Wild Horse and Burro Program, Research Coordinator, Bureau of Land Management, 2150 Center Ave., Building C, Fort Collins, Colorado, 80526

Subject: National Research Council's 2015 report to BLM

Mr. Cain,
In reference to the proposed Mare Sterilization Research Environmental Assessment, I am providing you the following information in support of your analysis. This letter includes the internal deliberations provided to BLM by the National Research Council regarding the three proposed wild horse sterilization studies that would take place in Burns, Oregon.

On March 6, 2014, the BLM made public its request for applications to a research program titled "Wild horse and burro sterilization or contraception – development of techniques and protocols." The National Research Council provided scientific reviews of research proposals that BLM received in response. The National Research Council's report to BLM (NRC 2015) included a letter and two appendices. In order to ensure that the reviews of those proposals were rigorous, confidential, and unbiased, the specific critiques of proposals were sent to BLM as nonpublic attachments labeled Appendix A and Appendix B. I also note here that, for administrative reasons including available funding, the specific proposals that BLM chose to fund were a subset of the proposals recommended in NRC (2015).

In this letter, I am quoting, in their entirety, the paragraphs of text in Appendix A that pertain to the three Oregon studies under your consideration, other than personally identifiable information. These proposals were labeled proposals 8, 9, and 19 by the review committee of the National Research Council (2015). After that text I am also copying over complete page images from the specific reviews of those three proposals from Appendix B, except again with personally identifiable information removed.

Sincerely,

Paul Griffin

"Appendix A

Recommended Proposals

In its public session with the Bureau of Land Management (BLM), the committee understood that the agency was looking for research projects that would yield results quickly and ones that may take more time to come to fruition. With that in mind, it has grouped the recommended proposals into ones that can be completed and (if successful) have their results implemented in 2 years or less, ones that may yield practical results in the medium term (2–5 years), and ones that hold promise to yield results in the long term (5–10 years). A strategy for setting funding priorities among the projects and ways in which BLM could work with the investigators to strengthen their proposals are suggested in the last section of this appendix.

RESEARCH PROPOSALS ON STERILIZATION THAT COULD BE COMPLETED IN 2 YEARS OR LESS

The committee grouped Proposals 8, 9, 12, and 10 because they all focused on permanent sterilization through straightforward surgical procedures or, in the case of Proposal 10, a single injection. They all also had relatively low budgets and should be completed within 2 years. The committee believes that all four proposals feature methods that could be used safely in the near future (1–3 years from now) and therefore recommends them all for funding (Table A-1). When these research activities have concluded, BLM will be in a position to evaluate which approach or combination of approaches works best under what conditions, such as time of year, open or pregnant mares, stage of pregnancy, and the terrain and size of the population in the Herd Management Area where a gather, sterilize, and release program is planned. It can then proceed with the best options, having evaluated the merits of each approach. With regard to Proposal 10, the committee does not think that treatment of stallions will have an effect on the population growth rate of herds. However, BLM will capture stallions with mares and foals when it conducts gathers, and having an easy-to-apply, one-dose treatment option available for all mature animals would be optimal for the agency. It should fund Proposal 10 to verify whether such an injection can be safely developed for free-ranging stallions.

The committee also examined a proposal on conducting ovariectomies on free-ranging mares: Proposal 19, Functional assessment of ovariectomy (spaying) via colpotomy of wild mares as an acceptable method of contraception and wild horse population control; PI, [*personally identifiable information omitted here*]. Ovariectomy is regularly conducted on domestic mares, but some of the protocols used in domestic animals after surgery would not be applicable to free-ranging mares because they cannot be held still for 48 hours. The committee did not view this as a research proposal because the procedure is already done regularly in mares and therefore it contains no science or experimentation related to technique. For that reason, the committee did not group Proposal 19 with the research proposals listed in Table A-1. Nevertheless, it evaluated the usefulness of ovariectomy as a tool for population-growth suppression and the risks associated with it. Details of the committee's conclusions (including the effects of ovariectomy on fetuses before 90 days of gestation, from 90 to 120 days of gestation, and after 120 days of gestation) are in Appendix B. In short, the committee believes that this procedure could be operationalized immediately to sterilize free-ranging mares but that the techniques in Proposals 8, 9, and 12 would be less invasive. If the research projects of Proposals 8, 9, or 12 prove successful, their procedures should replace the procedure described in Proposal 19."

The following four pages are copies from NRC (2015) Appendix B, Proposal Review Comments. These are the reviews for the three proposed studies that would take place in Burns, Oregon, but with personally identifiable information redacted.

Proposal Number: 8

Proposal Title: Hysteroscopy and laser ablation of the oviduct papillas as a minimally invasive method of sterilization in standing, sedated wild horses and burros

Principal Investigator: [redacted] Oregon State University

Funding Recommendation: Fund.

COMMITTEE DISCUSSION SUMMARY

The objective of this proposal is to sterilize nonpregnant mares by hysteroscopic laser ablation of the oviductal papilla while the mares are under standing sedation. Fertility would be assessed by allowing treated mares to mate with a fertile stallion.

The committee finds the simplicity of this proposal to be its greatest strength. The procedure is minimally invasive and would require only restraint in the stocks with standing sedation. In practiced hands, the entire procedure should take 20–30 minutes per horse. With some training, many veterinarians could become proficient in performing this procedure. There is no question that the laser would damage the oviductal papilla. Whether the scar damage is sufficient to sterilize the mare permanently is the question at hand in this proposal.

The committee considered this proposal in conjunction with Proposals 9 and 12, which also aim to sterilize mares through minimally invasive procedures. The committee concludes that Proposals 8, 9, and 12 should all be funded. The budgets for these proposals are not large, and each should be completed in a short period (no more than 2 years). When these research activities have concluded, BLM would be in a position to evaluate which approach or combination of approaches works best under what conditions, such as time of year, open or pregnant mares, stage of pregnancy, and the terrain and size of the population in the Herd Management Area where a gather, sterilize, and release program is planned.

That being said, a number of improvements could be made in Proposal 8, and the committee is skeptical about one important factor. The committee is not confident that many mares gathered from an HMA would be eligible for this procedure because it is aimed at nonpregnant mares. Free-ranging mares are extremely sound reproductively, and many are in foal by the age of 2 years. Free-ranging mares that are not pregnant after the age of 2 years are probably subfertile. Therefore, the procedure would be applicable primarily to subfertile mares or yearlings that are 8 months old and/or weigh around 300 kg. The committee is not confident that many gathered horses will fit that description. It would not be practical to conduct a gather to perform only this procedure given the likelihood of a low number of candidate fillies and subfertile mares.

Regarding the low number of candidates for this procedure, the committee wonders whether inducing early embryonic death is acceptable. If it were acceptable, this procedure could be used in early spring in most mares. Abortion itself would not be induced because any embryos lost would simply be resorbed by the mare rather than expelled.

Another option would be to use this approach in tandem with the 1-year PZP vaccine. A gather could be conducted in year 1 to treat all captured mares with the PZP vaccine, after which they would be released. That would help to ensure a large number of nonpregnant mares when a gather occurred in the following year. That approach would add expense by requiring two

gathers in consecutive years, but infertility after the second year would be permanent (assuming that the procedure is successful), and the need for future gathers would be obviated for some time.

With regard to improving the proposal, many details are omitted or assumed by the investigators. The committee interprets the proposal to indicate that the investigators plan to use 50 mares from a BLM holding facility in Burns, Oregon. If that is the case, it could be stated more clearly. No control group of mares is mentioned. Similarly, it is not said how the fertility of the stallion given access to the mares would be determined. And, methods for capturing, sedating, and minimizing pain and stress in the animal are not described or addressed.

Another issue not addressed in the proposal is tubal pregnancies. The investigators report that if a mare is bred in the preceding 6–7 days, tubal pregnancy may result. In an animal with a 21-day cycle, 5% of open mares would be expected to be in estrus on any given day, so in 6–7 days as many as 30% of open mares could have been recently bred. Tubal pregnancy would be a painful, iatrogenic condition and should be considered as a welfare concern.

A proof-of-concept study could be carried out quickly with domestic mares before the technique is introduced to the horses in Burns or perhaps the step in Burns could be skipped entirely. Using domestic mares that could be easily handled would allow well-managed breeding (via artificial insemination) with semen of known fertility. Pregnancy status could then be diagnosed within 2 weeks of insemination. After proof of the concept, the technique could be moved into a free-ranging herd to test the difficulty of using it in true field conditions.

The committee was confused by the statement at the end of the proposal: “Beginning in the spring, assuming our experimental population has remained at Burns. . . .” It is not clear why the investigators cannot assume that the experimental population would still be available. If that population were not available, this would be another justification for conducting the experiment in domestic mares to which access could be guaranteed from the start to the finish of the experiment.

Finally, BLM would need to invest in many expensive endoscopes and have access to a number of trained veterinarians if the procedure is to have an effect on the population growth rate of a herd. The costs for the proposed project are appropriate, although the indirect costs included in the budget are higher than the 15% for the Wild Horse and Burro Program.

Proposal Number: 9

Proposal Title: Minimally invasive tubal ligation of wild horse and burro mares as a method of contraception and population control

Principal Investigator: [redacted] Oregon State University

Funding Recommendation: Fund.

COMMITTEE DISCUSSION SUMMARY

The procedure put forward in this proposal uses a flexible endoscope inserted through the anterior vagina to cauterize and transect the oviduct. Before treatment, the mare would be sedated, and then the abdomen would be distended with filtered air or carbon dioxide to aid in visualization of the ovaries and oviducts. The endoscope would pass through an incision in the anterior vagina and be used to visualize each oviduct, and the oviduct would be cauterized and transected. An epidural would be performed if necessary. The ligation of the oviduct would render the mare permanently sterile but still able to cycle normally. The investigators plan to perform this procedure on pregnant mares.

The committee is concerned that the ovaries may not be visible in late pregnancy because the mare's ovaries are pulled medially and anteriorly as the pregnant uterus moves over the pelvis and down to the floor of the abdomen. The collapse of the anterior vagina would also prevent passage of the endoscope in pregnant mares. Conducting this study would answer whether or not those concerns are warranted.

The committee considered this proposal in conjunction with Proposals 8 and 12, which also aim to sterilize mares through minimally invasive procedures. The committee concludes that Proposals 8, 9, and 12 should all be funded. The budgets for these proposals are not large, and each should be completed in a short period (no more than 2 years). When these research activities have concluded, BLM will be in a position to evaluate which approach or combination of approaches works best under what conditions, such as time of year, open or pregnant mares, stage of pregnancy, and the terrain of and size of the population in the Herd Management Area where a gather, sterilize, and release program is planned.

The committee offers some caveats regarding this proposal. The major risk to the mare would be abdominal pain in the 24 hours after the procedure. Injection of lidocaine or similar products into the ovary or oviduct during the procedure is not mentioned. Given the experience of some committee members, this additional step is recommended for pain management.

The proposal could be written more clearly and with more detail. It states that mares would be restrained in a hydraulic, padded chute that is specifically and successfully designed for routine processing of free-ranging horses. However, no further information is provided regarding animal-handling facilities. It is also unclear whether the investigators would have access to the number of animals (50) that are proposed for use in this study.

The committee is skeptical of the claim that four horses could be treated in an hour. Given the time needed to inflate the abdomen, two is more likely. There is also the issue of skilled practitioners: this approach would require more training than the form of sterilization discussed in Proposal 8.

The costs for the proposed project are appropriate, although the indirect costs included in the budget are higher than the 15% for the Wild Horse and Burro Program.

Proposal Number: 19

Proposal Title: Functional assessment of ovariectomy (spaying) via colpotomy of wild mares as an acceptable method of contraception and wild horse population control

Principal Investigator: [redacted] Oregon State University

Funding Recommendation: Fund with nonresearch money.

COMMITTEE DISCUSSION SUMMARY

This proposal focuses on demonstrating the value of ovariectomy in free-ranging horses. The investigator proposes to evaluate the feasibility of using surgery as a management tool in controlling the growth rate of free-ranging horse herds.

The proposal contains no science or experimentation related to technique. Colpotomy, as described in this proposal, is not a new technique; the only novelty in the proposal is that the procedure would be performed on free-ranging rather than domestic horses. The committee did not consider this difference to be a matter of research.

Nevertheless, the committee evaluated the proposal's usefulness as a tool for population growth suppression and the risks associated with it.

Ovariectomy via colpotomy is a relatively common procedure and a standard veterinary practice that is performed widely by practitioners in domestic horses. The death rate associated with the procedure is low. Domestic mares are typically cross-tied to keep them standing for 48 hours post-surgery to prevent evisceration through the unclosed incision in the anterior vagina. That protocol would not be possible with free-ranging mares because they cannot be held still for so long. Therefore, there is some concern that the investigator may see more fatalities after surgery than the 1% quoted in the protocol, which is based on domestic mares. The procedure should be 100% effective in sterilizing treated mares.

The proposal does not state at what early stage of pregnancy a mare would be excluded from the study. The mare's ovaries and their production of progesterone are required during the first 70 days of pregnancy to maintain the pregnancy. It is the opinion of the committee that if this procedure were performed in the first 90 days of pregnancy, the fetus would be resorbed or aborted by the mother. If performed after 120 days, the pregnancy should be maintained. The effect of ovary removal on a pregnancy at 90–120 days of gestation is unpredictable because it is during this stage of gestation that the transition from corpus luteum to placental support typically occurs. The proposal also does not state how long it would take to perform the procedure on a mare. That would be useful information for BLM to have in assessing its practicality.

The committee believes this procedure could be operationalized immediately to sterilize mares, with the caveat that fatalities may be higher than the 1% reported in the literature. The sterilization techniques put forward in Proposals 8, 9, and 12 would be safer—with less risk of hemorrhage and evisceration—and probably less painful. Therefore, if the techniques in Proposals 8, 9, and/or 12 prove to be successful after the research has been conducted, the committee thinks that these techniques should replace Proposal 19's method of ovariectomy via colpotomy as surgical approaches for permanent sterilization.

Sterilization of Dominant Males Will Not Limit Feral Horse Populations

Kurt J. Nelson, Wildlife Biologist
Carson National Forest, Questa, New Mexico[1]

Abstract

Sterilization of dominant stallions is impractical for controlling feral horse populations. Evidence does not support the premise that reproductive units are stable, with one male and many females. Individual horses, including reproductively active females, move between bands during the breeding season.

[1]*The author was a graduate student, New Mexico State University, Las Cruces. This research was supported by the Rocky Mountain Forest and Range Experiment Station with headquarters at Fort Collins in cooperation with Colorado State University and by the New Mexico State University Agricultural Experiment Station in Las Cruces. The manuscript was submitted as New Mexico State University Agricultural Experiment Station Journal Article 774. Supervision was provided by David R. Patton, project leader at the Station's research work unit at Tempe in cooperation with Arizona State University.*

Sterilization of Dominant Males Will Not Limit Feral Horse Populations

Kurt J. Nelson

Management Implications

Permanent or temporary sterilization of the dominant stallion in a feral horse herd has been suggested to control horse populations. This control method would work only if bands of horses were stable, if reproductive units consisted of one male and many females, and if females did not move between bands. A study of the behavior of bands of horses from the Jicarilla herd shows that female fidelity is weak or nonexistent and that some breeding in the bands is by subdominant males. The amount of sterilization that would have to be done to control horse numbers indicates that the technique is not practical. Another reason to avoid selective sterilization of dominant males is that these animals represent the best genetic material for the population.

Introduction

The Wild Free-Roaming Horses and Burros Act (PL 92-195) of 1971 provides federal protection and custody for feral equids, including feral horses (*Equus caballus*), on specified public lands. Prior to 1971, feral horse populations were limited through relatively unrestricted removal of animals. Since protection began in 1971, some of these populations may have increased at rates approaching 20-25% per year (Blaisdell 1977), resulting in overuse of available resources (Hall 1972). An acceptable method is needed to regulate feral horse numbers at levels compatible with environmental constraints while maintaining the populations at viable levels.

Population management has three distinct goals: (1) to keep a species on a "sustained yield basis" (harvest game management); (2) to increase the density of a species that is dangerously low (endangered species management); or (3) to decrease the density of a species (pest management) (Caughley 1976). With respect to feral horse populations on western rangelands, population management might be viewed as an amalgamation of goal 2, maintaining viable populations of feral horses, and goal 3, limiting growth of local populations that reach pest proportions.

One suggested technique for imposing population control artificially is temporary or permanent sterilization of the dominant stallions in a feral horse population to reduce the rate of reproduction (Baxter 1977, Frei 1977). The technique is appealing because it requires manipulation of only a few animals, and it is acceptable to various agencies and preservation groups (National Wild Horse Forum 1977).

The hypothesis that sterilization of dominant stallions would control population is based on the following assumptions:

1. Only certain males (harem stallions) participate in the breeding.
2. The number of breeding males is small relative to the number of reproductively active females, so that one male breeds many females.
3. A feral horse society is composed of groups that are stable over time.
4. Any changes in band affiliations are primarily among the immature, prereproductive individuals in the population.

If any of these seemingly plausible assumptions is untrue, sterilization is not practical as an artificial means of imposing density limitations.

This hypothesis thus raises questions on feral horse biology: What is the sex and age composition of the population? When do mating and parturition occur? At what age do both males and females reach sexual maturity? What type of social organization is expressed? Are the dominant stallions of feral horse bands doing all of the breeding within their bands? Do peripheral males participate in breeding receptive females? How stable are feral horse bands, and how much exchanging of members between bands occurs? How are bands formed and who forms them?

Only recently have there been attempts to obtain information on the population biology of feral horses (Feist 1971, Feist and McCullough 1976, Green and Green 1977, Hall 1972, Hall and Kirkpatrick[2]).

Various authors have described the social organization of both wild and feral equids. Generally, they have noted two distinct types: those equids in which the males are strictly territorial, such as in Grevys zebra (*Equus grevyii*) (Klingel 1969a, 1975a, 1975b), in some

[2]*Hall, R., and J. F. Kirkpatrick. 1975. Biology of the Pryor Mountain Wild Horse. Unpublished report, 21 p. Bureau of Land Management, Salt Lake City, Utah.*

U18401 2866632

feral ass (*E. asinus*) populations in Death Valley (Moehlman 1974), and those equids in which the males are nonterritorial and form harem units, such as in plains zebra (*E. quagga*), mountain zebra (*E. zebra*) (Klingel 1966, 1967, 1968, 1969b, 1975b), and feral horse (*E. caballus*) (Fiest 1971, Feist and McCullough 1976, Green and Green 1977).

Feist (1971), Feist and McCullough (1976), and Green and Green (1977) stressed the highly stable nature of the harem social unit in their studies of feral horse populations. Band stability, it is hypothesized, is determined by the stallion's dominance over the other individuals of his band. Interchanges that did occur were primarily in the prereproductive segment of the population. Thus, a feral horse society is thought to be one of female fidelity to a particular band and not one of sporadic association with many different bands.

It can be concluded from computer simulations of population responses to changes in demographic parameters that sterilization of the dominant stallions is an impractical method of population control (Nelson 1978). It was shown that to initiate a population decline, the percent of successful breeding of females must be reduced to less than 10% (fig. 1).

Another method of control of these populations appears to be continuous cropping of 15% of the population per year. Cropping of entire band units would cause the least disruption to the social structure of the entire population. For a discussion of such a cropping procedure, see Fowler and Smith (1973). For a more thorough discussion of the computer simulations see Nelson (1978).

The research presented here is an evaluation of male sterilization techniques based on observations of population biology.

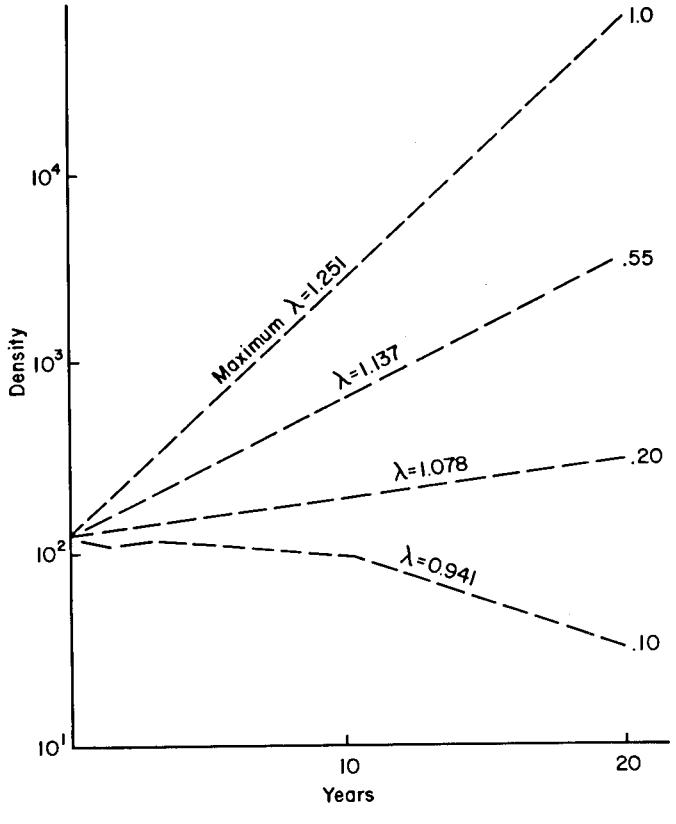

Figure 1.—Changes in the finite rate of increase in a feral horse population as a result of varying percent breeding. Proportion breeding shown at end of each line.

Study Area

The study area was on the Jicarilla District of the Carson National Forest, 90 km northeast of Farmington, N. Mex. The northern portion of this public land has been designated as the Jircarilla Wild Horse Territory and is approximately 29,000 ha. This study was restricted to 14,200 ha. The study area is heterogeneous, including four major canyons (10,000 ha) administered by the USDA Forest Service (FS) and 4,200 ha of land administered by the Bureau of Land Management (BLM). There is movement of feral horses across the FS-BLM boundary line.

Topographic features include wide canyon bottoms, steep-sided rocky slopes, and broad mesas. Elevations range from 1,800 to 2,275 m. The area lies within the San Juan Basin, with underlying rock of the Wasatch and Naciminento formations. The mesa soils are of sandstone origin and quite variable. The slopes and bottomlands are a mixture of soils derived from shale and sandstone and are easily eroded (Dane 1948, Simpson 1950). There are alluvial deposits 6 m or more in depth in the main canyons; canyon bottoms vary in width from a few hundred meters to 1.5 km or more. Deep gullies have been cut through the alluvia, and sheet erosion is common.

Precipitation occurs in the form of winter snow and summer rains. Water availability is limited during the dry months prior to the onset of summer rains. The development of stock tanks to hold runoff and the presence of intermittent springs along the main canyons provide water sources during the drier months. With the onset of the summer rainy season, water is readily available throughout the area.

Vegetative types include sagebrush-grass association, pinyon-juniper woodland association, pinyon-juniper/sagebrush-grass ecotone association, pine/Douglas-fir association, and revegetation association.

Approximately 800 ha of range revegetation has been done in the study area over the past 10 years. These areas begin vegetative growth 3 to 5 weeks earlier than the surrounding nonmanipulated land. A corresponding increase in use of these areas by feral horses, mule deer (*Odocoileus hemionus*), and elk (*Cervus elaphus*) was noted in response to early spring growth. Revegetation areas provide an important food source before spring growth begins on other parts of the range. A substantial road network exists on the study area enabling fairly complete coverage from a vehicle.

Methods

This study involved intensive observation of daily and seasonal activity of selected feral horse bands. The usual procedure was to observe a band for 4 to 12 hours. Most of the study area was visited at least every 2 or 3 days.

A 20X spotting scope, 8X binoculars, and a tape recorder were used. Observations were recorded in three formats, adapted from procedures outlined by Altmann (1974). Behavior-time matrices, including both social and nonsocial behaviors, were constructed for observations of bands and individuals within bands. The number of horses engaged in different activities was recorded at 5-minute intervals, and the relative position of the horses plotted. During each hour that a band was observed, activities of a randomly chosen individual were observed for 30 minutes and recorded separately. For individuals, observed activities were noted as occurring within any given minute during the 30-minute observation period (Lagerspetz 1964, Conley 1976). Band identification, date, time, weather conditions, vegetative association, and location were recorded for all observations. In addition, sex, age, identifying color and marks, and familial relationships (as discernible) were recorded on the individual's data sheets. A continuous account of all other behavior was recorded throughout an observation period in conjunction with the other two formats. From these three methods of recording information, construction of a complete behavior profile is possible for both individual and group activity patterns over the course of a year.

An aerial count of the feral horse population was conducted January 18-20, 1977, after sufficient snowfall to facilitate observation. This aerial survey and knowledge of the number of horses in the study area were used to estimate total population size.

Fieldwork began on September 13, 1976, and terminated August 17, 1977. Approximately 1,100 hours of behavior observations on individual horse bands and 400 hours of behavior observations on individuals within bands were recorded during the field study.

Results

The aerial census revealed 226 individuals in this population. The population segment that received intense study consisted of 116 individuals in 17 different bands. Each band included a mature stallion, one to six mature females and their offspring, and an assortment of immature females not necessarily of familial relation. Two bands contained more than one stallion.

Table 1 shows the age structure and composition of this population segment. Four age classes could be recognized: (1) foal, individuals up to 1 year of age; (2) yearling, individuals from 1 to 2 years of age; (3) immature, individuals from 2 to 3 years of age, and (4) mature, individuals 3-1/2 years and older. Some overlap exists in the immature and mature age classes because of difficulty in determining the age of certain females. If the three youngest age classes are grouped together, 52.6% of the population was born between 1975 and 1977.

Table 1.—Sex and age composition of the population segment that received intense study in summer 1977

	Foal	Yearling	Immature	Mature	Total	Percent
Male	12	7	10	17	46	39.7
Female	9	9	14	38	70	60.3
Total	21	16	24	55	116	100.0
Percent of total population	18.1	13.8	20.7	47.4	100.0	
Ratio of males to females	1.33	0.77	0.71	0.44	0.66	

Very little is known of reproduction in feral horses. Nishikawa et al. (1952), Hafez and Jainudeen (1974), and Nishikawa and Hafez (1974) gave a thorough summary of reproduction in domestic horses. A brief description of reproduction in domestic horses provides a reference to evaluate feral horse reproduction. In domestic stallions, sexual maturity may be attained before the age of 2 years. Testicular growth begins at 11 months with spermatogenesis occurring by 12 months. Males possess viable sperm year-round, although photoperiod appears to affect both the quantity and quality of semen. A domestic stallion can normally service 60 to 80 females during the breeding season. In female domestic horses, sexual maturity may be attained as early as 12 to 18 months. Estrous may be acyclic at first, then becomes cyclic. The length of the estrous cycle varies from 16 to 24 days, and duration of estrus itself is 3 to 11 days. Ovulation occurs 24 to 48 hours prior to the end of estrus. Diestrus lasts 14 to 19 days when ovulation occurs and 7 to 10 days when ovulation does not occur. The duration of gestation is 340 ± 30 days. A post-partum estrus may occur 5 to 15 days following birth. In domestic horses, reproductive efficiency is low, with a 60-65% conception rate and 50% foaling rate. Abortion frequency is 10% with mares 3 to 6 years old having the lowest abortion frequency. Prenatal mortality is common to lactating mares mated early in the season and to those which conceive during post-partum estrus.

Based on recent field observations of feral horse populations, it appears that reproduction in feral horses is similar to that in domestic horses. Feist (1971) and Feist and McCullough (1975) observed that 43.2% of mature females foaled in 1970. Two mares in the immature age class foaled, and two sets of twins also were noted. The breeding season of this population of feral horses was restricted to the spring and summer, with all foals born between April and June, and a peak in foaling in May. All mating occurred within the

harem unit with all copulations by the dominant male stallion. The behavioral sequences of mating have been described by Feist and McCullough (1976).

In the Jicarilla feral horse population, mating was observed throughout the year. Most observed copulations coincided with the spring and summer foaling season. Of 19 observed copulations, 17 were by dominant harem stallions. These stallions copulated with female members of their own bands and other receptive females. Nine of the observed copulations were with females from another band.

Evidence does not support the premise of stable reproductive units. Fidelity to a particular band is weak or nonexistent in many females of this population.

Twenty-one foals were born to the 38 mares in the mature class giving a 0.55:1 ratio. There were no twins. This rate of recruitment indicates most females do not foal in successive years, a finding that is further supported by field observations that 29% of the mares had foals in each of the past 2 years. The peak foaling period in this population occurred from April through May. By the end of May, 66% of all foals had been born, although foaling continued through the end of August.

There were differences in reproductive effort between females with access to revegetation areas and females without such access. Females with access to these areas began foaling on April 6 and completed foaling in May. Other females began foaling on May 3 and continued through August. Of the mature females, 64% had access to revegetation areas. These females contributed 73% of the foals (table 2).

Mortality was low in this feral horse population. During the study, 25 skulls were collected and age-at-death estimates were derived using tooth-eruption and tooth-wear criteria following procedures used by Ensminger (1969). Twenty-two of these horses were less than 12 years of age at the time of death. The presence of canine teeth indicated 15 of the skulls were from male horses (Ensminger 1969). There was no mortality in the foal class. Of 21 foals born in the spring and summer of 1977, all survived through August 1977 when this study ended. It is possible some mares gave birth to foals that died prior to being observed.

Table 2.—Differences in reproductive effort of females with access to revegetated areas and females without access

Activity area	Females	Foals	Foal to mare ratio	Standard error
	------- *percent* -------			
Revegetated areas	64	72	0.62	±0.08
Nonrevegetated areas	36	28	.43	± .10
Total	100	100	.55	± .06

Different mortality rates between sexes are evident in this population. The male to female ratio at birth approaches 1.0; however, the sex ratio approaches 0.4 in the mature age classes. This suggests that males are incurring higher mortality or that a disproportionate number of males left the study area. Of 10 males in the immature age class, only 4 were in harem units, while all 14 females in this immature class associated with one or more harem bands.

Mountain lion (*Felis concolor*) and coyote (*Canis latrans*), both present in the study area, are potential predators on feral horse populations (Dobie 1952, Young and Goldman 1946). However, no deaths within this population could be attributed to predation during the study.

Observations suggest that survival patterns are characterized by low mortality in the foal and yearling classes, and higher male mortality in the immature and mature age classes. Dispersal movements are included as a component of mortality estimates, thus making estimates conservative.

Social Structure

A band is a recognizable aggregate of individuals in a somewhat stable association. A band may be a harem group or it may be an all-male aggregation of immature, subdominant members of the population. Female aggregations were not classified as bands because they were in frequent association with one or more harem groups over the course of the year. An assumption in this study was that the stallion is the alpha individual, thus band identity was determined by his presence or absence. Most bands contain a core of individuals which usually remain together with the stallion. I have called such a group the primary band. If a female was recognized as a member of a particular band but was not with the stallion, she was classified as out of the band.

The dynamics of group formation and group structure are of particular importance in a social system. Feral horse bands were formed in four ways: (1) peripheral males acquiring females from existing bands (observed three times); (2) peripheral males forming a band with females which had previously been moving between bands (observed twice, although neither was permanent); (3) a peripheral stallion assuming control over a harem band following disappearance of the dominant stallion (observed once); and (4) bands splitting into two new bands as a result of competition between two mature males (observed once and appeared to be happening in another band at the close of field observations).

Size and composition of some bands were fairly stable while others were unstable. Changes in band size and composition occurred throughout the year, but there was a strong seasonal pattern in some bands. The monthly mean size of each band indicated an increase in general movements of individuals between bands and out of bands during the spring and summer months. Certain bands having access to revegetation areas exhibited greater interchange of members be-

tween bands (fig. 2). Prior to the onset of breeding and parturition in late March, these bands begin to break up, with females and their offspring moving between adjacent bands. By May, very few females were with their primary band, and were either with another band, by themselves, or with all-female factions of a previous band. Bands not having access to revegetation areas appeared to be relatively stable (fig. 3). Considerable movement occurred even among the more stable bands but was usually short-term, with individuals returning to their primary band (fig. 4).

Sixty-one percent of the females in the study area were either alone, or with other females and no stallion, or in association with another band at some time during the year. Females moved more during the time of breeding and parturition. This amount of movement would not necessarily negate the hypothesis that the population could be controlled by sterilizing dominant males, provided the animals involved in the movement were the nonreproductive and/or immature segments of the population. However, the most active segment of females were mature (78% of the observed movements). Immature females had a higher movement activity in the fall and winter periods. Yearling females generally stayed with their primary band, moving only with other females.

Discussion

These findings suggest that dominant males do most of the breeding and that there are few such males relative to the number of sexually active females. However, the majority of the observations were of bands which included a dominant stallion, resulting in a bias in favor of such observations. While copulations involving peripheral stallions were not observed, the fact that females associate with these males at various times, and spend long periods of time outside any harem band, suggests that some reproduction may be attributable to these males.

An explanation for the disproportionate sex ratio in the mature age class is not readily available. Two solitary stallions and one group of five immature and subdominant stallions were observed during the study. Dispersal of males to areas outside the study area or differential mortality directed toward the male segment of the population are two possible reasons for the observed imbalance; however, it seems possible that males from other areas would immigrate into this population segment, resulting in no net changes.

Most movements of individuals between bands or out of bands coincided with the breeding season. Not only was there movement between groups, but this movement included the reproductively active females. The high percentage of the female population involved in either long- or short-term movements outside the primary band negates the effectiveness of male-limited population control. Evidence that over 50% of the observed copulations were with females from other bands further indicates the ineffectiveness of sterilizing only certain harem stallions.

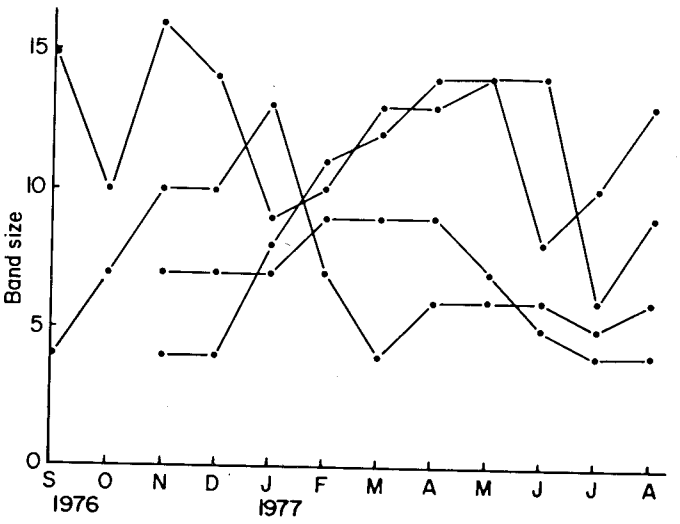

Figure 2.—Maximum monthly band size of four bands with access to revegetated areas.

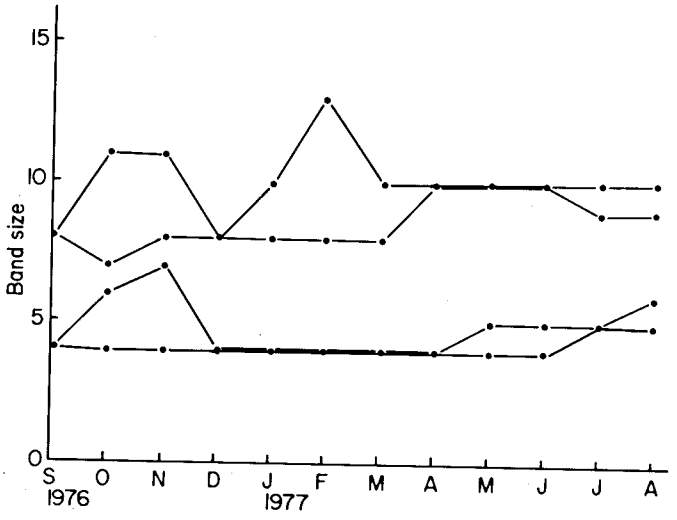

Figure 3.—Maximum monthly band size of four bands without access to revegetated areas.

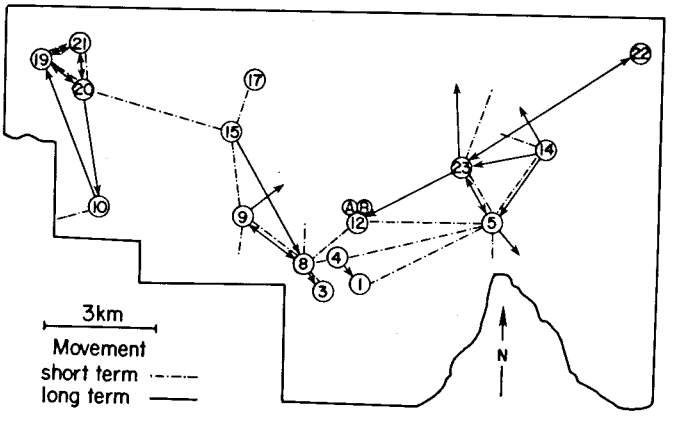

Figure 4.—Movement of individuals between bands and out of bands within the study area in the Jicarilla feral horse population.

Given the potential of feral horse populations to increase as evidenced in the past few years, it seems unlikely that sterilizing dominant males would reduce reproduction enough over the time necessary to cause a decline in numbers. Approximately 25% of the harem stallions were replaced each year. If these observations are representative of feral horse populations in general, male-sterilization techniques would have to be implemented on a yearly or every-other-year basis, an impractical management approach.

In addition to failing to limit the population, selective sterilization of alpha males would eliminate the major contributors of quality genetic material from the gene pool. Breeding by peripheral, subdominant males, might then introduce inferior genotypes, a result which runs counter to the management objective of maintaining viable feral horse populations.

