After identifying and rectifying the problems and deficiencies, the gestation then became somewhat *prolonged*.

At last, successful delivery!

Angus O. McKinnon

We all owe a great deal to Jolynn Gower who was our managing editor from Elsevier. How she handled the difficulties of delinquent authors and editors with such level-headed aplomb was a surprise and an inspiration to us all. The only reason the project eventually came together was through her untiring efforts to keep us all on track.

CHAPTER 24

Selected Reproductive Surgery of the Broodmare

ANGUS O. MCKINNON
JAMES R. VASEY

The notes herein are a compilation of some of the techniques that are used at the Goulburn Valley Equine Hospital and are not intended as an exhaustive, heavily referenced treatise of all available techniques. No attempt has been made to discuss all reproductive techniques or conditions requiring intervention. The procedures herein work very well for us. However, readers should be aware that different methods are employed successfully by others. We would be grateful to those who have different ideas and experiences if they would communicate them by e-mailing Dr. McKinnon at aom@iinet.net.au. Many of the techniques presented are modifications of existing techniques, newer techniques, and/or areas we feel warrant special attention. We have assumed that readers are at least familiar with both relevant anatomy and standard documented surgical correction of reproductive-related problems.

Topics discussed have been dictated by our experience and preference for an individual or alternate technique when many techniques exist. A busy equine practitioner can expect to encounter most of these problems in any individual breeding season. Most of the techniques relate to restoring or improving fertility, and most are elective and require experience to make the correct diagnosis and therapeutic approach.

PATIENT SELECTION

In consideration of the client, patient, and general perception of our professional abilities as well as the merit of our interference, care should be exercised to select only those patients that are likely to respond favorably to surgery (Box 24-1). For example, it is pointless to perform a sophisticated, expensive surgery for vesico vaginal reflux if the mare has sustained chronic uterine damage and fibrosis that will render her infertile despite an excellent surgical outcome. Full reproductive evaluation is necessary before surgery in any candidate subjected to physical insults such as recto-vaginal lacerations and fistulas for longer than 1 year.

SEDATION AND ANESTHESIA

Most procedures are performed with the mare standing, using local infiltration or epidural anesthesia. Apart from minor procedures (Caslick's vulvoplasty), we prefer to have mares tranquilized and restrained in appropriate stocks such as facilities for cross tying and/or tail elevation. Tranquilization and analgesia are provided most commonly with intravenous (IV) detomidine (mg) and butorphanol (mg). Longer surgeries may require the repeated IV use of low doses of xylazine (100 mg). Cost and length of tranquilization/analgesia are important considerations. Some have other physiological effects, such as increased urinary output with xylazine. Detomidine provides excellent tranquilization and analgesia; however, effects are often still apparent hours after administration. Epidural anesthesia may be extremely effective; however, variation in response and individual susceptibility and time before appropriate anesthesia is obtained occasionally make it less rewarding than tranquilization and local infiltration for some of the procedures discussed here. Techniques for epidural anesthesia have been discussed elsewhere.[1] One word of warning: epidural administration of more than 7 to 9 ml of 2% local anesthetic to a 500 kg mare can be associated with loss of motor control to the hind limbs and recumbency. These mares are difficult to manage and may require support for 2 to 4 hours.

Epidural injection of xylazine for perineal analgesia has been reported to be very efficacious. A dose of 0.17 mg/kg (around 75-100 mg in an average horse) was as effective as local anesthetic agents for analgesia and had nil or minimal effects on depression of motor nerves in the lumbosacral intumescence. Another advantage was demarcation of the area of analgesia with an area of sweating (dermatome) that was consistent both temporally and topographically.[2] In our experience the perineal dermatome is not always obvious. In addition it takes around 35 to 40 minutes for good analgesia to be recognized associated with xylazine epidural anesthesia. Currently we prefer to use a combination of xylazine (70 mg) and lidocaine (60 mg [3 ml]), q.s. saline to 10 ml for most horses. With this regime, loss of tail tone has occurred associated with a successful "block" within 5 to 10 minutes and surgery generally has begun by approximately 30 to 45 minutes post administration. Our most common method of epidural anesthesia is to begin with the infusion of 1 ml of local anesthetic through a 25 gauge needle subcutaneously above the first moveable coccygeal/sacral joint (usually C1 and C2). Next, a 38-mm, 18-gauge needle (bevel forward and introduced at 45 degrees) that has a small amount of fluid left to create a meniscus on the needle hub is introduced through the

Box **24-1**

Considerations for Favorable Response to Surgery

The probability of a successful outcome (i.e., pregnancy, live foal, etc.) must be evaluated with regard to the following:

- Severity and nature of the problem
- Breeding history of the mare
- Value of the mare and/or offspring (commercial or sentimental)
- Cost of the procedure
- Mare age
- Fertility of the stallion
- Availability and suitability of sophisticated breeding techniques such as AI, ET, etc.
- Long-term value of interference (i.e., temporary or permanent improvement)
- General health of the candidate
- Perpetuation of heritable conditions
- Insurance and informed client consent
- Ethical considerations
- Experience of the veterinarian
- Quality of on-farm management

local bleb. Recognition of the fluid being aspirated into the needle infers correct placement, and the appropriate amount of solution is injected slowly into the epidural space whilst continually evaluating the ease of administration to ensure that the needle tip is still in place.

Occasionally epidural anesthesia is difficult to achieve (infusion outside the spinal cord before proper epidural placement, hemorrhage through the needle and tissues, anatomic abnormalities and fat horses). Provided local anesthesia can be obtained by infiltration without adverse affects on wound healing, we prefer to perform surgery without the epidural and provide incremental IV administration of xylazine (i.e., 50-100 mg to already tranquilized patients when or if minor surgical discomfort is recognized).

In some instances we have been able to identify correct epidural placement by injecting the anesthetic slowly while moving the needle until there is an obvious change in the amount of pressure needed to advance the solution. These situations are usually associated with a mare with abnormal anatomy (i.e., after a traumatic foaling) and lack of movement of fluid in the needle hub.

VESTIBULE AND VULVAL LIPS

Pneumovagina

There are 3 barriers to aspiration of air and contaminants into the cranial reproductive tract.

1. The vulval/vaginal lips
2. The vestibular sphincter
3. The cervix

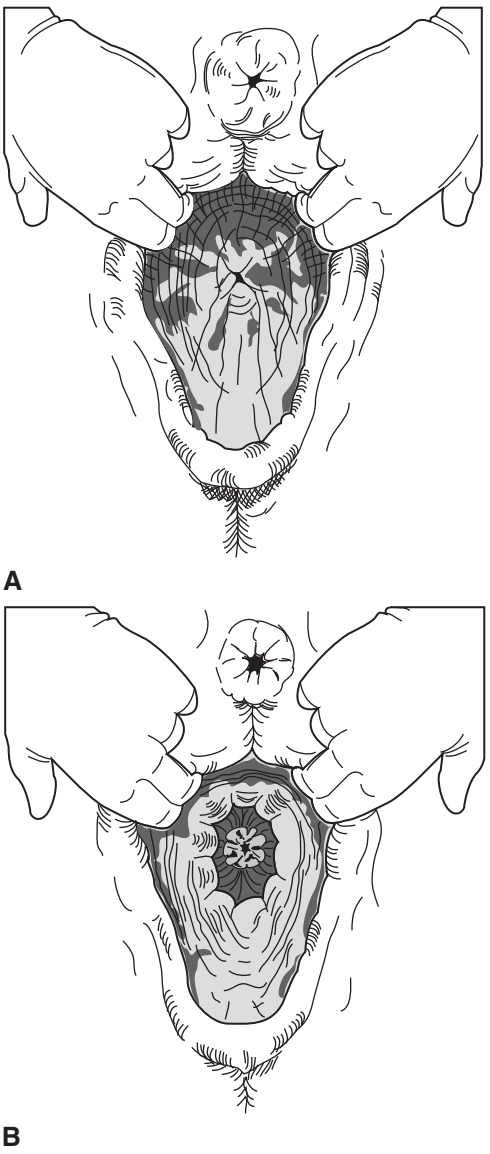

Figure 24-1 **A,** Retraction of vulval lips reveals an intact vestibular sphincter. **B,** Retraction of vulval lips reveals an open vestibular sphincter that is likely associated with pneumovagina.

It would appear that the vestibular barrier is more important than previously recognized; however, when any of these protective barriers are rendered incompetent, contamination and concomitant vaginitis, cervicitis, and metritis may result. Pneumovagina can result from faulty perineal conformation, previous injury to perineal tissues, or effects of poor body condition. Pneumovagina can also be iatrogenic (i.e., reproductive examination or breeding).

Recognition of potential candidates for pneumovagina are made from anatomical observations[3] (i.e., predisposition is associated with a low pelvis, tilted vaginal lips, and a sunken anus) (Figure 24-1). If possible, mares should be examined during estrus when the reproductive tract is relaxed. Parting the vulval lips results in loss of integrity of the vestibular sphincter and an audible ingress of air

to the cranial vagina. Recognition of foamy exudates from the vaginal lips may often be noted during rectal examination. In addition, ultrasonography has been used to visualize air in the uterus.[4] If in doubt after clinical evaluation regarding a mare's potential to aspirate air into the vagina, we recommend treating by surgery all mares that have been barren one or more breeding seasons, unless other causes of reduced fertility are obvious (i.e., stallion, farm management).

Caslick's Vulvoplasty

Caslick's vulvoplasty was first described by Dr. E. A. Caslick in 1937 and involves apposition of the vulval lips.[5] Local anesthesia of vulval lips, removal of a thin portion of mucosa from the mucocutaneous junction, and apposition of the cut edges is simple, quick, and effective. Length of apposition is determined by height of pelvis relative to vulval lips. In general the join should continue to a point at least 3 to 4 cm below level of the pelvis, and approximately 3 cm should be left unopposed to allow for urination. If this is not possible, other surgical techniques (see below) may be necessary.

Points for consideration

- For suture material we use 0 catgut (Metric 4) on a continuous spool. The benefit of gut is that it is gone or degraded by either pregnancy testing (~15 days) or the next breeding cycle (if the mare is empty). Other materials that are nonabsorbable or delayed-absorbable may damage the stallion if the mare is rebred.
- For suture pattern, a simple continuous pattern is quicker and just as effective as a simple pattern interrupted. However, failure to appose the deepest layers of the exposed tissues may result in fistula formation. Failure to exit/enter in the middle of the cut tissue caused by taking bites too deep will result in wound breakdown.
- Method of mucosa removal:
  - Tissue should be removed from the mucosal surface of the vestibule, not the skin of the vulva lip.
  - Removing too much will result in fibrosis and difficulty for the next veterinarian (Figure 24-2, *A*).
  - If multiple procedures are performed in 1 season, freshening with a scalpel blade is sufficient, provided a careful suture pattern is placed (Figure 24-2, *B*).
  - Incision with a scalpel blade rather than mucosal removal is recommended for maidens (i.e., race mares) (Figure 24-2, *C*). This results in a thinner join that is easily opened at the breeding farm.

Postoperative treatment

- Frequent rectal palpation within 2 weeks will result in fistula formation.
- Remove (open) 2 to 3 weeks before anticipated foaling.

Variations. Placement of a breeding stitch (usually doubled heavy gauge suture material or umbilical tape) will save unnecessary replacement and facilitate breeding and some manual vaginal manipulations for treatment (Figure 24-2, *D*). Care is needed with natural service to prevent penile trauma. We routinely treat or bred (AI) mares by passage of an infusion pipette into the vagina (past the vestibular sphincter) and use rectal manipulation of the pipette through the cervix similar to, but with a little more difficulty than cattle.

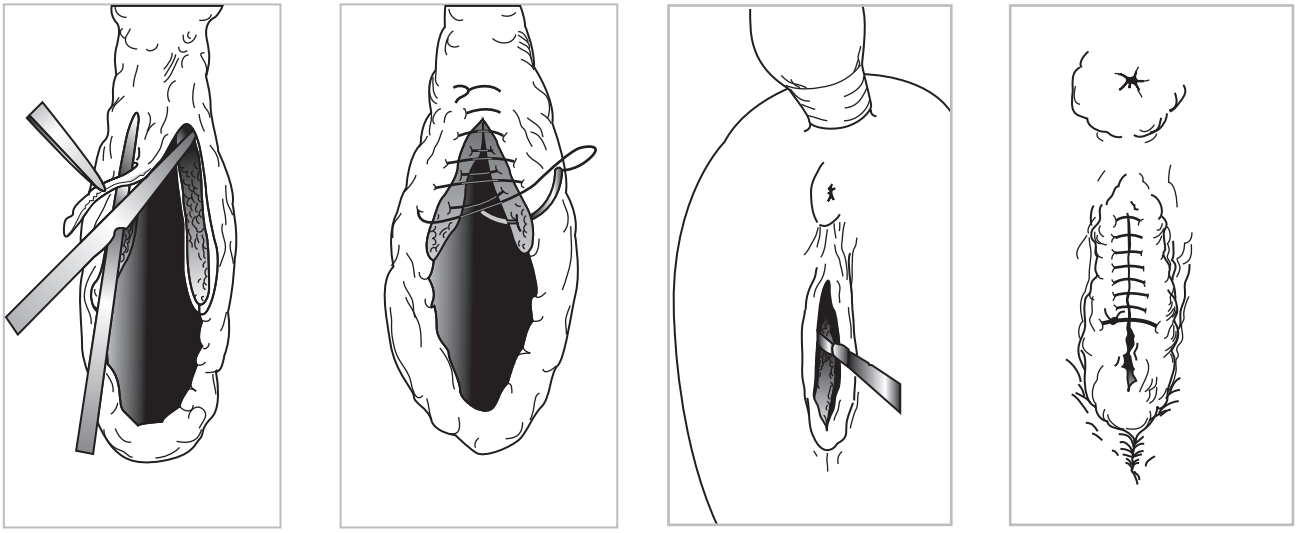

Figure 24-2 **A,** Careful trimming of the mucocutaneous junction without removing skin from the vulval lips facilitates many more identical surgeries. **B,** Simple continuous suture is all that is necessary, but suture placement will help avoid fistulas. **C,** A scalpel blade is recommended for the first Caslick a mare has, especially maidens in work. **D,** A breeding stitch may be useful in preventing the Caslick from opening with vaginal examination or natural service.

Episioplasty

This procedure is used in cases with more severe anatomic abnormalities where the Caslick vulvoplasty is ineffective and in mares with extensive or repeated second-degree perineal lacerations. Technically the previous surgery is an episioplasty as well; however, we use the term to describe the more extensive procedure previously referred to as (1) a deep Caslick, (2) the Gadd technique, or (3) a perineal body reconstruction.[6] The procedure is designed to restore some degree of function to the perineal body. (Figure 24-3)

The surgery is performed on the standing mare with local anesthesia. Visualization is improved by good retraction and light sources. We prefer to perform all perineal surgeries using a centrally mounted beam as the light source.

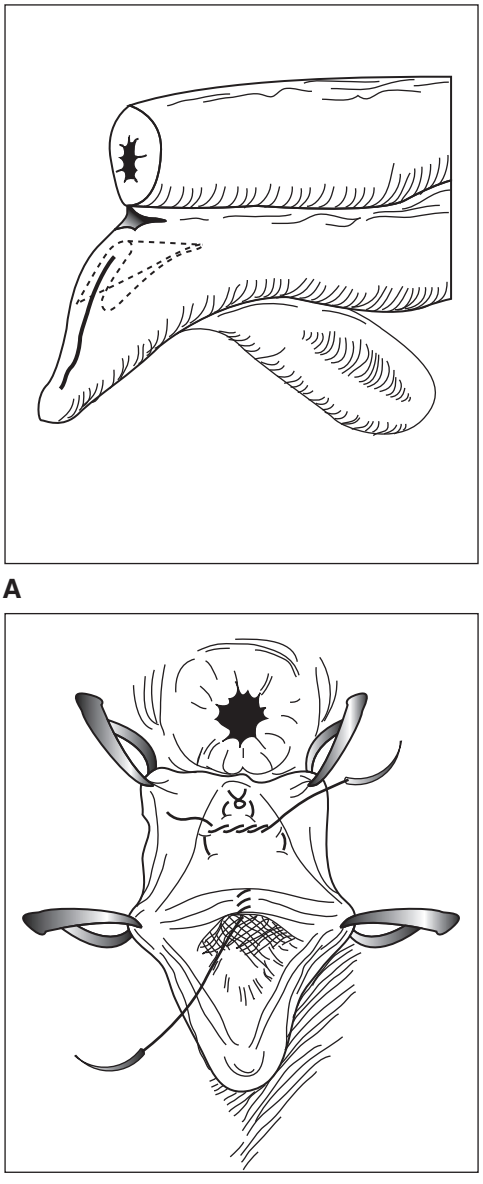

Figure 24-3 **A,** The *dotted lines* outline the area to be apposed with the formation of a new perineal body. **B,** The ventral layer of the perineal body consists of the vaginal mucosa. The perineal body is created from apposition of the vaginal mucosa where the tissue has been denuded.

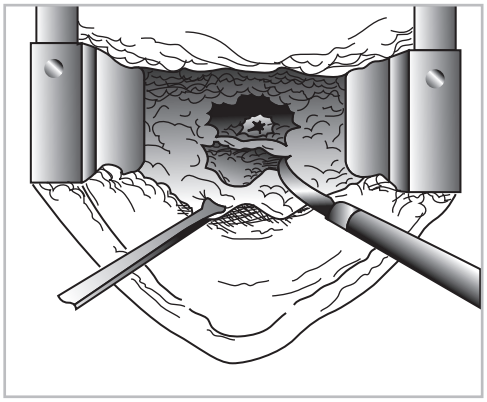
A triangular portion of the dorsal caudal vestibule is removed from both sides. Apposition of the ventral borders of the incision and obliteration of the potential space above result in an increase in the size of the perineal body and a decreased propensity of the vestibule to create negative pressures.

The ventral borders are apposed with a continuous absorbable suture (2/0 vicryl) and dead space with single interrupted sutures. The mucocutaneous junction is closed similar to the Caslick procedure.

Points for consideration

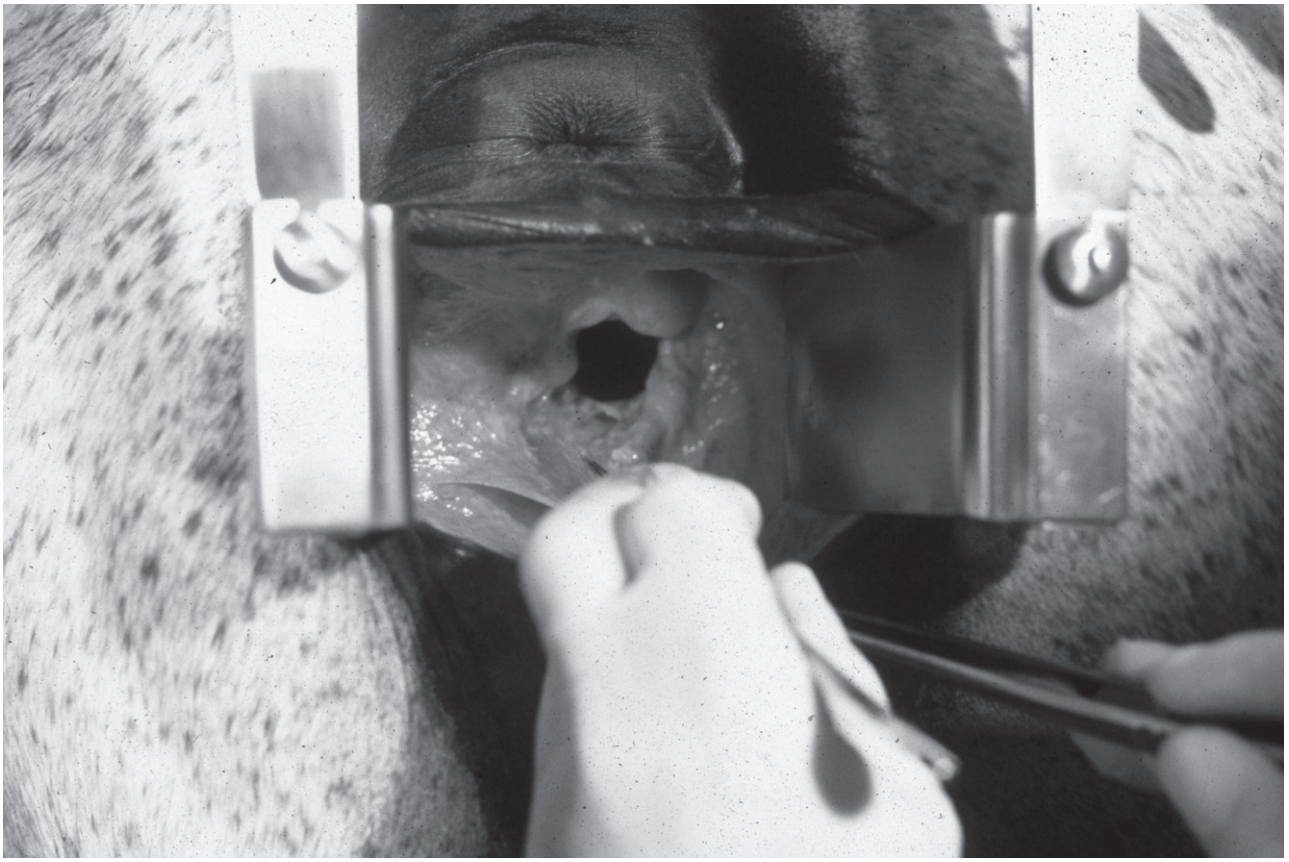
- The procedure appears most beneficial when combined with a perineal body transection (see below).
- Failure to "open" the dorsal vestibule and vulval lips before foaling (2-3 weeks) may result in severe perineal laceration.
- The surgery usually takes longer (30-40 minutes) than expected (10-15 minutes) and is sometimes associated with significant and annoying obscuring hemorrhage.

Urovagina



Pooling of urine in the vagina is a problem for a variety of reasons. In 1985 Jay Belden, then of Fossil Creek Farms, showed me his technique for urovagina. Before this time, both of us had tried other described techniques and were not particularly happy with the outcome. After approximately 34 surgeries between us using Jay's technique, we decided the technique was efficacious and should be presented. The resultant publication is summarized below.[4]

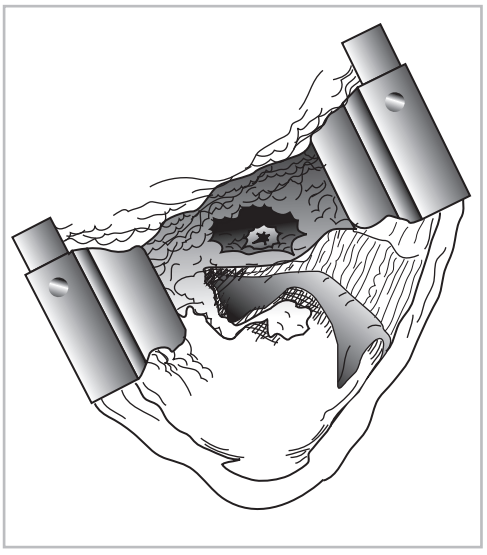
The midline caudal border of the transverse vaginal fold is grasped with Allis tissue forceps and retracted caudally toward the surgeon 2 to 4 cm cranial from the caudal border of the transverse fold. A horizontal transverse incision to the submucosa is made with a No. 12 Bard Parker blade (Figure 24-4). The incision is continued laterad and then slightly dorsad to the vaginal wall. The vaginal retractors are then repositioned, and a No. 20 Bard Parker blade is used to extend the incision from the lateral border of the transverse folds caudad. This incision is made approximately one half to two thirds of the distance between the vaginal floor and roof and is extended to the vulvar labia. The caudal cut edge from the transverse fold incision and the ventral cut edge of the vaginal wall incision are dissected so that the free tissue flaps are reflected caudad and mediad, respectively. This causes vaginal mucous membranes of the free tissue flaps to be reflected ventrally and the underlying cut surface to be exposed dorsally. Next, the retractors are repositioned and an identical incision is made on the opposite vaginal wall, extending from the lateral extremity of the transverse fold caudally toward the surgeon.



Dissection of the tissue flap from the transverse fold is continued until the caudal cut edge can be reflected approximately 3 to 6 cm toward the surgeon. The dissection of both vaginal wall flaps is continued ventrally until the cut edges can be reflected without tension past the midline (Figure 24-4, *C*). The suture pattern used to appose the submucosal tissue layer is a continuous

modified Connell's, using 2-0 gut (Figure 24-4, *D*). The final configuration is in the shape of a Y, with the apex pointing caudally. The first suture line begins cranially and laterally at the junction of the transverse fold and vaginal wall incisions and is ended at the midpoint of the transverse fold reflection. Cut edges of the transverse fold and vaginal wall are inverted so that denuded tissues are in apposition. The second suture line begins on the opposite side, at the junction of the transverse fold and vaginal wall incisions, and is continued to the end point of the first suture pattern and then on the midline, toward the surgeon, to the caudal end of the vaginal wall reflections. The result is an extended tunnel from the urethral orifice (under the transverse fold) to the caudal vaginal vault. It is important to have minimal tension associated with the suture line and have all apposed edges inverted so that dissected or denuded tissues are in apposition (Figure 24-4, *E* and *F*)

The denuded tissues created dorsally by the dissection of the transverse and vaginal folds are allowed to heal by second intention. If necessary, an episioplasty is performed after surgery.