Future Research

The biology of this population has been made more complex by the differential behavior of individuals with access to revegetation areas compared to those without access to such areas. The higher foal:mare ratio of females with access to revegetated areas implies increased reproductive value with increasing nutritional resources. Clegg and Ganong (1969) found that domestic mares would breed at any season if well fed. Hall (1972) relates reproductivity to nutrition in the Pryor Mountain feral horse population, since foaling coincided with the onset of spring growth of vegetation. That these females with access to revegetation areas are foaling earlier in the spring suggests that the timing of reproductive efforts are tied to differences in forage availability and are in this sense vegetation generated. While these differences do not directly relate to the questions of limiting population growth by sterilizing dominant males, a management alternative might be to concentrate on those groups of animals which exhibit higher production, if the goal is to limit growth of the population. Research completed by the University of Arizona will provide new information on the use of revegetated areas by wild horses.[3]

Untersuchungen zu den Auswirkungen des Kastrationszeitpunktes von Lamahengsten (*Lama glama*) auf ihr Verhalten

S. Nickolmann[1], S. Hoy[1], M. Gauly[2]

[1]Institut für Tierzucht und Haustiergenetik (geschäftsführender Direktor: Prof. Dr. G. Erhardt) der Justus-Liebig-Universität Gießen, [2]Institut für Tierzucht und Haustiergenetik der Georg-August-Universität Göttingen

Schlüsselwörter:
Lama, Kastration, Verhalten, Androgen

Zusammenfassung:

Gegenstand und Ziel: In der Arbeit wurde der Effekt der Kastration auf das Verhalten sowie den Hormonstatus von Lamahengsten in Abhängigkeit vom Alter der Tiere untersucht. **Material und Methoden:** Bei je sechs adulten und juvenilen Hengsten wurden das Sozial- und Sexualverhalten vor und nach Kastration beobachtet sowie Plasmatestosteronwerte bestimmt. **Ergebnisse:** Bei den fertilen Althengsten war die durchschnittliche Zahl geringer sozialer Distanzen signifikant niedriger. Die Anzahl stieg nach Kastration in beiden Gruppen ebenso wie der Anteil direkter Körperkontakte. Die Zahl kurzer Auseinandersetzungen sank bei den Althengsten nach Kastration ebenso wie der Anteil der Kämpfe mit eindeutigem Ausgang. In beiden Untersuchungsgruppen veränderte sich die Rangordnung der Tiere durch die Kastration. Vor dem Eingriff führten alle Althengste Deckakte ohne Unterbrechung aus. Danach unterbrachen alle die Kopulationen mehrfach bei reduzierter Gesamtdeckzeit. Bei den Junghengsten fanden sich vor der Kastration nur kurze Deckzeiten mit vielen Unterbrechungen. Die Plasmatestosteronwerte betrugen bei den adulten Hengsten 4,1 ng/ml (± 2,8) und bei den Junghengsten 1,1 ng/ml (± 1,0). Die Testosteronwerte und Rangindices waren nicht korreliert. **Schlussfolgerung und klinische Relevanz:** Die Gruppen unterschieden sich signifikant in Verhalten und Hormonstatus. Die Kastration führte in beiden Gruppen relativ rasch zu einer besseren Verträglichkeit der Tiere. Die sexuelle Aktivität wurde durch die Kastration signifikant beeinflusst. Das grundsätzliche Interesse an Stuten blieb allerdings bei den Althengsten erhalten. Die Kastration ist für Hengste, die nicht zur Zucht eingesetzt werden sollen, anzuraten. Sie sollte möglichst vor der Geschlechtsreife durchgeführt werden, aber nicht vor einem Alter von 12 Monaten.

Key words:
Llama, castration, behaviour, androgen

Summary:

Objective: The aim of the study was to prove the effects of castration on behaviour and hormone levels in sexually mature and immature Llama males. **Material and methods:** The study comprised six sexually mature and six sexually immature llama males. Their social and sexual behaviour was observed before and after castration. Testosterone levels were analysed regularly. **Results:** The percentage of low social distances was significantly lower in mature males and increased in both groups after castration as well as the number of direct body contacts. Short agonistic interactions and the percentage of fights with clear result (one male was the winner or looser) decreased after castration in mature males. In both groups order of rank changed after castration. Before castration all mature males mated the female without breaks. After castration they interrupted copulations several times and total time of mating was decreased. Immature males showed short mating times with many interruptions before castration. The testosterone level changed between the months of observation in the mature male group. In the mature male group blood testosterone level was 4.1 ng/ml (± 2.8), and in the immature group it was 1.1 ng/ml (± 1.0). There were no correlations between testosterone level and order of rank. **Conclusion and clinical relevance:** Mature and immature males differed significantly in behaviour and hormone levels. Castration did improve social behaviour as the number and intensity of agonistic interactions decreased. Sexual behaviour was also significantly affected by castration in mature males. It can be concluded that keeping and handling of geldings is less problematic. Therefore, castration can be recommended as a management tool after 12 months of age, but before sexual maturity.

Effects of castration on the behaviour of male llamas (*Lama glama*)

Tierärztl Prax 2008; 36 (G): 319–323

Eingegangen: 29.01.2008; akzeptiert: 04.04.2008

Einleitung

Die Lama- und Alpakahaltung erfreut sich in Mitteleuropa mittlerweile im Hobby- und Freizeitbereich einer großen Beliebtheit (10). Lamas werden unter anderem zum Trekking genutzt. Dazu eignen sich besonders männliche Tiere, die nicht bzw. nicht mehr züchterisch zum Einsatz kommen. Bei der Hengsthaltung können jedoch Probleme auftreten. Geschlechtsreife Hengste zeigen ein ausgeprägtes Aggressionsverhalten gegenüber anderen Hengsten, in dessen Folge mitunter lebensbedrohende Verletzungen entstehen (7). Die Haltung mehrerer geschlechtsreifer Hengste in Stutenherden ist deshalb nicht möglich. Bei den nicht domestizierten Neuweltkameliden (Guanako und Vikunja) vertreibt der Althengst die Junghengste aus dem Herdenverband, wenn diese die Geschlechtsreife erreichen (14). Aus diesem Grund sowie zur Kontrolle des Reproduktionsgeschehens in der Herde werden in der Praxis geschlechtsreife Hengste häufig einzeln gehalten. Die Einzelhaltung, ohne Kontakt zur Herde, muss als nicht tiergerecht bewertet werden. Häufig führt sie zur Entwicklung von Verhaltensanomalien. Die gemeinsame Haltung kastrierter männlicher Tiere scheint dagegen problemlos möglich (8). Männliche Kastraten gelten bei verschiedenen Tierarten als unproblematischer im Umgang (20). Auch bei Neuweltkameliden erlischt nach frühzeitiger Kastration das geschlechtsspezifische Aggressionsverhalten, sodass Wallache sowohl mit anderen Wallachen als auch in Stutenherden mit Fohlen und Junghengsten gehalten werden können (4). Dabei spielt möglicherweise der Zeitpunkt der Kastration eine wichtige Rolle. Er bestimmt mit, in welchem Maße das Verhaltensrepertoire ausgebildet bzw. tradiertes Verhaltensrepertoire noch verändert werden kann (1). Für Lamas wird entsprechend ein früher Kastrationszeitpunkt empfohlen. Nachteile der frühen Kastration zeigen sich jedoch in anatomischen Problemen, wie dem eunuchiden Riesenwuchs, weshalb die Tiere zum Kastrationszeitpunkt ein Mindestalter von 12 Monaten erreicht haben sollten (12).

Ziel der vorliegenden Arbeit war, den Effekt der Kastration auf die geschlechtliche Entwicklung und das Verhalten von Lamahengsten in Abhängigkeit vom Alter und der geschlechtlichen Reife der Tiere zum Zeitpunkt des Eingriffs zu untersuchen. Darüber hinaus wurden mögliche Effekte der Testosteronkonzentration im Hinblick auf die Rangordnung ermittelt.

Material und Methoden

Tiere und Versuchsbedingungen

Für die Untersuchungen standen 12 Lamahengste (*Lama glama*) zur Verfügung. Eine Gruppe umfasste sechs geschlechtsreife, fertile Hengste im Alter von 3–8 Jahren, die andere Gruppe sechs infertile Tiere im Alter von 9–18 Monaten (zu Beginn der Untersuchungen zeigten alle Tiere noch eine präputiale Verklebung).

Die Untersuchungen fanden in der Lehr- und Forschungsanstalt Oberer Hardthof der Justus-Liebig-Universität in Gießen über einen Zeitraum von 10 Monaten (Mai bis März) statt. Beide Herden wurden auf zwei unterschiedlich großen Weiden mit Unterstand gehalten (erste Weide: ca. 2500 m², zweite Weide ca. 5000 m² Fläche), wobei einmal wöchentlich ein Wechsel der Weiden erfolgte. Ein Sichtkontakt der Gruppen untereinander oder zu Stuten bestand nicht.

Die Lamahengste wurden mit Heu und Wasser ad libitum versorgt und erhielten jeden zweiten Tag Kraftfutter (Kraftfutter für Schafe bzw. Pferde, 100 g pro Tier und Tag). Außerdem stand ein Salz- und Mineralleckstein zur freien Verfügung. Alle Tiere hatten freien Zugang zu Futter und Wasser.

Versuchsdurchführung

Vier Monate nach Untersuchungsbeginn wurden die Hengste mittels skrotaler Methode kastriert (18), die Junghengste und die Althengste jeweils an einem Tag. Alle Tiere waren zu diesem Zeitpunkt älter als 12 Monate.

Im wöchentlichen Wechsel wurde jede Herde auf der größeren Weide von einer Beobachtungskanzel aus durch eine Person im Time-sampling-Verfahren (5-Minuten-Raster) von Montag bis Freitag für 8 Stunden täglich (2 × 4 Stunden) zu unterschiedlichen Tages- und Nachtzeiten beobachtet. Die wöchentliche Beobachtungszeit umfasste so fast zwei volle Tage. Zu jedem Beobachtungszeitpunkt wurden die geringen sozialen Distanzen zwischen den Tieren erfasst (direkter Körperkontakt, Abstand < 1 m ohne Kontakt, Abstand 1–5 m). Der bstand bezog sich dabei auf die am nächsten zueinander befindlichen Körperteile.

Die Tiere konnten aufgrund ihrer individuellen Färbung eindeutig identifiziert werden, sodass eine zusätzliche Kennzeichnung unterblieb. Die Focal-sampling-Methode (6) wurde verwendet, um verschiedene Parameter im Funktionskreis des Sozialverhaltens (agonistische Interaktionen mit Sieg oder Niederlage innerhalb der Dyade, Kampfelemente, soziale Distanzen, Verhaltensweisen der Kontaktaufnahme) zu erfassen. Die Berechnung der Rangordnung erfolgte nach folgender Formel: $R = V - D / V + D$ (15, 19). Dabei bedeutet R den Rangindex, V die Frequenz gewonnener und D die Frequenz verlorener Auseinandersetzungen. Die Indices können zwischen –1 und +1 liegen, wobei +1 absolute Dominanz und –1 absolute Subdominanz bedeuten (15, 19). Weiterhin wurden die Dauer der Auseinandersetzungen (in Sekunden) gemessen und agonistische Verhaltensweisen (z. B. Drohen, In-den-Hals-Beißen) dokumentiert. In die agonistischen Interaktionen (AI) waren alle Hengste involviert (zwischen 38,5% und 63,8% der AI wurden von den jeweiligen Hengsten als Akteur eingeleitet), sodass auf der Basis der von Lundberg (15) und Puppe (19) entwickelten Formel eine fundierte Aussage zur sozialen Rangordnung möglich wurde. Unentschiedene agonistische Interaktionen (beide Tiere in einer Dyade weichen einander aus) blieben bei der Berechnung der Rangindices unberücksichtigt.

Zur Bewertung des Sexualverhaltens wurden die Hengste im Untersuchungszeitraum einmal pro Woche einzeln immer derselben deckbereiten Stute zugeführt. Es wurde Wert darauf gelegt, dass die Reihenfolge der Hengste stets wechselte. Erfasst wurden das Interesse an der Stute, bei Kopulation die individuelle Deckzeit (die Maximalzeit wurde auf 5 Minuten begrenzt) sowie etwaige Unterbrechungen des Deckakts.

Einmal wöchentlich erfolgte bei allen Tieren eine Blutprobenentnahme aus der Vena jugularis zur Bestimmung der Testosteronkonzentration (11, 16).

Statistische Auswertung

Die statistische Auswertung der Daten erfolgte mit dem Programmpaket SPSS Version 8.0 für Windows, wobei folgende statistische Verfahren zur Anwendung kamen: Prozedur ANOVA (multipler Mittelwertvergleich nach Student-Newman-Keuls), Prozedur Kreuztabellen (Chi-Quadrat-Unabhängigkeitstests in Kontingenztafeln) sowie Korrelations- und Regressionsanalysen.

Ergebnisse und Diskussion

Die Individualdistanz zwischen Tieren ist ein wichtiger Indikator des Sozialverhaltens (5). Die Häufigkeit des Vorkommens geringer sozialer Distanzen gibt damit Auskunft über die Verträglichkeit der Tiere (2). Die Distanzen zwischen den Tieren wurden in

der vorliegenden Studie in Bereiche bis 1 m und 1–5 m eingeteilt. Außerdem wurde das Vorkommen direkter physischer Körperkontakte vermerkt. Bei den Althengsten war die durchschnittliche Zahl geringer sozialer Distanzen signifikant ($p < 0,01$) niedriger als bei den Junghengsten. Die Anzahl stieg nach Kastration rasch an ($p < 0,01$). In der Althengstgruppe fanden vor der Kastration 41,5% (n = 105) von allen engen sozialen Kontakten (n = 253) im Bereich bis zu 1 m statt, 58,5% (n = 148) im Bereich von 1–5 m. Nach Kastration stieg die Häufigkeit der engen sozialen Kontakte im Bereich bis 1 m auf 63,9% (n = 133). Der Anteil der sozialen Kontakte mit physischem Körperkontakt verdoppelte sich nahezu von 19,9% vor auf 39,1% nach Kastration ($p < 0,01$). Innerhalb der Junghengstgruppe waren ähnliche Entwicklungen feststellbar. Es wurden 514 Verhaltensweisen vor und 386 nach der Kastration beobachtet und ausgewertet. Der Anteil geringer sozialer Distanzen im Bereich bis 1 m war allerdings bereits vor Kastration signifikant ($p < 0,01$) höher (59,5%) als der Anteil sozialer Kontakte bis 5 m. Bei 24,1% der Beobachtungen hatten die Tiere vor der Kastration direkten Körperkontakt. Nach Kastration lagen bei 68,7% der Beobachtungen der geringen Distanzen die Abstände zwischen den Tieren unter einem Meter. Bei 33,7% der Beobachtungen hatten die Tiere direkten Körperkontakt. Die Unterschiede in der Junghengstgruppe waren zu den beiden Zeitpunkten signifikant ($p < 0,05$).

Die Kastration führte damit in beiden Gruppen relativ rasch nach dem Eingriff zu einer deutlich günstigen Beeinflussung des Sozialverhaltens, das heißt zu einer besseren Verträglichkeit der Tiere. Dies deckt sich mit Beobachtungen bei anderen Tierarten mit ähnlichen sozialen Strukturen wie z. B. dem Pferd (13).

Zur Bestimmung des Aggressionspotenzials und der Rangordnung wurden die Ergebnisse der beobachteten agonistischen Interaktionen sowie deren Dauer festgehalten. Die Dauer agonistischer Interaktionen kann genutzt werden, um die Intensität von Kämpfen und möglicherweise daraus resultierende Verletzungen zu bewerten (6). Allerdings traten im Untersuchungszeitraum keine klinisch relevanten Verletzungen auf, weder bei den Althengsten noch bei den Junghengsten. Es wurde auch kein Tier aus dem Gruppenverband ausgeschlossen. Auseinandersetzungen von weniger als einer Minute sind häufig gefährlicher bzw. ernsthafter als länger anhaltende Kämpfe. Bei Letzteren besteht häufig eine Vermischung mit spielerischen Elementen. Dies zeigte sich auch bei den eigenen Untersuchungen. Bei den Althengsten konnten 301 AI vor und 421 AI nach der Kastration dokumentiert werden. Bei den Junghengsten beliefen sich die entsprechenden Stichprobenumfänge auf 257 bzw. 218 AI. 77,4% aller Auseinandersetzungen dauerten in der Gruppe geschlechtsreifer Tiere vor Kastration kürzer als eine Minute. Nach der Kastration reduzierte sich der Anteil auf 64,6% ($p < 0,01$). Bei den jungen Hengsten lag das Verhältnis bei 59,5% vor und 58,3% nach Kastration ($p > 0,05$) (Abb. 1). Der Schwerpunkt der eigenen Untersuchungen richtete sich auf das agonistische Verhalten, wobei verschiedene Verhaltensweisen der Aktion (= des Angriffs) dokumentiert wurden, unter anderem „Halsbeißen", „Verfolgen", „Beinebeißen", „Halsdrücken", „Genitalienbeißen", „Ohrenbeißen", „Schreien". Submissive Verhaltensweisen, die generell methodisch schwieriger zu erfassen sind, wurden indirekt über die Einhaltung unterschiedlicher sozialer Distanzen berücksichtigt.

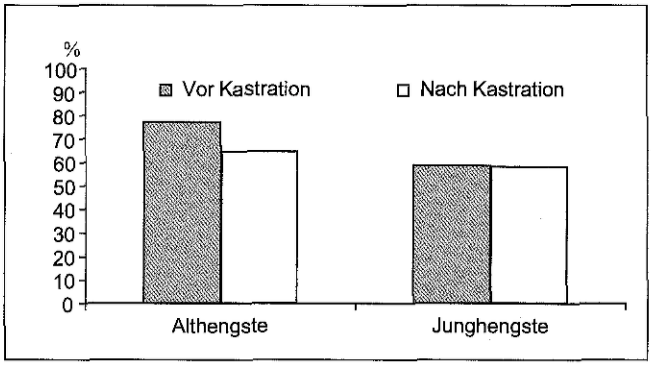

Abb. 1 Häufigkeit (%) kurzer agonistischer Interaktionen (bis 1 Minute) vor und nach Kastration

Während bei den Althengsten vor Kastration etwa 55% aller Kämpfe einen eindeutigen Ausgang hatten, nahm nach der Kastration der Anteil der unentschiedenen Kämpfe hochsignifikant ($p < 0,01$) zu. Die eindeutig gewonnenen und verlorenen Interaktionen sanken auf etwa 44% und die Intensität der Auseinandersetzungen verringerte sich. Dies entspricht den Ergebnissen anderer Untersuchungen bei Neuweltkameliden (17). Offensichtlich änderte sich auch die Motivation für Auseinandersetzungen, indem post castrationem 11% der AI spielerische Ursachen hatten und eine Unterschreitung der Individualdistanz nur noch in 10,2% der Fälle aggressives Verhalten auslöste.

Die ermittelten Rangindices lagen vor Kastration bei den Tieren der geschlechtsreifen Gruppe zwischen –0,5 und +0,7. Nach Kastration variierten sie zwischen –0,7 und +0,9 (Tab. 1). Bei den Hengsten der unreifen Gruppe lagen sie vor Kastration zwischen –0,6 und +0,9, danach zwischen –0,7 und +1,0 (Tab. 2). In beiden Untersuchungsgruppen veränderte sich die Rangordnung der Tiere über einen Zeitraum von 6 Monaten nach Kastration, blieb dann aber relativ stabil. Dies entspricht den Erfahrungen bei anderen Tierarten.

Tab. 1 Rangindices und Rangplätze vor und nach Kastration bei Althengsten

6	–0,1	3	+0,4	2

Abb. 2 Vor Kastration hatten alle adulten Hengste die Stute ohne Unterbrechung für 5 Minuten gedeckt. Danach wurde der Deckakt stets mehrfach unterbrochen.

Vor Kastration hatten alle Althengste die Stute ohne Unterbrechung für 5 Minuten gedeckt (Abb. 2). Nach Kastration unterbrachen alle Hengste die Deckakte vor Ablauf der maximal definierten Zeit. Die durchschnittliche Deckdauer reduzierte sich auf 280 Sekunden mit mehreren Unterbrechungen. Dabei fielen extreme Variationen zwischen den Hengsten auf (88–283 Sekunden). Einige Hengste reduzierten die Gesamtdeckzeit (Summe der einzelnen Deckintervalle) bis zum Ende der Untersuchungen nur unwesentlich. Alle Hengste unterbrachen die Deckakte allerdings immer wieder. Die Junghengste deckten vor der Kastration die Stute durchschnittlich 55 Sekunden lang. Nur in 18% der Fälle wurde die Kopulation nicht mehrfach abgebrochen. Nach Kastration veränderte sich die durchschnittliche Deckzeit nicht signifikant. Allerdings erfolgte nur noch in 6,4% der Fälle eine Kopulation ohne Unterbrechung. Kastrierte Tiere zeigen also immer noch ein mehr oder weniger entwickeltes, wenn auch reduziertes Interesse an den Stuten.

Unterschiede im Deckverhalten unter Bezug auf die Rangposition traten nur bei Althengsten und nur nach der Kastration auf. Während die beiden ranghöchsten Hengste noch bei 88,9% bzw. 77,8% aller Deckakte kopulierten, ergab sich bei den übrigen Hengsten ein Abfall auf 16,7 bis 5,6%.

Die für die Kopulation erforderliche Libido wird in starkem Maße durch den zentralnervalen Effekt der Androgene gesteuert. Da es nach Kastration zu einem unmittelbaren Abfall der Testosteronkonzentration kommt, erklärt sich damit das Auftreten reduzierter Deckzeiten bzw. das verringerte sexuelle Interesse (3). In der vorliegenden Untersuchung konnte für die Althengste keine Beziehung zur geschlechtlichen Aktivität (Erfahrungen) vor dem Versuch hergestellt werden, da diese unbekannt war. Die bis zum Zeitpunkt der Untersuchung gesammelten Erfahrungen (tradiertes Verhalten) mögen einen Einfluss auf das Sexualverhalten genommen haben und somit die Variationen zumindest zum Teil erklären (13).

Die Plasmatestosteronwerte betrugen bei den geschlechtsreifen Hengsten vor Kastration durchschnittlich 4,1 ng/ml (± 2,8), bei den unreifen Hengsten 1,1 ng/ml (± 1,0). Bei den geschlechtsreifen Tieren schwankten die individuellen Durchschnittswerte zwischen 1,8 und 7,9 ng/ml ($p < 0,01$). Die Werte lagen damit im Bereich der Literaturangaben (9). Die Testosteronwerte variierten bei den Althengsten zwischen den Untersuchungsmonaten vor dem Zeitpunkt der Kastration signifikant (Abb. 3). Saisonale Schwankungen wur-

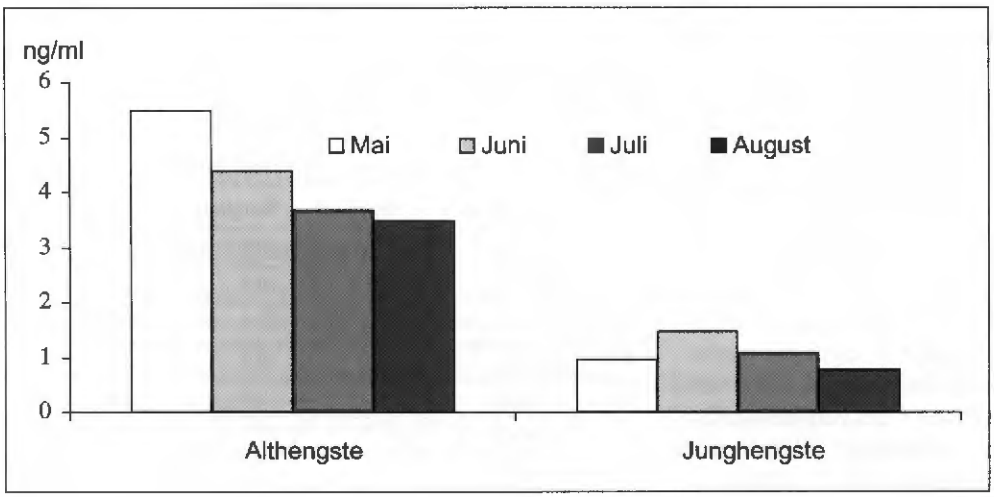

Abb. 3
Mittlere Testosteronwerte (ng/ml) beider Gruppen pro Monat

den in der Literatur bereits beschrieben (9). Zwischen Testosteronwert und Rangindex konnte keine signifikante Korrelation berechnet werden. Die verwendete Formel zur Berechnung des Rangindex führte zu keiner Überschätzung der sozialen Stellung einzelner Hengste, da es keine ungewöhnlich hohen Zahlen an agonistischen Interaktionen in einzelnen Dyaden gab.

Schlussfolgerungen

Die Gruppen der geschlechtsreifen und der juvenilen Hengste unterschieden sich signifikant in Verhalten und Hormonstatus. Die Unterschiede glichen sich nach Kastration an. Nach Kastration schwächte sich das Aggressionsverhalten der Althengste signifikant ab. Während vor der Kastration ausgeprägte Territoriumskämpfe auftraten, die meistens einen eindeutigen Ausgang hatten, und keine spielerischen Interaktionen zu beobachten waren, traten nach Kastration deutlich mehr unentschiedene Kämpfe und spielerische Auseinandersetzungen auf. Die Zahl der geringen sozialen Distanzen sowie die der direkten Körperkontakte stieg signifikant an, ebenso die Häufigkeit der spielerischen Interaktionen. In beiden Gruppen verschob sich nach Kastration die Rangordnung. Die Rangordnungen waren in den Beobachtungszeiten vor und nach Kastration sehr stabil. In der Junghengstgruppe wurden bereits vor Kastration agonistische Interaktionen auf einem zahlenmäßig niedrigeren Niveau beobachtet. Es kam häufiger zu direkten Körperkontakten.

Die sexuelle Aktivität wurde bei den adulten Hengsten signifikant durch die Kastration beeinflusst. Das grundsätzliche Interesse an Stuten blieb allerdings erhalten.

Grundsätzlich kann festgestellt werden, dass die Kastration das Sozialverhalten günstig beeinflusste, das heißt eine bessere Verträglichkeit vor allem der adulten Tiere zur Folge hatte. Die Kastration ist deshalb für Hengste, die nicht zur Zucht eingesetzt werden sollen, anzuraten. Der Eingriff sollte noch vor Eintritt der Geschlechtsreife erfolgen, wobei ein Alter von mehr als 12 Monaten noch als ausreichend früh angesehen werden kann. Auch Zuchthengste lassen sich tiergerecht in Gruppen halten, wenngleich nach Literaturangaben und den eigenen Untersuchungen mit relativ regelmäßig auftretenden agonistischen Interaktionen unterschiedlicher Schwere (z. B. unterschiedliche Dauer, Verletzungsgefahr) gerechnet werden muss.

Gelding Is Likely To Cause Wild Horses Undo Suffering

Bruce Nock, MS, PhD
Departments of Psychiatry and Neuroscience
Washington University School of Medicine

Nuclear receptor subfamily 3, group C, member 4, call it NR3C4, is an intracellular protein that is widely expressed in many types of cells and tissues throughout the body. It is a ligand-dependent transcription factor that is inactive until an androgen, either testosterone or its metabolite, 5α-dihydrotestosterone, forms a high-affinity ionic bond with it. The resulting NR3C4-androgen complex translocates from the cell cytosol to the cell nucleus where it binds to androgen-response elements in the regulatory regions of target genes. It then regulates the flow of genetic information from DNA to messenger RNA. The NR3C4-androgen complex plays key roles in an array of biological processes, including those integral to normal brain development, structure and function, and maintenance of musculoskeletal, reproductive, cardiovascular, immune and haemopoietic systems.

Gelding, i.e., castration, removes the primary source of androgen from the body. Gelded horses can live long and happy lives … in captivity aided by our management and the lack of challenges associated with life in the wild. However, a gelded horse lacks the capacity to regulate the transcription of significant genetic information. All of the physiological and structural processes mentioned above are compromised … not just his capacity to reproduce. He lacks androgen-dependent biochemical, physiological and anatomical advantages that evolved over millions of years to allow him to 1) survive without undue suffering, and 2) reproduce. Anyone who would ask a gelded horse to negotiate the challenges of a natural environment and lifestyle is either callus or has only a superficial knowledge of the impact of castration on an individual.

There is extensive scientific literature pertaining to the role of androgens in physiology and behavior. There is no justification for releasing gelded horses back into a natural environment. There is already sufficient evidence indicating it is likely to cause unwarranted suffering. If I were to propose such an experiment as part of a grant application, the federal government would require that I get institutional approval for the project based on the judgement of the *Institutional Animal Care and Use Committee* — a panel comprised of 14 full-time faculty investigators, a veterinarian, one layperson not affiliated with Washington University School of Medicine, and one non-scientific member. That committee is charged with assuring animals are humanely treated and, importantly, that experiments with animals provide significant new information that is not already available and cannot be acquired by means other than animal experimentation. When managing horses and proposing research projects (i.e., Antelope and Triple B Complexes Gather Plan, part 2.2.3.3.), the federal government should be held accountable to the same standards it rightfully imposes on others.

Menopause & Wild Horses

Menopause is a natural biological process. Even so, the physical and emotional consequences can be so severe some women seek hormone replacement therapy despite warnings of potential health risks. Sleep disruption, hot flashes, loss of energy, night sweats, insomnia, mood swings, headaches, dizziness, heart palpitations, sexual disinterest, joint stiffness, weight gain, depression, anxiety, irritability, urinary incontinence and so on are all listed as potential consequences of menopause. In addition, postmenopausal women are at increased risk for osteoporosis, heart disease, macular degeneration, glaucoma and colon cancer.

Menopause is generally defined as the permanent end of menstruation and fertility. However, it might be more accurately defined by the cessation of ovarian function. Most importantly for this discussion, it is associated with a reduction in the synthesis and release of estrogens, e.g., estradiol-17ß, and progestins, e.g., progesterone.

It is the decline in the levels of these ovarian hormones that cause trouble for so many women. And, of course, it is these hormones that hormone replacement therapy restores.

You might be wondering what this has to do with wild horse management, right? Let me explain. In 2010, the Bureau of Land Management (BLM), raised the possibility of gelding males (removing their testes) and spaying females (removing their ovaries) before returning them to the range.[1] Now, they have once again proposed spaying females as a method to control wild horse populations. Technically speaking, horses have estrus cycles, not menstrual cycles.[2] Nevertheless, spaying removes the primary source of estrogens and progestins from the body, just like menopause, and there is no reason to believe the consequences are less severe for mares than they are for woman. In fact, for woman the surgical removal of the ovaries results in more severe symptoms of menopause, because in natural menopause the ovaries continue to produce low levels of female hormones. It is hard to imagine that removal of these hormones from the body by spaying won't compromise a mare's ability to survive and thrive in the wild.

You see, the ovarian hormones are powerful steroid hormones. They have widespread effects on physiology and behavior. Estrogen, for example, is essential for

---

[1] Working Toward Sustainable Management of America's Wild Horses and Burros: Draft Goals, Objectives and Possible Management Actions, Bureau of Land Management, Department of the Interior, June 2010.

[2] If conception does not occur during a cycle, animals that have menstrual cycles slough off the uterine lining during menstruation, whereas animals that have estrous cycles reabsorb the uterine lining. The function and components of the reproductive endocrine system, the hypothalamic-pituitary-gonadal axis, are essentially the same.

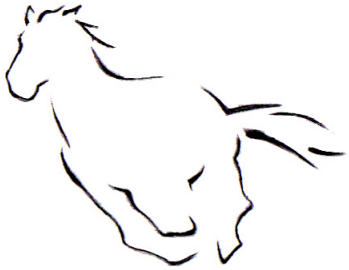
healthy bone. When estrogen production declines due to menopause, whether naturally occurring or surgically induced, or after exposure to radiation or chemotherapeutic drugs, bones become brittle and break easily. Spaying mares is likely to have similar effects on bones density and strength. I wonder, does the BLM really think returning mares to the open range in a condition associated with the increased risk of breaking bones is a good idea? Have they given it any thought at all? The image of a horse suffering with a broken leg on the open range due to compromised bone density isn't a pretty one.

Ovarian hormones also influence many neural circuits throughout the brain by binding to transcription factors which regulate the activity of certain genes.[3] In addition to the hypothalamus and other brain areas related to reproduction, they affect the activity of serotonin pathways, catecholamine neurons, and the basal forebrain cholinergic system. They influence the functioning of the hippocampus, a brain region involved in spatial and declarative memory. Ovarian steroids also have measurable effects on affective state, e.g., mood/emotion, and cognition … the mental processes involved in learning, memory, problem solving and decision making. They affect cardiovascular health and immune function. And, anyone who has watched mares in "heat" might guess, ovarian hormones have potent effects on social relations too … an

[3] My PhD thesis research at the Institute of Animal Behavior, Rutgers University, focused on the regulation of these transcription factors in brain by neurotransmitter systems: Nock, B.: Noradrenergic Regulation of Female Sexual Behavior and Hypothalamic Steroid Receptors, PhD Thesis, Rutgers University, 1980.

effect incompatible with the BLM's goal of creating a "thriving natural ecological balance" for the wild horses (see [4]).

But, taking out the ovaries doesn't just remove ovarian hormones from the body. There's more to it … a lot more. It affects other endocrine systems as well. Even forty years ago endocrinologists appreciated the subtle intricacies of endocrine system function and the complexities of hormone interactions. My endocrinology professor in graduate school, Dr. Alan Leshner PhD, drove home time and again the point that "No hormone works independently of other hormones." Take away one hormone and it affects the levels of other hormones too. Remove ovarian hormones and pituitary hormone releasing and inhibiting hormone activity changes, gonadotropic hormone levels go up, adrenocorticotrophic hormone levels go up, cortisol levels go up, thyroid hormone levels go down, and so on and so on. It's a fact. Moreover, the assessment of the long-term consequences of such hormonal imbalances requires in-depth, long-term comprehensive field studies by professional scientists … individuals trained and experienced in the art and science of science. Veterinarians don't currently know the consequences. BLM personnel don't currently know the consequences. The National Science Foundation doesn't currently know the consequences. But, it is reasonable to suggest based on what we do already know that spaying is likely to have serious consequences for a mare's ability to survive and thrive on the open range.



---

[4] Nock, B.: Wild Horses and Ecological Balance. Liberated Horsemanship Press. Commissioned by The American Wild Horse Preservation Campaign.

So, the idea of spaying mares as a method of population control doesn't sit well with me when I think beyond how it impacts reproduction. I'm also skeptical about whether it can be done safely in the field. Taking out the ovaries which reside in the abdominal cavity is a much more serious procedure than removing the testes of a male. When we ovariectomize rats for research, we do it in a state-of-the-art animal facility. We're required, by federal law, to use sterile procedures and defined recovery and followup protocols. I'm wondering, can and will the BLM, a federal agency, adhere to the practices the federal government requires us to follow for rats when removing the ovaries of horses in the field? I seriously doubt it is possible.

Even if such precautions are effectively implemented, I doubt the wisdom of returning spayed horses to the open range when bone health, mental and emotional processes and social behaviors have been compromised. The endocrine system is one of the major signaling systems of the body and ovarian hormones are major components. They are powerful agents which function to coordinate behavior and physiology. Inducing what could be described as physiological chaos by removing ovarian hormones and disrupting the normal functioning of neural and other endocrine systems to boot is very likely, in my opinion, to compromise a mares ability to thrive as a fully integrated herd member. *Bruce - 314-740-5847 BruceNock@mac.com*

ABSTRACT

An important determinant in the selection of any contraceptive agent is the impact on ovarian function, both in the short and longer term. In this study, ovarian activity was monitored in mares immunised with one of the following vaccine formulations; native porcine zona pellucida (pZP), recombinant zona pellucida proteins ZP3 and ZP4 (reZP), pZP and reZP combined or a commercially available anti-GnRH vaccine. The ZP antigens were prepared in an adjuvant formulation consisting of 6% polymeric adjuvant (Montanide™ PetGel A, Seppic, France) and 500 μg polyinosinic-polycytidylic acid - TLR3-agonist (Poly(I:C) HMW VacciGrade™, Invivogen, USA). A vehicle-only control group was administered the adjuvant formulation without antigen. Ovarian activity was monitored using clinical observations (transrectal palpation and ultrasonography of the reproductive tract) in addition to blood sampling for serum progesterone and anti-Müllerian hormone (AMH) concentrations while employing a low sampling frequency. Treatments and measurements were initiated in December (southern hemisphere summer) and subsequent data collection was performed in January, February, March and May. Both reZP and anti-GnRH vaccination were associated with clinically evident ovarian suppression in the short term. Ovarian activity in mares administered a reZP or anti-GnRH vaccine was significantly different to adjuvant control and pZP treated mares. Serum AMH concentrations were different between pZP and anti-GnRH treated mares 3.5 months after the final vaccination. Serum AMH concentrations were significantly correlated with mare age, serum progesterone and ovarian volume.

1. Introduction

A number of antigens have been proposed as targets for fertility control *via* vaccination. These include peptide hormones, oocyte and sperm proteins and other molecules associated with fertilization and early embryonic development [1]. Two immunogens studied extensively in the horse and other species as potential contraceptive agents are gonadotrophin releasing hormone (GnRH) and native porcine zona pellucida (pZP) proteins [1].