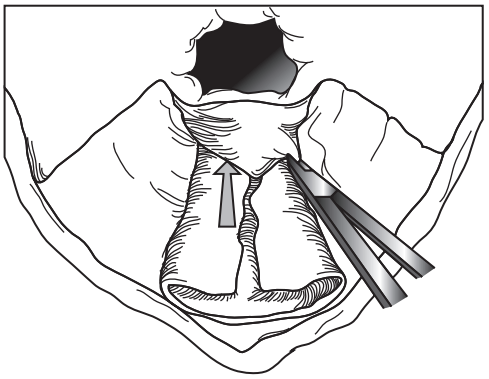


A

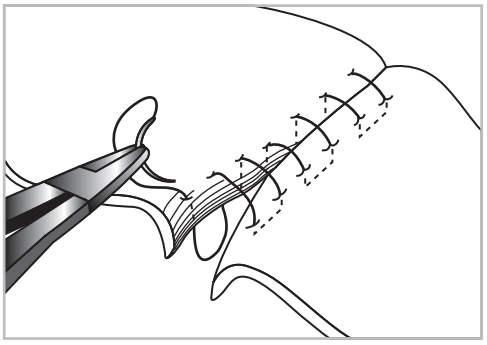
B

Figure 24-4 **A,** The first incision is along the transverse fold of the vestibular sphincter. **B,** A No. 12 blade (hook blade) facilitates the undermining of the transverse fold.

Continued



C



D

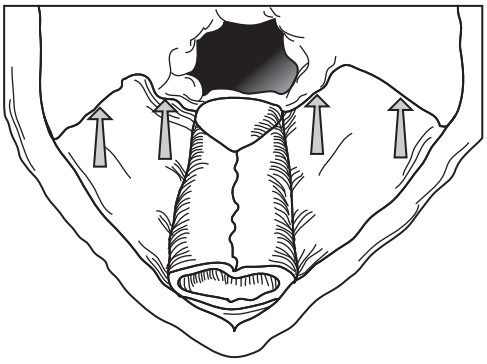


Figure 24-4, cont'd **C,** The lateral vaginal wall is dissected after the retractors are repositioned. **D,** The vaginal wall is dissected from between one half to two thirds of the wall until the free mucosal flap can be passed across midline without undue tension.

E

F

G

H

Figure 24-4, cont'd **E,** The reflected two vaginal walls and the reflected undermined transverse fold are all brought together and inverted, leaving the denuded surface in the vestibule. **F,** The suture pattern is a modified Connell. **G,** The finished urethral tunnel. **H,** There is not much tension on the newly created urethra.

Additional points

- The technique described is our technique of choice for treatment of all mares with urovagina. Other treatments such as perineal body transection or caudal relocation of the transverse fold are often only temporarily effective.
- Episioplasty performed at the same time may result in excessive ablation of vestibule.
- In some mares, urine will pool in the caudal relocation of the urethral tunnel and it will be voided during exercise, commonly resulting in urine staining of the perineum. While this does not affect fertility, it is unsightly and may be treated by incision into the new urethral tunnel to a point 2 to 4 cm cranial to the vulval lips but not far enough to allow urovagina to recur.

Perineal Body

Surgeries of the perineal body are necessary to correct severe anatomic defects (perineal body transection [PBT]) or injuries due to foaling (perineal lacerations and fistulae).

Perineal Body Transection

Perineal body transection has been described to be beneficial for both pneumovagina and urovagina.[7] Our experiences suggest definitely the former but only occasionally the latter.

The primary indication for PBT is mares with such external reproductive conformation that we are not able to prevent pneumovagina after either Caslick's vulvoplasty or episioplastly (i.e., mares with a severely sunken anus and most or all of the vulval lips positioned above the brim of the pelvis (Figure 24-5, *A* and *B*).

The procedure is performed with local anesthesia with or without tranquilization. Local anesthesia (40-70 ml) is liberally infused into the perineal body and laterally to include the vaginal walls to a depth of 8 to 14 cm.

Towel clamps positioned just ventral to the anal sphincter and dorsal to the dorsal commissure of the vulva are used to provide retraction and tension while a 4- to 6-cm horizontal incision is made midway between the anus and dorsal vulva. The incision is continued for a short distance (2-5 cm) along either side of the vulva. Sharp and blunt dissection are used to completely transect the muscular and ligamentous supporting tissues between the rectum and vestibule (Figure 24-5, *C*, *D*, and *E*). Depending on the individual mare, the dissection proceeds cranially for 8 to 14 cm and finishes before entering the peritoneal cavity. The aim of the surgery is to allow the vulval lips to assume a more horizontal position by freeing them from attachments to the rectum. Generally the surgery is finished when the desired external conformation is achieved after allowing for wound contraction.

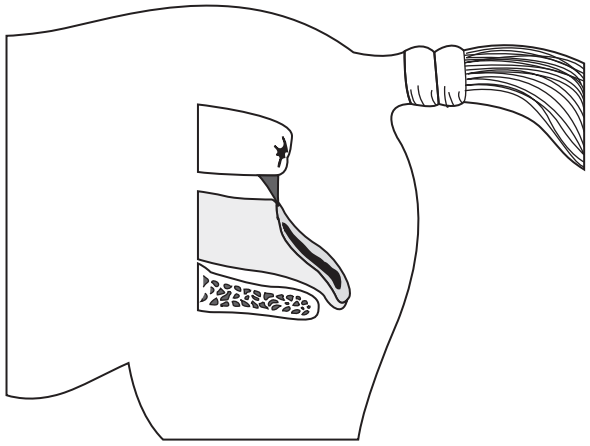
Closure of the skin incision was originally recommended[7]; however, we commonly leave the incision open. Closing the skin occasionally results in dehiscence and also seems to influence the result after wound contracture occurs. The wound heals by second intention, which is surprisingly rapid (2 to 3 weeks).

Points for consideration

- Placing a hand in the vestibule enables accurate dissection. Penetration of the vagina or rectum should be avoided.
- The wound is unsightly while healing, and we recommend careful client communication and/or hospitalization for 1 to 2 weeks.
- The benefits from corrective surgery are immediate, and mares can be bred at the first opportunity, provided that qualified personnel are available. Natural service is generally delayed 2 to 3 weeks to allow strengthening of the dorsal vestibule and vagina.
- Despite the surgery causing moderate hemorrhage, we have not had to take any special precautions or protective measures.

Perineal Lacerations

Most perineal injuries occur at the time of foaling and are associated with a mal-presented or oversized fetus, extensive, vigorous, inappropriate or sometimes unavoidable manual manipulation during parturition and/or violent expulsive efforts of the mare. Maiden mares are by far the most commonly injured with third degree perineal lacerations.

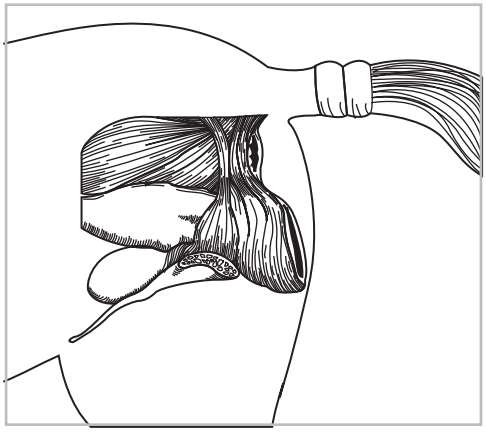


The injuries are commonly referred to as first, second, or third degree perineal lacerations (PL). First degree PL involve only the mucosa of vestibule and skin of the dorsal commissure of the vulva. Minor first degree PL may require no treatment. Extensive lacerations may require episioplasty or perineal body reconstruction. If tissue damage results in significant edema, inflammation, and infection, then surgical correction is often delayed for 2 to 3 weeks.

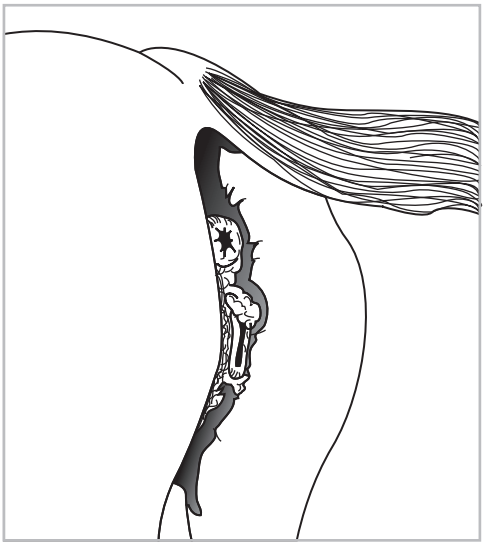
Second degree PL involve both the mucosa and submucosa of the dorsal vulva, and some of the musculature of the perineal body, in particular the constrictor vulvae muscle. There is no damage to rectal mucosa.

Third degree PL result in tearing of the vestibular and sometimes vaginal wall and disruption of the perineal body, anal sphincter, and rectal wall. This results in a common opening between the rectum and the vestibule.[8] The constant presence of feces in the vestibule and occasional unpleasant sound from air movement make repair imperative for breeding and recommended for future riding horses.

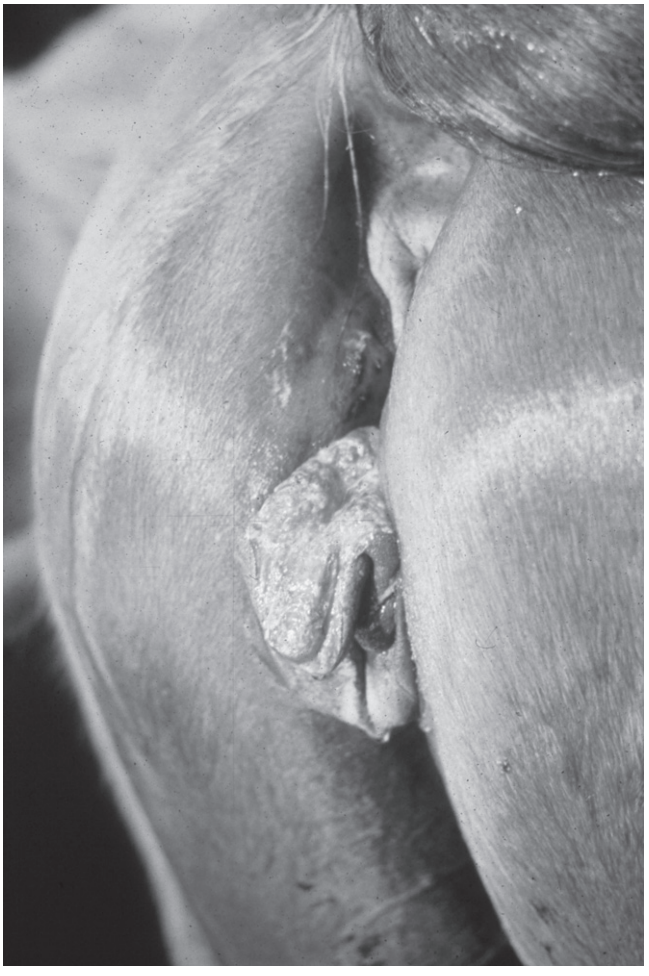
Immediate care for the mare at foaling involves antibiotics, anti-inflammatories, and protection against tetanus. The surgical correction is delayed at least 4 weeks to allow initial second intention wound healing to occur. Heroic repair at the time of foaling is almost never successful.[8] The longer the injury is left untreated, the more opportunities for continual contamination of the reproductive tract; however, this is related to functional capabilities of the vestibular sphincter, and many people will wait until weaning if a live foal was delivered. The cervix must be examined before surgical correction of PL, and if a prolonged time between foaling and repair has occurred, a full reproductive evaluation including biopsy is warranted.



Surgical technique. There are many methods described. Most importantly, the procedures are modifications of either a single- or two-stage repair. A modification of the single-stage repair is the technique we prefer.[9]



A



B

C

D

E

Figure 24-5 **A,** The ageing process of the mare and her conformation has allowed the vestibule and vagina to be positioned mostly above the pelvic brim. **B,** This conformation results in pneumovagina and occasional urine pooling. **C,** The musculature associated with the rectum and vestibule/vagina must be transected to allow the vulval lips to relax caudal. **D,** The surgery often results in the tip of the vulva relaxing to create a shelf if the incision is left not sutured. **E,** The final result, about 48 hours after surgery.

Before surgery vigorous efforts are made to modify the consistency of the feces. Mares are held off feed for at least 24 hours and given a mineral oil drench (2-3 liters) before beginning surgery. After surgery mares are placed on pasture if available, and mineral oil is administered by stomach tube daily for 3 days as necessary to maintain a soft fecal consistency.

Mares are restrained standing, tranquilized, and epidural anesthesia is employed.

Fecal material from the rectum is removed as far cranial as possible. Large wads of cotton are inserted into the cranial rectum to absorb fecal fluid and prevent fecal contamination of the surgical site. Tissues are cleansed and prepared for aseptic surgery. Towel clamps are inserted into the ventral anal sphincter in a configuration that when apposed represent the ideal surgical apposition point. In addition, towel clamps are placed on the dorsal vulval commissure and then retracted to provide visualization for surgical access or, alternatively, stay sutures are used to retract the vulva. An incision is made along the scar tissue line marking the junction between the vestibule/vagina and rectum. Tissues ventral to the incision are dissected to create mobilized vestibular mucosa and submucosa that when apposed from side to side will form the ventral border of the perineal body. Tissues dorsal of the incision are debrided, and rectal submucosa is undermined to allow sufficient mobilization to invert by side-to-side apposition the ventral border of the terminal rectum. All tissues are then sutured concurrently and incrementally from cranial to caudal. The rectal and vaginal reflections are apposed by a continuous modified inverting Connell suture. Suture material preferred is a No. 1 delayed absorbable (i.e., PDS) for the fibrous layer, 0 PDS for the vagina, and 2/0 for the rectal mucosa. When the suture pattern of the rectal submucosa has proceeded 2 to 3 cm, the suture material is retracted and then the vaginal or vestibular submucosa is similarly apposed. The resulting dead space in between, the *recreated perineal body*, is obliterated by multiple interrupted or continuous apposition sutures. The three areas of apposition are then alternatively progressed caudally, 2 to 4 cm each time, diverging at the perineal body, until the ventral vestibular submucosa stitch can be tied and vulval lips closed by a Caslick. The apposing suture of the rectal submucosa is terminated at the dorsal perineal body at the level of the defect in the anal sphincter. The anal sphincter may or may not be apposed at all. Adequate dissection of vestibular and rectal submucosa is necessary to prevent undue tension on the continuous suture patterns.

Postoperatively, apart from antibiotics, anti-inflammatories, and protection against tetanus, the management of fecal consistency is most important (Figure 24-6).

Two-stage repair. In the first stage the aim is to recreate the rectovestibular shelf (i.e., close the vestibular cavity and recreate a portion of the ventral perineal body). Because the rectal mucosa is not apposed and anal sphincter not repaired, there is less tension on the sutures, minimal straining, and potentially less dehiscence.

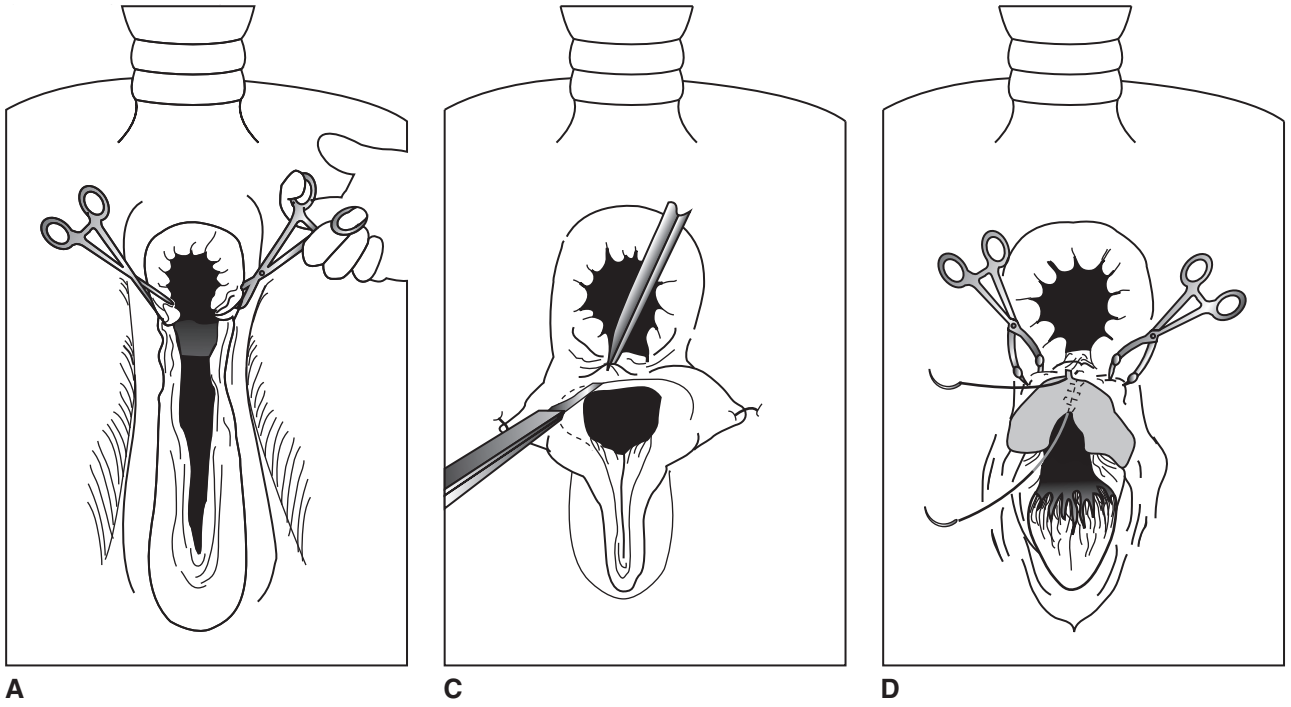
The surgical technique is described elsewhere; however, it is very similar to the single-stage repair except the rectal mucosa and dorsal perineal body are not apposed until 3 to 4 weeks later (second stage).[8,10]

Points for consideration

- Techniques are largely dictated by experience. We believe inexperienced surgeons will have less difficulty with the two-stage repair.
- The better the surgeon's anatomical and functional understanding of the perineal body, the more likely a favorable outcome will follow.
- If a two-stage repair is attempted, economic consideration for the client appears warranted as single-stage repair is just as successful with experienced surgeons.
- Fertility is good after successful repair. A slightly higher incidence of perineal trauma is expected with these mares.

Rectovestibular Fistula (RVF)

RVF most commonly results from foaling injuries, although it can occur from breeding, sadism, or other accidents. Some will heal without surgical intervention, so surgical correction is attempted at least one month or more after the injury. In the last five years we have been breeding the mares on an induced (prostaglandin) second postpartum estrous period and then immediately (within 2 days) performing the fistulae repair. The fertility of mares undergoing this technique has been excellent (~75% per cycle). For this to be successful, as much fecal material as possible is removed immediately before breeding (either natural or AI). After breeding the uterus is lavaged at least daily until repair is performed.



Most surgeons treat RVFs by converting them to third degree PL and repairing as previously described, either standing or under general anesthesia.[11] For deep (cranial) RVFs, a perineal body transection has been utilized.[9]

During the last 15 years we have repaired RVF with a transrectal approach, which we first described in 1991.[12] A similar technique was described in the 1996 AAEP proceedings by Dr. Stephen Adams.[13] In our hospital, modified Finochetto retractors (Scanlan Instruments, Englewood, Colorado) are inserted into the rectum through the anal sphincter.[9] These retractors make the surgery quite simple. The fistula is debrided and closed in three layers, with continuous suture patterns and without conversion into a third degree PL. The vestibular portion may be closed through the vagina or rectum and is inverted into the vestibule. The middle layer (perineal body) is closed from the rectum, and the rectal portion inverted into the rectum. When we previously described the surgical correction, it was recommended to alternate the orientation of the closure.[12] Now we recommend that all three layers are closed transversely, not longitudinally. The fistula middle layer is closed with 0 or 1 PDS, the vagina with 0 PDS, and the rectum with 0 or 2/0 PDS (Figure 24-7).

Restraint and postoperative care is similar to mares with perineal lacerations; however, not as much attention is given to fecal softening.

Points for consideration

- The caudal border of the fistula may be difficult to debride and is most commonly rotated toward the surgeon by grasping it with forceps (from the rectum) and everting it caudally. On occasion it may be helpful to have the surgeon's hand in the vagina while working on this part of the fistula. The use of a No. 12 blade greatly facilitates dissection of the fistula ring.

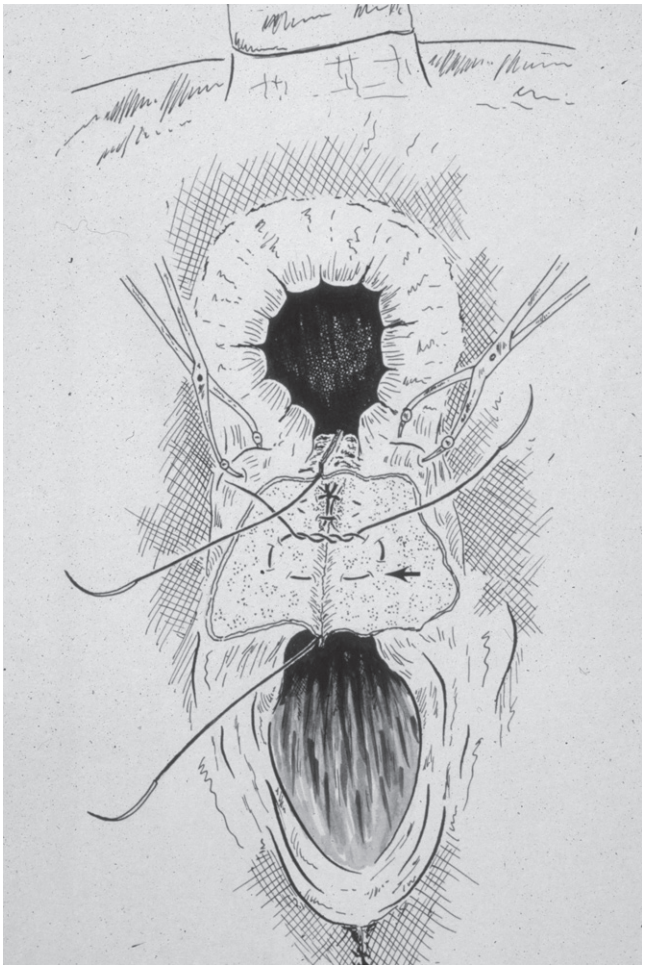


Figure 24-6 **A,** Towel forceps are used to identify the ideal position of the rectum at the end of the surgery. **B,** Typical appearance of a mare before surgery. **C,** The incision before beginning dissection. **D,** After dissection of the scar tissue, the tissues are sutured according to their origin (rectal mucosa, perineal body, and vaginal wall). **E,** The three suture patterns are incrementaly increased to ablate dead space in the perineal body and provide integrity of the rectal and vaginal layers.

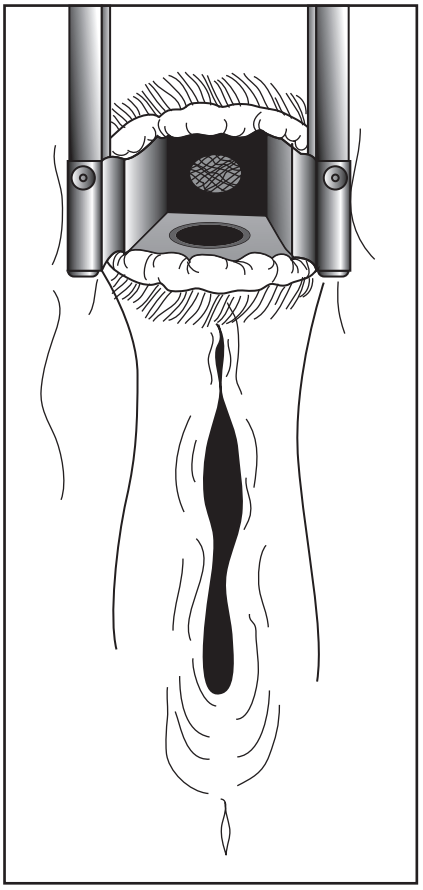

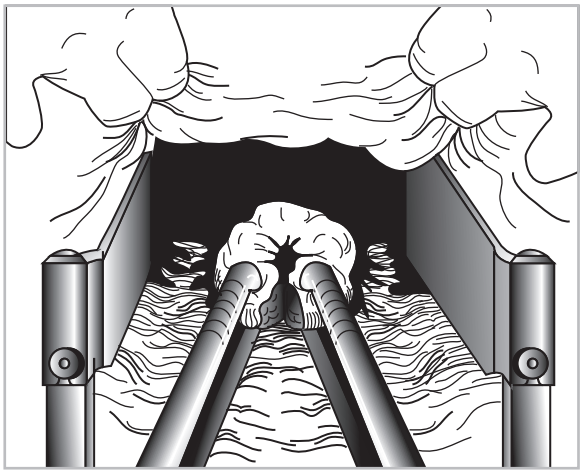

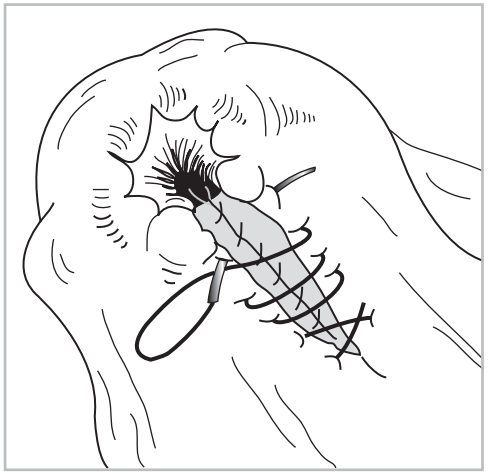

Figure 24-7 The fistula is easily approached per rectum if good retractors are available

Cervix

Cervical Lacerations

Injuries to the cervix most commonly occur at foaling. Many are not associated with a recognized dystocia. Assessing degree of compromise to the cervix as a barrier to intrauterine infection may be difficult. In general, examination immediately after foaling will reveal only the most major defects. Most cervical lacerations are identified later and are best evaluated in diestrus because increased tone facilitates assessment of degree of apposition of cervical folds and damage to the muscular layer. Manual palpation is essential for accurate diagnosis. Many mares with major cervical defects are still able to conceive and carry a foal to term.