An important determinant for the selection of a contraceptive agent is the effect on ovarian function, both in the short and long term [1]. The presumed immunocontraceptive mechanism of pZP in the horse involves antibody binding to the ZP sperm receptor sites and subsequent prevention of sperm-oocyte binding and fertilisation. Based on this supposition, pZP immunisation should not affect the hypothalamic-pituitary-gonadal axis, thereby permitting continuation of cyclical ovarian activity [2,3] and associated behaviours [1]. However, pZP-based immunocontraception causes irreversible ovarian damage in some species [4–6]. By contrast, anti-GnRH vaccines trigger production of antibodies that

neutralise endogenous GnRH, which prevents receptor binding and activation of pituitary gonadotrophs. The suppression of gonadotrophin secretion causes reproductive quiescence characterised by cessation of cyclical ovarian activity [7,8]. Anti-GnRH vaccines therefore also suppress both physiological and behavioural oestrus in the immediate [7,9–11] and longer terms [8]. Ovarian suppression onsets within three months of treatment [8–12] and is associated with decreased ovarian weight [12], length [9], volume [11,12], and reductions in serum progesterone [9–12], oestradiol-17β [10], LH [12] and FSH [12] concentrations. Ovarian suppression has also been reported in mares subsequent to immunocontraception using pZP vaccine [13–15]. In this respect, apparent cessation of oestrous cyclicity and erratic cyclicity into the non-breeding season have been reported after long term treatment (>3 years) with pZP vaccines [1,16]. More recently, 93% of mares treated with a pZP vaccine ceased cyclical activity within four months of treatment [17]. Abrogated cyclicity was associated with both consistently low serum progesterone and minimal ovarian activity as determined by clinical, macroscopic and histological examination of the ovaries. Recombinant vaccines have been developed by the expression of porcine ZP3 and ZP4 in *Escherichia coli* (reZP) [18]. A recent report has described the intensively monitored ovarian function and fertility of pony mares subsequent to treatment with either a pZP or a reZP vaccine [19]. Control mares retained cyclical ovarian activity throughout the trial whereas six out of seven pZP treated mares and one reZP mare entered an extended (albeit reversible) anoestrus characterised by clinically apparent ovarian suppression and basal serum ovarian steroid concentrations. Pregnancy was established in 0%, 57% and 100% of pZP treated, reZP treated and control mares, respectively [19]. A recent vaccination trial in donkey jennies studied the effects of pZP and reZP on oestrous cyclicity and fertility [20]. The vaccines were similarly formulated to that of previous pZP and reZP vaccines administered in horses [19], using Freund's adjuvants. Seven of 9, 6/8 and 0/8 jennies entered anoestrus within three months after the final vaccination for the reZP, pZP and control jennies, respectively. No jennies in the two vaccinated groups became pregnant compared to 6/8 control jennies.

The advantages of a reZP (compared to pZP) vaccine include production efficiency and the avoidance of contamination with non-ZP proteins and heat-resistant microorganisms [19,21,22]. However, the efficacy of pZP or reZP as an immunocontraceptive agent relies on the inclusion of a strong adjuvant [23]. Freund's complete modified adjuvant (FCMA) is typically used for the primary inoculation followed by Freund's incomplete adjuvant (FIA) for booster inoculations. Freunds' adjuvants can cause undesirable side effects, which can be severe and persist for months [23]. The use of alternative adjuvants that produce a similar or better immune response with less severe side effects would be advantageous.

A more complete understanding of ovarian suppression subsequent to ZP-based immunocontraception will better define the mechanism of the contraceptive effect [19]. However, populations requiring contraception are typically managed under extensive conditions and, therefore, practical methods with limited intervention opportunities are commonly required for monitoring effects [21]. Anti-Müllerian hormone (AMH) has been proposed as a tool for assessing ovarian function during ZP-based immunocontraception [24] as it is reportedly a consistent [25] and useful biological marker of ovarian function [26].

The current study aimed to describe ovarian function in mares managed under extensive conditions following treatment with pZP or reZP vaccines formulated using non-Freund's adjuvants or a commercially available anti-GnRH vaccine. In addition, AMH concentrations were compared between treatment groups.

We hypothesised that immunocontraception using pZP proteins formulated with non-Freund's adjuvants would have similar ovarian effects as anti-GnRH vaccination. Furthermore, immunocontraception using reZP proteins formulated with non-Freund's adjuvants were expected to elicit similar ovarian responses as pZP vaccination. Additionally, we anticipated changes in AMH concentrations in ZP immunocontracepted mares.

2. Materials and methods

2.1. Mare selection, management and environment

A population of mixed breed mares (light body type: Arabian, Quarter Horse, Draught and Thoroughbred cross; age: 2–10 y) were studied from November 2016 to May 2017. Inclusion criteria were non-pregnant, normal oestrous cyclicity, good physical and reproductive health and no previous immunocontraceptive treatment [19]. Fifty barren or maiden mares were initially screened for inclusion during a 30-day monitoring period. In this group, regular oestrous cyclicity was confirmed in 26 mares on the basis of periodic changes in the serum progesterone concentration [27]. Lactating mares at the same site were recruited following re-establishment of oestrous cycle activity (assessed by transrectal palpation and ultrasonography of the reproductive tract). Thirty-nine mares were ultimately enrolled (26 maiden or barren and 13 lactating). Mares were maintained on a single extensive mountainous grassland site (3000ha) in pre-existing groups. The study site was located at 29° 51′ 30.8664″ S 29° 20′ 46.9068″ E. The study occurred during the physiological breeding season [28]. The natural day length and environmental temperature range at the beginning and end of the study period were 13 h 18 m, and 7–31 °C and 10 h 20 m, and −3 to 24 °C, respectively.

2.2. Study design

Horses (n = 39) were stratified by body condition scores (BCS: 1–9) [29], parity and age (Table 1) for random assignment to one of five treatment groups. Repeated measures data were gathered *via* clinical observation and venous blood collection.

2.3. Formulation of vaccines

The same adjuvant formulation was used for each of the control, pZP-only, reZP-only and combined pZP and reZP groups. Each vaccine dose (1 mL) was constituted by combining the antigen, 6% polymeric adjuvant (Montanide™ PetGel A, Seppic, France) and 500 μg polyinosinic-polycytidylic acid - TLR3-agonist (Poly(I:C) HMW VacciGrade™, Invivogen, USA). The amount of antigen *per* treatment was as follows: 100 μg pZP (Trumpeter Farms and Veterinary Service, Winters, California, USA) for pZP treatments; 250 μg recombinant ZP3 (containing tetanus toxoid epitope) and 250 μg ZP4 (containing bovine RNase epitope; reZP; supplied by BioSciences, CSIR, South Africa) for reZP treatments and no antigen for the control group. Multi-dose vials of each vaccine formulation were prepared, lyophilised and reconstituted with sterile water for injection.

2.4. Vaccine administration

The adjuvant control group (n = 8) was treated on d = 35 and again five weeks later (d = 70).

The pZP-only group (n = 7) received an initial vaccination at d = 35 followed by an identical booster vaccination after five weeks (d = 70).

The reZP-only group (n = 8) received an initial vaccination at

Table 1
Treatment groups sub-divided on the basis of mare distribution by: age, median (range); parity, median (range); and BCS (1–9), median (range). P > 0.05.

Mare information	Treatment					P value
	Control (n = 8)	pZP-only (n = 7)	reZP-only (n = 8)	pZP and reZP (n = 8)	GnRH (n = 8)	
Age (years)	4 (2, 9)	4 (2, 8)	4 (2, 10)	3 (2, 7)	4 (2, 7)	1.000
No. previous parities	1 (0, 3)	1 (0, 3)	1 (0, 5)	1 (0, 3)	1 (0, 4)	1.000
BCS (1–9)	5 (4, 7)	6 (4, 7)	5 (4, 7)	5 (3, 7)	6 (2, 8)	0.700

Body condition score (BCS).

d = 0, followed by two identical boosters at five week intervals (d = 35 and d = 70).

The pZP and reZP group (n = 8) received an initial vaccination of pZP at d = 35 followed by a booster vaccination of reZP after five weeks (d = 70).

The anti-GnRH group (n = 8) received an initial 2 mL vaccination containing 400 μg GnRH-protein conjugate with an diethylaminoethyl (DEAE)-dextran adjuvant (Improvac®, Zoetis, South Africa) at d = 35 followed by an identical booster vaccination five weeks later (d = 70).

All vaccines were administered by deep intramuscular injection into the gluteal muscle mass; boosters were administered into the contralateral musculature.

2.5. Data collection

Animals were examined and samples collected in December (d = 0), January (d = 35), February (d = 70), March (d = 105) and May (d = 175). Transrectal palpation and ultrasonography of the reproductive tract was performed at d = 0, d = 35, d = 70, d = 105 and d = 175. During the examination, ovarian volume, presence of follicles ≥15 mm diameter, presence of a CL (confirmed retrospectively by serum progesterone >1 ng/mL), uterine and cervical tone and the presence of uterine oedema were recorded for each mare. Oestrous cyclicity or activity was defined as the presence of follicles ≥15 mm and ovarian volume ≥25 cm^3 (prolate ellipsoid formula) and the confirmation of an ovulation (if present) was confirmed by the presence of a previously unrecorded CL or corpus haemorrhagicum in conjunction with serum progesterone levels >1 ng/mL. In the absence of a CL, oestrous cyclicity was determined on the basis of observed tubular genital tract characteristics [30]. Ovarian inactivity was defined as bilaterally small ovaries (both <25 cm^3), the absence of a CL or any follicles ≥15 mm and basal (<1 ng/mL) serum progesterone [8,11,19,31].

Blood samples were collected by jugular venipuncture at d = 0, d = 35, d = 70, d = 105 and d = 175. Samples were centrifuged and serum stored at −20 °C until assayed.

2.6. Pasture breeding

Three mature, clinically-healthy and proven fertile stallions (6–8 years of age) were selected for pasture-based breeding. One stallion was randomly selected for each of the three breeding herds and introduced in March (d = 105). All stallions remained with the mares until July. Foaling outcome was assessed at the end of the subsequent physiological breeding season based on available records.

2.7. Hormone assays

Serum progesterone was measured using a chemoluminescence technique (Immulite® 1000, Siemens, Germany) [32]. Serum AMH concentrations were determined using a commercially available ELISA according to the manufacturer's instructions (AMH Gen II ELISA; Beckman Coulter, Brea, CA, USA). This assay has been validated for use in mares [33] and the detection limit of the assay was 0.08 ng/mL. Intra- and inter-assay coefficients of variation were 3.7% and 4.4% respectively, for a low AMH concentration (3.82 ng/mL), and 3.4% and 4.0%, for a high AMH concentration (16.45 ng/mL).

2.8. Statistical analyses

Data concerning the presence/absence of individual measures of normal oestrous cyclicity were compared among treatment groups using mixed effects logistic regression. Quantitative data were log transformed and analysed using mixed effect linear regression. Regression models included fixed effect terms for treatment group, sampling time (categorical with five levels), a group by time interaction (AMH only) and age to adjust for potential confounding. Mare was included as a random effect and a first-order autoregressive correlation structure was used to account for repeated sampling. Post-hoc tests in the mixed-effects models were adjusted using the least significant differences (LSD) or Bonferroni method. Serum AMH concentrations at each sampling time were compared among groups using one-way ANOVA with multiple *post-hoc* comparisons adjusted using Bonferroni correction of P values. Pairwise correlations were estimated using Spearman's rho or Pearson's correlation coefficient as appropriate. Statistical testing was performed using commercially available software (IBM SPSS Statistics Version 25) and significance was set at $P \leq 0.05$.

3. Results

3.1. Ovarian activity

Treatment groups were comparable in respect to age, parity, and BCS (Table 1) and all mares had evidence of cyclic ovarian activity prior to treatment (Table 2). Treatment (P = 0.001) and time (P < 0.001) both had a significant effect on the presence/absence of normal ovarian activity. Mares in the control and pZP treated groups expressed normal cyclical ovarian activity most commonly followed by mares within the combined pZP and reZP, reZP-only, and GnRH treated groups in descending order of frequency. When summarized for all observation times, control mares were more likely to be cycling compared to reZP (P = 0.005) and GnRH (P < 0.001) treated mares. Similarly, pZP treated mares were also more likely to be cycling compared to reZP (P = 0.002) and GnRH (P < 0.001) treated mares. Five weeks after the first treatment and first booster for reZP-only (d = 70), 8/8 control mares, 6/7 pZP-only mares, 5/8 pZP and reZP mares, 3/8 reZP-only mares and 2/8 anti-GnRH mares were demonstrating normal oestrus cyclicity. Five weeks after the final booster (d = 105), 5/8 control mares, 4/7 pZP-only mares, 3/8 pZP and reZP mares, 1/8 reZP-only mares and 0/8 anti-GnRH mares were demonstrating normal oestrus activity. By the end of the active monitoring period (d = 175), 3/8 control

mares, 3/7 pZP-only mares, 0/8 pZP and reZP mares, 0/8 reZP-only mares and 0/8 anti-GnRH mares had evidence of normal ovarian activity. At the end of the subsequent breeding season the records for seven mares were available. Three control mares foaled and one pZP-only mare experienced a late-gestation abortion.

3.2. AMH

Treatment group had a significant effect on the serum AMH concentrations collected over the entire study ($P = 0.030$). Furthermore, there were significant differences among treatment groups at d = 105 ($P = 0.037$) and d = 175 ($P = 0.019$). No post hoc pairwise comparisons were significant at d = 105 but at d = 175, mares treated with the anti-GnRH vaccine had higher concentrations compared to pZP-only treated mares ($P = 0.029$). The difference between pZP-only treated and control mares at this time-point was not significant ($P = 0.084$). Serum AMH concentrations changed over time in reZP-only mares with higher concentrations at d = 70 compared to d = 105 ($P = 0.047$) (Table 3). Serum AMH concentrations were positively correlated with ovarian volume ($r = 0.171$, $P = 0.035$) and mare age (ordinal categories; >3 y, 3–6 y, >6 y) ($\rho = 0.269$, $P < 0.001$) but negatively correlated with serum progesterone ($r = -0.373$, $P = 0.014$).

4. Discussion

The immunocontraceptive method of action of pZP in the horse, and other species, has been proposed to involve the prevention of sperm–zona binding, with oestrous cyclicity presumed to continue undisturbed [2,3]. However, the results of the present study demonstrate varying degrees of ovarian suppression across all treatment groups. Significantly more reZP-only and anti-GnRH mares stopped cycling sooner after vaccination than either the control or the pZP-only mares. A two-pronged treatment protocol utilising pZP as the primary inoculation and reZP for the booster had a protracted effect. Ovarian suppression following anti-GnRH vaccination has been reported and the mechanism (suppression of FSH and LH secretion) is well understood [7,8,11]. There is increasing evidence that, at least in some species, ovarian suppression is a contributory factor in the contraceptive efficacy of ZP vaccination [4,5,15–17,19,34]. However, more research is required to define the mechanism of ZP-associated ovarian suppression.

A previous study from our research group reported higher incidences of anoestrus and a superior contraceptive effect in mares treated with pZP compared to reZP [19]. However, the reZP vaccine [18] used in that study was manufactured in a different laboratory, was formulated with Freund's adjuvant and only a single booster treatment was administered. The current study is the first to report a non-Freund's adjuvant for ZP-based immunocontraception in the horse.

The reduction in ovarian activity in control mares was possibly an effect of season. A significant effect of time on ovarian activity was evident for all groups, and while this is expected in seasonally breeding animals, it was a limitation of the current study. Reproductive activity is determined by season, primarily photoperiod, and to a lesser extent nutrition and environmental temperature [35]. The physiological breeding season in the southern hemisphere is October to March but variations have also been reported [28,30]. Only 26 of the 50 mares initially assessed for the study were cyclic at the end of November and this delayed the initial administration of treatments and subsequent introduction of stallions for breeding. An additional limitation was the paucity of foaling records at the end of the following breeding season. Further investigations into the contraceptive efficacy, reversibility and safety of the novel formulation used in this study are warranted.

The AMH results of the present study were partially consistent with previous reports [24]. Mean AMH concentrations differed across groups at d = 105, but differences between pZP-only and

Table 3

anti-GnRH mares were only evident at d = 175. The reduced sampling frequency and relatively small group sizes in this study might have contributed to the absence of other significant differences. As a result, it is not clear whether AMH is a suitable indicator of the effect of ZP vaccination on ovarian follicular activity in mares managed under extensive conditions (i.e. sampled infrequently). However, AMH concentrations were correlated with ovarian volume and serum progesterone, suggesting that it can be useful under certain circumstances. Previous work by our research group noted the potential of serum AMH concentrations for monitoring ovarian function following immunocontraception in mares [24]. Samples were collected weekly from October to March in this previous work [19,24] but only analysed for five strategic time periods. The results of the previous study served to inform the frequency of sampling and study design for the current project. Among other hypotheses, the current study investigated the premise that less intensive sampling for serum AMH would still be useful for monitoring ovarian function. This is important because most populations of horses that require immunocontraception are feral or semi-feral, greatly limiting the ease and frequency of interventions such as blood sampling. Sample collection coinciding with other interventions, such as inoculations, would enhance practicality in such circumstances. Serum AMH has less cyclical variability in the horse [25] and may therefore be less influenced by season than clinical measures of cyclicity.

Serum AMH tended to be higher in older mares and there is a need to further investigate the dynamics of AMH concentrations in younger, albeit sexually mature, mares. This positive correlation between age and AMH has also been reported in Japanese Black cows [36].

In conclusion, a non-Freund's adjuvated reZP vaccine is a promising alternative for immunocontraception in the mare when ovarian suppression is an acceptable outcome. Serum AMH concentrations following ZP-based vaccination may be used to infer reductions in both ovarian volume and serum progesterone under extensive conditions.

Authorship

M.B. Nolan and M.L. Schulman contributed to the study design, data collection, data analysis and interpretation, preparation and final approval of the manuscript. H.J Bertschinger and G.T. Fosgate contributed to the study design, data analysis and interpretation, preparation and final approval of the manuscript. R. Roth and M. Crampton prepared the reZP and contributed to final approval of the manuscript. I.S. Martins contributed to the data collection and final approval of the manuscript. T.A.E. Stout contributed to data interpretation and preparation and final approval of the manuscript.

Immunocontraception in Wild Horses (*Equus caballus*) Extends Reproductive Cycling Beyond the Normal Breeding Season

Cassandra M. V. Nuñez*, James S. Adelman, Daniel I. Rubenstein

Department of Ecology and Evolutionary Biology, Princeton University, Princeton, New Jersey, United States of America

Abstract

Background: Although the physiological effects of immunocontraceptive treatment with porcine zona pellucida (PZP) have been well studied, little is known about PZP's effects on the scheduling of reproductive cycling. Recent behavioral research has suggested that recipients of PZP extend the receptive breeding period into what is normally the non-breeding season.

Methodology/Principal Findings: To determine if this is the case, we compiled foaling data from wild horses (*Equus caballus*) living on Shackleford Banks, North Carolina for 4 years pre- and 8 years post-contraception management with PZP (pre-contraception, n = 65 births from 45 mares; post-contraception, n = 97 births from 46 mares). Gestation lasts approximately 11–12 months in wild horses, placing conception at approximately 11.5 months prior to birth. Since the contraception program began in January 2000, foaling has occurred over a significantly broader range than it had before the contraception program. Foaling in PZP recipients (n = 45 births from 27 mares) has consistently occurred over a broader range than has foaling in non-recipients (n = 52 births from 19 mares). In addition, current recipients of PZP foaled later in the year than did prior recipient and non-recipient mares. Females receiving more consecutive PZP applications gave birth later in the season than did females receiving fewer applications. Finally, the efficacy of PZP declined with increasing consecutive applications before reaching 100% after five consecutive applications.

Conclusions/Significance: For a gregarious species such as the horse, the extension of reproductive cycling into the fall months has important social consequences, including decreased group stability and the extension of male reproductive behavior. In addition, reproductive cycling into the fall months could have long-term effects on foal survivorship. Managers should consider these factors before enacting immunocontraceptive programs in new populations. We suggest minor alterations to management strategies to help alleviate such unintended effects in new populations.

Introduction

The extirpation of predator species has resulted in the expansion of free-ranging ungulate populations in North America [1], necessitating their regulation. Immunocontraceptive management has become increasingly popular as culling programs are seldom well-received by the general public. In females, the most common form of immunocontraception, porcine zona pellucida (PZP), stimulates the production of antibodies that bind sperm receptors on the egg's surface, thereby preventing sperm attachment and fertilization [2].

In recent decades, the wild horse (*Equus caballus*) has become a model for evaluating the effects of PZP, thanks chiefly to the seminal nine-year study of contracepted mares on Assateague Island National Seashore [3]. Subsequent research on this population has shown that PZP has little to no effect on recipient physiology or behavior [4,5,6]. For example, in Assateague horses, PZP has no effect on the duration of individual estrous cycles [6], and researchers have reported only minor ovulation failure and depressed urinary oestrogen concentrations with repeated applications [4]. However, behavioral research on the horses of Shackleford Banks, North Carolina, and other wild ungulate species suggests that PZP affects the reproductive physiology of recipient animals [7,8,9]. In each of these studies, females treated with PZP extended reproductive behaviors into the non-breeding season. While these results are consistent with an extension of ovulatory cycling into the post-breeding season when most females are normally anovulatory [10,11], this possibility has not yet been tested.

Mares are seasonally polyestrous and extended estrous periods have been documented [11]. Tropical species, for example, are less strictly seasonal, and in some cases, reproduce throughout the year [12,13]. In addition, variability in the cycling schedules and receptivity of individual mares [14], and the performance of estrous behavior and copulatory activities during the non-breeding season [15] have been documented in temperate species. Such

variation in ovulatory scheduling and receptivity suggest that the seasonality of reproductive behavior in *Equus caballus* females is characterized by a substantial degree of plasticity. As the physiological state of contracepted animals has been significantly altered, the possibility of prolonged extended cycling is even more feasible.

In wild horse societies, the harem is the core social group, consisting of usually one, but sometimes two or three harem male(s), one to several female(s), and their offspring [16,17,18,19,20,21]. Harem males will sometimes fight to acquire mares from other groups, but stallions almost always retain their mares [18,19,20,22]. In temperate environments, food availability is lower during the fall and winter months and free-ranging horses will alter their activity to maximize food intake and reduce energetic costs [23,24]. Mares are typically anovulatory at this time and sexual behavior in males is largely absent [11,14].

On Shackleford Banks, increased reproductive behavior in the post-breeding season by mares has resulted in increased male attentiveness [9]. Such behavior (by males) has been shown to restrict the movement of females, thus reducing their grazing efficiency [21,25]. The occurrence of this behavior during a time of year when animals typically increase group spread to acquire adequate forage [19,24], represents a change in behavior fundamental to the animals' survival [26,27]. Offspring conceived during the post-breeding season are likely subject to decreased resource availability as lower quality forage can affect mares' ability to produce sufficient milk [27]. Finally, regardless of the timing of titer decline post-treatment [9,28,58], when anti-PZP antibody titers decrease during the fall months [28,29], extended reproductive cycling among recipient mares will increase their chances of conception, thereby lowering the vaccine's overall efficacy. Determining whether PZP recipients are likely to extend reproductive cycling is therefore of great importance if managers are to limit animal numbers while still maintaining functional, healthy populations.

Here we use the birth dates of foals to estimate dates of conception for PZP recipient and non-recipient mares on Shackleford Banks, North Carolina. Gestation length in wild horses is 11–12 months [30]. Therefore, dates of conception can be reliably estimated as approximately 11.5 months prior to birth. Breeding normally occurs from March through August, with most births occurring in April and May [11]. Given the extension of reproductive behavior in PZP- treated mares [9], we hypothesize that PZP recipients will extend cycling into the non-breeding season more often than will non-recipients. Therefore, when PZP recipients conceive and give birth, they will do so later on average and over a wider range of months than will non-recipients.

Methods

Study area

This study was conducted on Shackleford Banks, a barrier island located approximately 3 km off the coast of North Carolina, USA. The island was 15 km in length, and varied between 0.5 and 3 km in width. The horse population on Shackleford Banks has been co-managed by the National Park Service and the Foundation for Shackleford Horses since 1996.

Study subjects

The reproductive units of Shackleford horses are typical of feral equids. They are coherent harem groups of one, or sometimes two or three stallion(s), one to several mare(s) and their offspring [18]. Predominantly, the harem groups are not territorial and animals move within overlapping home ranges, although this has not always been the case [18].

Management

PZP Contraception. In January 2000, the National Park Service began the application of PZP for the purposes of immunocontraception. The National Park Service administers PZP in the spring (late February through April) each year. Mares receive their initial treatment at 1.5–2 years of age. Each injection includes 100 micrograms of PZP with an adjuvant (combined at the darting site). Initial doses include Freund's Complete Adjuvant, Modified, Mycobacterium butyricum (Calbiochem #344289). All succeeding doses include Freund's Incomplete Adjuvant (Sigma #F5506). In a given year, an average of 63% of all reproductive mares are inoculated with the vaccine (range = 37–88%). The authors of the present study are not and have never been in charge of making management decisions regarding this herd.

Gathers and Removals. The National Park Service began their management of the Shackleford Banks population prior to the use of PZP, performing five gathers between November 1996 and January 2000. During these gathers the majority of the population was rounded up and individuals testing positive for equine infectious anemia were removed and either euthanized or quarantined. As such forms of management could conceivably influence reproductive cycling, we analyzed foaling dates before and after gathers (but before contraception management) using a linear mixed effects model (see Statistical Analyses).

From January 2000 – January 2008, 38 foals (conceived due to contraception failure or administration scheduling) were removed from the island for the purpose of population control. The majority of removals (92%) were conducted in the January following the foals' birth.

Foaling Data

We recorded foaling data before contraception management (1995–1997) during a study of mother-infant behavior [31]. We obtained foaling data for 2000 and post-contraception years (2001–2008) from the National Park Service at Cape Lookout National Seashore, North Carolina. Although PZP was first administered in 2000, foals born in this year were conceived before contraception management. As such, we considered 2000 a pre-contraception year.

We identified individual horses by color, sex, age, physical condition, and other distinguishing markings including freeze brands. We monitored pregnant mares 2–3 times per week to ensure accurate estimation of foaling date. Births are not commonly witnessed, as mares will generally give birth away from their harem group [31]. This does not significantly affect the determination of birth dates because typically, mares return to their groups within hours (depending on the length of the foaling process and the mares' and foals' condition afterward). In the event that we did not locate mares for more than one week, the birth dates of new foals were estimated by comparing the condition of the foals' coat, mane and tail hair, and locomotor ability to that of foals for which the exact age was known. Using these methods, we were able to estimate birthdays within a range of 1–2 days to 1 week. Focal animals in this study were observed from a minimum of 15 m away at all times. The observers did not obstruct or manipulate the animals' natural behavior in any way. As such, approval for this study by a review board or ethics committee was unnecessary.

We designated births as coming from current recipient, prior recipient, or non-recipient mares. Current recipients received PZP

treatment the year they conceived (the year previous to foaling). Prior recipients received PZP treatment at some point earlier in their lifetime, but not the year of conception. Non-recipients had never received PZP at the time of conception.

Physical Condition

Physical condition is an important factor to consider when monitoring reproductive behaviors. Animals in better condition will have more resources to allocate to mating behavior and physiology than will animals in poorer condition. We assessed mare condition via rump scoring. We determined rump scores examining the curvature of the line between the tailbone and the point of the hip. Scores were based on a scale from 1 to 5; a score of 1 being the poorest [32].

Weather Data

We collected all climatology data from the Morehead City WNW Station at 34° 44′N; 76° 44′W, approximately 8 km from the study site. We obtained all data from the National Climate Data Center (2009) [33].

Statistical Analyses

We analyzed data in R version 2.11.1 (R Core Group, Vienna Austria) and JMP, version 7 (SAS, Cary NC, USA). We used Fligner-Killeen tests to determine if variation in foaling dates differed before and after contraception management and between PZP recipients and non-recipients. This test is more conservative than Fisher's or Bartlett's tests and is less sensitive to outliers and non-normal data [34]. Results from these tests show Bonferroni corrected *P*-values.

We used linear mixed effects models to analyze monthly weather patterns. These statistical models included year as a random effect and the following fixed effects: linear through fourth order polynomial functions of month (to account for nonlinear fluctuations in temperature and rainfall), management regime (before or after contraception management), and two-way interactions with management regime. We selected best fit models using Akaike's Information Criterion adjusted for small sample size (AICc). Because temperature data were temporally auto-correlated, we included an autoregressive moving average correlation structure [35]. For each year of the study, we calculated the mean of the monthly residual values from both the rainfall and temperature models from July through November. We included these terms in the mixed effects models described below to determine if weather affected foaling date.

To test for differences in foaling date with PZP treatment, while controlling for pseudo-replication and unequal variances, we used a linear mixed effects model. The model included mare ID as a random effect and a function allowing different variances across groups (pre-contraception management, post-contraception management non-recipient, post-contraception management current recipient, and post-contraception management prior recipient) [35]. We included mare age as a covariate, as this has been suggested to influence female reproductive behaviors and physiology [36,37]. Additionally, a one-way ANOVA revealed no differences in mare age among treatment groups ($F_{2,84} = 2.03$, $P = 0.14$), suggesting that age did not confound differences among groups. From the above mixed effects model, differences in foaling dates among current, prior, and non-recipients were calculated using an F-test for linear combinations [35].

As gathers could have affected foaling date, we used a linear mixed effects model to test for differences between foaling dates before and after gathers (but before contraception management). After controlling for weather and mare age, mean foaling date did not differ before and after gathers ($P = 0.63$). Additionally, the range of birth dates did not differ significantly between these groups (SD before gathers = 1.04, SD after gathers = 0.77, $P = 0.36$). Finally, AICc from our analysis of foaling dates (see Results) suggested that combining data before and after gathers yielded a more parsimonious model than did separating those categories (AICc separating pre- and post-gathers = 551.02, AICc combining pre- and post-gathers = 550.60). Consequently these groups were combined as pre-contraception management animals for all analyses.

To determine whether the number of PZP applications (total or consecutive) or the number of years between pregnancies (total or consecutive) influenced foaling date, we ran separate linear mixed effects models using these as predictor variables. Each model used only data from PZP recipients and included mare ID as a random effect. To determine if results from this analysis could be influenced by year, we ran a linear mixed effects model on post-management, non-recipients predicting foaling date by year.

We analyzed PZP efficacy using a generalized linear mixed effects model with a binomial error distribution and mare ID as a random effect [38]. This analyzed the probability of conceiving using age at first PZP application and the number of consecutive PZP applications as fixed effects. All mixed effects models initially included two-way interactions, which were removed if their *P*-values were >0.10.

Results

Foaling

After contraception management, foaling occurred over a broader range of months than before contraception management (see Fig. 1, SD pre-contraception = 0.91 months, SD post-contraception = 2.04 months; Fligner-Killeen Test for Homogeneity of Variances: Median Chi Square = 28.10, $P<0.0001$; pre-contraception: n = 65 births from 45 mares over 4 years; post-contraception: n = 97 births from 46 mares, over 8 years). In the eight years following contraception management, mares receiving PZP foaled over a broader range of months than did non-recipient mares (see Fig. 1, SD recipients = 2.40 months, SD non-recipients = 1.54 months; Fligner-Killeen Test for Homogeneity of Variances: Median Chi Square = 11.76, $P = 0.001$; recipients: n = 45 births from 27 mares; non-recipients: n = 52 births from 19 mares).

On average, current PZP recipients gave birth 3.36 months later than did pre-contraception mares, according to our linear mixed effects model, which controlled for heterogeneity of variances, weather influences, and mare age (estimate = 3.36, SE = 0.51, t = 6.64, $P<0.001$; overall model: Likelihood ratio (compared to null model): 40.79, generalized $r^2 = 0.48$, $P<0.001$). Mares that had received PZP earlier in their lifetime, but not during the year of conception (prior recipients), gave birth 0.90 months later than pre-contraception mares on average (estimate = 0.90, SE = 0.40, t = 2.27, $P = 0.03$). Non-recipient mares that never received PZP themselves, but gave birth after the general population was managed with PZP, gave birth 1.01 months later than pre-contraception mares on average (estimate = 1.01, SE = 0.25, t = 4.04, $P = 0.001$). This translates into current PZP recipients giving birth 2.34 months later than non-recipient animals and 2.46 months later than prior recipients (F-tests for linear combinations: $F>16$, $P<0.001$ for each comparison). Furthermore, birth dates were about 0.38 months later for each degree centigrade above average in the latter half of the breeding season and 0.05 months later for each centimeter of rain above average (temperature residuals July-Nov: estimate = 0.38, SE = 0.13, t = 2.84, $P = 0.001$; rainfall residuals July-Nov: esti-

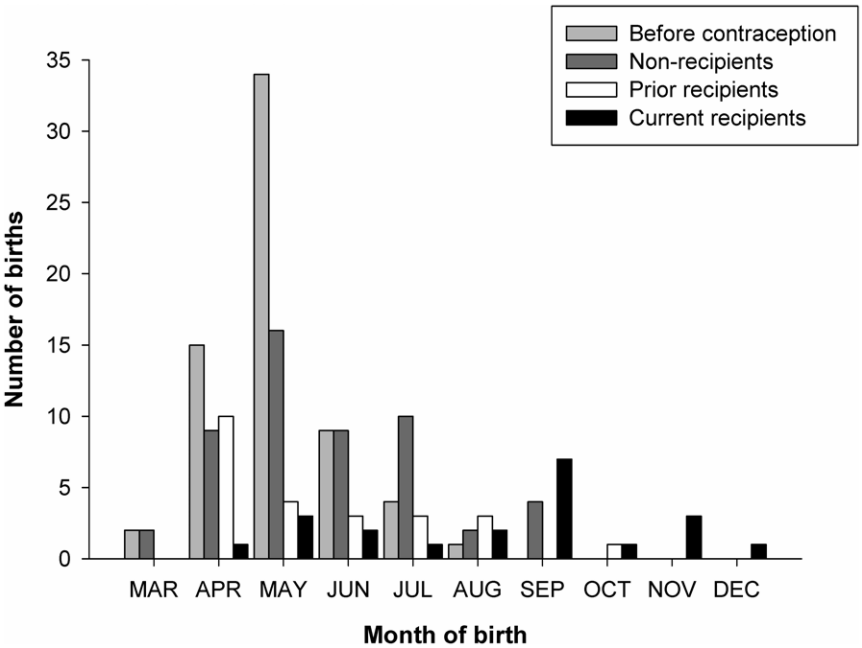

Figure 1. The distribution of births for mares on Shackleford Banks, NC, pre-contraception and post-contraception management. Mares gave birth over a wider range of months after the onset of contraception; this effect was more pronounced in PZP recipients than non-recipients.
doi:10.1371/journal.pone.0013635.g001

mate = 0.05, SE = 0.03, t = 1.83, $P = 0.07$). In general, mares gave birth 0.05 months earlier for every year of age (estimate = −0.05, SE = 0.02, t = −2.03, $P = 0.05$).

Among mares treated with PZP, those receiving a higher total number of applications foaled later in the season than did those receiving fewer applications, with each additional application associated with a 0.5 month delay in foaling date (Linear Mixed Effects Model: estimate = 0.55, SE = 0.21, t = 2.61, $r^2 = 0.65$, $P = 0.01$, see Fig. 2A). In addition, each consecutive PZP application was associated with a 0.8 month delay in foaling date, on average (Linear Mixed Effects Model: estimate = 0.83, SE = 0.23, t = 3.64, $r^2 = 0.65$, $P<0.0008$, see Fig. 2B). While the consecutive and total number of PZP applications were highly correlated, comparing the AICc between the prior two models suggested that the number of consecutive PZP treatments more accurately predicted month of birth than did the total number of PZP treatments (AICc total = 202.96, AICc consecutive = 196.83). The number of years that mares did not conceive (total or consecutive), however, did not correlate with foaling date (Linear Mixed Effects Model: total years: estimate = 0.31, SE = 0.26, t = 1.19, $r^2 = 0.57$, $P = 0.24$; consecutive years: estimate = 0.26, SE = 0.28, t = 0.92, $r^2 = 0.44$, $P = 0.36$). It is unlikely that these patterns resulted from a general trend across years, as birth dates among non-recipient animals did not change with calendar year (Linear Mixed Effects Model: $r^2 = 0.17$, estimate = 0.05, SE = 0.09, t = 0.57, $P = 0.57$).

Mare Condition

A generalized linear model, which controlled for mare age, showed that among post-contraception animals, recipient mares (both current and prior) were in better physical condition, with rump scores approximately 0.4 points higher than those of non-recipients (overall model (compared to null model): Chi Square = 7.74, $P = 0.05$; PZP treatment: estimate = 0.38, SE = 0.15, Chi Square = 6.13, $P = 0.01$; age: estimate = −0.005, SE = 0.06, Chi Square = 0.007, $P = 0.93$; PZP treatment × age: estimate = −0.02, SE = 0.06, Chi Square = 0.13, $P = 0.72$).

Weather

The best fit model of monthly mean temperature showed that overall temperatures were approximately 0.6°Cwarmer after the onset of contraception management (see Fig. 3A; overall model: Likelihood ratio (compared to null model) = 358.40, $P<0.0001$, generalized $r^2 = 0.88$; month: estimate = −8.49, SE = −.97, t = −8.78, $P<0.0001$; $month^2$: estimate = 3.88, SE = 0.29, t = 13.43, $P<0.0001$; $month^3$: estimate = −0.45, SE = 0.03, t = −13.70, $P<0.0001$; $month^4$: estimate = 0.015, SE = 0.001, t = 12.20, $P<0.0001$; contraception management (before): estimate = 0.58, SE = 0.27, t = −2.13, $P = 0.06$). The best fit model of monthly precipitation showed no overall differences between the periods before and after contraception management, but there were significant interactions between month of the year and the periods before and after contraception (see Fig. 3B; overall model: Likelihood ratio (compared to null model) = 38.43, $P<0.0001$, generalized $r^2 = 0.20$, $P<0.0001$; month: estimate = −11.19, SE = 4.96, t = −2.25, $P = 0.03$; $month^2$: estimate = 3.66, SE = 1.46, t = 2.51, $P = 0.01$; $month^3$: estimate = −0.38, SE = 0.17, t = −2.27, $P = 0.02$; $month^4$: estimate = −0.01, SE = 0.006, t = 1.88, $P = 0.06$; contraception management (before): estimate = 6.99, SE = 4.22, t = 1.66, $P = 0.12$; month × contraception management (before): estimate = −2.97, SE = 1.43, t = −2.07, $P = 0.04$; $month^2$ × contraception management (before): estimate = 0.22, SE = 0.11, t = −2.03, $P = 0.04$).