In general only those mares with a cervical defect that progresses cranially to involve the junction of the external Os with the vagina are candidates for surgery at our practice. In addition, only mares with obvious subfertility are usually considered (i.e., uterine infection, barren one or more years, etc.)

Surgical technique. Mares are restrained standing and tranquilized. Local anesthesia is preferred with 40 to 60 ml of 2% lidocaine infused dorsally and laterally deep in the vaginal tissues around the cervix.

The most difficult aspect of cervix surgery in the mare is adequate exposure. Modified Finochietto retractors are preferred, and the cervix is drawn caudally by Knowles forceps.[9]

The forceps used must have large teeth that facilitate retraction with vigorous caudal pressure without tearing out of the cervix. With this technique it is generally not necessary to use specially extended cervical instruments (Figure 24-8).

The forceps are placed about 1 to 2 cm on either side of the defect or laceration. Slight rotational movement provides excellent access to the fibrous scar of the defect. The scar is debrided to the level of the cervical musculature, and the external vaginal mucosa of the cervix is slightly undermined. The internal cervical mucosa is undermined and trimmed. Original reports of cervical closure describe a three-layer closure.[9] We prefer two. The internal layer is closed with a 1 PDS with a cutting needle by a continuous pattern through the muscular layer. The external layer is closed with a simple continuous layer using 2/0 or 0 PDS. Occasionally it is necessary to trim excessive cervical folds that prolapse into the suture pattern and result in fistula formation; however, care in

not removing too much is recommended to avoid creating a cervix with major orientation deviations. In addition, it is easy to inadvertently include cervical mucosa on the wrong side of the lumen if the cervical forceps are not positioned well. Patency of the cervical Os is continually confirmed during placement of sutures.

Postoperative treatments for the mare are antibiotics and protection against tetanus. After 21 days, patency of the lumen is assessed by careful manual examination. Frequently, mild adhesions attempt to form. Their occurrence is of no major concern, and gentle manipulation and daily application of a corticosteriod, antibiotic, and oil-based cream, after the surgical site has healed, result in return to normal function.

Points for consideration

- The most craniad portions of the external cervical Os appear to be the most important barriers to infection. Overzealous surgical apposition of the caudad cervix results in a very small external Os that broadens cranially and does not create a good enough seal in diestrus or relax enough during estrus to allow adequate drainage of uterine contents.
- Previously repaired cervix problems often are injured again at breeding and/or foaling. AI is recommended, or a breeding roll at the very least, if natural service is necessary.

Ovaries

Ovariectomy

Some indications for ovariectomy include: mares displaying continual annoying nymphomania; ovarian neoplasia; use of ovariectomized steroid treated mares as recipients for embryo transfer; or mares to be used as tease/jump mares (with or without exogenous hormone administration).

Most techniques describe ovariectomy by a ventral midline approach with ovarian pedicle ligature before excision. However, this is expensive and in our experience occasionally unnecessary. Ovariectomy by colpotomy (vaginal approach) with hemostasis and excision performed with an ecraseur ("crusher") is an approach not often utilized, despite having been described centuries before the advent of powerful restraining pharmaceuticals. Of course there are many occasions when flank or ventral midline approaches will be necessary, particularly for mares with ovarian neoplasia.

Colpotomy

Mares are not fed for 24 hours before surgery. Mares are restrained standing and tranquilized. The tail is secured dorsally. The external perineum is cleansed, and the vaginal cavity is lavaged with sterile saline (1 liter). No epidural anesthesia is necessary. Blunt/Blunt scissors (Metzenbaum) are used to puncture the cranial vaginal wall in a position between 4 and 5 o'clock relative to the external Os of the cervix and near the border of the pelvic canal. The scissors are advanced 4 to 6 cm, then opened and withdrawn through the vaginal wall in the opened position. The resultant hole enables a single finger to bluntly enlarge the opening to admit a hand. The peritoneum is punctured with a single digit, and ovaries and uterus identified and palpated. Swabs that have been previously sewn together and then sterilized are soaked with 50 ml of local anesthetic and applied circumferentially to each ovarian pedicle for at least 1 minute each. A "Hauptner" ecraseur is used to remove each ovary individually. Frequently the ovarian attachments to the ovary have to be manually stretched to allow ovarian removal. The vaginal incision is not closed; however, we recommend a Caslick be performed.

Mares are treated with anti-inflammatory medication (i.e., phenylbutazone, 2 g IV) approximately 10 to 20 minutes before beginning surgery. Delaying phenylbutazone administration or use of oral preparations may result in moderate abdominal discomfort manifested by sternal recumbency. Other prophylactic administrations are antibiotics and protection against tetanus. Mares are not cross tied but usually are boxed overnight and then turned out onto pasture the next day.

We have used this technique in many mares, including mares with small granulosa theca cell tumors up to approximately 10 cm, without complication.

Reported complications are evisceration, hemorrhage, removal or penetration of bowel, fatal peritonitis, and local infection. The incidence of these problems is likely related to the experience of the surgeon and speed of the surgery.

Clearly the technique has potential drawbacks (i.e., size of ovary or structure is limited to less than approximately 10 cm). However, the procedure is safe and efficacious in many instances and able to be performed expediently by personnel experienced with examination of female reproductive tract.

Points for consideration

- Occasionally some mares strain during the procedure. Allowing more time for improved analgesia or additional analgesia appears effective.
- Many of the complications such as evisceration and infection appear to be minimized by presurgical administration of IV phenylbutazone to prevent postsurgical recumbency; a Caslick; and prophylactic antibiotics.
- The procedure is safe, expedient, and efficacious, and the complication rate is similar to or less than male castration.
- Mares with uterine infection or urovagina are not considered for this technique.

Uterus

Uterine Torsion

Uterine torsion is an infrequent but serious complication of the late gestation mare. Most occur in the last two months of gestation and are recognized by mild to moderate colic that responds temporarily to analgesics. Unlike cattle, most uterine torsions of the mare are preterm and not associated with parturition. Definitive diagnosis is based on careful rectal examination. Identification of the ovarian pedicle and uterine ligaments should suggest whether the rotation is clockwise (to the right and downwards when viewed from behind) or counterclockwise. The uterine ligament on the side to which the rotation

has occurred is pulled directly downward and under the uterine body. The other uterine ligament is displaced medially and runs over the uterine body toward the side of rotation and then downward. The greatest tension is on the ligament that the rotation is turned toward. Occasionally diagnosis of direction of torsion is difficult per rectum.

Technique for correction depends on stage of gestation and value of the animal. At term, manual rotation of the fetus through the cervix is often possible. Before imminent parturition, nonsurgical repositioning (rolling) is possible but may occasionally result in uterine rupture.

The mare is positioned in lateral recumbency on the side to which the uterus has rotated (i.e., clockwise torsions result in the mare being placed in right lateral recumbency). The mare is quickly flipped over to her other side and hopefully uterine weight allows the mare's body to pivot about the fetus and reposition the problem. Degree of success can be ascertained by repeated rectal palpation. Another approach is to place a board with weight (i.e., a person) on the upper flank and turn the mare slowly. In this case the board keeps the foal in position during rotation.

Alternative techniques for correction include standing flank laparotomy and ventral midline approach. Standing flank laparotomy has been our preferred method for correction if the mare and/or foal are valuable and there is no evidence of uterine rupture. This technique has a lower probability of creating uterine rupture and avoids the stress of anesthesia.

Standing Flank Laparotomy

For standing flank laparotomy, the mare is moderately sedated, and the paralumbar fossa on the side toward which the rotation is directed is clipped and prepared for aseptic surgery. Local anesthetic (40-80 ml) infused in a vertical line is administered at or slightly cranial to the anticipated incision in the middle of the paralumbar fossa. The skin and paniculus (cutaneous) muscle are incised vertically, and external and internal abdominal oblique muscles are separated along their direction of orientation (grid approach). The transverse adominus is bluntly dissected and the peritoneum punctured with a single finger. The direction of the torsion is confirmed, and a prominent part of the foal under the uterus is grasped and used to gently rock and lift the uterus toward the surgeon. Resolution of the torsion is usually immediately obvious; however, on occasion, lengthening the incision to allow two hands to enter the abdomen or a bilateral flank incision with two surgeons is sometimes necessary. The external and internal abdominal oblique muscles and subcutaneous tissues are apposed by a simple continuous suture pattern with a No. 1 or 2 absorbable material. The skin is closed with a continuous simple or interlocking pattern of nonabsorbable material.

Points for consideration

- Abdominal ultrasonography should be used to verify that the fetus is still alive and, if possible, assess uterine integrity.
- Survival of the mare and/or foal may be influenced by degree of uterine torsion, ease of correction, elapsed time before correction, and stage of pregnancy.
- Regardless of the stage of gestation, if the cervix is open at the time of recognition of uterine torsion, delivery after standing intravaginal/intrauterine manipulation or ventral midline access for reposition and caesarian section is preferable to standing flank laparotomy or rolling of the mare.
- Occasionally a standing flank laparotomy will not have a successful surgical outcome due to the degree of rotation. If a more severe rotation (>360 degrees) is suspected or an excessively elevated heart rate (>70 beats/min) is identified, it may be better to perform a ventral midline laparotomy to better assess uterine health and gain the best physical advantage for uterine positioning. In addition, the fetus can be removed.

Seasonal Movements and Home Ranges of Feral Horse Bands in Wyoming's Red Desert

RICHARD MILLER

Abstract

Feral horses have seasonal movement patterns which correspond to their use of water sources and areas near ridges. Home ranges of horse bands varied in size from 73 to 303 km². Some bands shared use of a common home range. Those bands having a common range followed similar movement patterns within their home ranges. A herd is defined as a structured social unit made up of bands following movement patterns within a common home range.

Movements of feral horses can be important to managers in determining the effects of the horses on the range and in setting boundaries of herd management units. Previously reported feral horse home ranges have varied from 0.9 km² on Sable Island (Welsh 1975) to 78 km² for a spring and summer home range in Stone Cabin Valley, Nev. (Green and Green 1977). As part of a general study of feral horses in Wyoming's Red Desert (Miller and Denniston 1979, Boyd 1980, Miller 1980, Miller 1981, Miller 1983), movements and home ranges of the horses were determined. The objectives of this portion of the study were to determine the size of band use areas and to determine if a pattern existed in time of use for any one area.

Methods

Research was begun in June 1976 and continued until September 1979. Bands were identified with a photo file and card file system keyed on color combinations and readily identifiable individual horses. When bands were identified their locations were plotted to quarter section of USGS to topographic maps. Bands were located from the ground using binoculars and a spotting scope. A number of locations were obtained while working on other portions of the study, such as while following breeding horses. When a band had not been located for 2 weeks, the known use area of that band and adjacent areas were searched. Between November 1977 and April 1979 bands were also located from an airplane during 16 flights made to study habitat use of feral horses and cattle (Miller 1983).

Author is formerly graduate student, Department of Zoology and Physiology, University of Wyoming Laramie 82071, and presently Wildlife Specialist II, Arizona Game and Fish Department, 2222 W. Greenway Rd., Phoenix 85023.
The author thanks Lee Boyd, Val and Ray Hobbs and R.H. Denniston II for their help. Flight time was paid for by: The International Society for the Protection of Mustangs and Burros; Wild Horse Organized Assistance; The Rock Springs District of the Bureau of Land Management; the Department of Zoology and Physiology of the University of Wyoming; Mrs. Margaret Haggard, Mr. and Mrs. C.T. Mallory; R.H. Denniston II; Lee Boyd and Ann Miller.

In determining home ranges I modified Mohr's (1974) minimum home range method in that 2 outside points were not connected if the area which would be included was easily observed and regularly covered during field work. Any band using such an area should have been easily spotted. I made this modification to avoid inflating home range estimates.

Results

Only one of the home ranges I determined in the Red Desert fell within the range of previously reported sizes (0.9 km² to 78 km²) (Welsh 1975, Green and Green 1977). Most home ranges were larger than any previously reported (Table 1). Locations and identification of bands was much more difficult during winter, as bands were much more wary in winter. A band which we could regularly approach within 400 m in the summer often could not be approached within 1 km in winter. This wariness, combined with limited access to the area and fewer field days available during fall and winter, limited the number of fall and winter locations.

The home ranges of some horse bands in the Red Desert overlap almost completely (Fig. 1, Bands A, H and L), and I believe these bands can be said to have a common home range. Bands with a common home range follow similar movement patterns within that home range. An illustration of this is that bands with similar movement patterns were often first located and last located near a partcular well or foraging site with a few days of each other (Table 2).