PZP Efficacy

We defined PZP efficacy during the year of administration as the number of vaccinated mares that did not became pregnant divided by the total number receiving the vaccine. Across the first four consecutive PZP applications, this efficacy declined from 97% to 87%, returning to 100% after five or more consecutive applications (see Fig. 4). A generalized mixed effects model shows that this pattern

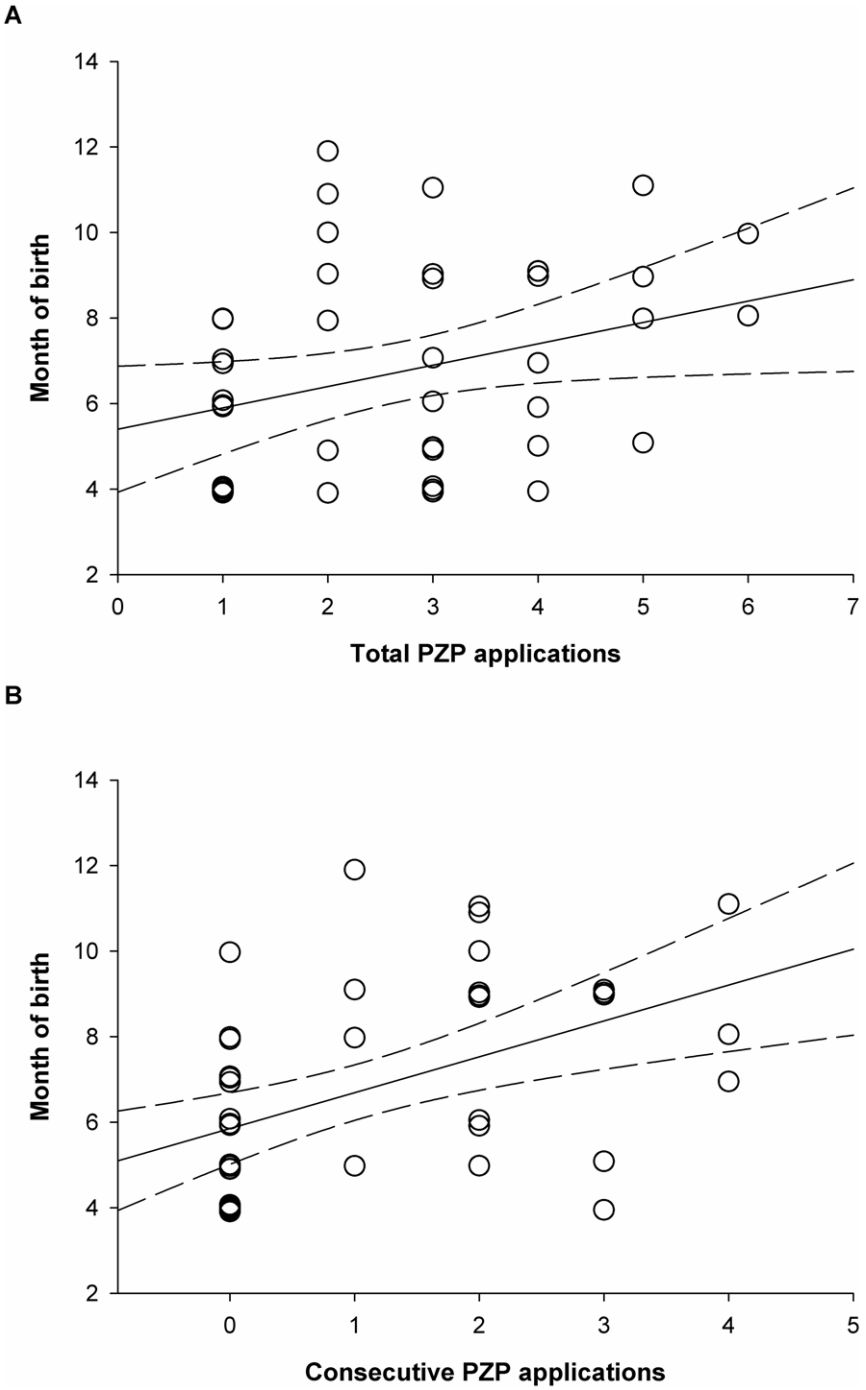

Figure 2. Birth month and number of A) total PZP applications, and B) consecutive PZP applications. In the events of ties, month of birth has been jittered by 0.2 years to allow clear visualization of every individual. Mares receiving more applications of PZP foaled later in the year on average than did mares receiving fewer applications. Although the number of total and consecutive applications is highly correlated, AICc suggests that the number of consecutive applications explains more of the variation in the data.
doi:10.1371/journal.pone.0013635.g002

is significant, even when controlling for mare age (overall model with binomial error distribution: Log Likelihood = −61.79, $P = 0.01$, generalized $r^2 = 0.17$; consecutive PZP applications: estimate = 2.98, SE = 1.20, z = 2.49, $P = 0.01$; $(\text{consecutive PZP applications})^2$: estimate = −0.51, SE = 0.22, z = −2.33, $P = 0.02$; age at first PZP application: estimate = 0.10, SE = 0.05, z = 1.84, $P = 0.07$). Prior research has shown that five to seven years of consecutive PZP treatment can be associated with ovulation failure [4]. The present dataset is consistent with this result, as no mare receiving the vaccine for five or more consecutive years became pregnant.

Discussion

Here we show that PZP recipients exhibited a change in their reproductive schedule: recipient mares gave birth over a broader time period than did non-recipients, with current recipients giving

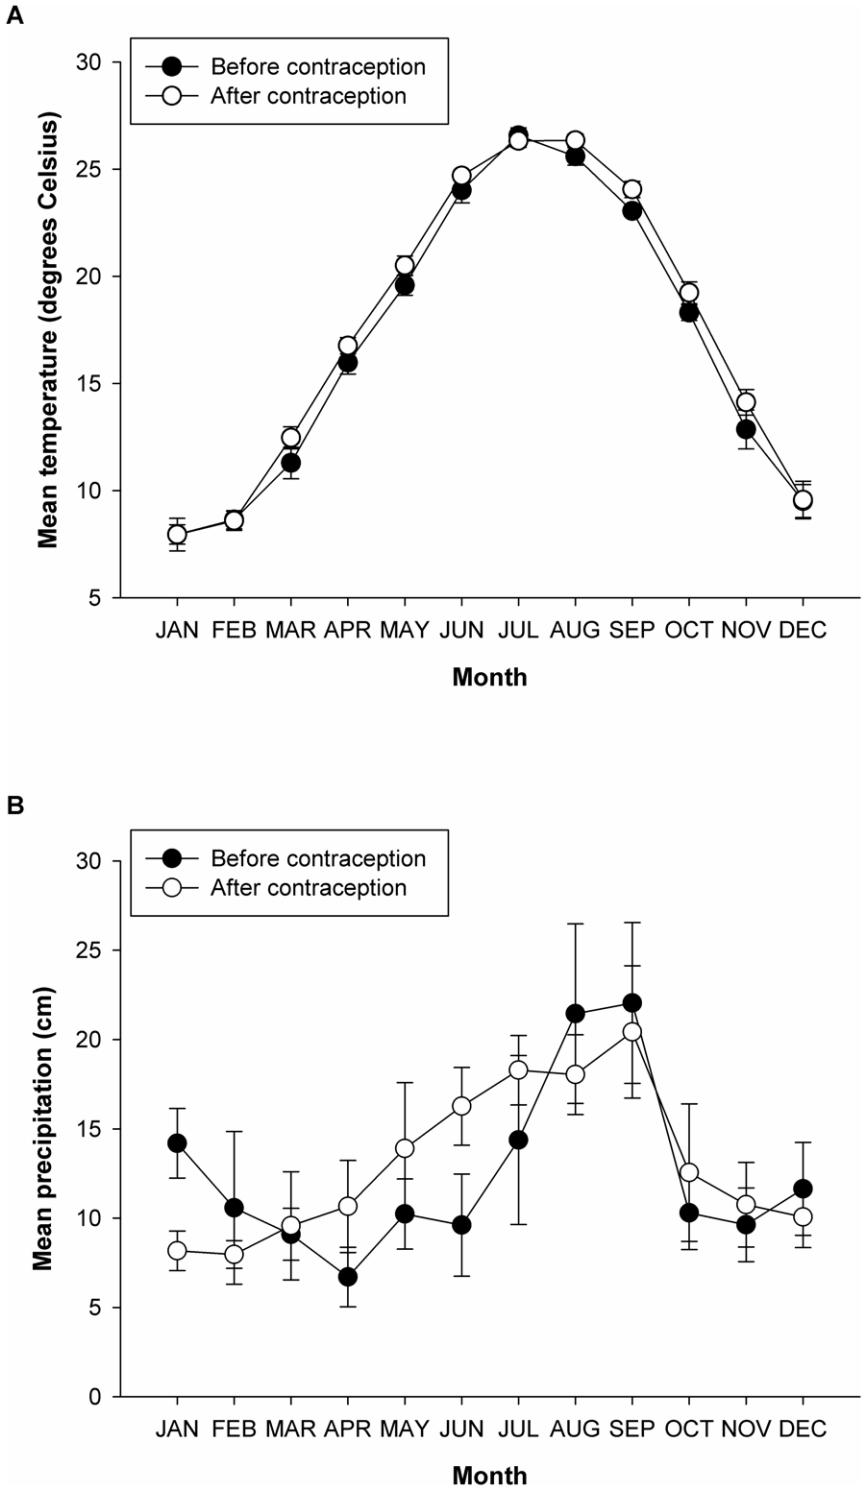

Figure 3. Weather data for six years pre-contraception (1995–2000) and eight years post-contraception (2001–2008) management. Data were collected from Morehead City, North Carolina, approximately 8 km from the study site (Shackleford Banks, North Carolina). Temperatures (A) were marginally warmer post-contraception than they had been pre-contraception. Overall rainfall (B) did not differ before and after contraception, though the seasonal patterns were marginally different pre- and post-contraception.
doi:10.1371/journal.pone.0013635.g003

birth later in the year than prior recipient and non-recipient mares. Given that gestation in wild horses lasts approximately 11 to 12 months [30], this change indicates a corresponding change in the schedule of ovulatory cycling. Contraception with porcine zona pellucida is popular amongst managers specifically because it effectively reduces the odds of conception without the application of exogenous steroids [2]. Long-term studies on Assateague Island have reported that PZP has little to no effect on reproductive

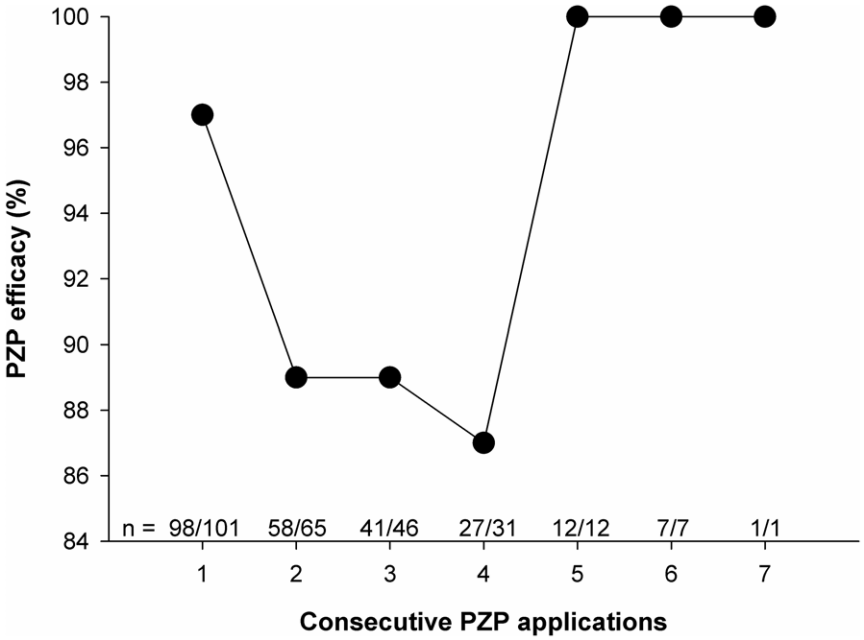

Figure 4. PZP efficacy and number of consecutive PZP applications. PZP efficacy was defined as the number of recipient mares that did not become pregnant divided by the total number of mares receiving the vaccine. Across the first four consecutive applications, PZP efficacy declined, returning to 100% after five or more consecutive applications (5–7 applications have been shown to result in ovulation failure and decreased oestrogen levels [5,40]).
doi:10.1371/journal.pone.0013635.g004

hormone levels, the schedule of reproductive cycling, or the social behaviors of recipient animals [4]. However, studies in other wild horse populations have shown that recipient mares both initiate and receive more instances of reproductive behavior during both the breeding [39] and non-breeding seasons [9]. This study provides the first evidence that mares treated with PZP can extend ovulatory cycling beyond the normal breeding season. This suggests that populations of wild ungulates can vary in their response to similar contraceptive treatment. Careful consideration of baseline population dynamics should be made prior to treatment in order to fully assess possible PZP effects.

Foaling Date

Mares receiving PZP at any point during their lifetime gave birth over a broader time period than did non-recipient animals. This larger variance among PZP mares is likely driven by the fact that current recipients gave birth later than did prior recipients (see Results, Fig. 1). Moreover, mares receiving more consecutive applications foaled later in the season than did mares receiving fewer applications. Increases in the average interbirth interval for recipient mares did not seem to be driving this result, as foaling date was not affected by the number of years (cumulative or consecutive) that mares failed to conceive. This discrepancy may be due to high variability in the conception and foaling dates of treated mares. First, it is less likely that an animal vaccinated with PZP will conceive at all, thus reducing sample size. Second, due to contraceptive failure, some treated mares will conceive during the normal breeding season, further increasing variability. Interestingly, prior to the application of PZP, the average month of birth did tend to increase with interbirth interval (Linear Mixed Effects Model: estimate = 0.30, SE = 0.17, t = 1.82, $r^2 = 0.06$, $P = 0.07$) [22], demonstrating at least some plasticity in the scheduling of reproductive cycling in Shackleford mares. On Assateague, PZP recipients experience normal reproductive cycling and mate at rates similar to non-recipients [40]. However, when such behavior fails to result in conception over several years, it follows that individuals extending reproductive cycling will be able to achieve conception later in the year if the contraceptive effects of PZP have decreased sufficiently [28,29].

Because feral horses are highly social, such changes can have cascading effects on other group members and throughout the population. Our research has shown that after contraception management, PZP recipients both attract and initiate more instances of reproductive behavior [9] and are more often the harem male's nearest neighbor during the fall/winter (Nuñez, unpublished data), indicating that group spreads are reduced. Such changes represent an increase in energy expenditure and a potential decrease in nutrient intake during a time of year when sufficient energy reserves are at a premium [27]. Moreover, early foal development in unmanaged populations typically occurs during the spring and summer when resources are plentiful [11,27]. Offspring born in the fall/winter months face nutritional and thermoregulatory challenges not experienced by their counterparts born during the normal foaling season, potentially making developmental benchmarks difficult to achieve [27].

Such predictions are not consistent with data from Assateague Island where mares show increased survival, only minimal physiological side effects, and no behavioral or demographic changes [4,5,6]. In addition, foal survival does not differ between foals born in or out of the normal foaling season [41]. However, on Shackleford Banks, recipient mares change groups more often, elicit and receive more instances of reproductive behavior, and receive more harassment from harem males [9,42]. Given these differences in mare response to PZP management in the two populations, it follows that predictions based on the data from one site are not necessarily applicable to the other.

These population differences may be due to the scheduling of PZP administration at the two sites. When the contraception

program on Assateague began in 1994, the priorities for treatment followed a hierarchical approach based on the previous breeding success of the population, ensuring that all mares were given an opportunity to reproduce [3]. Females for which there was a high priority for treatment included those that had produced at least one surviving offspring. Low priority females included those that were less than four years of age. Females greater than four years old that had not produced surviving offspring did not receive treatment. In addition, the plan stipulated that only mares that had produced at least three surviving offspring or two generations of offspring would receive more than three consecutive years of treatment. Foals were not to be removed as removal increases a mare's reproductive success in the subsequent year [43,44,45]. Finally, it was recognized that this plan was subject to change as the population numbers decreased [46]. In the present study, Shackleford mares were contracepted between 1.5 and 2 years of age and received an average of 3.4 ± 0.2 (mean $\pm$ standard error) consecutive years of contraception, regardless of their productivity. To further control population numbers, foals born to these mares (due to contraception failure or changes in the application schedule), were likely to be removed. This difference in PZP administration and subsequent discrepancy in early life experience may contribute to the behavioral differences between the populations, as the ability to conceive with a harem male is likely critical to establishing lasting harem fidelity [16] and the retention of foals (until at least two years of age) is important to maintaining normal reproductive function [43,44,45].

Possible Mechanisms

Although the effect was more pronounced in recipients of PZP, both recipients and non-recipients showed a wider range of foaling dates after contraception management (after 2001). While relatively rare, such extended periods of estrous have been documented in several equine species. Tropical species, for example, have been observed to reproduce throughout the year [12,13,47]. Similarly, studies of temperate species have shown that individuals can vary significantly in reproductive timing [14] and estrous behaviors during the non-breeding season [15]. Our data show that Shackleford mares exhibit at least some plasticity in their reproductive cycling. This plasticity enables mares to time their reproductive cycling according to ecological, sociological, and physiological cues.

For example, our results show that the reproductive changes exhibited by Shackleford mares correlate with warmer temperatures occurring later in the calendar year, after contraception management. Increases in rainfall late in the breeding season also correlate (albeit weakly) with later births. Both warmer temperatures and increased rainfall could result in higher resource availability [27] and afford females the additional reserves necessary to extend reproductive cycling into what is typically the non-breeding season.

The physical condition of mares may also play an important role in the extension of reproductive cycling. On Shackleford Banks, recipient mares are currently in better physical condition than are non-recipients. This is likely due to the fact that successfully contracepted mares are unconstrained by the costs of pregnancy and lactation [48]. Recipient mares will therefore have more resources to allocate to additional reproductive cycles. This effect of PZP, coupled with warmer temperatures occurring later in the year, may act to increase a mare's chances of conceiving later in the calendar year, if PZP antibody titers are sufficiently low [29].

Additionally, extended cycling in non-recipient mares could be influenced by the physiology and behavior of recipients. Shackleford males exhibit higher rates of sexual behavior towards recipient females during both breeding and non-breeding seasons [9,42]. These overt social stimuli may entrain some non-recipients to continue reproductive behaviors and cycling into the early fall. Such stimuli are commonly used to induce receptivity in several domestic species including horses [49], pigs [50], and cows [51]. In the wild, courtship signals from conspecifics advance gonadal cycles or maturation in several taxa, including mammals [52,53,54], birds [55], amphibians [56], and reptiles [57]. Given the importance of social cues in the timing of reproduction among such diverse species, this possibility warrants further investigation in Shackleford mares.

Finally, the declining efficacy of PZP with increased consecutive applications is likely a contributing factor to the later foaling dates of recipient mares. Lyda and colleagues' research with captive, wild mares has shown that antibody titers against PZP remain high for up to ten months after initial treatment [28]. In addition, research with both Shackleford and Assateague horses has shown that initial applications of PZP are often effective over multiple years [9,58], suggesting that antibody titers can remain high for longer. However, laboratory research has shown considerable variability in anti-PZP titers [29], as did Lyda and colleagues' work in which half the mares treated with PZP and Freund's Complete Adjuvant fell below contraceptive levels within the ten months of study [28]. Our data show that increasing the number of consecutive applications can reduce the single year efficacy of PZP by roughly 10%, indicating that either antibody titer or reactivity can decrease more rapidly with consecutive applications. Such patterns could result from the induction of immunological tolerance [59], which reduces responsiveness to self-tissues or repeatedly encountered, non-pathogenic antigens [60]. PZP is designed to mimic host tissue and induce an immune response against self tissue: the recipient's own zona pellucida [2]. As such, it seems reasonable that at least some animals would mount tolerance mechanisms to combat this autoimmunity. In addition, the repeated application of a specific antigen generates an antibody response that is increasingly more specific to that particular antigen [29]. The antibodies produced by mares against porcine zona pellucida should, therefore, become less cross reactive with horse zona pellucida over time. Of course, PZP efficacy will vary depending on mare age and timing of inoculation [61]. Regardless, if PZP recipients extend reproductive cycling and behavior into the non-breeding season, any decrease in efficacy that leaves them fertile in the fall/winter will help drive increases in late season conception.

Although the removal of offspring can induce estrous cycling in ungulate species [62], it is unlikely that the removal of foals has influenced foaling date among PZP-treated mares on Shackleford Banks. Thirty-nine foals (conceived due to contraception failure or administration scheduling) have been removed from the island. Approximately 55% of these foals were born to non-recipient animals. The majority of foal removals were conducted in the January following foal births. Given that non-recipient animals did not give birth later than September and most recipient animals gave birth before December, it is unlikely that foal removals in January induced late-season estrus in Shackleford mares. It is equally unlikely that increases in mare condition due to the alleviation of lactation costs resulted in early resumption of estrus the following spring [27]. If that were the case, during the early spring months we would expect to see an increase in the number of foals born to mares subjected to offspring removal. This is not borne out by the data. Still, the removal of foals is ill-advised as it increases mare fecundity the following year [43,44,45].

Management Implications

When the alternative (gather and removal) is considered, PZP is currently managers' most humane and effective option for population control. However, careful study of the animals' demography, physiology, and behavior is necessary prior to and during treatment to ensure that a) the potential effects of PZP can be assessed accurately, and b) within managerial constraints, unintended effects of PZP are ameliorated. Differences in habitat, resource availability, and demography among conspecific populations will undoubtedly affect their physiological and behavioral responses to PZP contraception, and need to be considered. For instance, while Assateague horses show no behavioral and only minor physiological responses to PZP, horses on Shackleford Banks [9,42] and in the western United States [39] alter social and reproductive behaviors in response to PZP. Our data suggest that mare condition and warming trends may present additional complications. Increases in physical condition and changes in average temperature may interact with management regimes, enabling mares to alter their reproductive physiology even further. Moreover, these data emphasize the importance of study during both the breeding and non-breeding seasons. Much of the research showing little to no effect of PZP on feral horse behavior or physiology has been performed exclusively during the breeding season [4,5,10], potentially missing important differences in recipient response.

If population numbers are managers' primary concern, our data show that giving five or more consecutive applications of PZP will result in 100% contraception efficacy. This is consistent with data from Assateague where mares receiving 5–7 consecutive PZP applications exhibited ovulation failure and decreased urinary oestrogen concentrations [5,40]. However, if managers are tasked with the maintenance of natural behaviors and foaling schedules, consecutive PZP applications should be avoided. Research has shown that one application of PZP is often effective over multiple years, exhibiting yearly efficacy declines similar to that of 2–4 consecutive treatments (on Shackleford) [9,58]. Our data show that current recipients gave birth later than both prior recipient and non-recipient animals. However, prior recipients of PZP gave birth on schedules similar to non-recipients, suggesting that breaks between treatments can ameliorate unintended behavioral and physiological changes in recipient animals. Contraception on such schedules will still maintain lower pregnancy rates, but will allow for the birth of a manageable number of offspring which are also important to the maintenance of normal behaviors [9]. These foals should be allowed to remain in the population for at least two years as earlier removal has been shown to increase a mare's reproductive success in the subsequent year [43,44,45]. Additionally, subadult, dispersing females should be allowed to settle into harems and have at least one foal before receiving contraception [16]. Management regimes such as this would of course necessitate a higher minimum population level. Additional research is needed to determine whether these larger, but still limited population sizes could achieve management goals. If so, this could prove a cost-effective means of controlling animal numbers while maintaining their natural physiology and behavior.

The broader implications of this research are considerable. As this study suggests, the physiological and behavioral effects of PZP are not fully understood. Still, the vaccine is currently administered to many different species including white-tailed deer, *Odocoileus virginianus* [7], elk, *Cervus elaphus* [8], black bears *Ursus americanus* [63], and African elephants, *Loxodonta Africana* [64]. As with conspecific equid populations, habitat, resource, and demographic differences among species will affect their responses to PZP contraception and need to be considered. For social species like the horse, a proper balance between managing population size and maintaining a more natural physiological and behavioral regime is particularly important.

Acknowledgments

We would like to thank Dr. S. Stuska of the Cape Lookout National Seashore, National Park Service, C. Mason of the Foundation for Shackleford Horses, and M.A. Kearns for their additional data, Dr. A. Graham for her insight, and two anonymous reviewers for their comments on the manuscript.

Due to the extirpation of their natural predators, feral horse populations have expanded across the United States, necessitating their management. Contraception of females (mares) with porcine zona pellucida (PZP) is a popular option; however, effects to physiology and behavior can be substantial. On Shackleford Banks, North Carolina, USA, treated mares have exhibited cycling during the non-breeding season and demonstrated decreased fidelity to the band stallion, but PZP's long-term effects on mare physiology and behavior remain largely unexplored. After the contraception program was suspended in this population, we examined how prior exposure to varying levels of PZP treatment impacted (1) foaling probability and foaling dates (a proxy for ovulatory cycling) from 2009 to 2014 and (2) mare fidelity to the band stallion and reproductive behavior during 2013 and 2015. Additionally, we evaluated the effects of time since the mares' last treatment on these factors. Mares receiving any level of prior PZP treatment were less likely to foal than were untreated mares. Among mares that received 1–3 PZP applications, foaling probability increased with time since last treatment before declining, at ~6 years post-treatment. Mares that received 4+ applications did not exhibit a significant increase in foaling probability with time since last treatment. Moreover, previously treated mares continued to conceive later than did untreated mares. Finally, mares previously receiving 4+ treatments changed groups more often than did untreated mares, though reproductive behavior did not differ with contraception history. Our results suggest that although PZP-induced subfertility and its associated behavioral effects can persist after the cessation of treatment, these effects can be ameliorated for some factors with less intense treatment. Careful consideration to the frequency of PZP treatment is important to maintaining more naturally functioning populations; the ability to manage populations adaptively may be compromised if females are kept subfertile for extended periods of time.

Key words: Contraception, feral horse, immunocontraception, management, prolonged subfertility

Introduction

The extirpation of predator species in North America has precipitated the expansion of free-ranging ungulate populations (Eberhardt *et al.*, 1982; McCullough *et al.*, 1997), escalating human–wildlife conflict (Conover, 1995). Perhaps the most well-known example is that of increasing white-tailed deer (*Odocoileus virginianus*) populations across the United States.

These deer damage crops, feast on suburban ornamentals, spread disease, and are involved in both vehicle and train collisions (Conover, 1997), resulting in human injury, the loss of human life and costs amounting to more than 1 billion USD of property damage per year (Mastro *et al.*, 2008). Elk (*Cervus canadensis*) populations have also increased in some areas, with severe ecological impacts. In the Yellowstone ecosystem, unfettered elk populations have been associated with an ecological cascade of diverse effects including a reduction in available forage (Ripple and Beschta, 2003) and subsequent decreases in various vertebrate species including grizzly bears (*Ursus ortcos*) (Ripple *et al.*, 2014) and various songbird species, including the Common Yellowthroat (*Geothlypis trichas*), Lincoln's sparrow (*Melospiza lincolnii*), and Warbling Vireo (*Vireo gilvus*) (Baril *et al.*, 2011). Feral horse populations have also greatly expanded across the United Sates. In the west, feral horses and livestock compete for forage and water (BLM, 2011), while in the east, feral horses can negatively impact barrier island plant (Furbish, 1980) and estuarine (Levin *et al.*, 2002) communities. Managers have few options with which to control these populations (e.g. culls, removals), and fewer still that are acceptable to the public (Hobbs *et al.*, 2000; Porton, 2005). Consequently, contraceptive management has become increasingly popular (Hobbs *et al.*, 2000; Porton, 2005).

A commonly used contraceptive in female ungulates, porcine zona pellucida (PZP), stimulates the production of antibodies that bind sperm receptors on the egg's surface, thereby blocking fertilization while still allowing ovulation and the associated cycles of sex hormones (Sacco, 1977). Because PZP does not affect hormone levels directly, it was previously suggested that PZP treatment did not significantly affect recipient behavior or physiology (Kirkpatrick *et al.*, 1996, 1997; Powell and Monfort, 2001; Turner *et al.*, 1997). However, research on white-tailed deer, elk and feral horses has shown that there can be unintended effects on reproductive behavior (McShea *et al.*, 1997; Heilmann *et al.*, 1998; Nuñez *et al.*, 2009; Madosky *et al.*, 2010; Ransom *et al.*, 2010) and physiology (Nuñez *et al.*, 2010; Ransom *et al.*, 2013); in feral horses, these effects can be exacerbated in mares receiving higher numbers of total and/or consecutive PZP applications (Madosky *et al.*, 2010; Nuñez *et al.*, 2010). Briefly, studies investigating the response of free-ranging elk and white-tailed deer to PZP treatment indicate that recipient females extend reproductive behaviors into the post-breeding season (McShea *et al.*, 1997; Heilmann *et al.*, 1998). Authors suggest that in response to repeated unsuccessful mating attempts, females continue cycling in an attempt to gain additional reproductive opportunities (McShea *et al.*, 1997; Heilmann *et al.*, 1998). In feral horses, PZP-induced subfertility was also correlated with reproductive cycling in the non-breeding season (Nuñez *et al.*, 2010; Ransom *et al.*, 2013), increases in the amount of reproductive behavior directed towards mares by band stallions (Ransom *et al.*, 2010), and an increase in group transfer and reproductive behavior by mares (Nuñez *et al.*, 2009; Madosky *et al.*, 2010). Few studies have documented how permanent such side-effects may be (Kirkpatrick, 1995; Madosky *et al.*, 2010; Ransom *et al.*, 2013) and to our knowledge, none have investigated whether the intensity of PZP management can influence female physiology and behavior after the suspension of treatment in managed populations.

Here, we examine the rate at which mares on Shackleford Banks, North Carolina, USA are able to return to their physiological and behavioral baselines after varying levels of contraception management and with increasing time since treatment. Specifically, we monitored per capita births and the effects of varying levels of PZP treatment on the likelihood of conception in individual mares, and foal birth dates from 2009 to 2014, during which time the contraception program was largely suspended. In addition, we examined mare group transfer and reproductive behavior in the summers of 2013 and 2015 to determine whether PZP-induced subfertility had any long-term behavioral effects on previously treated mares. This information is critical to understanding the full effects of long-term subfertility on individuals and populations, and will be integral to designing best-management practices for PZP contraception.

Methods

Study area

Shackleford Banks is a barrier island ~3 km off the coast of North Carolina, USA. The island measures ~15 km in length, and varies between 0.5 and 3 km in width. The Shackleford horses are of Spanish origin and were likely first introduced ~400 years ago (Conant *et al.*, 2012). Currently, the population is co-managed by the National Park Service and the Foundation for Shackleford Horses (National Park Service, 2004). In 1997, federal law was instituted mandating the maintenance of at least 100–110 horses on Shackleford Banks (United States Congress, 1997). The National Park Service and the Foundation for Shackelford Horses limit the population to ~120 individuals, to reduce damage to the ecosystem.

Study subjects

The reproductive units of Shackleford horses are typical of feral equids, consisting of coherent bands of one, or sometimes two or three stallion(s), with one to several mares and their offspring (Rubenstein, 1981). Double-male bands are present, though they make up a small portion of the Shackleford population (5–10% of bands during the course of this study). In addition, differences in the degree of band territoriality have been associated with the island's varying ecology, making the region in which animals reside a reliable proxy for social variation in this population (Rubenstein, 1981). Though the bands are predominantly non-territorial, individual bands are spatially distinct from one another (Feist and McCullough, 1976; Rubenstein, 1981, 1986). Interactions that occur between different bands typically involve younger individuals engaging in exploration and/or play, the dispersal of sub-adult individuals

(both male and female), male–male assessments and/or contests, and the transfer of mares from one band to another (personal observation). Historically, band membership has been long lasting with most changes involving the dispersal of immature individuals. Band stallions sometimes fought to acquire mares from other groups, but stallions almost always retained their mares (Feist and McCullough, 1976; Rubenstein, 1981). More recently, PZP-induced subfertility has been associated with decreases in mare fidelity to the band stallion, increases in mare reproductive behavior, and mare cycling in what is typically the non-breeding season for these mares (Nuñez *et al.*, 2009, 2010; Madosky *et al.*, 2010).

PZP contraception

The National Park Service began the application of PZP for the purposes of immunocontraception in January 2000. In 2009, the program was provisionally suspended because the population was deemed stable (Mason, 2017). The contraception of all but five previously treated mares was halted, and all previously untreated mares of reproductive age were given one dose and booster of PZP. All treatments were administered by the National Park Service from late February through April each year. Each injection contained 100 micrograms of PZP plus an adjuvant (mixed at the darting site). Initial doses contained Freund's Complete Adjuvant, Modified, *Mycobacterium butyricum* (Calbiochem #344 289). All subsequent boosters contained Freund's Incomplete Adjuvant (Sigma #F5506).

For the animals in this study, PZP deterred pregnancy in 99.91% of cases when administered during the same year (Stuska, 2014). These values are similar to those published for Assateague horses, in which PZP deterred pregnancy in 94% of cases (Turner *et al.*, 1997). Over the course of the contraception program, ~19% of pregnancies were due to contraception failures. The contraception histories for the mares considered in this study are displayed in Table S1.

Pregnancy and foaling

Fecal samples are collected by the National Park Service in January of each year. All pregnancy testing is completed by enzyme immunoassay of fecal material at the Science and Conservation Center at ZooMontana in Billings, Montana. Using the methods of Kirkpatrick *et al.* (1991), water extracts of fecal samples are assayed for estrone conjugates and nonspecific progesterone metabolites. In addition, the National Park Service has tracked the foaling records, including foal birth dates, for each mare since 2000 (Stuska, 2014). These data were used to supplement assay results.

Behavioral and demographic sampling

Behavioral and demographic sampling was conducted primarily by two observers (C. Alvarez in 2013 and H. Carr in 2015) and was supplemented with data from three additional observers (B. Streater, 2013; M.A.F. Kent and K.E. Monroe, 2015). All observers were trained by C.M.V. Nuñez. We observed behavior in the majority of reproductive mares (aged 4 years and older) present during the study. We recorded group changing and reproductive behavior for 73% (43/59) and 95% (55/58) of mares in 2013 and 2015, respectively. The number of bands we observed comprised 68% (13/19) and 95% (18/19) of bands on the island in 2013 and 2015. Comparable to previous studies (Nuñez *et al.*, 2009; Ransom *et al.*, 2010), we observed mares for 7 weeks each year from mid-June to late August, totaling 350.15 hours of observation, averaging 3.13 h per mare (range = 1–6.05, SE ± 0.12). Horses were identified individually by color, sex, age, physical condition and other distinguishing markings including freeze brands. Ages are known from long-term records for the identified horses of Shackleford Banks (Nuñez, 2000).

We located each band an average of 0.87 times each week (range = 0.28–1.83, SE ± 0.03). We recorded its GPS location and composition, paying particular attention to the presence or absence of females. Group transfers were recorded if a mare was (a) not in the band she had been seen with previously, or (b) in a different band than she had been seen with previously. Mares did not need to remain with the 'new' group for a minimum length of time for the behavior to be considered a group transfer since even short-lived changes can affect band stability (Madosky *et al.*, 2010) and mare stress physiology (Nunez *et al.*, 2014). We remained with each group for a minimum of 30 min to ensure that individuals recorded as absent were not actually nearby, but out of our sight; when compared to 60-min field observations, 30 min ensured accurate data collection and allowed for larger sample sizes (Nuñez *et al.* 2010). We rarely witnessed mare transfer activity directly ($n = 1$); therefore, mare absence from a band was an important metric with which we measured the number of mare transfers between groups. On average, transfer behavior was confirmed by the mares' presence in new bands within 12.32 days of mare absence (range = 2–31, SE ± 1.44).

All incidences of reproductive interest (including copulation, mounting, genital sniffing, and rump rubbing) directed to and initiated by mares were recorded *ad libitum* during scan sampling (Altmann, 1974) as in Nuñez *et al.* (2009).

Statistical analyses

We analyzed data in R version 3.1.1. We used a linear mixed effects model (nlme package; Pinheiro and Bates, 2000) to determine whether the number of births had increased after the suspension of the contraception program ($n = 157$ total births; 112 births during the program; 45 births after program suspension). All births, regardless of mare age and treatment status at the time of foaling, were included in this analysis. Models included year as a random effect and the following fixed effects: mare treatment (previously treated/untreated), timing (during/after the contraception program), the interaction between mare treatment regime and timing, and a function allowing different variances across groups. We analyzed our data in both raw and arcsine-square root

transformed formats as per Ahrens *et al.* (1990). The arcsine-square root transformation has been shown to correct deficiencies in the normality of error terms, homogeneity of variance, and additivity of percentage data (Ahrens *et al.*, 1990).

To determine whether a mare's contraception history (number of total treatments received) affected her ability to foal in the years following contraception suspension, we used a generalized linear mixed model with a penalized quasi-likelihood (PQL) function (package MASS (Venables and Ripley, 2002)). The GLMM accounts for intra-subject correlation and individual heterogeneity (Jang and Lim, 2006) while the PQL function has proven reliable for the analysis of independent counts (Dean *et al.*, 2004). Models included mare identity as a random effect and the following fixed effects: linear and second-order polynomial functions of mare age (to account for both linear and non-linear effects on the likelihood of foaling), mare contraception history (0 treatments/1–3 treatments/4+ treatments (Kirkpatrick and Turner, 2002), n = 68 mares, Table S1), and island region.

To test for differences in mares' average foaling date with contraception history, we used linear mixed effects models, including a function allowing different variances across groups, and the following fixed effects: linear and second-order polynomial functions of mare age, mare contraception history (0 treatments/1–3 treatments/4+ treatments), and island region. We considered 37 births from 24 mares for this analysis (see Table S1).

To examine mare group changing and reproductive behavior, we analyzed the number of group changes mares made and the number of instances of reproductive interest both initiated and received by mares (n = 59 mares) over two field seasons conducted in 2013 and 2015 (see Table S1). We used linear mixed effects models including mare as a random factor, and the following fixed effects: linear and second-order polynomial functions of mare age, mare contraception history (0 treatments/1–3 treatments/4+ treatments), and island region. All behavioral data were Poisson distributed and log-transformed for analysis.

Parameters were removed from models by backwards elimination if $P > 0.05$. For each analysis, final models were run including linear and second- order polynomial functions of time since last treatment; for this analysis, only mares receiving at least one PZP treatment were considered (see Table S1). Mares less than 4 years of age and the 5 individuals that received treatment between 2009 and 2014 were excluded from all analyses save our per capita birth analysis (see above). In addition, where applicable, models were run both with and without mares belonging to double-male bands. Excluding these mares did not significantly change our findings; therefore, the models presented here include mares belonging to both single- and double-male bands. Where appropriate, we selected best fit models using Akaike's Information Criterion adjusted for small sample size (AICc) (Burnham and Anderson, 2002).

Results

Births

Not surprisingly, yearly per capita births were considerably lower for treated mares than for untreated mares during the contraception program (Linear Mixed Effects Model: mare treatment regime (previously treated); estimate = −0.41, SE = 0.08, t = −5.30, P = 0.0003). This pattern did not change from 2009 to 2014 when the contraception program was largely suspended; previously contracepted mares continued to exhibit subfertility even after the cessation of treatment (Linear Mixed Effects Model: treatment group (previously treated) * timing (after contraception suspension); estimate = 0.07, SE = 0.13, t = 0.50, P = 0.62, Fig. 1). Results were similar with arcsine-square root transformed data (Ahrens *et al.*, 1990) (Linear Mixed Effects Model: mare treatment regime (previously treated); estimate = −0.46, SE = 0.10, t = −4.61, P = 0.0007; treatment group (previously treated) * timing (after contraception suspension); estimate = 0.13, SE = 0.17, t = 0.74, P = 0.50). AICc analysis suggested that models without a variance function were a better fit to the data (AICc without variance function = 5.97 (raw), 24.19 (arcsine transformed); AICc with variance function = 8.89 (raw), 28.20 (arcsine transformed)).

Contraception history and foaling after contraception suspension

Even while controlling for the effects of mare age (Generalized Linear Mixed Model, mare age: estimate = 0.59, SE = 0.27, t = 2.20, P = 0.03; mare age^2: estimate = −0.02, SE = 0.01, t = −2.18, P = 0.03), previously treated mares were less likely to give birth during the study period, regardless of the number of prior treatments received (Generalized Linear Mixed Model, number of treatments (1–3 treatments): estimate = −3.00, SE = 1.24, t = −2.40, P = 0.02; (4+ treatments): estimate = −4.19, SE = 1.27, t = −3.30 P = 0.001, Fig. 2). Island region had no effect on the probability of mare foaling (all $P > 0.20$). These results cannot be explained by inherent subfertility in mares slated for treatment; prior to contraceptive treatment, all mares exhibited equivalent fertility (Generalized Linear Mixed Model, treated vs. untreated: estimate = 0.36, SE = 0.43, t = 0.84, P = 0.41, Table S2).

In addition, we sought to determine whether time since last treatment impacted the probability of foaling in previously treated mares. We found that mares previously receiving 1–3 treatments exhibited an initial increase in foaling probability, followed by a subsequent decrease (Generalized Linear Mixed Model, time since last treatment: estimate = 2.03, SE = 0.43, t = 4.67, $P < 0.00001$; time since last treatment^2: estimate = −0.18, SE = 0.04, t = −4.07, P = 0.0001, Fig. 3A). Conversely, mares receiving 4+ treatments did not exhibit a discernable increase in foaling probability even after several post-treatment years (Generalized Linear Mixed Model, time since last

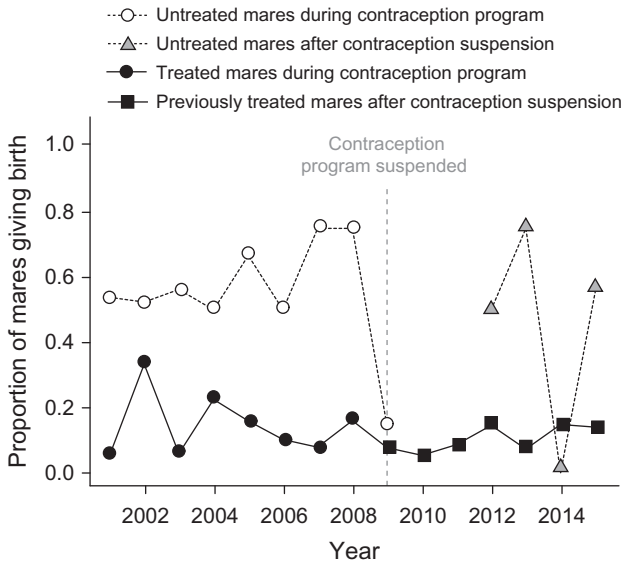

Figure 1: Proportion of mares giving birth in the years during and after contraception management. During the contraception program, treated mares (black circles) showed markedly lower birth rates than did untreated mares (open circles). In 2009, all untreated mares received PZP, leaving no untreated animals of reproductive age on the island in 2010 and 2011. Even after the suspension of treatment, previously treated mares (black squares) did not return to a level of fertility comparable to untreated mares before 2009 (open circles) or to younger, untreated animals that became reproductive between 2012 and 2015 (gray triangles).

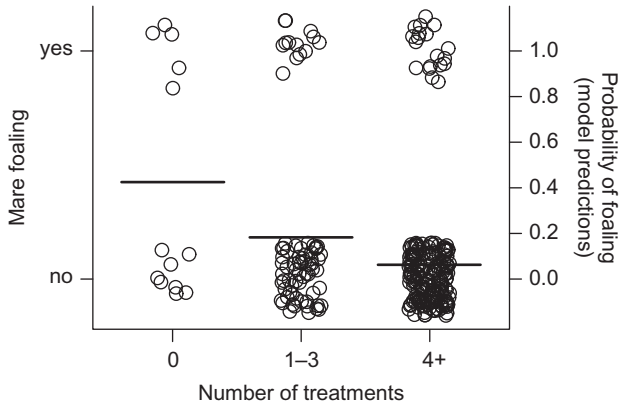

Figure 2: Probability of foaling and contraception treatment; circles represent individual births. Mares previously receiving any level of treatment were less likely to give birth than were untreated mares.

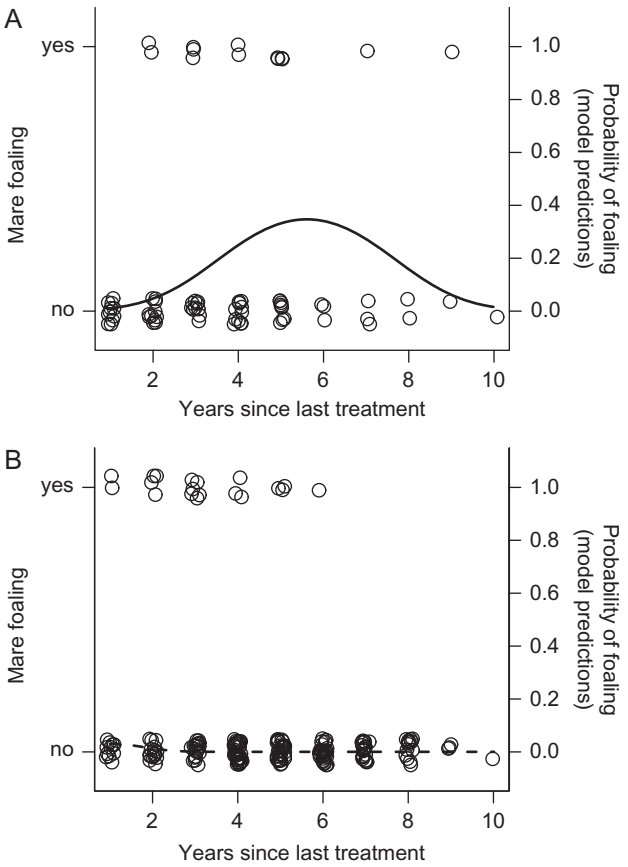

Figure 3: Probability of foaling after contraception suspension and mare treatment; circles represent individual births; solid and dashed lines indicate model predictions. Mares previously receiving 1–3 treatments (**A**) showed a gradual increase in foaling probability, peaking at ~6 years post-treatment, followed by a subsequent decrease. Mares previously receiving 4+ treatments (**B**) did not show a significant increase in foaling probability regardless of time since last treatment.

treatment * number of treatments (4+treatments): estimate = −0.79, SE = 0.25, t = −3.14, P = = 0.002, Fig. 3B).

Foaling date

Mares previously receiving any level of treatment gave birth later in the year than did untreated mares (Linear Mixed Effects Model, number of treatments (1–3 treatments): estimate = 2.29, SE = 0.78, t = 2.92, P < 0.00001; (4+ treatments): estimate = 3.50, SE = 0.90, t = 3.88, P < 0.0001, Fig. 4). Mares having received 1–3 treatments and 4+ treatments did not differ in their average foaling date (Tukey Honest Significant Difference Test: estimate = 1.21, SE = 0.87, z = 1.39, P = 0.34, Fig. 4). Island region and linear and second-order polynomial functions of both time since last treatment and mare age proved insignificant (all P-values > 0.08). Results suggested that models including a variance function were a better fit to the data (AICc with variance function = 155.56; AICc without variance function = 163.02).

Mare fidelity and reproductive behavior

Contraception history had a significant effect on mares' group changing behavior. Even after controlling for the effects of mare age (Linear Model: estimate = −0.04, SE = 0.01, t = −3.04, P = 0.004), mares that previously received 4+ contraceptive treatments changed groups more often than did

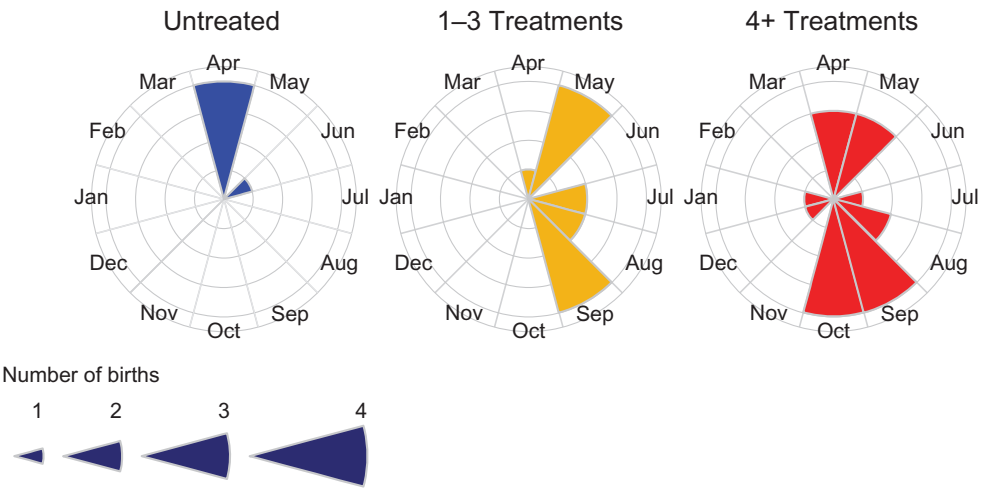

Figure 4: Average foaling date for untreated mares vs. previously treated mares. Mares previously receiving any level of treatment foaled later in the season than did untreated mares. Mares previously receiving 1–3 and 4+ treatments did not differ in their average foaling date.

untreated mares (Linear Model: estimate = 0.75, SE = 0.27, t = 2.80, P = 0.007, Fig. 5). Mares that previously received 1–3 treatments were equivalent to both untreated mares (Linear Model: estimate = 0.43, SE = 0.26, t = 1.66, P = 0.10, Fig. 5) and those receiving 4+ treatments (Tukey Honest Significant Difference Test: estimate = 0.32, SE = 0.15, z = 2.04, P = 0.10, Fig. 5). Island region, linear and second-order polynomial functions of time since last treatment, and second-order polynomial functions of mare age proved nonsignificant (all P-values > 0.08). Results suggested that models without variance functions were better fits to the data (AICc without variance function = 206.55; AICc with variance function = 207.62).

Contraception history did not affect mare reproductive behavior (Linear Mixed Effects Model: all P-values > 0.10). Results suggested that models without variance functions were better fits to the data (AICc without variance function = 131.49; AICc with variance function = 133.76). Island region, linear and second-order polynomial functions of both time since last treatment and mare age proved insignificant (all P-values > 0.07).

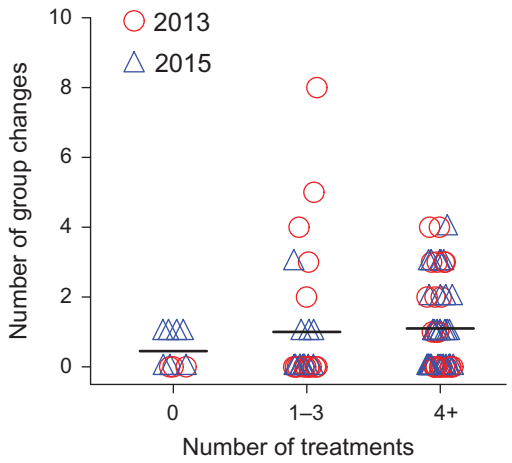

Figure 5: Number of group changes for untreated mares vs. previously treated mares in 2013 (red circles) and 2015 (blue triangles). Mares previously receiving 4+ contraceptive treatments made more group changes than did untreated mares. Mares previously receiving 1–3 treatments did not differ from untreated mares or those receiving 4+ treatments. Segmented lines indicate mean values.

Discussion

We investigated the likelihood that previously treated mares on Shackleford Banks, North Carolina USA, would return to baseline fertility, foaling dates and behavior after the cessation of contraceptive treatment with PZP. Mares received varying numbers of total PZP inoculations, allowing us to more closely investigate the effects of treatment intensity on mare fertility and subsequent effects to mare behavior. This contraceptive has been administered to several mammalian species including, white-tailed deer (*O. virginianus*) (Miller *et al.*, 1999), elk (*C. canadensis*) (Shideler *et al.*, 2001), black bears (*Ursus americanus*) (Lane *et al.*, 2007), bison (*Bison bison*) (Duncan *et al.*, 2013), and African elephants (*Loxodonta africana*) (Fayrer-Hosken *et al.*, 2000); these species have evolved an array of reproductive behaviors and social systems, which are vital to their survival and well-being. A more complete understanding of PZP contraception's potential long-term effects on recipient physiology and behavior is, therefore, of utmost importance if we are to manage and conserve species in the most effective and ethical manner possible. Feral horses have evolved a complex social structure, the maintenance of which is paramount to the overall health of group members

(Kaseda *et al.*, 1995; Linklater *et al.*, 1999). Careful study of mare physiological and behavioral responses to long-term contraception management can serve as a model for other social species for which the formation and maintenance of social bonds is necessary for survival.

Even when controlling for the effects of mare age on fertility, previously treated mares were less likely to give birth than were untreated mares during the study period. Moreover, the number of treatments that mares previously received affected the likelihood that mares would return to fertility after treatment suspension. Regardless of age, mares that previously received 1–3 treatments were more likely to return to fertility than were mares that received 4+ treatments. These results cannot be explained by inherent subfertility in mares slated for treatment: prior to contraceptive treatment, all mares exhibited equivalent fertility. In addition, time since last treatment was an important predictor of foaling probability for mares that received 1–3 treatments, but not 4+ treatments. Mares receiving 4+ treatments remained largely subfertile even after several post-treatment years. Conversely, mares that received fewer treatments exhibited a gradual increase in foaling probability until ~6 years post-treatment, after which, foaling probability decreased. This decrease was likely due to the typical age-specific reproduction in feral mares (Garrott *et al.*, 1991; Carnevale *et al.*, 1994). Feral mares more than 15 years of age exhibit decreased foaling rates (Garrott *et al.*, 1991) and pony mares at or older than 20 years of age are less likely to ovulate at regular intervals (Carnevale *et al.*, 1994). In this study, mares that previously received 1–3 treatments were, on average, 12.42 years of age in 2009, when they received their last inoculation. At 6 years post-treatment, these mares would have been old enough to exhibit the reproductive senescence typical of the species. However, the fact that mares receiving fewer treatments were able to return to fertility while mares receiving more treatments were not is telling; these results demonstrate that mares can retain more natural physiological functioning with less intense contraceptive treatment.

Foaling date was also was also affected by contraception history. Mares previously receiving any level of treatment exhibited later foaling dates than did untreated mares. The persistence of this effect after treatment suspension may be related to increases in mare condition commonly associated with contraception treatment (Turner and Kirkpatrick, 2002). In domestic mares, increased body condition or 'fatness' has been associated with higher circulating levels of leptin (Fitzgerald and Bates, 2000). Mares exhibiting higher circulating leptin were more likely to exhibit reproductive activity during the winter months, suggesting that leptin may modify mare reproductive response to inhibitory photoperiod (Fitzgerald and McManus, 2000). Treated Shackleford mares exhibit the increased physical condition typically demonstrated by contracepted mares (Nuñez *et al.*, 2010). It may be, therefore, that increases in body condition and concomitant increases in circulating leptin have contributed to prolonged effects on mare cycling even after contraception treatment suspension.

Potential effects of late birth dates to foal survival are difficult to assess on Shackleford Banks. In the past, animals perceived to be in poor condition have been removed from the island and adopted off, complicating the analysis of foal survival. As such, we cannot look to our data with confidence to determine if foal survival is compromised by later birth dates. Notably, foal survival is affected by birth date in western feral horses (Ransom *et al.*, 2013). In these populations, the probability of foal survival decreases as parturition date moves further away from the summer peak in resources (Ransom *et al.*, 2013), though these animals are undoubtedly subject to harsher environmental conditions than are Shackleford horses.

Contraception history also had an effect on mare fidelity to the band stallion. Mares that previously received 4+ treatments changed groups more frequently than did untreated mares. Mares that previously received 1–3 treatments did not differ from either untreated mares or those that previously received 4+ treatments. Combined with our findings on fertility, these results demonstrate that unintended side-effects of PZP treatment have the potential to become long term, i.e. they persist with continued subfertility, even if treatment, per se, has ended. However, our results also show that with less frequent treatment, some of these effects can be ameliorated with time, enabling more flexible population management.

Interestingly, our mare fidelity results are similar to those demonstrated in previous studies conducted during the contraception program (Nuñez *et al.*, 2009; Madosky *et al.*, 2010). In those studies, treated mares transferred groups more often than did untreated mares. These behaviors were linked to the presence of a foal (Nuñez *et al.*, 2009): mares with foals, regardless of treatment status, tended to change groups less often, indicating that mares, having successfully reproduced with a stallion, were more likely to remain with said stallion and/or, that mares with foals required a more stable environment in which to raise offspring. In the present study, we found that mares that had previously received 4+ treatments changed groups more often than did untreated mares. The lower foaling probability exhibited by these mares, even after several post-treatment years, is likely the proximate mechanism behind this behavior, rather than PZP treatment, per se. These results show that changes in mare behavior formerly associated with active contraception treatment have persisted with prolonged subfertility, lending additional support to the assertion that such unintended side-effects can persist, even after active contraceptive treatment has ended. Moreover, such behavior represents a significant decrease in mare fidelity by previously treated mares. Prior to the contraception program, Rubenstein (1981) reported that across the entire island, only 10.8% of mares transferred groups, indicating high band fidelity by females. This is in stark contrast to

what was found in our previous study, during which 53% of mares changed groups (Nuñez *et al.*, 2009), in the 2 years of the Madosky study during which 66% and 73% of mares changed groups in 2007 and 2008, respectively (Madosky *et al.*, 2010), and in our current study, during which 42% and 49% of mares changed groups, in 2013 and 2015, respectively.

Contrary to our results from an earlier study (Nuñez *et al.*, 2009), previously treated mares did not engage in more reproductive behavior than did untreated mares. The disparity in our results may be due to differences in the timing of the two studies: the current study was conducted during the breeding season, when breeding behavior is relatively frequent amongst reproductive individuals; our previous study was conducted during the non-breeding season when breeding behavior is more variable. It is worth noting that in the Madosky study (2011), also conducted during the breeding season, Shackleford mares treated with PZP received more harassment from band stallions than did untreated mares. Taken together, these results could suggest that the amount of reproductive behavior in previously treated mares has returned to baseline levels. However, it is not clear whether 'harassment' (Madosky, 2011) is indicative of reproductive behaviors as we have defined them here. As such, our ability to compare results across time is limited.

Our results demonstrate the potential for long-term physiological and behavioral effects to PZP-treated individuals and that these effects can persist with continued subfertility, even after the cessation of treatment. However, our results also suggest that with less frequent treatment, these effects can be ameliorated with time, enabling more flexible population management.

Our results also contrast with claims that PZP is 'completely reversible'; claims upon which feral horse management decisions have been defended (BLM, 2010). Similar long-term subfertility with intense PZP treatment has been found in feral horse populations living on Assateague Island National Seashore, MD (Kirkpatrick and Turner, 2002), in the closely related, but critically endangered Przewalski's horse (*E. ferus przewalskii*) (Feh, 2012), and in feral horses living in the western United States (CO and WY) (Ransom *et al.*, 2013), indicating that these effects are not limited to specific sites or populations, but are pervasive amongst equids. In the Assateague study, nearly 70% of mares receiving three consecutive PZP treatments failed to demonstrate fertility for 1–4 years post-treatment (Kirkpatrick and Turner, 2002). In the Przewalski's horse, only 45% of 20 mares that had been treated with PZP for three consecutive years demonstrated fertility; those that did foal, did not do so until 6.7 years after their last treatment, on average. Moreover, four of nine females receiving only one treatment (one primer injection and one booster injection) did not produce offspring for 4+ years post-treatment (Feh, 2012). Though the mechanism behind the prolonged subfertility in Przewalski's mares is unknown, some of the Assateague mares demonstrated ovulatory failure (Kirkpatrick *et al.*, 1992; Kirkpatrick and Turner, 2002). In western feral horse populations, previously treated mares were less likely to give birth and gave birth later into the calendar year for up to six post-treatment years, again demonstrating the potential for long-term side effects of prolonged, PZP-induced subfertility (Ransom *et al.*, 2013).

The present study demonstrates that the intensity of treatment is also important: mares previously receiving 4+ treatments are less likely to return to fertility and exhibit decreased fidelity to the band stallion. Mares receiving any level of treatment are more likely to give birth later into the calendar year. Conversely, mares receiving 1–3 treatments are more likely to return to fertility and demonstrate behavior more typical of the species (Feist and McCullough, 1976; Rubenstein, 1981; Berger, 1986). These results largely support our previous assertion that more natural physiology and behavior can be maintained in feral horses with less aggressive contraception schedules (Nuñez *et al.*, 2009).

Results similar to those demonstrated in this study have been documented in several captive species (Penfold *et al.*, 2014). A retrospective analysis, combined with published literature and reliable anecdotal reports, demonstrated that extended periods of infertility in females can induce reproductive changes that negatively impact future fertility. This was the case for individuals treated with a contraceptive agent and also for those left untreated, but separated from male counterparts (Penfold *et al.*, 2014). The mechanisms underlying these impacts are varied, but include endometrial hyperplasia [(Asian (*Elephas maximus*) and African elephants, Seba's bats (*Carollia perspicillata*), felids], uterine insufficiencies [wildebeest (*Connochaetes*)], asymmetric reproductive aging [white rhinoceros (*Ceratotherium simum*)], and enlarged ovaries and exuberant uterine responses [stingrays (*Myliobatoidei*)] (Penfold *et al.*, 2014).

The close association with PZP-induced subfertility and mare behavior demonstrated here points to an important link between animal physiology and behavior that should be considered when implementing any management program. Alterations to an animal's reproductive physiology—for whatever managerial gain—will likely be associated with concomitant changes in behavior (McShea *et al.*, 1997; Heilmann *et al.*, 1998; Nuñez *et al.*, 2009; Gilman *et al.*, 2010; Madosky *et al.*, 2010; Ransom *et al.*, 2010). The effects of these subsequent changes—both to management program efficacy and to animal welfare—ought to be weighed against the perceived advantages of our physiological manipulations.

The broader implications of this research are notable. Because other methods for controlling feral horse populations can have pronounced side effects and are often unpopular with the public, PZP is undoubtedly an important option in a manager's toolkit (Hobbs *et al.*, 2000; Kirkpatrick and Turner, 2003; Porton, 2005). However, our results suggest

that the best use of this tool will balance attaining target population sizes against over-treating individual animals. Although the prolonged effects of PZP contraception outlined here could actually assist managers in keeping population sizes low (in feral horses and other over-abundant wildlife), the use of PZP with small populations and/or those of conservation concern should be approached with caution (Ransom *et al.*, 2014). For instance, the fact that mares do not easily return to fertility after the cessation of treatment could limit the ability of populations to rebound in the face of stochastic declines. In the case of Shackleford Banks horses, prolonged PZP-induced subfertility has likely reduced the ability to adaptively manage the population; stopping treatment has not resulted in increased fertility, particularly for mares that previously received 4+ treatments. Given these results and the prolonged effects of PZP-induced subfertility on foaling schedules and behavior (and the potential for additional effects to non-recipient animals (Ransom *et al.*, 2010)), we suggest that monitoring individual treatment histories, or modeling the statistical probability of multiple treatments per individual, could prove critical in maintaining more natural physiological and social dynamics, all while allowing for maximal flexibility in attaining management objectives.

Behavioural effects of ovariohysterectomy on bitches

V. O'Farrell and E. Peachey

Small Animal Clinic, Royal (Dick) School of Veterinary Studies, Summerhall, Edinburgh EH9 1QH

Journal of Small Animal Practice (1990) **31**, 595-598

ABSTRACT

A questionnaire about their dogs' behaviour was administered to the owners of 150 spayed bitches at the time of spaying and again six months later. It was also administered twice with the same time interval to a control group of 150 unspayed bitches, group matched for breed and age. Principal component analysis of the questionnaire responses yielded 13 factors. On two of these factors, 'indiscriminate appetite' and 'dominance aggression towards family members', the scores of the spayed bitches showed a significant increase compared with their controls. The spayed bitches most likely to show an increase in dominance aggression were puppies under one year, already showing some aggression.

INTRODUCTION

In bitches, the most frequently performed surgical operation is that of ovariohysterectomy, or spaying. Although it is sometimes performed for medical reasons, its most usual purpose is the avoidance of pregnancy and the inconveniences of a bitch in oestrus. It is occasionally undertaken as a treatment for a behavioural problem. It is sometimes stated that spaying affects temperament adversely (for example that spayed bitches 'lack personality' or are 'frankly neurotic' (Jones and Joshua 1982)). It has been observed clinically (Voith and Borchelt 1982, O'Farrell 1986) that owners of bitches presenting with problems of aggression frequently report an exacerbation after spaying. However, there are no objective and controlled studies in this area. The aim of the present study was to fill this gap.

MATERIALS AND METHODS

The owners of 150 bitches were interviewed at the time that the bitch was spayed and again six months later. They were an unselected sample, being the first 150 owners contacted through veterinary practices who were available for interview. These formed the experimental group. The control group was composed of 150 unspayed bitches: their owners were also interviewed twice with an interval of six months. The controls were matched for breed with the bitches in the experimental group and the groups were matched for age. No dog was included in the study which was less than four months old at initial interview or which had been acquired less than one month previously.

Questionnaire

The interview took the form of a questionnaire with 60 items. Twenty of the items were concerned with basic information about the dog and its circumstances: age, age when acquired, number of dogs and people in the household, number of pregnancies, etc. The rest of the questionnaire was concerned with the dog's behaviour over the previous month. The following areas were covered: aggression (to owners, visitors, other dogs), fears, activity level, excitability, destructive chewing, reactions to separation from owner, behaviour in the car, roaming, feeding, urination and defecation and scavenging. Most of the questions were phrased in such a way that the replies were in the form of an estimated absolute or relative frequency of the behaviour.

RESULTS AND DISCUSSION

To simplify the results of the responses to the 40 behavioural items, the correlations between the items were subject to principal component analysis. The results are shown in Table 1.

Table 1. Principal component analysis of questionnaire items (Varimax rotation)

	Factor loadings
Factor 1. Protective aggression (9·8% of variance)	
Threatens people outside family	0·76
Barks, growls when owner opens door to someone	0·68
Gets excited when owner opens door to someone	0·60
Factor 2. Aggression towards other dogs (7·2% of variance)	
Growls at other dogs	0·85
Growls at dogs outside the household	0·83
Factor 3. Urination or defecation indoors (5·2% of variance)	
Urinates in house	0·83
Defecates in house	0·78
Factor 4. Destructive behaviour (4·8% of variance)	
Destructive when left alone	0·88
Destructive chewing generally	0·81
Factor 5. Phobias (4·4% of variance)	
Afraid of visitors	0·73
Afraid of specific kind of person (eg, men)	0·76
Afraid of things (eg, vacuum cleaner)	0·57
Factor 6. Dominance aggression towards family members (4·3% of variance)	
Threatens if disturbed when resting	0·78
Threatens family members	0·72
Threatens when groomed	0·50
Threatens when something taken away (eg, food)	0·35
Factor 7. Excitement in car (3·6% of variance)	
Sits quietly in car	−0·85
Jumps about or barks in car	0·81
Factor 8. Indiscriminate appetite (3·5% of variance)	
Eats meals quickly	0·83
Eats any commercial dog food	0·83
Eats rubbish, carrion, etc	0·36
Factor 9. Dislike of separation from owner (3·3% of variance)	
Follows owner to door on departure	0·74
Looks miserable when owner leaves	0·63
Takes no notice when owner leaves	−0·55
Factor 10. Territorial urination (3·1% of variance)	
Adopts non-squatting posture when urinating	0·74
Urinates frequently on walks	0·72
Factor 11. Activity level in the house (2·8% of variance)	
Moves around constantly	0·74
Reacts to noises	0·48
Follows owner around house	0·38
Factor 12. Perverse appetite (2·7% of variance)	
Eats dog faeces	0·87
Eats rubbish, carrion, etc	0·57
Factor 13. Reactivity (2·6% of variance)	
Reacts to noises	0·72
Threatens when groomed	0·45
Barks when left	0·43

Table 2. Differences between experimental and control groups at first interview

Spayed group	
1 Was acquired at older age	P<0·001
2 Had fewer administrations of synthetic progestogen	P<0·01
3 Had fewer dogs in household	P<0·0001
4 Reacted less to separation (factor 9)	P<0·01
5 Jumped about less in car	P<0·01
6 Roamed more from house	P<0·02

Table 3. Change in factor scores in unspayed group between first and second interview

Factor	Change
1 Protective aggression	+
2 Aggression towards other dogs	+
3 Urination or defecation in the house	− (P = 0·002)
4 Destructive behaviour	−
5 Phobias	−
6 Dominance aggression towards family members	−
7 Excitement in car	− (P < 0·05)
8 Indiscriminate appetite	− (P < 0·01)
9 Reaction to separation from owner	−
10 Territorial urination	+ (P < 0·01)
11 Activity level in the house	−
12 Perverse appetite	−
13 Reactivity to stimuli	−

Where changes are significant, significance level is shown (Wilcoxon test)

For each interview, a score on each factor was calculated by summing the score on the relevant items, weighted by their factor loadings. In analysing the results, for the most part, these factor scores were used, rather than the scores on the individual items.

Next, the results were examined to see if there were any significant differences between the spayed and unspayed groups at initial interview. Any significant differences between the groups would mean that groups were not matched on those variables. The mean age of the experimental group was 33·47 months (SD 33·95). The mean age of the control group was 33·29 months (SD 30·52). These ages were not significantly different: the groups, therefore, had been successfully matched for age. There were, however, significant differences between the groups on some variables: these are shown in Table 2. The relevance of these differences is discussed later.

The factor scores on first and second interview for the unspayed bitches were then compared (Wilcoxon test for matched pairs) to determine what changes in behaviour had occurred due only to the passage of time. The changes in the factor scores are shown in Table 3. It can be seen from this table that significant decreases occurred in urination and defecation in the house, excitement in the car and indiscriminate

Table 4. Change in factor scores in unspayed group between first and second interview by age

Factor	Change		
	11 months and under	12-24 months	25 months and over
1 Protective aggression	+	+	−
2 Aggression towards other dogs	+	+	−
3 Urination or defecation in the house	− (P = 0·003)	−	−
4 Destructive behaviour	−	−	+
5 Phobias	+	+	− (P = 0·002)
6 Dominance aggression towards family members	−	−	−
7 Excitement in car	− (P = 0·02)	−	−
8 Indiscriminate appetite	− (P = 0·01)	−	−
9 Reaction to separation from owner	+	−	−
10 Territorial urination	+ (P = 0·005)	+	+
11 Activity level in the house	−	+	−
12 Perverse appetite	−	+	−
13 Reactivity to stimuli	−	+	−

Where changes are significant, significance level is shown (Wilcoxon test)

appetite: a significant increase occurred in territorial aggression. The unspayed group was then divided into three age groups: 11 months and under (puppies), one to two years and over two years. The changes occurring in these groups over the six months were examined. These are shown in Table 4. It can be seen that where significant changes occurred in the group as a whole, these were due to changes in the puppy group. These changes are not surprising: they are the changes one would expect in puppies as they mature. The finding, however, is reassuring, as it confirms the validity of the questionnaire. It is interesting that fears do not follow the same pattern: they do not decrease until the bitch is over two years old.

The changes in the spayed group from first to second interview were then calculated and the changes compared with the changes in the unspayed group (Wilcoxon test). The comparison was also made with the puppies excluded, in case changes in the puppy group were masking changes due to spaying. The factors for which the changes in the spayed and unspayed group differed significantly are shown in Table 5.

The first question to be considered is whether these differences are due to spaying or whether they might be accounted for by any of the differences between the two groups at initial interview. It seems unlikely that the difference on factor 6 (dominance aggression) or on factor 8 (indiscriminate appetite) could be accounted for by any of the initial differences. However, in the case of factor 7 (excitement in the car) the items which loaded on this factor were 'does not sit quietly in the car' and 'jumps about in the car'. On examining the changes on these two items, it was found that changes in the 'jump about' item were solely responsible for the significant difference in the changes between the groups on factor 8. The initial scores of the two groups on the 'jump about' item were significantly different (Table 2): it cannot be concluded, therefore, that spaying caused an increase in excitement.

With regard to factor 8 (indiscriminate appetite), it seems safe to conclude that the relative increase in the experimental group when puppies were excluded was due to the effects of spaying. Presumably this behavioural change

Table 5. Change in factor scores between first and second interview: significant differences between experimental and control groups

Factor	
6 Dominance aggression towards family members	
Spayed group increase	
Unspayed group decrease	
	P<0·05
7 Excitement in car	
Spayed group increase	
Unspayed group decrease	
	P<0·05
8 Indiscriminate appetite (puppies excluded)	
Spayed group increase	
Unspayed group decrease	
	P<0·05

Table 6. Changes in dominance aggression by age

Age	Aggression increases	Aggression stays the same	Aggression decreases	Total
11 months or less	S = 13 U = 4	S = 28 U = 31	S = 4 U = 6	S = 45 U = 41
12-24 months	S = 6 U = 6	S = 31 U = 26	S = 5 U = 7	S = 42 U = 39
2 years +	S = 14 U = 11	S = 38 U = 43	S = 11 U = 16	S = 63 U = 70
Total	S = 33 U = 21	S = 97 U = 100	S = 20 U = 29	

S Number of bitches in spayed group
U Number of bitches in unspayed group

Table 7. Changes in dominance aggression by initial aggression score

Initial Aggression	Aggression increases	Aggression stays the same	Aggression decreases	Total
Some aggression	S = 16 U = 8	S = 7 U = 5	S = 20 U = 29	S = 43 U = 42
No aggression	S = 17 U = 13	S = 90 U = 95	—	S = 107 U = 108
Total	S = 33 U = 21	S = 97 U = 100	S = 20 U = 29	

S Number of bitches in spayed group
U Number of bitches in unspayed group

Table 8. Changes in dominance aggression by age and initial aggression

	Aggression increases	Aggression stays the same	Aggression decreases	Total
Bitch under 12 months showing some initial aggression	S = 6 U = 1	S = 2 U = 0	S = 4 U = 6	12 7
Bitch over 12 months showing no initial aggression	S = 10 U = 10	S = 64 U = 64	—	74 74

sometimes results in the weight gain which is often cited as a possible side-effect of spaying.

Similarly, it seems safe to attribute the change in factor 6 (dominance aggression towards family members) to spaying. The results were examined more closely in an attempt to discover which bitches are most at risk of developing increased aggression following spaying. Table 6 shows the changes occurring in bitches spayed at different ages. It can be seen that although there is no clear trend with increasing age, the greatest difference between experimental and control group occurs in the youngest age group. Table 7 shows a comparison between bitches showing some aggression at initial interview and those showing none. It can be seen that there is a greater risk of aggression increasing in those already showing some aggression. Combining the variables age and initial aggression, Table 8 compares puppies under one year old already showing some aggression with dogs over one year showing none. If a puppy showing some aggression is spayed, there is a 50/50 chance that her aggression will increase. If she is not spayed, the chances are 6 to 1 that her aggression will decrease. On the other hand, if an adult bitch showing no aggression is spayed, this does not increase at all the chances that she will subsequently show some aggression: these are 6 to 1 in either case.

CONCLUSIONS

There is no evidence that spaying has beneficial effects on behaviour (excluding, of course, behaviour directly connected with oestrus).

The operation should not be undertaken as a treatment for behavioural problems.