Figure 1 illustrates home ranges for bands from more than one herd and shows that herd home ranges do overlap. Association of bands from different herds is not unusual at a water source or feeding site. All bands from one herd do not always move at the same time but usually follow similar patterns in their movements and usually move as groups of bands (Table 2).

Bands of horses followed very similar movement patterns each year of the study, arriving in a portion of their home range at approximately the same time each year. In effect, they followed something similar to a rotation grazing system in which the same pasture is used at the same season each year. A composite of the seasonal locations of 6 bands which had overlapping home ranges and similar movement patterns (Fig. 2) shows discrete winter and summer seasonal use areas, indicating the similarity in movements and habitat selection. The large sizes of the April–May and the August–November seasonal ranges (Fig. 2) reflect the variation in weather conditions during those 2 seasons and the responses of the

horses to weather (Miller 1983).

Discussion

An interband dominance hierarchy has been described for the bands whose movements are reported here (Miller and Denniston 1979). Miller and Denniston (1979) suggested that a structured social unit made up of bands existed and defined that unit as a herd. The data presented here show that some of these same bands follow similar movement patterns within overlapping home horses. An expansion of the definition of a herd given in Miller and Denniston (1979) follows: a herd is a structured social unit made up of bands following similar movement patterns within a common home range. An examination of the home ranges presented in Green and Green (1977) and in Feist and McCullough (1976) suggests that herds may also be found in other feral horse populations.

Herds may be a deme or a breeding unit and could show significant morphological variation as found in demes of Uganda kob (Buechner and Roth 1974). Support for this idea is found in the variation in the proportion of certain coat colors seen in horses from different localities in the Red Desert. Pintos and greys, which are infrequently seen in the population as a whole, are common in certain areas.

Clutton-Brock and Harvey (1977 and 1978) suggested that large home ranges result where resources are strongly clumped. widely dispersed or unpredictable in abundance. Altmann (1974) and Crook et al. (1976) have predicted extensive home range overlap where several essential resources have very restricted distributions. Denham (1971) made a similar argument that clumping of populations should be high where predictability of resources is low. W ter sources and ridges which are used as cover in the Red Desert can be considered strongly clumped or as having restricted distributions and as being widely dispersed from one another. Marquiss (1957), studying vegetation composition and ground cover of relict areas in the sagebrush grassland type adjacent to my study area, found variations in ground cover and composition which were significant at the 0.01 level between sites and between years. From his data I believe vegetation and hence forage in this section of the Red Desert may be considered both patchy and unpredictable in availability from year to year. If these factors are producing the large home range sizes, extensive home range overlap, and strongly clumped population distributions found in the Red Desert horses, then changes in the distribution and/or availability of resources can be expected to change home range and movement patterns.

Herds of horses, because they follow similar seasonal movement patterns and thus have similar habitat using patterns within a common home range, are logical management units for future feral horse mangement in the Red Desert.

The One-Migrant-per-Generation Rule in Conservation and Management

L. SCOTT MILLS* AND FRED W. ALLENDORF†

*Wildlife Biology Program, School of Forestry, University of Montana, Missoula, MT 59812, U.S.A., email smills@selway.umt.edu

Abstract: *In the face of continuing habitat fragmentation and isolation, the optimal level of connectivity between populations has become a central issue in conservation biology. A common rule of thumb holds that one migrant per generation into a subpopulation is sufficient to minimize the loss of polymorphism and heterozygosity within subpopulations while allowing for divergence in allele frequencies among subpopulations. The one-migrant-per-generation rule is based on numerous simplifying assumptions that may not hold in natural populations. We examine the conceptual and theoretical basis of the rule and consider both genetic and nongenetic factors that influence the desired level of connectivity among subpopulations. We conclude that one migrant per generation is a desirable minimum, but it may be inadequate for many natural populations. We suggest that a minimum of 1 and a maximum of 10 migrants per generation would be an appropriate general rule of thumb for genetic purposes, bearing in mind that factors other than genetics may further influence the ideal level of connectivity.*

La regla de Un-Migrante-Por-Generación en Conservación y Manejo

Resumen: *Debido a la continua fragmentación y aislamiento de habitats, el nivel óptimo de conectividad entre poblaciones se ha convertido en un tema central en la biología de la conservación. Una regla común sostiene que un amigrante por generación en una subpoblación es suficiente para minimizar la pérdida de polimorfismo y heterocigosidad en las subpoblaciones y al mismo tiempo permite la divergencia de frecuencias alélicas entre subpoblaciones. La regla de un-migrante-por-generación se basa en numerosas suposiciones simplifican que tal vez no sucedan en poblaciones naturales. En este trabajo examinamos las bases conceptuales y teóricas de la regla y consideramos factores genéticos y no genéticos que influyen en el nivel deseado de conectividad entre subpoblaciones. Concluimos que un migrante por generación es un mínimo deseable, pero puede ser inadecuado para muchas poblaciones naturales. Surgerimos que un mínimo de uno y un máximo de diez migrantes por generación seria una regla general apropiada para fines genéticos, sin olvidar que factores no genéticos pueden influir en el nivel ideal de conectividad.*

> . . . evolution depends on a certain balance among its factors. There must be gene mutation, but an excessive rate gives an array of freaks, not evolution; there must be selection, but too severe a process destroys the field of variability, and thus the basis for further advance; prevalence of local inbreeding within a species has extremely important evolutionary consequences, but too close inbreeding leads merely to extinction. A certain amount of crossbreeding is favorable but not too much. In this dependence on balance the species is like a living organism. At all levels of organization life depends on the maintenance of a certain balance among its factors.
>
> —S. Wright (1932:365)

Introduction

By the 1930s Sewall Wright had clearly established—based on experiments and historical breeding records—

Paper submitted December 1, 1995; revised manuscript accepted May 20, 1996.

that inbreeding depression in small, isolated populations typically leads to adaptive decline and extinction (Provine 1986). In Wright's view small amounts of gene flow between partially isolated demes are necessary for long-term persistence. Prompted by Wright's work, the question of how many immigrants ("migrants" in population genetics literature) are needed to prevent population differentiation became the subject of a vast body of theoretical analysis (for review see Slatkin [1985, 1987]). From this analysis emerged a genetic rule of thumb that one migrant individual per local population per generation (OMPG) is sufficient to obscure any disruptive effects of drift (Spieth 1974; see also Kimura and Ohta 1971; Lewontin 1974).

Biologists concerned with population insularization caused by habitat fragmentation began advocating the application of this principle for conservation purposes. Several of the most cited papers advocating, in some sense, the movement of one individual per generation between isolated populations for conservation purposes include Franklin (1980), Frankel and Soulé (1981), and Allendorf (1983). More recently, the OMPG concept has been widely applied by scientists and managers charged with initiating connectivity between potentially isolated populations. For example, Gogan (1990) makes the statement for mammals in general that "Immigration to a subpopulation of only one individual once every five years reduces concerns about inbreeding depression to a negligible level." Triggs et al. (1989) suggest for the critically endangered kakapo (*Strigops habroptilus*) that "In future generations, exchanges of one young kakapo per generation between populations should be made to help maintain genetic variation and reduce inbreeding."

Mace and Lande (1991) have used the OMPG rule as a criterion for fragmentation in defining threatened species categories of the World Conservation Union. In the United States nearly every recovery plan that considers genetic issues and insularization applies the OMPG rule. For example, the black-footed ferret (*Mustela nigripes*) recovery plan states that "If the effective population size is to be maintained among many smaller populations, then exchange of genetic material at the rate of one individual/generation between local populations to ensure random and adaptive divergence among populations is necessary" (U.S. Fish and Wildlife Service 1988:18).

The simplicity of the OMPG—and its widespread adoption—belies confusion over the derivation of the rule, its real generality, and the specifics of implementing it (Varvio et al. 1986). Indeed, immediately after stating that subpopulations would not become fixed for different alleles if there were "an interchange of only one individual every other generation," Wright noted that violations of simplifying assumptions may mean that ". . . an interchange of the order of thousands of individuals per generation between neighboring subgroups of a widely distributed species might well be insufficient to prevent a considerable random drifting apart in their genetic compositions" (Wright 1931:128). Thus, from the outset Wright acknowledged the complicating role of the social, ecological, and genetic characteristics of immigrants; these real-world complexities are often neglected in contemporary reference to the OMPG rule.

Human-caused habitat modification is reducing many continuous populations to isolated or semi-isolated fragments (Soulé et al. 1988; Mills 1995). In light of these changes, concerns over the appropriate level of gene flow in fragments are well grounded, both because of the increased potential for demic extinction in isolated populations (Senner 1980; Soulé 1987; Lynch & Gabriel 1990; Mills & Smouse 1994) and because of potential consequences for adaptation to future disturbances (Soulé 1980; Frankel & Soulé 1981). The issue of actually prescribing gene flow in a management context is complicated, however, and it has received little empirical or theoretical consideration.

We describe the OMPG rule, present its theoretical underpinnings, and discuss its application and limitations from a genetics perspective. Finally, we make recommendations that apply both to highly manipulated systems, where managers physically move individuals, as well as to systems in which the movement rate is affected by the size and shape of available habitat or movement corridors.

The One-Migrant-per-Generation Rule

The one-migrant-per-generation rule originated in Wright's analysis of the interplay between genetic drift and gene flow in determining the expected patterns of genetic divergence among a series of subpopulations. Consider a large number of subpopulations in which genetic drift produces genetic divergence among the subpopulations at a rate inversely proportional to the local effective population size (N_e), which is assumed to equal the census size, N. Assume that in each generation a proportion m of the individuals in each subpopulation are migrants from outside that subpopulation and that the allele frequency in migrant individuals is the average allele frequency in all subpopulations. Such migration will limit the amount of divergence that will occur among subpopulations.

This model leads to the surprisingly simple result that at equilibrium the amount of divergence among subpopulations for reasonably small values of m is approximately

$$F_{ST} \approx \frac{1}{4mN + 1}, \quad (1)$$

where F_{ST} is the proportion of total gene diversity (heterozygosity) due to divergence among subpopulations. Note that because m is the proportion of migrants and N is the population size, mN is the actual number of migrants entering a subpopulation each generation.

The amount of divergence among subpopulations as measured by F_{ST} is independent of the total amount of gene diversity in a population (H_T). The F_{ST} can also be thought of as the reduction in heterozygosity within subpopulations (H_S) caused by random genetic drift and divergence among subpopulations. That is,

$$F_{ST} = 1 - \frac{H_S}{H_T}, \quad (2)$$

and F_{ST} is usually called the fixation index. In the case of more than two alleles, each allele may have a different fixation index. Nei (1973) introduced an analogous value (G_{ST}, the coefficient of genetic differentiation) that can be used to describe genetic differentiation for many loci with more than two alleles (Chakraborty & Leimar 1987).

This analysis has two notable results. First, the amount of divergence is dependent only on the number of migrants (mN) and is in a sense independent of population size. For example, we expect the same amount of divergence among subpopulations of size 1000 with 2.5% migration as we do among subpopulations of size 50 with 50% migration; in both cases there are 25 migrants per generation.

The dependence of divergence on the number of migrants, rather than the population size (N) or rate of migration (m), may at first seem counter-intuitive. Divergence, however, results from the opposing effects of migration and genetic drift. The larger the subpopulations, the slower they are diverging through drift; thus, proportionally fewer migrants are needed to counteract the effects of drift. Small subpopulations diverge rapidly though drift, and thus proportionally more migrants are needed to counteract drift.

The second notable aspect of this result is that remarkably small amounts of migration can have powerful genetic consequences on divergence among subpopulations at equilibrium; for example, OMPG is expected to yield an equilibrium F_{ST} of 0.2 (Fig. 1). If we examine the actual distribution of allele frequencies among subpopulations, it is clear that OMPG will also make it unlikely that polymorphism will be lost within subpopulations (Fig. 2; Wright 1931; Fig. 6). With at least one migrant per generation, subpopulations are unlikely to reach equilibrium gene frequencies where one allele or the other is lost (frequency of zero) or "fixed" (frequency of 1.0).

Nevertheless, substantial divergence in allele frequencies across populations is expected with one migrant per generation (Wright 1931, 1969; Allendorf & Phelps 1981). Thus, OMPG provides a desirable balance between drift and gene flow by preventing the loss of alleles and minimizing loss of heterozygosity within subpopulations but allowing genetic divergence to exist among subpopulations. Low amounts of exchange will maintain qualitative similarity among subpopulations and also allow substantial quantitative divergence in allele frequencies.

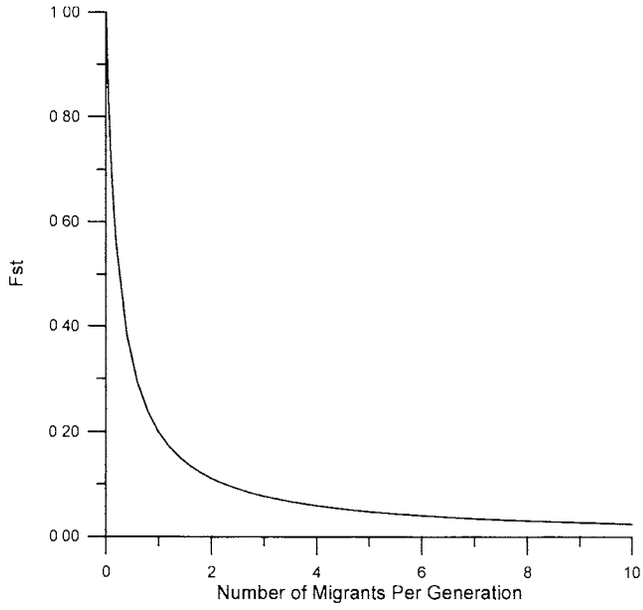

Figure 1. Relationship between number of migrants per generation (mN) *and the fixation index* (F_{ST}).