Spaying is accompanied by the risk of certain behavioural changes. There is a risk of increase in indiscriminate appetite. More importantly, there is a risk of increase in dominance aggression towards family members. This risk is greatest in puppies under one year already showing some aggression. For these, some alternative method of controlling oestrus (eg, a synthetic progestogen or a surgical procedure which does not remove all ovarian tissue) might be preferable. (Unfortunately, the figures do not, of course, indicate whether the risk diminishes for these dogs as they get older). On the other hand, there seems no risk of increased aggression resulting from spaying for older dogs not showing any aggression. In addition the study showed no adverse effects on other kinds of behaviour.

ACKNOWLEDGEMENTS

Our thanks are due to Gill McConnell, Royal (Dick) School of Veterinary Studies and to Pat Dugard, Dundee Institute of Technology, for statistical advice and help. This research was funded by the Crusade Against Cruelty to All Animals.

Objective: To compare surgical trauma, perioperative pain, surgical time, and complication rate in mares undergoing standing bilateral ovariectomy by natural orifice transluminal endoscopic surgery (NOTES) or laparoscopy.
Study Design: Experimental study.
Animals: Healthy mares (n = 12).
Methods: Ovariectomy was performed with a vessel-sealing device by transvaginal NOTES (n = 6) using a flexible endoscope and specialized instruments or by bilateral flank laparoscopy (n = 6). Preoperative and postoperative complete blood count (CBC), plasma fibrinogen concentration, serum amyloid A concentration, peritoneal nucleated cell count, and total protein concentration were compared using repeated measures ANOVA. Surgical times were compared using an unpaired t-test. Mares were monitored for 2 weeks postoperatively and necropsy was performed at 3 weeks (n = 6) or 3 months (n = 6) to assess short- and medium-term effects of each procedure. Complication rate, necropsy, and bacteriology findings were compared using a Fishers exact test. Significance was set at $P < .05$.
Results: All surgical procedures were performed successfully and all but one laparoscopy mare were bright, alert, and maintained a good appetite until euthanasia. Mean ± SD surgical time was similar between groups (NOTES: 100 ± 40 minutes; laparoscopy: 107 ± 47 minutes). There were no significant temporal differences in vital parameters, CBC, plasma fibrinogen concentration, serum amyloid A concentration, peritoneal nucleated cell count, and total protein concentration between groups.
Conclusions: Bilateral ovariectomy by transvaginal NOTES or laparoscopy resulted in minimal inflammation and surgical trauma.

Minimally invasive techniques are continuing to expand in veterinary surgery, with decreased soft tissue trauma, reduced postoperative pain and morbidity, and faster return to function cited as key advantages.[1] Standing laparoscopy is currently the gold standard minimally invasive technique for elective bilateral ovariectomy in mares. This technique allows excellent viewing and hemostasis through small body wall incisions.[2]

Natural orifice transluminal endoscopic surgery (NOTES) consists of passing a flexible endoscope through a natural orifice (typically vagina or mouth), creating an opening to access the abdomen (typically transvaginal or transgastric routes) and perform intra-abdominal procedures. Since 2004,[3] flexible endoscopy for abdominal surgery has been used in laboratory studies[4,5] and is currently being performed for cholecystectomy in human clinical trials.[6] A recent retrospective case-control study compared transvaginal cholecystectomy to conventional laparoscopic cholecystectomy.[7] Whereas similar complication rates between groups were reported, the NOTES group had a lower need for postoperative analgesia, a faster recovery, and better cosmetic results compared to the laparoscopy group. Controlled studies comparing transgastric NOTES to laparoscopy in pigs suggest that viewing, cardiopulmonary and immunologic effects are similar.[8–12]

This study was supported by the Minimally Invasive Surgery Grant from the American College of Veterinary Surgeons and Ethicon Endo-Surgery, and by the State of Indiana and the Purdue University School of Veterinary Medicine Research account funded by the total wager tax.

NOTES techniques have recently been introduced to veterinary surgery,[4,13] and our group described transvaginal ovariectomy in 10 mares using a NOTES approach.[14] Transvaginal abdominal exploration using flexible and rigid endoscopes was also recently reported in horses.[15] Transvaginal access uses the principles of the colpotomy technique to access the abdominal cavity of mares. Ovariectomy by blind colpotomy using a chain écraseur has been used in standing mares because it is a quick and inexpensive procedure that avoids skin incisions.[16,17] However, disadvantages of the colpotomy technique include blind access to the abdominal cavity and pedicle transection by mechanical means that can potentially lead to major intra- and postoperative complications including fatal hemorrhage, peritonitis, intestinal puncture, and evisceration through the colpotomy site.[18] By providing direct viewing during the transvaginal abdominal approach, and of the surgical site during hemostasis and transection of the ovarian pedicle, the transvaginal NOTES approach has the potential to increase the safety of the colpotomy technique for bilateral ovariectomy in healthy mares.[15]

Because the NOTES approach eliminates the need for skin and body wall incisions, it may offer advantages over standard laparoscopy with respect to fewer incisional complications and faster return to function. A single small vaginal wall incision allows access to both sides of the abdominal cavity when performing a NOTES ovariectomy.[14] Compared to conventional laparoscopic ovariectomy, the transvaginal approach has fewer incisions through a thinner muscle layer, resulting in less overall tissue disruption for surgical access. This has the potential to decrease the risk for incisional complications such as seroma, infection, or dehiscence, as well as reduce the degree of postoperative incisional pain. A concern raised with the introduction of NOTES in the clinical setting has been the perceived increased risk of abdominal infection after access through a nonsterile orifice.[19] However, to date, an increased risk of abdominal infection after transvaginal NOTES compared to laparoscopy has not been documented. Clinically, perioperative antimicrobial administration and disinfection of the natural orifice have been used to limit contamination during surgery.

Surgical invasiveness, as measured by postoperative pain and recovery time, is more easily and accurately evaluated in people than in horses. Even though pain scoring systems have been described and validated in horses,[20] pain assessment is associated with a certain degree of subjectivity. Acute phase proteins, such as serum amyloid A (SAA) or fibrinogen, provide a quantitative assessment of inflammation and correlate well with the degree of surgical trauma in horses.[21] We are unaware of a controlled study comparing the outcome of NOTES to laparoscopic procedures in horses. Should NOTES ovariectomy be shown to have advantages over laparoscopy, the spectrum of minimally invasive abdominal surgeries in the horse could be expanded using natural orifice surgical techniques.

Our primary objective was to compare perioperative pain and surgically induced trauma in standing mares undergoing bilateral ovariectomy by NOTES or conventional laparoscopy. Further, we compared surgical time and complication rate of the 2 procedures. We hypothesized that transvaginal NOTES would improve the clinical outcome after bilateral ovariectomy in the mare by minimizing soft tissue trauma and reducing pain and inflammation when compared to a conventional laparoscopic approach.

MATERIALS AND METHODS

Horses

Twelve mares of various breeds (age 8–18 years; weighing 358–625 kg) were studied. The mares had no history of previous abdominal surgery and were determined to be healthy and free of reproductive abnormalities based upon physical, rectal, and ultrasound examinations. Mares were admitted 7 days preoperatively for an acclimation period and were monitored daily for 2 weeks postoperatively. Each mare was randomly assigned to either the transvaginal NOTES or laparoscopic ovariectomy group with 6 horses in each group. All surgeries were performed during the same month (July); however, no attempt was made to manipulate the reproductive cycle in the mares or to time the surgery with the stage of the reproductive cycle.

Preoperative Phase

Mares were housed in the same facility for the duration of the study. During this acclimation phase, preoperative behavior scores and activity levels were measured. Hay was withheld for 3 days and a complete pelleted feed was removed 24 hours before surgery, but mares had free access to water. Complete blood count (CBC), plasma fibrinogen concentration, and SAA concentration were determined preoperatively. A catheter was placed in the left jugular vein and potassium penicillin (22,000 U/kg, intravenously [IV]) and flunixin meglumine (1.1 mg/kg, IV) were administered within 1 hour of surgery. Mares were restrained in standing stocks and sedated with detomidine hydrochloride (0.01 mg/kg, IV) and butorphanol tartrate (0.01 mg/kg, IV). Caudal epidural anesthesia was performed with a combination of xylazine hydrochloride (0.2 mg/kg) and morphine (0.2 mg/kg), made up to a volume of 15 mL with sterile (0.9% NaCl) solution. Additional doses of detomidine hydrochloride and butorphanol tartrate were administered IV if the mare displayed signs of pain during surgery (kicking, shifting weight, and excessive body movement). In the NOTES group, the perineal region was clipped, the vulva and vaginal walls were cleaned and aseptically prepared using a surgical scrub brush of chlorhexidine gluconate 4% solution (Pre-scrub II™, BioMed Systems Inc, Norwalk, CT), as previously described.[14] A 30 F Foley catheter was introduced into the bladder and left in place for the duration of surgery to allow decompression of the bladder. The

pelvis and perineal region were draped, leaving a fenestration for the vulva. In the laparoscopy group, both paralumbar fossae were clipped, aseptically prepared, and draped for surgery.

Surgical Procedures

A surgical resident (KP) with similar proficiency in NOTES and laparoscopy techniques performed all surgical procedures assisted by 2 board certified surgeons (TBL, LJF).

NOTES Group. Transvaginal ovariectomy was performed as described.[14] The technique previously described was modified by using a 15-mm optical trocar (instead of a 12-mm trocar) in order to accommodate the endoscope for viewing entry into the abdominal cavity. Briefly, the cervix and vaginal fornix were identified using a 1-m-long single working channel flexible endoscope (Olympus® GIF P-140, Olympus America, Inc., Center Valley, PA). The transvaginal portal was made through the vaginal wall at the 11 o'clock position, 4 cm away from the cervix by introducing a 15-mm controlled access cannula (Endopath® Xcel™ Bladeless, Ethicon Endo-Surgery, Inc., Cincinnati, OH) under endoscopic guidance followed by placement of a 33-mm diameter Endopath® Large-Port assembly (LTK33, Ethicon Endo-Surgery, Inc.). Once the 33-mm diameter cannula was inserted through the vaginal wall, the endoscope was introduced in the abdominal cavity and the ovaries were identified. On-demand room air introduced by pressing the air ingress button on the endoscope was used to improve observation. No positive-pressure insufflation was used and intra-abdominal pressures were not recorded. Local anesthesia was achieved by infiltrating 35-mL 2% lidocaine hydrochloride in the mesovarium of each ovary using a 17-g endoscopic injection needle (17-Gauge Lance-A-Lot, Mila International, Inc., Erlanger, KY). Claw-jaw laparoscopic grasping forceps (ARO910136 BM, Arrow Medical Supply, Inc., Libertyville, IL) were used to grasp and elevate the ovary during hemostasis and transection of each ovarian pedicle using a 60-cm long, 10-mm diameter customized vessel sealing device (LigaSure™, Valley Lab, Boulder, CO).[14] All instruments and endoscope were positioned side by side within the 33-mm cannula and therefore, no extra portals were made throughout the procedure. After complete transection of the ovarian pedicle, the ovary was removed through the vaginal opening after removal of the 33-mm cannula. The 33-mm cannula was reinserted and the procedure was repeated for the second ovary, which was removed through the same vaginal opening after removal of the cannula. Each ovarian pedicle was examined to ensure complete hemostasis. The transvaginal portal site was closed primarily by placing a single cruciate suture of 1 polydioxanone through the mucosa and muscularis layers of the cranial vaginal wall. Culture swabs of the cranial vaginal fornix (after sterile preparation and before placement of the transvaginal portal) and the edges of the incision (before closure) were obtained using a guarded uterine swab (Culture swab 25 in., Continental Plastics, Delavan, WI) and submitted for microbial culture to determine bacterial contamination during surgery.

Laparoscopy Group. Each proposed portal site was infiltrated with 20-mL 2% lidocaine hydrochloride. The 1st portal was made in the left paralumbar fossa, midway between the last rib and tuber coxae and just dorsal to the crus of the internal oblique muscle. A 1.5-cm stab incision was made and an 11-mm diameter, 20-cm-long laparoscopic cannula (30103 H3, Karl Storz Endoscopy, Goleta, CA) with a blunt obturator (62103 AL, Karl Storz Endoscopy) was introduced into the abdomen perpendicular to the skin. A 10-mm diameter, 33-cm long 0°-angled laparoscope (62033 APA, Karl Storz Endoscopy) was placed in the 1st portal and intra-abdominal location was confirmed. The abdomen was insufflated with CO_2 (620-040-600, Stryker Endoscopy, San Jose, CA) at a flow rate of 6–8 L/min to an intra-abdominal pressure of 12–15 mmHg. Two additional portals were made in a similar fashion, 1 between the 17th and 18th ribs ~3 cm ventral to the ventral border of the tuber coxae and the other about 10 cm ventral to the initial portal. The laparoscope was transferred to the cranial most portal and the left ovary was identified. The mesovarium was infiltrated with 35-mL 2% lidocaine hydrochloride using a laparoscopic injection needle (250-080-703, Stryker Endoscopy) inserted through the dorsal instrument portal. The injection needle was removed and the left ovary was grasped using 10-mm claw-jaw grasping forceps (60510 FSL, Karl Storz Endoscopy) placed through the ventral instrument portal. Hemostasis and transection of the ovarian pedicle was achieved with a 10-mm vessel-sealing device (LigaSure™) inserted through the dorsal instrument portal.[22] After the dissection was complete, the left ovary was kept in the jaws of the grasping forceps and passed underneath the rectum to the right side of the abdomen.

The procedure was repeated in a similar manner on the right side. The right ovary was removed first, by extending the ventral instrument portal site ~4 cm dorsally. The skin and external oblique muscle were incised using sharp dissection while a grid technique was used for deeper muscle layers. The left ovary was transferred to the right-sided grasping forceps and removed similarly through the right body wall incision. The incision used for ovary removal was closed in 3 layers. The body wall, incorporating internal and external oblique muscles, was sutured with 1 polydioxanone in a cruciate pattern. The subcutaneous tissue was closed with 0 polydioxanone in a simple continuous pattern. The skin was closed with 2-0 polypropylene in a simple continuous pattern. The other laparoscopic portal sites were closed in 1 layer with 2-0 polypropylene in a simple interrupted pattern in the skin. Culture swabs (Culturette, Becton Dickinson Microbiology Systems Inc., Sparks, MD) of the skin before incision (after sterile preparation) and swabs of the body wall musculature before closure, were obtained and submitted for microbial culture.

Postoperative Phase

Time 0 (t0) was identified as the time the horse returned to the stall after surgery. Mares were administered a single dose of potassium penicillin (22,000 U/kg, IV) immediately after surgery upon return to their stall. Flunixin meglumine (1.1 mg/kg, IV) was administered every 12 hours for 2 days after surgery. In the laparoscopy group, skin sutures were removed 14 days postoperatively.

Monitoring

Surgical Variables. Total surgery time was recorded for each surgical procedure and was defined as the time from completion of the caudal epidural to final closure of the portal sites, including the time necessary for sterile preparation of the surgical site and setup of the operating room. Intraoperative complications such as hemorrhage of the ovarian pedicle after transection, poor viewing, instrument failure, retroperitoneal insufflation, or drop of the ovary were recorded. At procedure completion, each ovary was measured and in the laparoscopy group, the length of the incision used to retrieve the ovaries was recorded. Postoperative monitoring of mares for surgical complications included observing for abdominal discomfort, fever, diarrhea, peritonitis, laminitis, incisional complications, vaginal edema, and discharge.

Physiologic Variables. Body weight was recorded 3 days preoperatively and at day 14. Complete physical examination was performed during the acclimation phase, before surgery (baseline examination), at time = 0, 6, 12, 18, 24, 36, 48, 60, and 72 hours, and then daily until study completion. CBC, plasma fibrinogen concentration, and SAA concentration were determined before surgery and at days 3 and 10 postoperatively. Blood for SAA measurement was collected into a plain tube, allowed to clot, centrifuged at $2500 \times g$ for 15 minutes, and the serum harvested and stored at –70°C. All samples were assayed after study completion by using a commercially available solid phase sandwich ELISA method (Phase Serum Amyloid A ELISA Kit TP 802, Tridelta Development Ltd, Bray, Ireland).[23] Peritoneal fluid was collected percutaneously in an aseptic manner at days 0, 3, 14, and at 3 months (long-term group) and the abdominal nucleated cell count determined using an automatic cell counter (Cell-Dyn® 3700, Abbott Laboratories, Abbott Park, IL). Abdominal total protein concentration was measured using a refractometer (Vet 360, Reichert®, Depew, NY). For total protein concentrations <1 g/dL, specific gravity was recorded and total protein concentrations were determined using published conversion tables.[24] Microbial culture of the peritoneal fluid was performed on day 14.

Pain Assessment. Heart rate was recorded before surgery, 5 minutes after initial sedation, and every 10 minutes during surgery. Postoperative behavior scores were recorded by one nonblinded observer at times 0, 6, 12, 18, 24, 48, and 72 hours after surgery and then daily for 11 days using a previously described numerical rating scale (NRS).[20,25] Briefly, the NRS of behavior was calculated as a sum of scores assigned for 9 observations and was subdivided into posture and socialization scores. Each observation was scored from 1 (absence of gross pain, head above withers, ears forward, alert, moves freely, freely lift feet when asked, responds to door opening, approach, and reaches for grain) to 4 (continuous signs of gross pain, head below withers, ears back, does not move, located in the middle or facing the back of the stall, unwilling to lift feet, no response to door opening, observer approaching, or offer of grain).

Activity level was recorded using a 3-dimensional accelerometer (AAM, Respironics Mini Mitter Division, Bend, OR) placed around the right front pastern beginning 2 days before surgery and continued for 6 days postoperatively. The device uses an accelerometer to measure the occurrence and intensity of motion and includes a sensor that produces a variable electrical current when the device is subjected to acceleration changes. Increased activity results in an increase in voltage and this information is stored as activity counts. This device has been used to continuously record the intensity, frequency, and duration of physical activity in dogs[26]; however, it has not been validated in horses.

Necropsy Examination. Mares were euthanized at 3 weeks (n = 6; 3/group) and 3 months (n = 6; 3/group) after surgery to evaluate short- and medium-term effects of the procedures. A complete necropsy was performed and the abdominal cavity was examined specifically for signs of peritonitis or adhesions. Surgical sites, adjacent organs, and the gastrointestinal tract were evaluated for gross pathology or local peritonitis. In the NOTES group, the vaginal vault was examined for hemorrhage/hematoma, adhesions, or gross evidence of infection (purulent exudate, abscess formation). The surgical sites with ~2 cm of surrounding connective tissue and the incision sites were removed en bloc and fixed in 10% neutral buffered formalin in preparation for histologic evaluation. Tissue samples were embedded in paraffin, sectioned at 4 μm, stained with hematoxylin and eosin and microscopic evaluation was performed. Swabs of the surgical sites obtained at necropsy were submitted for microbial culture.

Statistical Analysis

Measured variables (physiologic and pain assessment variables) were compared to baseline values determined before surgery. Data were expressed as mean ± SD or median and interquartile range and $P < .05$ was considered significant. The main effects of treatment (2 levels), time (2, 3, 4, or 24 levels), and the interaction between treatment and time were evaluated using repeated measures ANOVA (Proc mixed, SAS 9.2, SAS Institute Inc., Cary, NC) and a compound symmetry covariance matrix. Non-normally distributed data were ranked before repeated measures ANOVA was performed to approximate a normal distribution

and homogeneity of variance. When indicated by a significant F-test for the interaction term, between treatment comparisons at each time interval, and within treatment comparisons to postoperative time = 0 minutes, were conducted using Bonferroni-corrected *P* values. Surgical time and amount of sedatives were compared between groups using an unpaired t-test. Proportional comparisons (complication rate, postmortem adhesions, abscess formation, and positive bacterial cultures) were made using a Fisher's exact test. Because the NRS of behavior was calculated as a sum of scores assigned for 9 observations and a valid statistical test for comparing combined scores is not available, statistical analysis was not performed and descriptive statistics are reported. A Spearman rank correlation test was used to determine whether the pain assessment variables of heart rate, NRS of behavior, and activity level were correlated. Sample size calculations performed before the study were based on the primary hypothesis using SAA concentration, heart rate, and mean surgical time as the primary outcome variables.

RESULTS

Mares were healthy and CBC, plasma fibrinogen concentration, and SAA concentration were similar between groups before surgery (Table 1). All surgical procedures were performed successfully and all mares survived until study completion.

Surgical Variables

Overall mean surgical times were 100 ± 40 minutes and 107 ± 47 minutes for transvaginal NOTES and laparoscopy, respectively ($P = .80$). There were no differences in the incidence of intraoperative and postoperative complications between groups. Intraoperative complications included difficult abdominal access and retroperitoneal insufflation (LAP, n = 1), suboptimal view of the surgical site (NOTES, n = 3), and mild hemorrhage of the ovarian pedicle during hemostasis/transection (NOTES, n = 3; LAP, n = 1). During hemostasis and transection of the right ovarian pedicle in 1 mare of the NOTES group, the tip of the vessel-sealing device was applied to the duodenum located immediately cranial to the ovarian pedicle. Energy was applied for ~1 second before it was recognized. The vessel-sealing device was immediately released and a small-blanched area was present on the serosal surface of the duodenum. Because the damage appeared to be confined to the serosa, no further action was taken and the procedure was completed. In the NOTES group, 1 ovary was dropped during removal through the vaginal opening. The ovary was identified immediately adjacent to the transvaginal portal and successfully retrieved. Ovaries were of similar size in both groups (NOTES, 6.2 ± 0.7 cm × 4.0 ± 0.5 cm × 4.5 ± 0.9 cm; LAP, 6.4 ± 1.2 cm × 4.1 ± 0.9 cm × 4.7 ± 1.3 cm). Mean length of the skin incision used to retrieve the ovaries in the laparoscopy group was 6.2 ± 1.8 cm.

Except for 1 mare in the laparoscopy group, all mares were bright, alert, and maintained a good appetite until euthanasia at 3 weeks or 3 months. In the laparoscopy group, 1 mare developed diarrhea in the immediate postoperative phase and signs of colic on day 3. The diarrhea resolved within 3 days and abdominal pain responded to administration of flunixin meglumine (1.1 mg/kg, IV) and butylscopolamine (0.2 mg/kg, IV). On day 7, this mare also developed incisional infection of all laparoscopic portal sites. The sutures were removed, the wounds flushed daily, and the mare was administered trimethoprim-sulfamethoxazole (30 mg/kg orally twice daily for 5 days). The surgery sites healed by second intention. *Staphylococcus aureus*, *Streptococcus* sp., *Escherichia coli*, *Klebsiella oxytoca*, and *Myroides* sp. were cultured from the incision sites.

All NOTES mares had vulvar edema with clear vaginal discharge, which resolved within 24 hours after surgery. In 1 mare, however, serosanguineous vulvar discharge developed on day 12. Palpation of the vagina led to retrieval of a blood clot but no ongoing bleeding was evident. The vagina was cleansed with warm water and the serosanguineous discharge stopped. The mare with the duodenal injury did not show signs of abdominal pain and kept a good appetite

Table 1 White Blood Cell Count, Plasma Fibrinogen Concentration, Serum Amyloid A Concentration, and Abdominal Nucleated Cell Count and Total Protein Concentration in 12 Mares Immediately Before Surgery (Day 0) and After Bilateral Ovariectomy via NOTES (n = 6) or Laparoscopy (LAP, n = 6). Data are Presented as Median and Interquartile Range. (*) Significant Difference from Baseline Within Each Group. Serum Amyloid A Concentration and Abdominal Total Protein Concentration Increased Significantly in Response to Surgery. ND = Not Determined

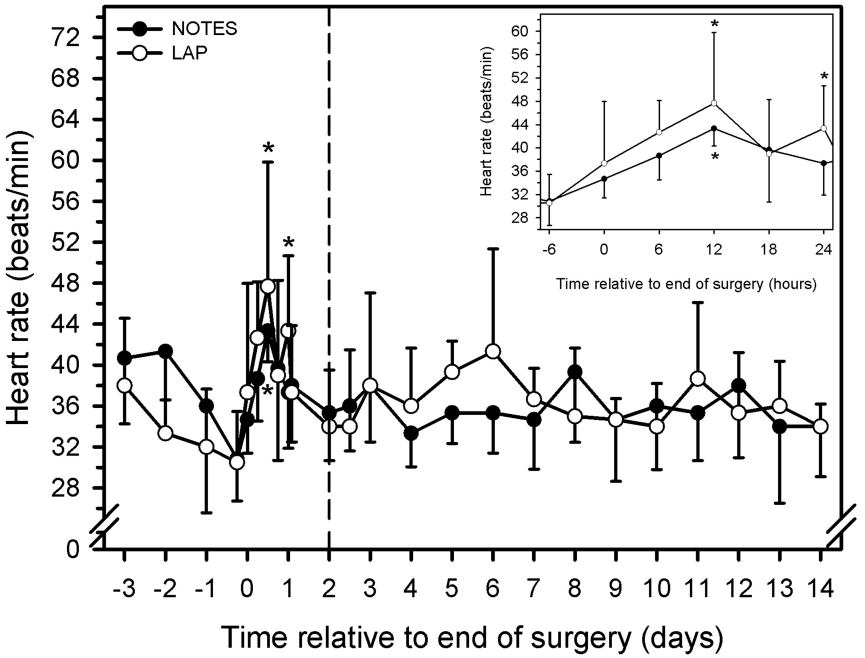

Figure 1 Mean ± SD heart rate in mares undergoing bilateral ovariectomy with NOTES or laparoscopy (6/group). Baseline evaluation was made 6 hours before surgery. Flunixin meglumine discontinued on day 2 (round dash line). The perioperative period (from t–6 to 24 hours postoperatively) is shown as an inset in the upper right corner of the graph. No significant difference between groups was found at any time point. (*) Significant difference from baseline (t–6) within groups. Return to baseline heart rate values after surgery was slower in the laparoscopy group (36 hours) than in the NOTES group (18 hours).

throughout the study. Other postoperative complications included transient fever (NOTES, n = 1; LAP, n = 3), incisional seroma (LAP, n = 3), persistent incisional swelling (LAP, n = 1), and subcutaneous emphysema (LAP, n = 6).

Physiological Variables

Body weight was similar between groups and remained stable throughout the study. There was no significant main effect of group or interaction effect between group and time in temperature, heart rate or respiratory rate at any time point of the study.

As expected, both groups had a significant elevation in heart rate after surgery (Fig 1). Heart rate returned to baseline values within 18 hours after surgery in the NOTES group and within 36 hours in the laparoscopy group. White blood cell count, plasma fibrinogen concentration, SAA concentration and abdominal nucleated cell count, and total protein concentrations over time are reported in Table 1. No significant differences in vital parameters, CBC, plasma fibrinogen concentration ($P = .10$), SAA ($P = .49$), peritoneal nucleated cell count ($P = .39$), and total protein concentration ($P = .59$) were found between groups across time. SAA concentration and abdominal total protein concentration increased significantly in response to surgery. Cytologic evaluation of the peritoneal fluid at days 3 and 14 revealed evidence of postoperative inflammatory response in all cases; however, no evidence of toxic or degenerative changes in neutrophils or intra/extracellular bacteria were observed. In the long-term group, peritoneal fluid cytology at 3 months revealed a transudate in all horses with normal differential counts.

Pain Assessment

There was no difference in the intraoperative respiratory and heart rates between groups. There was no significant difference in the total amount of detomidine hydrochloride ($P = .85$) or butorphanol tartrate ($P = .96$) administered during the procedure.

All mares appeared comfortable after surgery; however, there was a significant decrease in measured activity levels from 2–6 days postoperatively compared with baseline levels in both groups (Fig 2). Mean NRS of behavior, including posture and socialization scores, was numerically similar between groups preoperatively (NOTES, 11.5 ± 1.8; LAP, 10.8 ± 1.2) and at all time points of the study. Mean NRS of behavior reached a maximal value immediately after surgery in both groups (t0: NOTES, 15.8 ± 2.8; LAP, 12.0 ± 1.6), whereas the scores returned to baseline values within 18 hours after surgery in both groups (t18: NOTES, 11.5 ± 3.4; LAP, 10.4 ± 1.7). There was a weak but significant correlation between the NRS of behavior and activity levels (Spearman's rho = 0.22; $P = .005$), the NRS of behavior and heart rate (Spearman's rho = 0.24; $P = .001$),

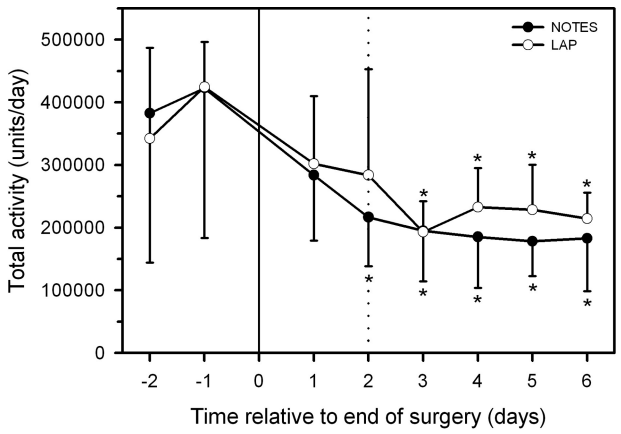

Figure 2 Mean ± SD activity levels in mares undergoing bilateral ovariectomy with NOTES or laparoscopy (6 per group). Day 0 is surgery day. Flunixin meglumine discontinued on day 2 (round dash line). No significant differences between groups were found at any time point. (*) Significant difference from baseline (day -1).

and the activity levels and heart rate (Spearman's rho = 0.23; $P = .003$).

Morphologic Findings

At 3 weeks postoperatively, there was no evidence of infection or adhesions in the abdominal cavity. Fibrosis of the small colon mesentery was found in 1 laparoscopy and 1 NOTES mare. A line of whitened tissue was present at all sites of transection of the ovarian pedicles. An incision line abscess was found in 2 mares from the laparoscopy group. One of these mares had secondary healing of all portal sites after suture dehiscence, whereas 1 mare had incisional swelling present for the duration of the study without wound drainage or suture dehiscence. A hemorrhagic lesion was found within the vaginal wall of the mare that had serosanguineous vaginal discharge at day 12, but no adhesion was present within the vaginal vault. The transvaginal portal site was completely closed and healed well in all 3 mares, without evidence of vaginal adhesions. The duodenum that was accidentally grasped with the vessel-sealing device was intact with a small area of serosal fibrosis at the injured site.

At 3 months postoperatively, there was no evidence of infection or adhesions within the abdominal cavity in any of the mares. All ovarian pedicle transection sites had fully healed. In 3 laparoscopy mares, the incision sites appeared completely healed. The transvaginal portal site was difficult to identify in all 3 NOTES mares and had healed completely.

Histologic evaluation of the ovarian pedicle transection sites revealed satisfactory healing of all surgery sites at 3 weeks and 3 months. Histological evaluation of the transvaginal portal sites revealed the presence of scar tissue consistent with complete tissue healing in all NOTES mares.

Microbiology Findings

There was no growth from pre- and postoperative swabs submitted from either group. A single isolate grew from peritoneal fluid obtained on day 14 in 1 (16%) NOTES mare. Of samples submitted from the ovarian pedicle transection sites at necropsy, there was 1 (8%) positive culture in the laparoscopy group and 3 (25%) in the NOTES group. Details regarding microbial findings and corresponding peritoneal nucleated cell counts, total protein concentrations, and cytologic findings are reported in Table 2.

DISCUSSION

Our aim was to determine whether transvaginal NOTES ovariectomy in the mare is associated with less-surgical trauma compared to the current gold standard minimally invasive technique, laparoscopy. Our data showed no difference between the 2 techniques in terms of pain and inflammation resulting from surgery, as measured by physiologic variables (heart rate, respiratory rate, rectal temperature), plasma or serum concentration of positive acute phase proteins (fibrinogen, SAA), peritoneal total nucleated cell count and total protein concentration, or pain assessment. Laparoscopy and transvaginal NOTES resulted in minimal inflammation and both techniques were performed successfully. Surgical time and complication rates associated with laparoscopy and transvaginal NOTES were similar. Thus, each method was found to provide a satisfactory minimally invasive technique for bilateral ovariectomy in standing mares.

Documentation of the response to surgical trauma resulting from these minimally invasive techniques was performed in an effort to quantify their invasiveness. SAA was used as the primary marker of tissue trauma because it is the only major acute phase protein with low concentrations in healthy horses that demonstrates a 10- to 1000-fold increase in acute phase states.[27] Concentrations of fibrinogen or SAA correlate well with the intensity of surgical trauma in horses.[21] As expected, SAA concentrations increased above the preoperative values at day 3 in response to the surgical trauma, and returned to baseline levels at day 10; however, there was no difference between groups at any time point of the study. Our results corroborate previous studies that demonstrated that SAA concentrations increase rapidly during the acute phase of inflammation and decrease rapidly after recovery because of its short half-life.[21,23] Three days after uncomplicated, standing castration, mean SAA concentration increased several 100-fold[23] whereas we demonstrated a relatively smaller increase after either transvaginal NOTES or laparoscopy. Our findings suggest that transvaginal NOTES and laparoscopy are both minimally invasive techniques that result in minimal tissue damage and a mild inflammatory response.

Longer surgical times and a steep learning curve are to be expected when introducing a new surgical technique.

Table 2 Description of Microbiological and Corresponding Cytological Findings of Peritoneal Fluid in Mares with Positive Culture at 14 Days, 21 Days, and/or 3 Months (92 Days) Postoperatively

Mare	Group	Day	Source	Bacteria	Peritoneal Nucleated Cell Count (/μL)	Peritoneal Total Protein (g/dL)	Cytological Findings
1	LAP	92	Right mesovarium	*Micrococcus* sp. *Pseudomonas vesicularis*	928	1.0	Normal peritoneal fluid
2	NOTES	92	Right mesovarium	*Bacillus Pumilus Corynebacterium* sp.	1000	1.0	Normal peritoneal fluid
4	NOTES	14	Peritoneal fluid	*Bacillus* sp.	45,600	3.2	Moderate neutrophilic inflammation, 84% nondegenerate neutrophils, no evidence of infectious agents
		92	Left mesovarium	*Staphylococcus epidermidis*	683	1.0	Normal peritoneal fluid
8	NOTES	21	Right mesovarium	*Gram negative rod*	38,300	3.0	Exudate with rare evidence of acute hemorrhage, 85% nondegenerate neutrophils, no evidence of infectious agents.

In contrast to our pilot study,[14] where operative times were extended during technique and instrument development, the surgical times for transvaginal NOTES ovariectomy were considered clinically acceptable. Accordingly, surgical times were similar for performing bilateral ovariectomy using either transvaginal NOTES or laparoscopy. This is in contrast to most published controlled studies comparing NOTES to laparoscopy in which longer operative times are consistently reported for NOTES procedures.[4,13] We found that mesovarial infiltration of local anesthetic was faster and more readily achieved laparoscopically using the laparoscopic injection needle when compared with using the flexible endoscopic injection needle passed through the working channel of the endoscope during the transvaginal NOTES procedures. The ovaries were more easily removed through the vaginal opening than through the body wall, especially in larger mares. Transvaginal NOTES may therefore be advantageous in mares with a thick body wall or narrow paralumbar fossa when ovary removal by laparoscopy may be challenging. However, laparoscopy would be preferred in cases of enlarged ovaries or other pathology of the reproductive tract when access or surgical field of view could be impaired with the transvaginal NOTES approach.

Intra-abdominal observation was considered excellent in all laparoscopic mares whereas in 3/6 NOTES procedures, viewing of the caudal abdomen was hindered by the presence of small intestine loops. The field of view with the endoscope was narrower than with the laparoscope and loops of bowel occasionally obscured the endoscopic view. Viewing of the ovarian structures was more consistent than in our preliminary study,[14] presumably because of a longer preoperative fasting regimen. Controlled pneumoperitoneum during transvaginal NOTES procedures could improve the intra-abdominal endoscopic view further. Most human studies describe the use of a hybrid NOTES technique using a laparoscopic portal at the umbilicus to create and maintain CO_2 pneumoperitoneum and thus facilitate the endoscopic procedure.[6,28] Recently, methods for monitoring,[29] regulating, and insufflating the abdomen through a flexible endoscope with either air or CO_2 were developed and assessed.[12] A well-sealed portal site is necessary for successful abdominal insufflation, whether it is performed with laparoscopic or NOTES techniques. During the transvaginal NOTES procedures, the flexible endoscope and 2 long-handled rigid instruments were introduced through the single 33-mm transvaginal portal resulting in an inability to create a sealed portal. A multi-instrument portal for transvaginal access similar to those used in single incision laparoscopic surgery could maintain a seal and permit abdominal insufflation for NOTES techniques.

Clinically, all but 1 mare recovered well after surgery. Heart rate and respiratory rates returned faster to baseline values in the NOTES group (18 hours postoperatively) than in the laparoscopy group (36 hours postoperatively). These results may indicate that transvaginal NOTES produced less pain postoperatively; however, pain assessment revealed that NRS of behavior scores returned to baseline values within 18 hours after surgery in both groups. Activity monitoring was used postoperatively to complement physiologic and behavioral pain assessments. We found that there was a weak but significant correlation between pain scores, activity levels, and heart rate. Accelerometers have been validated in people[30] and dogs,[26] and to our knowledge our study is the first report of using accelerometers in horses to quantify activity pre- and postoperatively. Although we did not validate the accelerometers by correlating our measurements to continuous video recording, each horse was used as its own control during the acclimation phase.

Activity levels followed the same pattern in both groups with an overall activity decrease in the immediate postoperative period with stabilization to levels lower than baseline from days 2 to 6. Lack of activity after surgery has been previously associated with pain in horses[20]; however, that study only assessed activity for the first 24 hours postoperatively. In the present study, the activity pattern observed postoperatively may reflect adaptation of the mares to the housing environment and the daily husbandry routine after surgery.

Alternatively, since activity levels were only significantly decreased after flunixin meglumine was discontinued, the reduction in activity could be as a result of pain. Interestingly, if this were the case, activity monitoring would be a sensitive indicator of postoperative pain in horses since pain assessments were unremarkable from days 2 to 6 and physiologic variables had all returned to baseline preoperative values. Continuous activity monitoring for a longer period (such as 21 days) may have helped elucidate whether decreased activity was pain or housing/husbandry related. Activity monitoring as an assessment of postoperative pain may warrant more detailed investigation.

We found a high incidence of incisional infection (33%) in the laparoscopy group. Our results might have been affected by the small sample size as they are in contrast to previous studies in which infection after laparoscopic ovariectomy occurred in only 6/129 mares (4%).[2,22,31–39] There was no evidence of incisional infection in the NOTES group during necropsy examination at 3 weeks or 3 months. Our results are consistent with a recent, large human retrospective study, in which incisional infection after transvaginal NOTES cholecystectomy was reported in 0.8% of patients.[40] Other complications reported included vaginal bleeding, urinary tract and vaginal infection, and rectovaginal abscessation, with a combined incidence of 1%. Except for the mare with postoperative serosanguinous discharge, vaginal examination was not performed during the course of the study because results from our preliminary study did not show evidence of infection of the transvaginal portal site in any mare at 7 or 14 days postoperatively.[14]

The elevation of peritoneal nucleated cell count and total protein concentration after surgery were similar between groups and likely reflected the mild inflammatory response associated with laparoscopic or transvaginal NOTES ovariectomy. Previous laparoscopic studies reported similar results and showed elevation of peritoneal nucleated cell counts 24 hours after CO_2 pneumoperitoneum.[41,42] The time required for the peritoneal nucleated cell count to return to baseline values after abdominal surgery is unknown and therefore, further studies are warranted to follow peritoneal fluid values over time after laparotomy, laparoscopy, or NOTES techniques.

Necropsy and histologic examination revealed no evidence of infection or adhesion with satisfactory healing of all surgery sites. The risk for intra-abdominal contamination and infection in transluminal procedures has been one of the major obstacles to the widespread clinical use of NOTES in people.[19] Intraoperative contamination was not detected through pre- and postsurgical incisional cultures in either group, and thus we found that vaginal preparation with 4% chlorhexidine gluconate solution was effective for transvaginal access. Microbiologic evaluation of the peritoneal fluid at 14 days, or the mesovaria at necropsy, was positive in 4 mares. Two mares from the NOTES group had a positive microbiologic culture within 21 days postoperatively, along with elevated peritoneal nucleated cell count (38,300–45,600 μL). Postoperative septic peritonitis has been previously defined as a combination of clinical signs (depression, fever, endotoxemic shock, and abdominal pain) and abnormal peritoneal fluid (peritoneal nucleated cell count $>100{,}000/\mu$L with cytologic evidence of free or phagocytosed bacteria).[43] Neither of these mares had clinical signs consistent with septic peritonitis and postoperative peritoneal nucleated cell counts were $<100{,}000/\mu$L, even in light of the positive bacterial cultures. There was no evidence of sepsis present on cytology and the peritoneal fluid in these 2 mares was consistent with a postoperative inflammatory response, as expected after abdominal surgery. In addition, the cytologic findings and peritoneal differential counts were similar to those obtained from mares without positive cultures at the corresponding time points.

At 3 months, 4 mares (NOTES, n = 3; LAP, n = 1) had positive microbial cultures upon sampling of the mesovaria at necropsy, while normal cytological findings and differential counts of the peritoneal fluid were present. Microbiologic identification and quantification of all plates with positive growth showed either 1 or 2 colonies in each instance with organisms interpreted as contaminants by the microbiologist in each case. This was consistent with cytological findings of the peritoneal fluid and the concern of contamination during transvaginal NOTES could not be substantiated in this study. It is possible that mares with positive microbiological cultures had recovered from a low-grade peritoneal infection, although there is a lack of clinical, histological, or cytological evidence to support this speculation. Further studies may be warranted to further characterize the potential for contamination during/after transvaginal NOTES in mares. Sterile preparation of the vagina and use of systemic perioperative antibiotics is recommended for transvaginal NOTES in mares based on our current results.

The remaining open question is whether or not transvaginal NOTES should be used instead of laparoscopy for ovariectomy in mares or in which cases one technique should be preferred over the other. Both techniques have disadvantages in the cost of the specialized equipment, the learning curve associated with the procedures and the need for a hospital setting. Furthermore, customized instruments are currently required for the transvaginal NOTES technique because of the insufficient shaft length of conventional laparoscopic instruments.[14] Although in the present study exclusion criteria were applied to history of previous surgery, we believe that transvaginal NOTES may offer an advantage in cases where adhesions are suspected along the parietal peritoneum. Because there is no need for skin or body wall incisions, transvaginal NOTES eliminates risks for body wall incisional complications (seroma, infection, dehiscence, or subcutaneous emphysema) and thus mares may be able to resume exercise within a few days after transvaginal NOTES ovariectomy.

One limitation of the present study may be considered the small number of mares used for comparison of the techniques and their outcome. Detecting no difference between groups for the outcomes evaluated warrants examination of the statistical power of these findings. With a sample size of 6 mares/group, power calculation showed that we had 80%

power to detect a difference of 13 μg/mL in SAA concentrations at 3 days. When designing the study, we anticipated that a SAA difference of 100 μg/mL between groups would be of clinical significance, based upon a previous study in horses when SAA concentrations reached ~500 μg/mL.[21] Based on our SAA data, a total of 42 horses/group would have been necessary to detect the small difference found, with a power of 80% and 95% confidence level (ie, P-value < .05). However, it is very unlikely that such small differences are of clinical significance. Similarly for our other primary outcome variables of heart rate and surgical time, we believe the findings of no difference between groups are clinically applicable.

Summarily, we found that transvaginal NOTES could be performed safely as an alternative to conventional laparoscopy for standing bilateral ovariectomy in healthy mares. These 2 techniques induced similar levels of surgical trauma and inflammation and both were shown to be acceptable in terms of clinical outcome. Like many new surgical methods, transvaginal NOTES requires specific instrumentation and experience and thus appropriate training is necessary before routine clinical use of the technique. Further evaluation in clinical cases is warranted.

ACKNOWLEDGMENTS

ABSTRACT

The effect of spaying (ovariohysterectomy) on racing greyhound performance was analysed. Using data from a longitudinal observational study design, random effects models were used to compare the racing performance before and after spaying. Greyhounds were matched by distance and date of racing, and then both spayed and entire bitches were compared for each stadium which had spayed greyhounds on the racing strength. The racing performance of entire females was selected from the anoestral period (from 90 days post-oestrus to the next oestrus).

Spaying had no real effect on performance, with a mean difference of +0.066 seconds (90% CI: −0.004, +0.135 s) over 480 metres. The effect of time since spaying had no effect (90% CI: −0.0002 to +0.0001 s/day). Spaying of racing greyhound bitches produced no overall change in performance, and had no apparent long term effect on performance. These results are discussed within the context of the current information on the advantages and disadvantages of spaying at a young age.

Introduction

The Greyhound Board of Great Britain (GBGB) wishes to determine the effect of spaying on the performance of female racing greyhounds in order to be able to advise trainers about an alternative to the use of oestrus suppressants, such as norethisterone. Recent analyses by the author (Payne, 2013) have shown that female greyhounds lose performance in the dioestral period. Thus there are performance penalties in allowing bitches to cycle normally. The aim of the present study was to determine whether spaying affects performance and to advise on the suitability of spaying (ovariohysterectomy or ovariectomy) as an alternative to the medical suppression of oestrus and dioestrus. Spaying would also help to reduce the rehoming costs on retirement, and eliminate the on-going veterinary costs associated with repeat examinations, and the prescription and supply of oestrus suppressants.

There are health benefits to spaying. In particular there is a reduced incidence of mammary neoplasia, which is time-dependent and greatest when the spaying is performed before the first season (odds ratio [OR] = 0.05), decreasing slightly if spayed before the second season (OR = 0.08), and decreasing further if spayed after the second season but before 2.5 years old (OR = 0.26); spaying after 2.5 years old has no protective effect again mammary neoplasms (Romagnoli, 2008). Given that 94.3% of actively racing female greyhounds are <5 years old, and 40.3% are <2.5 years old, there is a high proportion (54%) of racing bitches which are >2.5 years, yet are not spayed until retirement, and so are not protected against mammary neoplasia (unpublished data). This is sufficient justification to investigate whether spaying during a bitch's racing career has any effect on performance whilst still gaining an important health benefit.

Recent investigations (Payne, 2013) have shown that the dioestral performance of female greyhounds changes within the same time frame as the changes in serum progesterone concentrations. On the basis of this evidence it was suggested that serum progesterone had a significant effect on performance as a direct consequence of its biochemical effects. Thus it would seem logical that spaying would remove these effects and produce a female greyhound which has a stable performance pattern throughout the year, and thus does not require any lay-off time post-oestrus under the GBGB Rules of Racing.[1]

In order to further investigate the effect of spaying on the performance of racing greyhounds, a comparison of the performances of entire versus spayed racing bitches was conducted to determine both the immediate and long-term effects of spaying.

Materials and methods

Study design

A longitudinal observational study was used. The entry point for each greyhound was the start of its racing career provided that it had never had its oestrous cycles suppressed. Only greyhounds attached to tracks were included in the study in order to produce a nested data set. Open race greyhounds can race at any track, and thus prevent nesting of the data (i.e. open race form creates a multi-membership model).

Participants

Greyhounds were selected into three groups: (1) spayed, then began racing, (2) spayed during their racing career, and a control group (3) of entire bitches that ran over the same distances and dates as groups (1) and (2). Previous work by the author (Payne, 2013) showed that performance is variable between oestrus and 80–90 days post-oestrus, after which the performance does not change with time. In order to compare with the performance prior to spaying, only the race performance for the entire bitches in the period more than 90 days post-oestrus to the next oestrus was used. Greyhounds left the study on the last date of their race form.

Data sources and management

A list of greyhounds reported to have been spayed between May 2004 and March 2012 was generated by the GBGB/PA Sport, along with their race form, together with a corresponding dataset representing entire bitches that had raced at the same stadia. Six stadia were included in the study, and only races of 480 m were used in the analysis. Since spaying is not a common procedure for greyhounds of racing age, the datasets for both the spayed and entire groups were matched for race date and stadium. This produced a dataset covering the six stadia comprised 347 spayed and 136 entire females ($n = 483$), together with 11,592 lines of race form. The dataset comprised the fields as shown in Table 1.

The data were held in a relational database management system (SQL Server Express 2012, Microsoft[2]) with a separate front-end in Access 2010 (Microsoft Office 2010[3]) which contained the structured query language (SQL) queries. Outputs from the queries were exported into Excel 2010 (Microsoft Office 2010[4]) for further calculations and thence for subsequent export into the statistical packages.

Variables and data calculations

The dependent variable was unadjusted race time (IndTime, in seconds to two decimal places) and was used as a relatively unbiased measure of performance. The effect of differing running conditions could not be reliably assessed, and was accepted as an unexplainable error. The outcome variable was the greyhound's actual race time for each race or trial (IndTime, seconds), as this provided the best unbiased estimate of performance. Adjusted times were not used as these are modified by a human judgement of the going allowance, and thus were considered to be biased.

The time since spaying was simply calculated as the interval between the date of spaying and date of the race, reported as an integer. This value was named days since spaying (DSS) and could be positive where a race was after spaying or negative where a race was before spaying. Thus day zero was the reported day of spaying.

When comparing performance between pre- and post-spay, the fixed binary variable spayed was used in the models. The entire or spayed state was thus indicated by the values of 0 for entire and 1 for spayed.

Race distance was described by the stadium categorical variable and represented a random effect. Age was not included, since there would be a high correlation between age and DSS.

DSS and spayed variables were calculated by SQL code, whilst repeat measure codes were produced in Excel 2010 by sorting the race form by race date for each greyhound and then generating an ordinal measure. Data checking and removal of illogical values were also performed in Excel 2010.

Study size and power analysis

Alpha and beta were calculated to be 10% and 6%, respectively, to balance and minimize the summed probability of committing Type I and Type II errors (Verrill and Durst, 2005; Nakagawa and Cuthill, 2007; Mudge et al., 2012). The effective sample size in the multilevel models was calculated to be $n = 164$, and could detect an effect size equivalent to 0.08 s for a race of approximately 29.8 s over 480 m, whilst maintaining alpha at 10% and beta at 6%. Results are expressed as the mean together with the 90% confidence interval (CI).

Statistical methods

The initial output from the SQL queries was exported into Excel 2010 for further calculations and analysed in Analyse-It v.3.15 (Analyse-it[5]) and StatsDirect v.2.7.9 (Stats Direct[6]) in order to generate the descriptive statistics. The data were then imported into MLwiN v.2.27 (University of Bristol[7]) in order to generate the multilevel models. The models were built by manual forwards addition, and random effects modelled by greyhound ID. The fixed effect of stadium ID provided a measure of the effect of the differences in track design despite the same race distances of 480 m. Thus the two levels were greyhound ID and repeat measures for the races. Two models were used to independently describe the effects of DSS and spaying. Once the models had been built in MLwiN and run as iterative generalized least squares (IGLS) models, the parameters were then used to generate Bayesian models using a Markov Chain Monte Carlo (MCMC) method via Gibbs sampling. Model checking was performed in MLwiN.

Table 1
Data fields extracted from the GBGB/PA Sport race form and signalment information.

Fields	Signalment table	Raceform table
Primary keys*	Greyhound ID*	Greyhound ID* Race date*
Data	Date of birth Date of spaying	Stadium ID Race distance Race time

Results

Descriptive statistics

Analysis of IndTime showed it to be normally spread, and a split of the race times by entire versus spayed showed similar times (Fig. 1), with a random scatter of race time against DSS (Fig. 2).

Multi-level models

The two multilevel models (MLM) described the effect of the time before and after spaying and the effect of spaying. The effect of time (DSS) on performance was negligible (90% CI: −0.0002, +0.0001 s/day). The analysis assumed a linear regression, which was reasonable considering previous findings (Payne, 2013) and by inspection of the scatter plot seen in Fig. 2.

The effect of spaying was marginal at +0.066 s. The 90% CI was −0.004 to +0.135 s, which includes zero, i.e. the null hypothesis of no effect could not be rejected. In more general terms, the results indicate that there was no evidence in this dataset for an effect of spaying. Additionally the residual error in the analyses was ±0.394 s, indicating that other unmodelled factors have a greater effect on race time. Model checking showed a normal distribution of the respective standardized residuals against DSS in the time model, and by group in the spayed model, together with a linear plot of standardized residuals against normal scores.

Discussion

The models show that spaying is unlikely detract from prior performance, and that post-spay the performance appears to be stable. Additionally, there were no differences over time between entire and spayed greyhounds. Both these results indicate that there are no significant short or long-term effects of spaying on performance ($P < 0.10$).

The comparison was made between race performances over 90 days since oestrus and after spaying. The finding that there was no difference adds support to previous findings that progesterone is likely to be involved in the depression of performance post-oestrus (Payne, 2013), since in both the over-90 day post-oestrus periods and the post-spay periods used in the current analysis, the progesterone levels were essentially zero due to either inactivity in, or absence of, the ovaries (Cox, 1970; Wheeler, 2011).

A specific analysis of the effect of spaying on athletic performance has not been undertaken before, so comparisons with previous studies are not possible. Likewise, this paper does not address any possible effects of reproductive hormones (or lack of) on musculoskeletal strength, in particular bone strength.

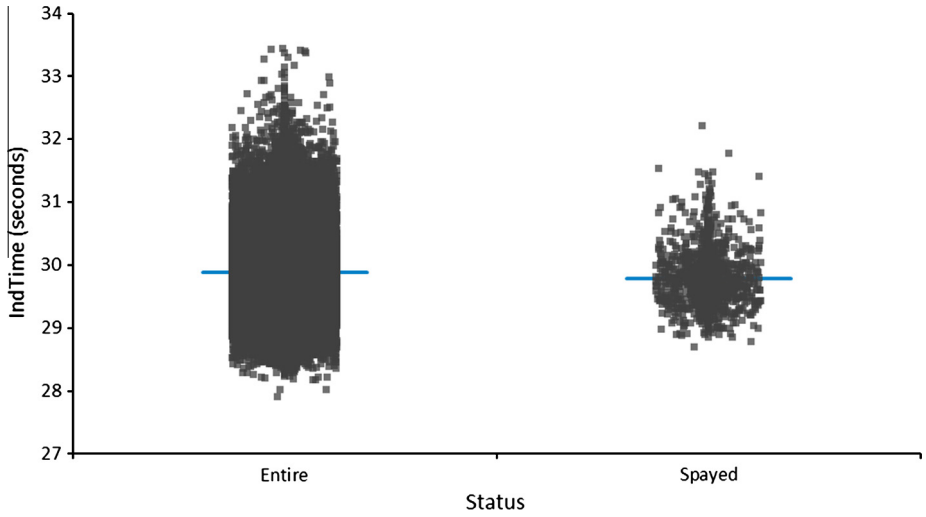

Fig. 1. Descriptive statistics for the entire dataset, split by entire versus spayed race times (IndTime). Mean race time for entire bitches = 29.880 s (SD = 0.596); mean race time for spayed bitches = 29.793 s (SD = 0.442). *N* = 11,592 races, 483 bitches. Distance = 480 m.

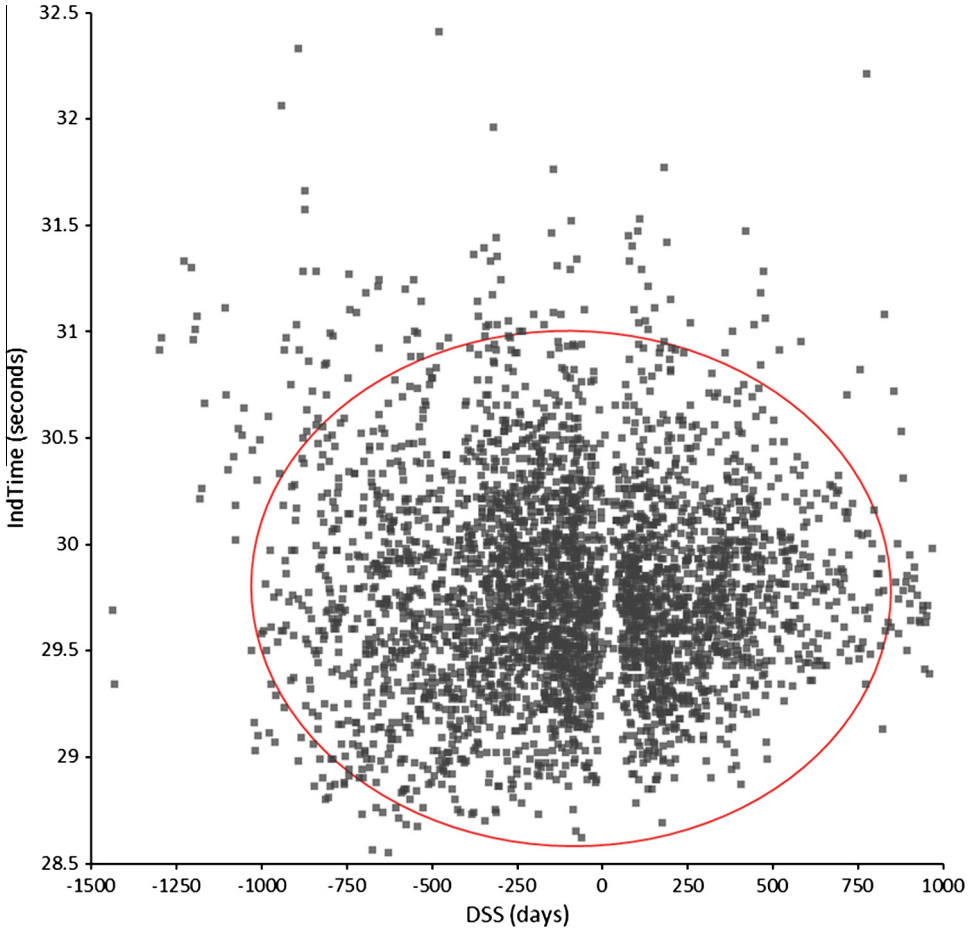

Fig. 2. Scatter plot of race time (IndTime, s) against days since spaying (DSS, days). Distance = 480 m. A negative DSS is the period before being spayed.

Against the benefits of spaying, the reported disadvantage of urinary incontinence has been found to be variable (de Bleser et al., 2011) and more likely to be related to tail docking and obesity (a possible consequence of spaying) than to the hormonal effects of ovariohysterectomy (Gregory, 1994), although Romagnoli (2008) does suggest spaying under 3 months old can increase the risks of incontinence. Neither tail docking nor obesity are likely to occur in racing greyhounds.

Conclusions

Spaying does not materially affect the individual racing performance of greyhound bitches, either as a shift in performance or as a gradual loss of performance ($P < 0.10$). Spaying during their racing careers can be considered for bitches that are unlikely to be bred from, and can secure recognized health benefits without a performance penalty as well as providing an alternative to the use of oestrus suppressant/postponement medications.

Conflict of interest statement

The author of this paper has no financial or personal relationship with other people or organizations that could inappropriately influence or bias the content of this paper.

Acknowledgements

The author thanks the Greyhound Board of Great Britain for funding the research, and for their aid in allowing access to the extensive dataset on race form. Thanks also to Debra Teo MRCVS for providing the initial list of spayed bitches.

of part of the normal bacterial flora leading to an acute oesophagitis and death in some from inspiration of regurgitated food and liquid.

No incidents of this type have been encountered among other broiler breeders within the same company. Managemental changes have been subsequently introduced as part of a husbandry development programme that are designed to give more even distribution of food and greater uniformity of birds within pens during rearing, which should help to avoid such incidents in the future.

Meat hygiene

From Mr F. Jagger

SIR,—Henry Carter's characteristic but not unjustified comments (VR, February 16, p158) prompt me to join in this correspondence.

As one, until lately, closely associated with meat hygiene politics I share his disappointment but not his despondency. I believe the BVA proposals as a step towards centralisation had much to recommend them and the Ministry's argument that "hybrid" control would be unworkable, unconvincing. The proposed dual accountability of the official veterinary surgeon to both the local authority and Ministry of Agriculture would seem to be but another example of "hybrid" control.

Nevertheless many of us have felt that veterinary and environmental health officers' interests must be harmonised having regard to the contribution each can most advantageously make in the realm of food hygiene. The proposed regulations in my view bring this position nearer.

If one applies the yardstick of "what is in it for us?" to the proposals, one learns:

(1) That the EHO shall be allowed to certify meat products for export in plants divorced from abattoirs, the meat used however bearing veterinary certification from the export plant of origin, and in this capacity he shall be accountable to the Ministry of Agriculture. (2) That the meat inspector status will not change. (3) That an OVS shall be in hygienic control of all export approved abattoirs where existing dual standards shall cease—not an insignificant step forward when viewed in the context of the continuing trend towards concentration of slaughter. (Two per cent of abattoirs are responsible for some 80 per cent of all meat produced in this country —a fair proportion of these abattoirs having export approval.)

What of the future? In the short term a considerable responsibility rests on those of us engaged in meat hygiene to demonstrate that the veterinarian has something positive and purposeful to contribute to the business of meat production and in the longer term the schools must persevere in their efforts to create a force dedicated to establishing the profession in its rightful place in the wide field of food hygiene.

Libidinous behaviour in a gelding

From Mr O. D. Pearce

SIR,—The letter from S. Borsberry (VR, January 26, p89) referring to libidinous behaviour in a pony gelding reminded me of a similar case brought to my attention last year.

The owners of a trekking centre bought in extra ponies for the summer and ran them together with their own horses, mares and geldings mixed.

They stated that they would often see the geldings covering the mares and had decided to keep a record of the offending ponies. During the course of the summer, seven out of 12 geldings had been seen to cover mares.

It would appear that the nearer the pony was to the native breed, the more active it was.

I had personally gelded one of the newly bought in ponies at least six years previously. It had never shown such behaviour until last summer, even though it had run with mares after it was gelded.

I wonder whether such change in behaviour can be explained by the pony feeling threatened by the changes in environment and pony population. The native pony would presumably have stronger herding instincts in this respect.

Penicillin: Suspected adverse reaction

From Mr A. B. Marshall

SIR,—The recent paper by Nurmio and Schulman (VR, February 2, p97) is a welcome addition to the few papers giving detailed observations of possible drug reactions, but their conclusion that "the pathogenesis of these reactions is most likely to be the hypersensitivity to penicillin" is not justified.

A literature search covering the period 1950-1978 reveals only about a dozen papers reporting possible penicillin allergy in the common domestic species. Some of these are mainly review papers and thus contribute little in the way of new observations.

Strikingly, only one paper makes any attempt to prove the involvement of the penicillin component. Leemann and others (1969) report anaphylactic shock or generalised urticaria in cows after penicillin injections, the incidence increasing markedly after a foot-and-mouth disease vaccination programme. Penicillin was used in the preparation of some FMD vaccines and Leemann and others initially postulated that this was the sensitising agent. However they could not detect anti-penicillin antibodies in the cattle sera. In skin tests of cattle that had experienced anaphylactic reactions they obtained negative results to fresh solutions of bulk benzyl penicillin and to penicillin degradation products but the commercial preparation elicited strong urticarial reactions. Thus the reactions were due to some component other than the penicillin. Further work demonstrated that carboxymethyl cellulose, a stabilising component in some penicillin suspensions, was the real cause of the allergy in these cows.

The majority of suspected penicillin allergies involve the procaine salt, see for example Anon (1978) (quoting FDA); Ndiritu and Enos (1977) and several other anecdotal reports. The procaine moeity has been established as causing allergy in pigs (Clarke and Clarke 1975), and Goodman and Gilman (1975) in discussing procaine benzyl penicillin preparations make the following statement, "The possibility of allergy to procaine must be considered when hypersensitivity to such preparations occurs." Direct procaine toxicity should also be considered.

The paper by Brisbane (1963 — quoted by Nurmio and Schulman) is based on a retrospective survey of 22 veterinarians and indicated that 1083 animals showed anaphylaxis or urticaria associated with pencillin or penicillin / streptomycin administration. However there is no data to show that the penicillin component caused the reaction and the particular penicillin salts involved are not stated. Ndiritu and Enos (1977) attribute adverse reactions in a foal and a cat given potassium penicillin to the potassium ion. The foal was subsequently treated uneventfully with procaine penicillin.

Three aspects of the paper by Nurmio and Schulman indicate that the reactions were not due to penicillin hypersensitivity. First, they saw no problems in the ampicillin treated group, although there is generally considered to be cross sensitivity between the members of the penicillin family (Dewdney 1977). Secondly, the very high incidence (17 of 17, 3 of 3 and 4 of 4) of adverse reactions to the particular preparation rules out allergy. Thirdly, procaine benzyl penicillin

How to perform ovariectomy through a colpotomy

T. Prado* and J. Schumacher

Department of Large Animal Clinical Sciences College of Veterinary Medicine, University of Tennessee, Knoxville, Tennessee, USA.
**Corresponding author email: tprado@utk.edu.*

Keywords: horse; ovariectomy; colpotomy

Summary

Bilateral ovariectomy of mares is performed most commonly to eliminate or diminish unwanted behaviour, create a teaser mare, sterilise a mare so that it can be registered in its breed association, or produce a recipient mare for embryo transfer. A practical technique of bilateral ovariectomy that can be easily performed without the mare sedated and without a surgical facility is ovariectomy through a colpotomy. Ovariectomy through a colpotomy is less expensive than ovariectomy using other approaches because it is performed with the mare standing, can be performed quickly and the only specialised instrument required is a chain écraseur. Complications of ovariectomy performed through a colpotomy are uncommon when the mare is correctly prepared for the procedure and when proper precautions are taken during and after the procedure.

Both ovaries are sometimes removed from mares to eliminate the regular oestrous cycle, create a teaser mare, or produce a recipient mare for embryo transfer (Hooper *et al.* 1993). Surgical approaches described for bilateral ovariectomy of mares include celiotomy through one or both flanks, or through the vagina (Hooper *et al.* 1993; Palmer 1993; Pader *et al.* 2011). A practical technique of bilateral ovariectomy that can be performed easily without anaesthetising the mare and without a surgical facility is ovariectomy through a colpotomy, with the use of an écraseur. Ovariectomy performed with an écraseur through a colpotomy, although once performed commonly (Nichols 1988; Embertson 2009), is now performed rarely because of perceived dangers associated with the procedure and the increasingly widespread use of laparoscopy to remove ovaries. Ovariectomy through a colpotomy is relatively inexpensive because it is performed with the mare standing, can be performed quickly and the only specialised instrument required is an écraseur. Removing one or both ovaries through a colpotomy avoids scarring, which is common when ovariectomy is performed using other approaches.

Ovariectomy through a colpotomy is usually performed to spay mares because most neoplastic ovaries are too large to be removed through a vaginal celiotomy. A neoplastic ovary is usually removed using a ventral midline, or oblique paramedian celiotomy (Moll *et al.* 1987; Westermann *et al.* 2003). Neoplastic ovaries less than about 10 cm in diameter, however, can be removed through a colpotomy (Colbern 1993; Moll and Slone 1998). Complications of ovariectomy performed through a colpotomy are uncommon when the mare is prepared properly for the procedure and when the correct precautions are taken during and after the procedure (Nichols 1988; Moll and Slone 1998; Embertson 2009; Pader *et al.* 2011).

Preparation of the mare for the surgery

Feed should be withheld for 24 h if the surgeon is inexperienced to reduce the number of faecal balls in the small colon, in order that a faecal ball is not confused with an ovary during the procedure. Administering 4 L of liquid paraffin 12–24 h in advance of surgery decreases the likelihood of faecal balls being present in the small colon. The mare is restrained in an equine stock and sedated with detomidine HCl (0.002–0.022 mg/kg bwt i.v.) and butorphanol (0.002–0.022 mg/kg bwt i.v.) (Pleasant and McGrath 1998). Administration of detomidine HCl should precede administration of butorphanol to avoid opioid-induced excitement. Sedation can be maintained by administering sedatives i.v. by constant rate infusion. Drugs commonly administered by constant rate infusion include detomidine alone (0.02 mg/kg bwt/h, i.v.), or in combination with butorphanol (0.012 mg/kg bwt/h, i.v.), or morphine (0.05 mg/kg bwt/h, i.v.) (Doherty and Valverde 2006). To avoid inducing excitement when using butorphanol in combination with detomidine, a loading dose of detomidine (0.008 mg/kg bwt i.v.) should be administered initially before a loading dose of butorphanol (0.022 mg/kg bwt i.v.) is administered (Doherty and Valverde 2006).

The mare is administered antimicrobial therapy and an anti-inflammatory, analgesic drug such as phenylbutazone (2.2 mg/kg bwt i.v.) and the perineum, vestibule and vagina desensitised by infusing 2% mepivacaine HCL (1.8 mg/kg bwt) alone, or in combination with, 2 or 10% xylazine HCl (0.18 mg/kg bwt), into the epidural space. A mare can be ovariectomised safely through a colpotomy without receiving epidural anaesthesia (authors' observation), but epidural anaesthesia, in addition to desensitising the vestibule and at least a portion of the vagina, prevents the mare from defaecating during surgery.

The tail is bandaged with rolled gauze, elevated and secured to the overhead cross-bar of the stock. The faeces are removed manually and the mare's ovaries and uterus evaluated by palpation per rectum. Hair surrounding the perineum is clipped and the perineum scrubbed with an antiseptic soap. Irrigating the vagina with 1 L isotonic saline solution not only cleans the vagina and vestibule, it also induces pneumovagina, easing the introduction of a hand and arm into the vagina.

Preparation of the surgeon

Although the procedure can be performed with the surgeon and assistant wearing only sterile obstetrical sleeves, we prefer to wear sterile surgical gowns, the arms of which are

© 2017 EVJ Ltd

covered with a sterile obstetrical sleeve to decrease friction between the arm and vagina. Sterile surgical gloves are donned over the hands of the obstetrical sleeves. The glove and sleeve on the surgeon's dominant arm are lubricated with sterile KY jelly to ease introducing the hand and arm into the vagina and into the abdomen after colpotomy.

Surgical procedure

A small pack of sterile gauze swabs, tethered to a sterile suture (e.g. umbilical tape) and saturated with local anaesthetic solution, such as mepivacaine HCl or lidocaine HCl, is introduced into the vagina with the surgeon's dominant arm (**Fig 1**). Pressing the pack to the fornix of the vagina for several minutes ensures that the mucosa at the fornix is desensitised. A stab incision is made with a No.10 or 15 scalpel blade, tethered to sterile strand of suture (e.g. umbilical tape), at the dorsolateral aspect of the fornix of the vagina, at the 10.30 or 13.30 h position, about 2 cm dorsolateral to the base of the cervix. This incision is cranial and dorsal to the vaginal branch of the internal pudendal artery (i.e. the vaginal artery) (Embertson 2009), which can usually be easily palpated when the vagina is distended with air (**Figs 2** and **3**). A right-handed surgeon can perform bilateral ovariectomy more easily through a colpotomy created on the right aspect of the vaginal fornix (i.e. the 13.30 h position), whereas a left-handed surgeon can perform bilateral ovariectomy more easily through a colpotomy created on the left aspect of the vaginal fornix (i.e. the 10.30 h position).

The blade is inserted through vaginal mucosa and submucosa and the stab incision is spread, first with the jaws of a haemostat and then with fingers, until an opening in the mucosa and submucosa is created that can accommodate the entire hand into the retroperitoneal space. Fascia and peritoneum are torn with a finger to create a hole into the abdominal cavity large enough to accommodate the hand and forearm of the surgeon. Trying to thrust a finger through the peritoneum, rather than tearing the peritoneum with a finger, is ineffective because this manoeuvre pushes the peritoneum away from the abdominal wall.

Fig 1: A pack of sterile gauze, tethered to a sterile suture and saturated with local anaesthetic solution, is introduced into the vagina.

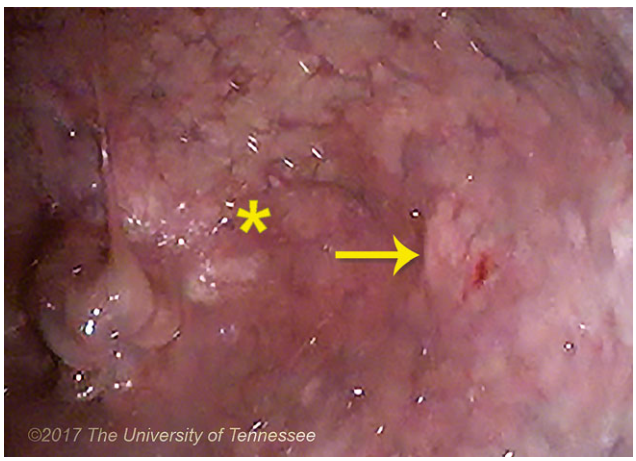

Fig 2: A stab incision is made with a No. 10 or 15 scalpel blade at the dorsolateral aspect of the fornix of the vagina, at the 10.30 or 13.30 h position, about 2 cm away from the base of the cervix and cranial and dorsal to the vaginal branch of the internal pudendal artery. *, site of incision; arrow, points to the vaginal branch of the internal pudendal artery.

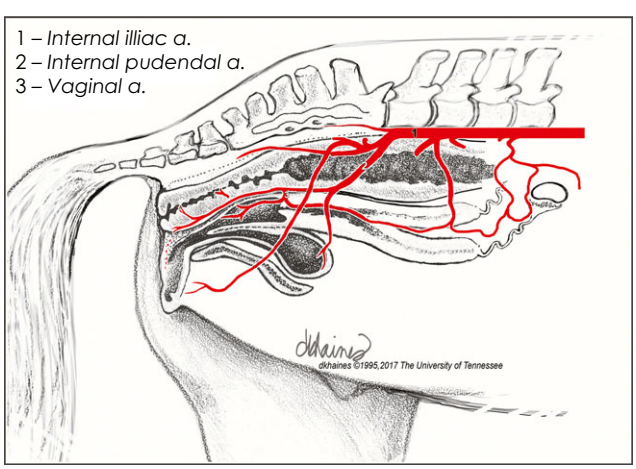

Fig 3: Schematic diagram showing the vaginal branch of the internal pudendal artery. 1, internal iliac artery; 2, internal pudendal artery; 3, vaginal artery.

The ovaries are identified and the pedicle of each ovary desensitised by pressing sterile gauze swabs, saturated with local anaesthetic solution, to each ovarian pedicle for several minutes (**Fig 4**). The gauze is tethered to a long, sterile suture (e.g. umbilical tape) to ensure that the gauze can be retrieved from the abdomen, if the gauze swabs are accidently dropped. The chain of the écraseur is secured over the dominant hand of the surgeon by placing four fingers through the loop of the chain of the écraseur and inserting the hand, the chain and the end of the écraseur through the colpotomy into the abdomen. The chain of the écraseur is positioned, with tension, against the surgeon's proximal row of phalanges as the end of the écraseur is introduced into the abdomen. The écraseur preferred by the authors is the Chassaignac écraseur[1] (**Fig 5**).

The left ovary should be removed first, if the colpotomy was created on the right side of the vagina, so that when

© 2017 EVJ Ltd

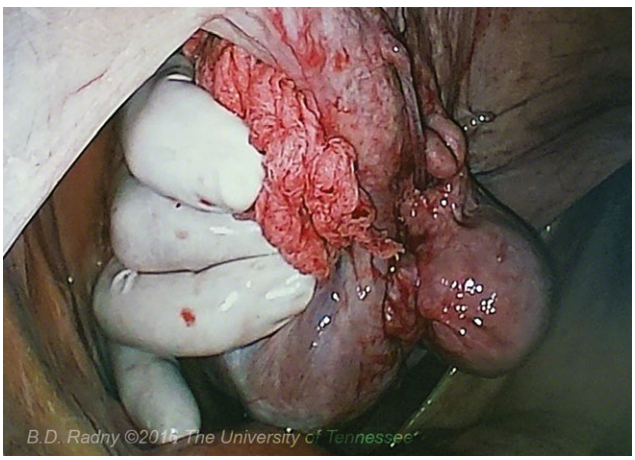

Fig 4: Ovaries are identified and the pedicle of each ovary is desensitised by pressing sterile gauze, saturated with local anaesthetic solution, to each ovarian pedicle.