We want to emphasize that OMPG is not a discrete quantitative threshold and does not imply panmixia (random mating) among individuals of different populations. Rather, the basis of OMPG originates from a qualitative evaluation of tradeoffs between loss of genetic diversity within populations versus homogenization among populations.

Assumptions of the Rule

The OMPG rule results from a simple model of population structure based upon a host of unrealistic assumptions. We consider the primary assumptions that affect the applications of the results of this basic model to conservation.

(1) *Island model of migration*: A migrant is equally likely to come from any subpopulation so that there is no geographical pattern to gene flow. The assumption is also usually made that there are an infinite number of subpopulations of equal size.

(2) *Selective neutrality and no mutation*: There are no selective differences among genotypes, and no new mutations enter the population. That is, gene-frequency dynamics are determined entirely by the interaction between genetic drift and gene flow.

(3) *Ideal populations*: The subpopulations have the characteristics of an ideal genetic population, so that the census number of individuals equals the effective population size. For general purposes, the ideal population consists of a constant number of N diploid individuals ($N/2$ females and $N/2$ males) in which all parents have

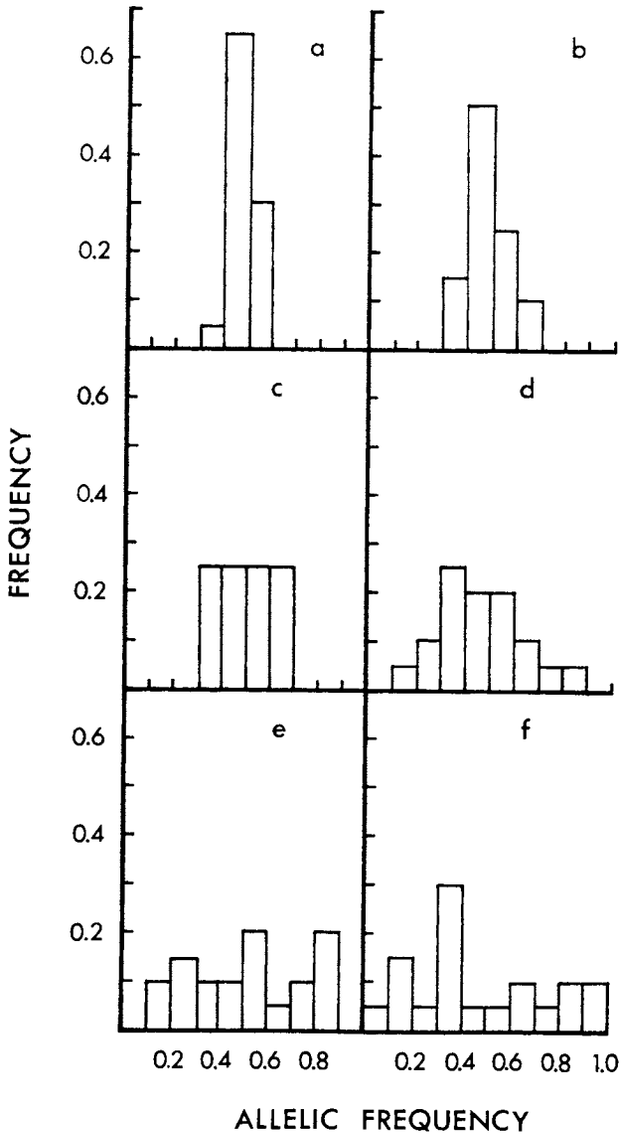

Figure 2. Distribution of allele frequencies in 20 subpopulations (N = Ne = *200 each) with different amounts of migration, based upon computer simulations of the island model for two alleles at a single locus (Allendorf & Phelps 1981). For panels a-e, number of migrants per generation decreases and* F_{ST} *increases, as follows:* mN = *25,* F_{ST} = *0.0080 (a);* mN = *10,* F_{ST} = *0.0175 (b);* mN = *5,* F_{ST} = *0.0509 (c);* mN = *2,* F_{ST} = *0.1104 (d);* mN = *1,* F_{ST} = *0.2513 (e); and* mN = *0.5,* F_{ST} = *0.3221 (f).*

equal probability of contributing an offspring to the next generation.

(4) *Demographic equality*: Immigrants have the same demographic attributes, in terms of survival and reproduction probabilities, as resident individuals.

(5) *Equilibrium*: The subpopulations persist long enough to reach steady-state or equilibrium conditions with respect to gene frequencies.

Limitations of the Rule

What are the consequences of violating the simplistic assumptions of the OMPG rule? We consider how population size may affect the predicted effects of OMPG, then evaluate each of its assumptions. In each case we determine whether each complicating factor is expected to increase or decrease the effectiveness of OMPG or whether "it depends."

Census Population Size

As noted in the derivation of the OMPG rule, one of its interesting and attractive features is that it is independent of population size, as long as gene dynamics are driven entirely by drift and gene flow (mutation and selection play no role). There are, however, at least two caveats to this generalization. First, mN migrants into a small population will represent a larger proportion of the population than if they had entered a larger population; any disruptive social or mating system effects of the immigration will therefore be magnified in smaller populations (Frankel & Soulé 1981; Frankel 1983).

Second, the usual formulation for the loss of genetic variation under drift-migration equilibrium (Eq. 1) is an approximation of the exact equation and holds true only when m (migration rate) is "small" (Wright 1969:291). For a fixed mN, such as one migrant, m becomes large with small population size. For example, when $N = 2$, $m = 0.5$, a large value that leads to less loss in variation (smaller F_{ST}), with the exact equation than expected with the approximation (Fig. 3). We note, however, that the overestimation of F_{ST} with the approximate equation is insignificant with subpopulation sizes large enough to be likely to persist in the face of demographic stochasticity for even relatively short periods of time. For example, for $N = 20$, the exact F_{ST} is 94% of the approximation.

Both of these issues imply that when populations become quite small less migration may be appropriate, both because of possible social disruption and because very small populations are not losing variation as fast as predicted by the F_{ST} approximation. Other factors, such as Allee effects and demographic or environmental stochasticity, lead to the opposite conclusion, with immigrants initiating an important "rescue effect" (Brown & Kodric-Brown 1977).

Island Model: Pattern of Migration

The immigrants in Wright's infinite island model are randomly chosen from the pool of an infinite number of subpopulations. If individuals in the real world come from nearby populations, their gene frequencies would differ little from the target population, so more immigrants would be necessary to prevent loss of variation

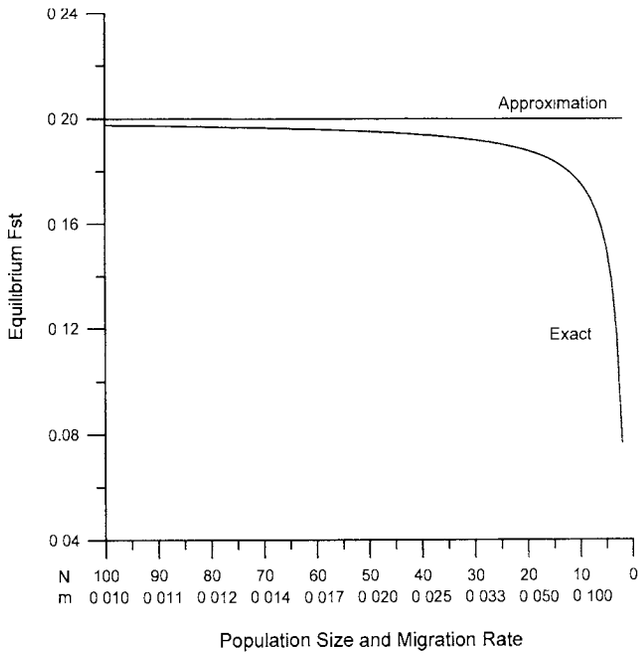

Figure 3. Expected F_{ST} *at equilibrium for one migrant per generation (*mN = *1) using the exact equation (from Eq. 12.2 in Wright 1969) and the commonly used approximation (Eq. 1). Unlike the approximation, which assumes small* m, *the exact equation changes as* m *changes.*

(Wright 1931; Levin 1988). Crow and Aoki (1984) conclude, however, that unless the number of populations is very large, this neighborhood effect is relatively small; in a finite population model, migrants from neighboring groups are about half as effective in their genetic effects. Kin-structured migration—in which individuals disperse in the company of relatives—will also have the effect of requiring more immigrants for the same effect on genetic drift (Levin 1988).

Directional movement patterns are an important and widespread exception to the assumption of the island migration model. In many situations migrants from a relatively large subpopulation may be moved into a smaller subpopulation that is isolated; this is referred to as a continent-island pattern of migration (Hedrick 1983:278). For example, grizzly bears (*Ursus arctos*) from the Yellowstone National Park region are isolated from other populations. The recovery plan for grizzly bears includes regularly moving bears from more northern populations in Montana that are contiguous with grizzly bear populations in Canada into the Yellowstone region (U.S. Fish and Wildlife Service 1993).

The genetic effects of this type of directional movement pattern are compatible with the OMPG rule. The isolated population can be considered one subpopulation of the island model in which migrants from the larger population represent the migrant pool of the island model. Thus, the predictions of the OMPG rule will be valid as long as the donor population is large so that genetic drift is minimal. Weishampel (1990) cautions that if the donor population has lower genetic variation than the receiving population, migration can actually decrease genetic variation in the population of interest.

Another characteristic of the pattern of migration is the interval between immigrants. In its simplest form the island model assumes that probability of migration per generation is constant. Will 1 migrant per generation have the same effect as 10 migrants every 10 generations? Lacy (1987:153) concludes that sporadic immigration should be just as effective as a steady supplementation, provided that the same long-term average rate is maintained. On the other hand, Levin (1988:645) concludes that "a variable migration rate homogenizes neutral allele frequencies less than a uniform migration rate with the same mean." This effect is quite small, however, based upon theory (Nagylaki 1979). Experimental work offers no insight into this question. In many cases the driving criteria for the timing of immigrants will probably not be genetic calculations but logistical concerns (transplanting one animal per generation will often be impractical) and behavioral and social considerations whereby groups of immigrants are more likely to experience successful reproduction.

In short, real-world deviations from the simple pattern of migration used to derive the OMPG rule mean that somewhat more than one migrant per generation may be necessary to achieve the desired genetic goals; the necessary increase will depend on particular circumstances, but it is probably small.

Island Model: Number of Subpopulations

The expected value of F_{ST} at equilibrium can be corrected as shown below to take into account a finite number (n) of subpopulations (Slatkin 1995):

$$F_{ST} \approx \frac{1}{4mNa + 1}, \tag{3}$$

where

$$a = \left(\frac{n}{n-1}\right)^2. \tag{4}$$

Total gene diversity (H_T) can be partitioned into within- and between-subpopulation components. Isolation causes a decrease in within-subpopulation variation (H_S), whereas fixation for different alleles maintains total gene diversity (H_T). As long as the subpopulations are connected by gene flow, an allele will eventually be lost from all subpopulations (and therefore the entire population) by genetic drift if there are a finite number of subpopulations. If the subpopulations are isolated, however, then different alleles will drift to fixation in differ-

ent populations, so more alleles will be maintained in the entire population.

There may be merit (Chesser 1983) in maintaining isolated populations so that more alleles can be retained in the entire population. Nevertheless, these benefits must be weighed against increased probability of extinction due to within-population inbreeding depression (Varvio et al. 1986; Mills & Smouse 1994). In short, the tradeoff between within- and among-population variation may dictate more or less migration than the OMPG rule does (Figs. 1 & 2).

Natural Selection and Mutation

The theoretical model upon which the OMPG rule is based assumes selective neutrality—that is, there are no differences in fitness among genotypes. Nevertheless, the OMPG rule itself does take into account natural selection. The OMPG rule was chosen because it is sufficient to avoid the loss of alleles in subpopulations caused by genetic drift but will allow the allele frequencies within subpopulations to respond to local selective pressures.

Even weak natural selection can have a major effect on the amount of genetic divergence among populations (Allendorf 1983). The effects of natural selection will be greater in larger subpopulations because of the reduced effects of drift in larger populations. In general, natural selection will not have a major effect on the distribution of allele frequencies if the selection coefficient (s) is less than the migration rate (m) (Wright 1940). Thus, natural selection will have less effect on allele frequency divergence among subpopulations with smaller subpopulations for the same amount of migration (mN) (Allendorf 1983).

The effect of selection upon the expected amount of divergence with a given amount of gene flow depends upon the pattern of selection. Similar selection in different subpopulations will tend to reduce divergence, whereas different selective conditions will increase divergence among subpopulations (Allendorf 1983). It is likely that both of these patterns of selection will occur at different loci within the same population. Thus, the OMPG rule seems appropriate when we consider the potential effects of natural selection.

Mutation is expected to have little effect on the application of the OMPG rule. The expected amount of divergence at equilibrium for G_{ST} (the multiple-allele form of F_{ST}) is independent of the mutation rate and the number of alleles, as long as the migration rate is much greater than the mutation rate (Hartl & Clark 1989). This condition will be met for all loci in which migration rates are on the order of one per generation ($mN = 1$) or greater.

Ideal Populations and Demographic Equality

The ratio of effective population size to census population size is expected to affect the consequences of varying migration rates. Wright (1931:128, 1969:292) noted that the smaller N_e is relative to the census N, the larger the number of migrants necessary to minimize differentiation. This is because as N_e decreases below N the population loses variation faster via drift, and a given migrant contributes less to the breeding population, than when N_e equals N. Therefore, populations with highly skewed N_e/N ratios, as is often the case in wild vertebrates (Frankham 1995), may require more than one migrant per generation. How many more are necessary is uncertain; presumably it will depend on why N_e is less than N (for example, because of skewed sex ratio or variance in family size) and on the reproductive characteristics of the immigrants.

Demographic equality also assumes that immigrants are equivalent to residents. To the extent that an immigrant is more or less likely to survive and breed relative to individuals in the target population, it may count as more or less than one migrant. It seems unlikely that immigrants will be demographically equivalent to resident individuals in most situations. In the case in which immigration is imposed by moving captured individuals, there are a variety of reasons to expect immigrants to be less likely to survive and reproduce than residents.

There are also a few situations in which immigrants may be more successful than residents. For example, individuals with rare genotypes have a reproductive advantage in plant species with self-incompatibility systems (Charlesworth 1985). Thus, immigrants from a genetically different subpopulation may have a reproductive advantage in this case.

Because deviations from ideal population structure will tend to compromise the effectiveness of migration relative to expectations, including social structure and taking into account the relative reproductive success of immigrants will mean that more than one migrant per generation may be necessary.

Equilibrium

The OMPG rule is based upon the assumption of equilibrium between the effects of migration and genetic drift. Equilibrium will be reached more quickly with smaller population sizes and higher migration rates (Varvio et al. 1986). Thus, greater migration may be initially desirable with larger subpopulations in order to reach equilibrium more quickly. Equilibrium between gene flow and drift is approached fairly quickly with small population sizes (Table 1; see also Allendorf & Phelps 1981; Table 2).

Before the population reaches equilibrium, the restorative effect of immigration is initially greater for small populations than for large because they have drifted to lower levels of variation (Lacy 1987). This implies that increases above OMPG may well be beneficial when migration is initiated for the first time.

Table 1. Observed and expected genetic divergence among five subpopulations of Leadbeater's opossum connected by gene flow in a simulation study (Lindenmayer & Lacy 1995).*

mN	H_s	*Expected* F_{ST}	*Observed* F_{ST} *20 yr*	*50 yr*	*100 yr*
0	0.28	1.000	0.170	0.309	0.509
0.7	0.60	0.186	0.105	0.128	0.130
1.5	0.70	0.096	0.074	0.068	0.079
7.4	0.80	0.021	0.021	0.022	0.024

**The* mN *values were calculated with the annual migration rate (*m*) used in the simulations, a generation interval of 3.71 years and an* N *of 40 based on carrying capacity (see text for discussion of using* N *versus* N_e*).* H_s *values represent observed mean heterozygosity within subpopulations at 100 years. Expected* F_{ST} *at equilibrium was calculated using Eq. 3 and the actual* mN *values used in the simulations. Observed* F_{ST} *values were calculated using Eq. 2.*

Implicit in the equilibrium assumption is that populations all persist long enough to reach equilibrium. McCauley (1993) reviews the consequences of relaxing this assumption: incorporating extinction and recolonization dynamics can either increase or decrease genetic differentiation, depending on how high population turnover rates are, where the migrants originate, how many migrants move together, and whether the migrants settle in unoccupied or occupied patches. Extinction and recolonization dynamics tend to accentuate population differentiation most when migrant individuals move into established populations more than colonizing new patches. Therefore, if conspecific attraction (Reed & Dobson 1993) tends to increase the likelihood of a dispenser settling in an already occupied area rather than an unoccupied area in a metapopulation, then those migrants will be less effective at minimizing differentiation in the metapopulation; if they settle more in empty patches, then extinction and recolonization dynamics predict that fewer migrants are needed to prevent differentiation (McCauley 1993).

In general, then, violation of the equilibrium assumption means that somewhat more than one migrant per generation may be beneficial. Extinction and recolonization dynamics could either increase or decrease the desirable number.

Empirical and Simulation Results

What insights can be gained from field studies, laboratory experiments, and comprehensive computer studies of natural populations that violate many of the above assumptions at the same time? Because it is not possible to test the predictions of the OMPG rule within a reasonable time frame for most species of interest, empirical tests will initially come from model genetic species with short generation times.

Little experimental work considers the issue of how many migrants are optimal in natural—or even captive—populations. The most direct experimental work is that of Spielman and Frankham (1992). They found strong and significant increases in reproductive fitness in 10 replicate inbred lines of *Drosophila melanogaster* that received only a single immigrant per generation. On average, OMPG restored nearly 50% of that fitness lost under isolation. Newman (1996) has found similar results with experimental populations of the plant *Brassica campestris*. One migrant per generation among 10 subpopulations had a significantly positive effect for five of six fitness components measured. In contrast to these results, Backus et al. (1995) found no increase in fitness associated with a single immigrant (although higher levels of gene flow did increase fitness) among five subpopulations of the housefly (*Musca domestica*).

Studies that use simulations or analytical approaches incorporating actual life-history information for long-lived species also provide insight into how effective OMPG is expected to be in the face of real-world deviations from the simplifying assumptions. For example, Hedrick (1995) used a variety of theoretical population genetic models to test the validity of the OMPG rule in the case of the Florida panther (*Felis concolor coryi*). The report of a workshop for genetic restoration of the Florida panther recommended an initial influx of 20% of the population, followed by gene flow of one animal per generation. Hedrick's models included various combinations of gene flow and genetic drift. He also examined several violations of the assumptions of the basic model: natural selection, directional gene flow, and nonequilibrium initial conditions. Despite these complicating factors, he concluded that this recommendation was sufficient to eliminate lowered fitness due to inbreeding depression and to retain adaptive alleles in the Florida population.

Allendorf et al. (1991) used simulations with the computer program GAPPS (Harris et al. 1986; Harris & Allendorf 1989) to examine the effects of immigration on effective population size and the rate of loss of genetic variation in an isolated population of grizzly bears in the Rocky Mountains. These simulations used a directional (continent-island) pattern of gene flow in a discrete-time, stochastic computer program that followed each individual bear from birth to death. The estimated effective population size of the isolated population was approximately 30% of the census population size. Their results are in general agreement with those expected with the basic model: the introduction of a few bears per generation greatly reduced the rate of loss of variation in the isolated population. The introduction of males had a greater effect than the introduction of females in the model, but this effect may be outweighed by the reduced likelihood of males being incorporated in the breeding population into which they are introduced be-

cause of the behavioral differences between males and females (Allendorf et al. 1991; U.S. Fish and Wildlife Service 1993).

Dobson et al. (1991) used GAPPS to simulate the viability of isolated populations of black rhinos (*Diceros bicornis*) in Kenya. They used an island-continent pattern of migration and demographic data obtained from black rhino sanctuaries. They also included the effects of inbreeding depression in some of their simulations. They found that one immigrant every 10 years had a major effect on the population size and persistence of isolated populations.

The most realistic test of the OMPG rule using simulations that we are aware of was done by Lindenmayer and Lacy (1995) with Leadbeater's possum (*Gymnobelideus leadbeateri*). They used the computer program VORTEX (Lacy 1993) to model the viability of metapopulations with subpopulations occupying a small number of habitat patches of varying sizes. They used values for life-history parameters drawn from extensive field studies, allowed local subpopulations to become extinct, and included the effects of inbreeding depression. Dramatic effects of migration were observed in their largest metapopulation, which consisted of five subpopulations of 40 individuals each (Table 1).

The results for Leadbeater's possum also can be used to quantitatively test the predictions in a system that violates many of the assumptions upon which the OMPG is based. The observed amount of genetic divergence among the five subpopulations estimated from the data of Lindenmayer and Lacy (1995) is similar to that predicted by the simple equilibrium model (Table 1). As expected, near-equilibrium values were obtained more rapidly with greater amounts of gene flow. Even with $mN = 1.5$, however, the observed F_{ST} value was nearly 75% of that expected at equilibrium after approximately five generations.

Recommendations for Implementing Gene Flow

When connectivity is implemented for genetic purposes, we are interested in finding the middle ground between loss of alleles in local populations (fixation, or loss in heterozygosity) and uniformity of allele frequencies across local populations. One migrant per generation is an appropriate lower limit to the amount of gene flow that is desirable. Nevertheless, sometimes more than an average of one migrant per generation will be necessary because of deviations in real populations from the ideal conditions assumed in developing the OMPG rule.

We hesitate to give "cookbook" prescriptions, but an increase in migration above the mean of one migrant per generation may be desirable under the following conditions: (1) inbreeding depression is thought to be a problem in the local population; (2) migrants are closely related to each other or to the local population; (3) social, behavioral, or logistical factors prevent single individuals from immigrating, so that movement is in pulses of several animals every several generations; (4) N_e is much less than total population size; (5) migrants are likely to be at a disadvantage in terms of survival and breeding success; (6) the receiving population has been isolated for many generations; and (7) demographic or environmental variation indicates a high danger of extinction without aggressive supplementation.

If one migrant per generation is not enough in many circumstances, then the next question is how much gene flow may be too much to maintain the balance we are seeking. This question is difficult to answer without extensive genetic and demographic information on the population under consideration. Concerns over local adaptation and outbreeding depression dictate that, under some conditions of phenotypic or genotypic dissimilarity, immigration into an isolated population should be minimized (for cogent discussions see Templeton [1986] and Leberg [1990]). Frankel and Soulé (1981) proposed an upper limit of 5 migrants per generation because of concerns with disruptive effects on social structure in small populations. We suggest that up to 10 migrants per generation is not likely to tip the balance too far by causing uniformity of allele frequencies across subpopulations (Fig. 2).

The characteristics of the migrants is as important as the number of migrants. Social, behavioral, and demographic characteristics that affect the likelihood of survival and reproduction of migrants may overwhelm genetic considerations in assessing the "ideal" candidates to recruit as migrants (Kleiman 1989; Stanley-Price 1989; Short et al. 1992). Likewise, considerations of mating system and social structure will affect the genetic impact of an immigrant. Greater numbers of randomly chosen migrants may be necessary to achieve the same genetic effect as fewer migrants chosen to maximize contribution to the effective population size.

Finally, we stress that criteria other than genetic variation will often play pivotal roles in determining the appropriate level of connectivity between semi-isolated fragments. For example, small populations subject to blinking out due to demographic or environmental stochasticity can experience a "rescue effect" (Brown & Kodric-Brown 1977), with immigrants increasing numbers away from the boundary of zero. In this case more migrants increase population persistence, regardless of genetic considerations. On the other hand, contagious diseases have been raised as a factor decreasing the benefits of connectivity (Wilson et al. 1994; Hess 1994).

Conclusions

The OMPG rule has provided much-needed guidance in management and has illuminated the need for genetic

connectivity among isolated populations. Like many theoretical applications in conservation, its utility is strongest when its complexity is appreciated (Doak & Mills 1994). We have seen several compelling real-world factors that suggest more than one migrant per generation may be necessary to achieve genetic goals, and some situations (albeit fewer) in which less connectivity is desirable. One key to practical decision making is to define clearly the desired genetic outcome, as well as other objectives and constraints of the supplementation program (Lacy 1987).

One migrant per generation is an acceptable minimum, but it may be inadequate for many natural populations. Different levels and schedules of supplementation are appropriate under different environmental conditions and with different species. Nevertheless, we suggest that a minimum of 1 and a maximum of 10 migrants per generation would be an appropriate general rule of thumb for genetic purposes.

Acknowledgments

M. A. Sanjayan provided early enthusiasm and references on the topic to L. S. M., and reviewed the manuscript. F. W. A. was supported by a grant from the National Science Foundation (DEB-9300135) while preparing this paper. We appreciate reviews and comments on various drafts by D. Doak, D. Tallmon, and W. Morris (who also suggested the examination of how expected and exact F_{ST} values diverge at small numbers). L. S. M. would like to acknowledge Michael Soulé, a mentor and friend; F. W. A. would like to acknowledge Michael Soulé, a bodhisattva and friend. This paper is contribution No. 96-1 of the Montana Forest and Conservation Experiment Station, Missoula.