Fig 5: The écraseur preferred by the authors is the Chassaignac écraseur[1].

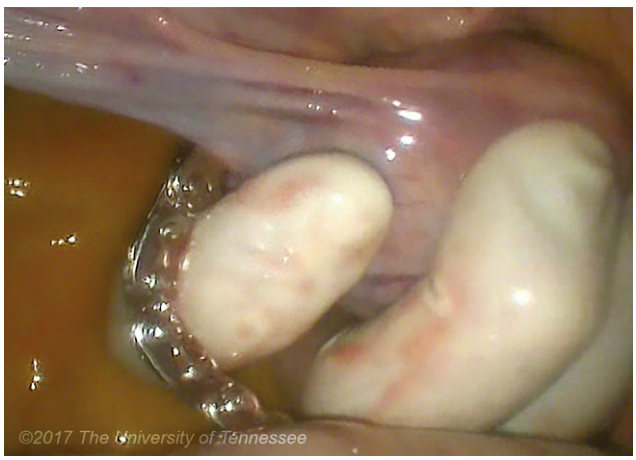

Fig 6: The chain of the écraseur is secured against the proximal row of the surgeon's phalanges, the ovary grasped, and the chain slipped over the hand to encircle the ovarian pedicle. This photograph was obtained through a laparoscope introduced into the abdominal cavity at the mare's flank, for the purpose of demonstrating ovariectomy through a colpotomy.

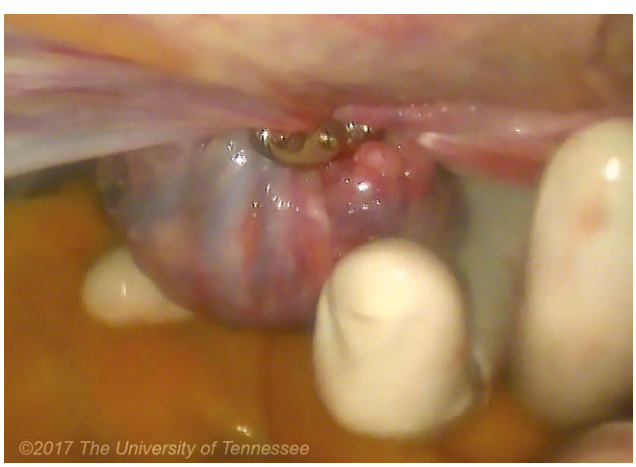

Fig 7: The chain is tightened, using the ratchet, until the pedicle is severed. This photograph was obtained through a laparoscope introduced into the abdominal cavity at the mare's flank, for the purpose of demonstrating ovariectomy through a colpotomy.

the right ovary is removed, the pedicle of the left ovary is not disturbed by the arm of the surgeon. When removing the ovary on the side contralateral to the colpotomy, the surgeon should ensure that his, or her, hand and the écraseur have passed beneath the small colon to access the ovary, so that the ovary is not grasped through the mesocolon. Removing an ovary encased by mesocolon risks severing a colonic vein and artery and creates a hole in the mesocolon through which intestine can become entrapped.

With the chain of the écraseur secured against the proximal row of the surgeon's phalanges, the ovary is grasped and the chain is slipped over the hand to encircle the ovarian pedicle (**Fig 6**). The chain is tightened around the pedicle, being careful that the chain encircles no other structure, such as a loop of intestine. The surgeon, or preferably an assistant surgeon, slowly tightens the chain by using the ratchet on the end of the écraseur while the surgeon holds the ovary and ensures that the ovarian pedicle is not stretched during this part of the procedure. The chain is tightened, using the ratchet, until the pedicle is severed (**Fig 7**). Stretching the pedicle while the chain is tightened may cause the pedicle to recoil when the pedicle is severed, which, in turn, may result in excessive haemorrhage from the ovarian artery. The ovary is extracted through the colpotomy and the contralateral ovary is removed in a similar manner.

The palm of a hand is held beneath each pedicle at the end of the procedure to feel for bleeding from the pedicle (**Fig 8**). If, on rare occasion, the amount of blood emanating from a pedicle is alarming, a long forceps, such as a Knowles cervical forceps, can be inserted vaginally, through the colpotomy, applied to the pedicle and left in situ for 1 h or more to induce haemostasis. The colpotomy is usually left unsutured to heal by second intention because suturing the colpotomy is difficult and may induce vaginitis, causing the mare to strain.

The mare should receive a Caslick's vulvoplasty if its perineal conformation is poor, to prevent pneumovagina and subsequent contamination of the vestibule, vagina and abdomen. Antimicrobial and analgesic therapy is continued for 3–5 days after surgery. The mare should be cross-tied for 2–3 days to prevent it from becoming recumbent because rising from recumbency increases abdominal pressure which, in turn, increases the likelihood of evisceration (Embertson 2009). Within about 3 days, the colpotomy contracts to a diameter that accommodates only one finger (**Fig 9**). The hole is usually completely sealed from the abdomen within

© 2017 EVJ Ltd

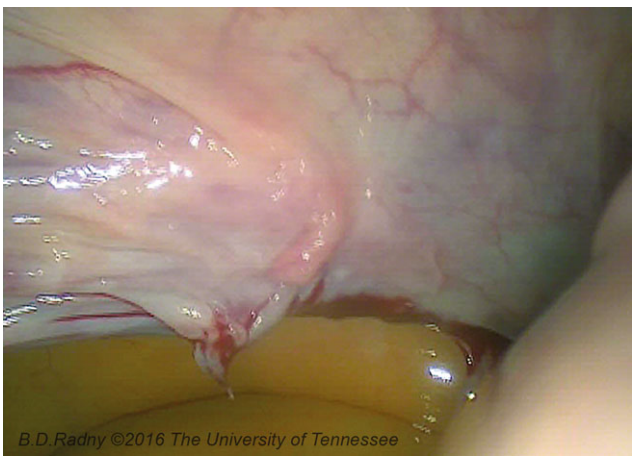

Fig 8: The palm of a hand is held beneath each pedicle at the end of the procedure to detect bleeding from the pedicle. This photograph was obtained through a laparoscope introduced into the abdominal cavity at the mare's flank, for the purpose of demonstrating ovariectomy through a colpotomy.

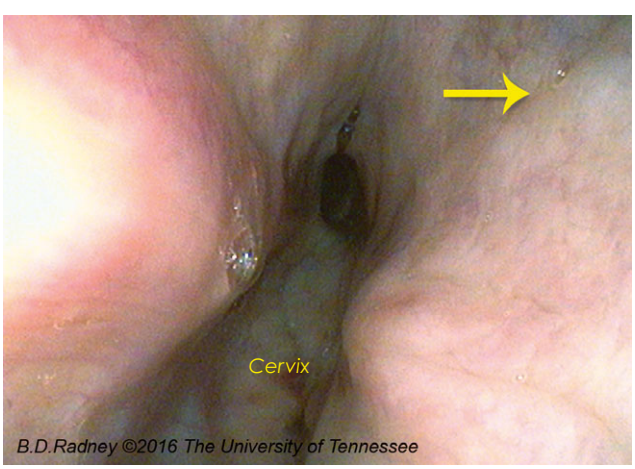

Fig 9: Endoscopic view of the fornix of the vagina 3 days after colpotomy. The colpotomy has contracted to a diameter smaller than that of one finger. The bulge in the vaginal wall (arrow) is the vaginal artery.

3 weeks (Moll and Slone 1998). The mare can be allowed unrestricted exercise after about 5 days (Nichols 1988; Colbern 1993; Moll and Slone 1998; Embertson 2009; Pader *et al.* 2011).

Discussion

The primary disadvantage of ovariectomy by colpotomy is that the ovarian pedicle is crushed and transected blindly, making detection of excessive intra-abdominal haemorrhage difficult. Because of this difficulty, the mare's haematocrit and serumal total protein should be determined before surgery and periodically after surgery to ensure that haemorrhage from the severed ovarian pedicles is not severe. Determining the magnitude of blood loss by monitoring the horse's haematocrit and total serumal solids during the first 6–24 h after ovariectomy, however, is difficult, because with severe blood loss, a decrease in total serumal protein is often not evident for 6 h and a decrease in haematocrit may not be evident for 12–24 h (Getman 2009).

Clinical signs associated with substantial blood loss include tachycardia, tachypnoea, a weak pulse, pale mucous membranes, prolonged capillary refill, cold extremities and weakness (Mudge 2014). If severe haemorrhage is suspected, the horse should receive fluid therapy and transfusion of blood from an acceptable donor should be considered. A complication of colpotomy itself is fatal haemorrhage caused by inadvertent perforation of the vaginal artery with a scalpel blade, but this artery is avoided if it is located by palpation before the fornix of the vagina is incised and if the incision is created at the proper location (Embertson 2009).

One of the authors (J.S.) has observed only two surgical complications after performing over 100 ovariectomies by colpotomy. One mare experienced severe haemorrhage, requiring multiple blood transfusions, but survived. The cause of severe haemorrhage was thought to result from transecting the ovarian pedicle while the pedicle was under tension. Another mare strained after surgery, presumably because of vaginitis induced by an unsuccessful attempt to suture the colpotomy. Straining gradually diminished over several days.

Persistence of unwanted behaviour is a complication of bilateral ovariectomy performed to eliminate or ameliorate that behaviour (Hooper *et al.* 1993; Kamm and Hendrickson 2007; Crabtree 2016). Success of ovariectomy in eliminating or ameliorating unwanted behaviour is likely if that behaviour occurs primarily during oestrus and if hormonal therapy has been shown to improve the mare's behaviour (Kamm and Hendrickson 2007). Ovariectomy is unlikely to resolve unwanted behaviour, if that behaviour is sexual behaviour that occurs during oestrus, because ovariectomy commonly results in continued display of sexual receptiveness with loss of normal cyclic activity (Hedberg *et al.* 2007).

Bilateral ovariectomy eliminates the production of oestrogen by eliminating the theca and granulosa cells of the ovarian follicles (Christensen 2011). Continued signs of oestrus displayed by ovariectomised mares is most likely due to absence of the corpora lutea, the primary source of progesterone, because progesterone is responsible for inhibiting the behavioural signs of oestrus (Watson and Hinrichs 1989).

Population dynamics of brushtail possums subject to fertility control

DAVE RAMSEY
Landcare Research, Private Bag 11052, Palmerston North, New Zealand

Summary

1. Reducing the fertility of pest species using immunocontraceptive vaccines holds promise for the humane and effective control of vertebrate pest populations. However, despite much research into the development of contraceptive vaccines, there are few data illustrating the effectiveness of fertility control for managing wild populations of vertebrate pests.
2. In New Zealand, introduced brushtail possums *Trichosurus vulpecula* have been the focus for the development of contraceptive vaccines to provide a possible alternative to lethal control techniques.
3. The effect of fertility control on the population dynamics of brushtail possums was investigated experimentally using surgical sterilization to suppress breeding on six 12-ha study sites between January 1996 and October 2000. Sterilization treatments, consisting of 0%, 50% and 80% of resident females sterilized, were applied at a particular site, with adjustments made annually on recruits to maintain levels of sterility. Mark–recapture trapping was used to estimate age-specific demographic rates and their relative contribution to age-specific population growth rates (λ).
4. Sterility treatments resulted in reductions to *per capita* rates of local recruitment (surviving young per adult female) of 60% and 74% on average for 50% and 80% levels of sterility, respectively. However, immigration by yearling-aged possums compensated for reductions in local recruitment because of sterility treatments, leading to the stable ($\lambda = 1$) population trajectories on sterility treatment sites.
5. There was some evidence that sterilized females had higher annual survival rates than fertile females, but otherwise there was no evidence of any other compensatory responses to imposed sterility. However, additional studies are needed to clarify possible density-dependent responses that could compensate for the effects of fertility control.
6. *Synthesis and applications.* Demographic compensation by pest populations can negate the effects of fertility control. Results from this study suggest that immigration can easily compensate for fertility control in pest species where adult survival is high and fecundity is low. This suggests that fertility control will need to be applied at large spatial scales to reduce this effect. Where adult survival makes a relatively high contribution to the population growth rate, the benefits of fertility control would be enhanced if integrated with conventional control to provide rapid initial population reduction.

Key-words: demographic contributions to lambda, immunocontraception, lambda, population growth rate, reverse-time mark–recapture, *Trichosurus vulpecula*

Journal of Applied Ecology (2005) **42**, 348–360
doi: 10.1111/j.1365-2664.2005.01006.x

Introduction

Australian brushtail possums *Trichosurus vulpecula* Kerr, introduced into New Zealand in the 1850s to establish a fur trade, are now a serious pest (Clout & Sarre 1997; Clout & Erickson 2000) and the main wildlife vector for bovine tuberculosis (Tb), which they transmit to livestock (Caley *et al*. 1999). Current methods of managing possums in the wild usually involve the use of poison bait, spread over large areas. While this method is effective, it is often costly and needs continual maintenance to give long-lasting results. There

are increasing concerns about possible effects on non-target populations and public health, as well as ethical considerations (Morgan & Hickling 2000). For these reasons, research is currently aimed at developing fertility control using contraceptive vaccines for possums, to provide a possible alternative long-term, cost-effective solution. Current research is mainly directed at reducing fertility by developing immunological blocks to fertilization or embryonic development (Cowan 1996; Cowan 2000), or manipulating hormonal regulation and gonadal development (Eckery *et al*. 1998).

While fertility control is seen as a possible solution to public concerns and animal welfare issues surrounding conventional lethal control, there are few data illustrating its effectiveness as a management tool. Models of fertility control in mammals suggest it will be relatively more effective on species with high fecundity and shorter lifespan (Hone 1992), and hence is predicted to be less effective on marsupials compared with eutherians, as marsupials generally have lower birth rates and higher survivorship than eutherians (Sinclair 1997). Models of fertility control for brushtail possums suggest the expected level of population suppression for a given sterilization rate is dependent on assumptions about the strength of density-dependent compensation, with fertility control being less effective if density-dependent compensatory responses operate through recruitment rather than adult survival (Barlow 1994; Barlow, Kean & Briggs 1997).

The mating system and social structure of the population may also influence the effectiveness of fertility control if they affect the birth and/or death rates (Caughley, Pech & Grice 1992; Barlow 2000). Ji, Clout & Sarre (2000) examined the responses of male possums in populations where 50% of the adult females were surgically sterilized. They found that surgically sterilized females continued to have oestrous cycles outside the normal breeding season. This resulted in an increase in the local density of males, which, it was hypothesized, were being attracted to the area because of the prolonged breeding activity. However, the potential effects of these behavioural and other compensatory responses to fertility control on the population dynamics of possums remain unknown. As compensatory increases in either adult or juvenile survival or immigration rates may compromise the efficacy of fertility control (Sinclair 1997), empirical evidence is needed on the magnitude of these responses (if any) before fertility control can be considered a viable management technique for brushtail possums.

To investigate the efficacy of artificially inhibiting the birth rate as an alternative control technique for brushtail possums, a field experiment was undertaken over 5 years to determine the effect of various levels of infertility (sterilized females) on population dynamics. Specifically, age-specific local recruitment, immigration and survival were estimated together with their relative contribution to the population growth rate (λ) for populations where either 50% or 80% of adult females had been made permanently infertile by surgical sterilization. Comparisons were made between these parameters and those on control sites where no sterility treatments were applied.

Materials and methods

STUDY AREAS

The experiment was undertaken on six 12-ha live trapping grids at two different locations. Three sites were established in the Orongorongo Valley, east of Wellington (174°58′E, 41°21′S), and three in the Turitea catchment, east of Palmerston North (175°41′E, 40°26′S), New Zealand. Sites were established in October–November 1995 in native podocarp/hardwood forest. Vegetation in the Orongorongo Valley was dominated by emergent species *Metrosideros robusta* A. Cunn., *Dacrydium cupressinum* Lamb., *Prumnopitys ferruginea* D. Don. and *Prumnopitys taxifolia* D. Don. (Fitzgerald 1976; Campbell 1990; Ramsey *et al*. 2002). The forest canopy was between 6 and 20 m and comprised mainly *Elaeocarpus dentatus* J. R. Forst. & G. Forst., *Laurelia novae-zelandiae* A. Cunn., *Melicytus ramiflorus* J. R. Forst. & G. Forst., *Hedycarya arborea* J. R. Forst & G. Forst., *Knightia excelsa* R. Br., *Weinmannia racemosa* L. f., *Schefflera digitata* J. R. Forst. & G. Forst., *Pseudowintera axillaris* J. R. Forst. & G. Forst. and five species of tree fern. The area also included stands of kanuka *Kunzea ericoides* A. Rich. and hard beech *Nothofagus truncata* Col. Ckn. The Turitea catchment site was situated in the Tararua ranges near Palmerston North and had vegetation comprising remnant podocarp/kamahi forest now dominated by a canopy of *Beilschmiedia tawa* A. Cunn. with associated *Melicytus ramiflorus*, *Hedycarya arborea*, *Knightia excelsa* and scattered *Dacrydium cupressinum* and *Prumnopitys ferruginea* (Esler 1969). At each site, between 132 and 150 cage traps were placed on a marked grid at 30 m spacing. Populations in the Orongorongo Valley typically have one birth pulse per year in autumn (March–July), while populations in the Turitea catchment have been observed to have an occasional second, smaller pulse of breeding in spring (September–December) (D. Ramsey, unpublished data).

POPULATION MONITORING

Trapping followed the robust design (Pollock 1982; Nichols & Pollock 1990), with each population trapped for a minimum of three primary sessions a year with each primary session consisting of secondary sessions of four or five consecutive nights trapping. Trapping started on all sites during October–November 1995 and continued until October 2000. The exception was the control site in the Orongorongo Valley, which has been continuously trapped since 1966 (Crawley 1973; Efford 1998). Newly caught possums were anaesthetized with ether (1995–99) or 50–100 mg ketamine hydrochloride (2000) (Parnell Laboratories New Zealand

© 2005 British Ecological Society,

Ltd, Auckland, New Zealand) by intramuscular injection and given a unique tattoo and ear tag. Before the animal was released at the point of capture, measurements were taken that included head, body and total lengths; testis length and width for males; weight and tooth wear. For females, an estimate of breeding success was made in late June by examining the pouch for young. Head lengths of pouch young were measured to estimate date of birth (Efford 1998) by assuming a head length at birth of 7 mm and a linear growth rate of 0·27 mm day^{-1} (Orongorongo Valley) or 0·35 mm day^{-1} (Turitea) (D. Ramsey, unpublished data). Pouch young caught with their mothers in September–October were usually large enough to tag. Recaptured animals were identified and weighed before being released. Animals not first caught with their mother were assigned a minimum age using a logistic regression algorithm discriminating on body-size measurements. Separate regressions were constructed for Orongorongo Valley and Turitea using possums whose birth cohorts were known. Independent possums were classified as either yearlings (= 20 months old) or adults (> 20 months old) (Efford 1998).

STERILIZATION TREATMENTS

Fertility control was imposed by surgically sterilizing females by ligating the oviducts. This method ensured ovarian function remained intact and mimicked the action of the most likely candidate fertility control vaccines. Three levels of sterilization treatment were applied, with 0%, 50% or 80% of adult females at a particular site sterilized. As the effect of surgery on survival of animals was unknown, sham operations (no sterilization) were undertaken to balance the level of surgical manipulation across treatments. However, no sham operations were undertaken on the Orongorongo Valley control (0% sterility) site, so that consistency could be maintained with the previous long-term monitoring data collected at this site. Two replicates of each treatment were undertaken, with one complete replicate at sites in the Orongorongo Valley and one replicate in the Turitea catchment. Treatments were assigned to sites within each area at random, with the exception of the control site in the Orongorongo Valley. Sterilization treatments were applied during January–April 1996, with adjustments to maintain sterility levels made annually on recruits. All trapping and surgical procedures were approved by the Landcare Research Animal Ethics Committee, Lincoln, New Zealand.

DECOMPOSITION OF THE ANNUAL POPULATION GROWTH RATE

A retrospective analysis (Caswell 2000) was undertaken to determine the relative contribution of demographic parameters (survival, recruitment) to the annual population growth rate (λ). Trapping undertaken in September–October was chosen as the annual census date because pouch young were marked with their mothers during this period. Capture data for the intervening periods were not used. Here λ is the realized annual growth rate rather than the asymptotic growth rate derived from population projection matrices (Caswell 2001), and is defined as:

$$\lambda_i = \frac{N_{i+1}}{N_i} \qquad \text{eqn 1}$$

where λ_i is the population growth rate during year i, and N_i and N_{i+1} are the population abundance estimates in year i and $i + 1$, respectively. Following Nichols *et al.* (2000), λ can be decomposed into contributions from survivors and new recruits as:

$$\lambda_i = \frac{\gamma_{i+1} N_{i+1} + (1 - \gamma_{i+1}) N_{i+1}}{N_i} \qquad \text{eqn 2}$$

where γ_{i+1} is the probability that a member of the population at time $i + 1$ (N_{i+1}) was a member of the population at time i (N_i) (e.g. survivors from time i), and hence $(1 - \gamma_{i+1})$ is the probability that a member of the N_{i+1} was recruited between time i and $i + 1$. Thus, the γ_{i+1} can be regarded as a measure of the relative contribution of survivors and recruits to population growth between years i and $i + 1$ (Nichols *et al.* 2000; Nichols & Hines 2002).

Recruitment into a population can potentially come either from reproduction from resident females (local recruitment) or from animals arriving from outside the study population (immigration). In order to decompose λ into contributions from local recruitment, immigration and survival, it is necessary to condition on age structure, as recruitment into the next age class that cannot be explained by survival from the previous age class must be a result of immigration (Stokes 1984; Nichols & Pollock 1990). Three age classes were considered in the analysis: pouch young, dependent young first caught with their mothers and tagged at approximately 8 months old; yearlings, possums first caught in the year following their birth at approximately 20 months old; and adults, all possums approximately ≥ 32 months old.

The relative contribution (γ) of demographic parameters (survival, fecundity/local recruitment and immigration) of each age class to the annual population growth rate λ was estimated using methods detailed in Nichols *et al.* (2000). This retrospective analysis uses reverse-time capture–recapture analysis to estimate γ. By reversing the time order of capture history data, inference can be made on the recruitment process, which is statistically equivalent to inference on the survival process using forward time (Pollock, Solomon & Robson 1974; Pradel 1996). However, the analysis of the contribution of different demographic components to λ for age-structured data is not straightforward (Nichols *et al.* 2000). For example, using reverse-time capture–recapture, it was desirable to condition on animals caught as yearlings at time $i + 1$ and estimate the probabilities that those animals were either pouch young of resident females at time i (γ_{i+1}) or new immigrants

© 2005 British Ecological Society,

arriving between time i and $i + 1$ $(1 - \gamma_{i+1})$. As there were three age classes, the population growth rate given in equation 1 can be partitioned into two components. The population growth rate of adults is given as:

$$\lambda_i^2 = \frac{N_{i+1}^2}{N_i^2} \qquad \text{eqn 3}$$

where N_i^2 and N_{i+1}^2 are the population abundance of adults in year i and $i + 1$, respectively. The population growth rate of the yearling component is given by:

$$\lambda_i^1 = \frac{N_{i+1}^1}{N_i^1} \qquad \text{eqn 4}$$

where N_i^1 and N_{i+1}^1 are the population abundance of yearlings in year i and $i + 1$, respectively. The N_i^a $(a = 2, 1)$ was estimated using the jack-knife closed population estimator (Burnham & Overton 1978), which is robust to individual heterogeneity in capture probabilities. Estimates of λ_i^2 and λ_i^1 and their sampling variance in each year were obtained using a bootstrap procedure. For each age class within each primary trapping session, a random sample of the capture histories over the secondary capture periods was selected (with replacement), conditional on the total number of individuals captured. The ratio of 50 bootstrap jack-knife estimates of abundance in year $i + 1$ and year i was used to generate 2500 estimates of the population growth rate. The mean and standard error of the population growth rate was estimated as the mean and standard deviation of these 2500 bootstrap estimates. An estimate of the overall average population growth rate over the study period was made by fitting a linear regression to the natural log of the jack-knife abundance estimates of the total population in September–October each year. The average growth rate ($\bar{\lambda}$) was estimated as e^b, where b was the slope of the regression line (Caughley 1977).

The decomposition of λ_i^2 is given by the following expression (Nichols *et al*. 2000):

$$\lambda_i^2 = \frac{\gamma_{i+1}^{22} N_{i+1}^2 + \gamma_{i+1}^{21} N_{i+1}^2 + (1 - \gamma_{i+1}^{22} - \gamma_{i+1}^{21}) N_{i+1}^2}{N_i^2} \qquad \text{eqn 5}$$

where λ_i^2 is the population growth of adult possums during the ith year; γ_{i+1}^{22} is the probability that an adult possum alive at time $i + 1$ was in the adult population at time i; γ_{i+1}^{21} is the probability that an adult possum alive at time $i + 1$ was in the yearling population at time i; and $1 - \gamma_{i+1}^{22} - \gamma_{i+1}^{21}$ is the probability that an adult possum alive at time $i + 1$ immigrated between time i and $i + 1$. Similarly, the decomposition of the population growth rate of the yearling subpopulation can be expressed as:

$$\lambda_i^1 = \frac{\gamma_{i+1}^{10} N_{i+1}^1 + (1 - \gamma_{i+1}^{10}) N_{i+1}^1}{N_i^1} \qquad \text{eqn 6}$$

where λ_i^1 is the annual population growth rate of yearling-aged possums during the ith year; γ_{i+1}^{10} is the probability that a yearling possum alive at time $i + 1$ was a dependent pouch young at time i; and $1 - \gamma_{i+1}^{10}$ is the probability that a yearling possum alive at time $i + 1$ immigrated between time i and $i + 1$. These γ_i^{rs} [rs = 22, 21 or 10, referring to either age classes 2 (adults), 1 (yearlings) or 0 (pouch young)] were estimated using the closed-form maximum likelihood estimators (MLE) detailed in Nichols *et al*. (2000), for example:

$$\hat{\gamma}_i^{22} = \frac{\hat{M}_{i,i-1}^{22}}{n_i^2}; \; \hat{\gamma}_i^{21} = \frac{\hat{M}_{i,i-1}^{21}}{n_i^2}; \; \hat{\gamma}_i^{10} = \frac{\hat{M}_{i,i-1}^{10}}{n_i^1}$$

Where:

$$\hat{M}_{i,i-1}^{rs} = \frac{m_{i,i-1}^{rs}}{\hat{p}_{i-1}^{s*}} \qquad \text{eqn 7}$$

and $m_{i,i-1}^{rs}$ are the members of the n_i^r that were caught as members of the n_{i-1}^s where n is the total number of animals caught in periods i or i^{-1} for either age class r or s. The capture probability parameter ($\hat{p}_{i-1}^{s*}$) in equation 7 is specific to reverse-time analysis and is calculated as:

$$\hat{p}_i^{s*} = \frac{\hat{p}_i^s \hat{\eta}_i^s}{1 - \hat{p}_i^s (1 - \hat{\eta}_i^s)} \qquad \text{eqn 8}$$

where $\hat{p}_i^s$ is the capture probability for age class s at period i using conventional forward time modelling, and $\hat{\eta}_i^s$ is the probability that an animal of age class s captured at period i survives trapping and handling and is released (Nichols & Hines 2002). Equations 7 and 8 were used to produce unbiased estimates of γ_i^{rs} in the presence of losses on capture. During 1998 and 1999 an attempt was made to limit the influx of immigrant yearling possums on sterility grids by removing a proportion of unmarked yearlings during the October trapping session. This attempt was largely unsuccessful. However, not accounting for losses on capture could produce biased estimates of γ_i^{21} as the yearling possums that were removed could not be seen again as adults. When there are no losses on capture (i.e. $\eta_i^s = 1$) the forward-time and reverse-time estimates of capture probability are equal (Nichols & Hines 2002).

Estimation of $\hat{\gamma}_i^{22}$ and $\hat{\gamma}_i^{21}$ was relatively straightforward, with the forward-time capture probability for adults ($\hat{p}_i^2$) and yearlings ($\hat{p}_i^1$) estimated by fitting Cormack–Jolly Seber (CJS) models, conditioning on age at first capture using the program MARK (White & Burnham 1999). Models were fitted that allowed for both time-dependent and time-independent age-specific capture probability, noting that the capture probability of pouch young cannot be estimated (e.g. a possum released as a pouch young that survived over the next year interval is caught as a yearling). Only models with time-dependent age-specific survival rates were considered as part of the candidate set of models. The set of models was ranked using methods detailed in Burnham & Anderson (1998) using Akaike's information criterion adjusted for sample size (AIC_c). The most general model considered (time-varying age-specific survival and capture probability) was tested for goodness-of-fit using the parametric bootstrap test in program

© 2005 British Ecological Society,

MARK. The overdispersion parameter c was estimated by dividing the observed deviance of the general model by the mean of 100 bootstrap samples. Models were corrected for overdispersion using this estimate of c, and the fit of all the models considered was compared using Akaike's information criterion corrected for overdispersion ($QAIC_c$) by taking the difference between all models and the model with the lowest $QAIC_c$ (Burnham & Anderson 1998; White & Burnham 1999). The relative support for each of the candidate models was assessed by calculating normalized Akaike weights (w_i) (Burnham & Anderson 1998). Once estimates of $\hat{p}_i^s$ were obtained, $\hat{p}_i^{s*}$ was estimated using data on losses-on-capture (see Appendix 2) to estimate $\hat{\eta}_i^s$.

In order to estimate $\hat{\gamma}_i^{10}$, it is necessary to have information on capture probability of pouch young $\hat{p}_{i-1}^0$ that is not directly available from standard age-structured models. Capture probability of dependent pouch young can be estimated from an approximation of the total size of the pouch young cohort:

$$\hat{p}_i^0 = \frac{n_i^0}{\hat{N}_i^0} \qquad \text{eqn 9}$$

where n_i^0 is the number of pouch young tagged with their mother, and $\hat{N}_i^0$ is an estimate of the total size of the pouch young cohort. This was obtained using:

$$\hat{N}_i^0 = \frac{n_i^{1f}}{\hat{p}_i^{1f}} BR_i^1 + \frac{n_i^{2f}}{\hat{p}_i^{2f}} BR_i^2 \qquad \text{eqn 10}$$

where n_i^{1f} and n_i^{2f} are the total number of yearling and adult female possums caught at time i, respectively; BR_i^1 and BR_i^2 are the breeding rates of yearling and adult female possums, respectively; and $\hat{p}_i^{1f}$ and $\hat{p}_i^{2f}$ are the capture probabilities of female yearling and adult possums, respectively, obtained from the conventional age-structured CJS analysis applied to capture histories for female possums.

An estimate of sampling variance for each of the MLE of the γ_i^{rs} was obtained by a bootstrapping procedure. Conditioning on each of the n_i^r ($r = 2, 1$) releases at time i, capture histories were simulated in reverse time using the point estimates of the γ_i^{rs} and age-specific capture probabilities. For each individual in each n_i^r, a random uniform number between 0 and 1 was drawn and compared with the appropriate γ_i^{rs}. If the random number was less than the estimate the animal was deemed to have been present at time $(i - 1)$, if otherwise it was not. If the animal was present at time interval $(i - 1)$ another random number was drawn and compared with the appropriate capture probability estimates from the forward-time age-structured model (i.e. p_{i-1}^s). If the random number was less than the estimated capture probability, the animal was assumed to have been caught at time interval i^{-1} and thus was entered as a member of the $n_i^s (r = 2, 1, 0)$. The n_i^r and simulated n_{i-1}^s were used to calculate the $m_{i,i-1}^{rs}$ and, hence, an estimate of the γ_i^{rs} using equation 7. This bootstrapping process was repeated 1000 times for each γ_i^{rs}, with the standard error estimated as the standard deviation of the 1000 bootstrap estimates.

Once estimated, the values of γ_i^{22}, γ_i^{21} and γ_i^{10} were compared between sterility treatments using generalized linear models. A binomial error structure was assumed by using a logit link function, with the number of n_{i-1}^s ($s = 2, 1, 0$) releases for each time period used as weights for each value of γ_i^{rs}. The rate of increase (λ_i^2 or λ_i^1) was included in the analysis as a covariate, to determine whether year-to-year variation in γ_i^{rs} was dependent on the age-specific rate of increase. Area (Orongorongo or Turitea) was also included as a fixed effect in the analysis.

Finally, estimates of λ_{i+1}^{10} were used to make an estimate of *per capita* local recruitment, defined as the number of pouch young born in year i surviving to the yearling age class in year $i + 1$ per adult female in year i, thus:

$$\hat{B}_{i+1} = \frac{\hat{N}_{i+1}^1 \hat{\gamma}_{i+1}^{10}}{\hat{N}_i^{2f}} \qquad \text{eqn 11}$$

where $\hat{B}_{i+1}$ is the *per capita* rate of local recruitment, $\hat{N}_{i+1}^1$ is the jack-knife estimate of abundance of yearling possums in year $i + 1$, and $\hat{N}_i^{2f}$ is the jack-knife estimate of abundance of adult female possums in year i. The sampling variance of $\hat{B}_i$ was calculated using the delta method (Seber 1982) as:

$$\mathrm{Var}(\hat{B}_i) = \frac{\mathrm{Var}(\hat{N}_{i+1}^1 \hat{\gamma}_{i+1}^{10})}{(\hat{N}_i^{2f})^2} + \frac{(\hat{N}_{i+1}^1 \hat{\gamma}_{i+1}^{10})^2 \mathrm{Var}(\hat{N}_i^{2f})}{(\hat{N}_i^{2f})^4} \qquad \text{eqn 12}$$

Where:

$$\mathrm{Var}(\hat{N}_{i+1}^1 \hat{\gamma}_{i+1}^{10}) = (\hat{N}_{i+1}^1)^2 \mathrm{Var}(\hat{\gamma}_{i+1}^{10}) + (\hat{\gamma}_{i+1}^{10})^2 \mathrm{Var}(\hat{N}_{i+1}^1) + \mathrm{Var}(\hat{N}_{i+1}^1)\mathrm{Var}(\hat{\gamma}_{i+1}^{10})$$

This assumes that each of the random variables is independent.

OTHER ANALYSES

The effect of the sterilization procedure on individual females was examined by comparing the annual survival of sterilized adult females with fertile adult females by fitting CJS models in the program MARK. Sterile and fertile individuals were categorized by site, which was included as a fixed effect in the analysis. The goodness-of-fit of the 'global' model was assessed using the pooled chi-squared goodness-of-fit tests from tests 2 and 3 using program RELEASE (Burnham *et al*. 1987). Models for capture probability were fitted first, and included the interactive effects of site, sterility and time. The 'best' model of capture probability was then used to model survival and included the same effects. Models were ranked as previously using AIC_c and Akaike weights (Burnham & Anderson 1998; Burnham & Anderson 2001).

The breeding rate of fertile females was compared between sterility treatments using logistic regression (Collett 1991). Area (Orongorongo/Turitea) was fitted

as a fixed effect in the model. The median birth date for pouch young born to resident females was similarly compared using ANOVA. All analyses were performed using Splus 6·1 (Insightful Corporation 2001).

Results

BREEDING STATISTICS

Low breeding rates occurred on all sites during 1996, with only 24% and 45% of adult females breeding on control sites in the Orongorongo Valley and Turitea, respectively (Fig. 1a). However, in subsequent years treatment levels of sterility successfully suppressed breeding, with median levels of 69%, 30% and 14% of adult females breeding on control, 50% and 80% sterility sites, respectively (Fig. 1a). Accounting for the fixed effect of area (Orongorongo or Turitea), the rate of breeding in fertile females was similar among sterility treatments (logistic regression $\chi^2_2 = 0{\cdot}79$, $P = 0{\cdot}67$; Fig. 1b) and, similarly, there were no significant differences in the median dates of birth (ANOVA $F_{2,25} = 0{\cdot}03$, $P = 0{\cdot}97$). The rate of spring breeding also did not appear to increase among fertile females at sites with imposed sterility ($\chi^2_2 = 1{\cdot}7$, $P = 0{\cdot}43$). Thus, sterility treatments did not significantly influence either the rate or the timing of breeding in unsterilized females.

POPULATION TRAJECTORIES

Between 1996 and 2000, population abundance exhibited no strong upward or downward trend on any site, with the exception of the Turitea control (0% sterility) site, which averaged a 20% annual increase (Fig. 2a,b and Table 1). Overall, average population growth rates ($\bar{\lambda}$) were close to unity for all sterility treatment sites (Table 1).

DECOMPOSITION OF THE ANNUAL POPULATION GROWTH RATE

Forward-time CJS models fitted to mark–recapture data from the September–October trapping sessions

each year to estimate annual age-specific capture probabilities indicated that models with capture probability constant across time and age classes, but differing for each site, were the most preferred based on $\Delta QAIC_c$ and Akaike weights.

The relative contributions to the adult population growth rate of adult survivors (γ_i^{22}), yearling recruits (γ_i^{21}) and immigrants ($1 - \gamma_i^{22} - \gamma_i^{21}$) and their bootstrap standard errors in each year are given in Appendix 1. Logistic regression analysis of γ_i^{22} revealed no significant differences between sterility treatments. However, there were significant differences between areas and a significant effect because of λ_i^2 (Table 2). Similar analysis for γ_i^{21} revealed no significant differences as a result of sterility treatment, area or λ_i^2 (Table 3). Survival of adults from the previous year (γ_i^{22}) made the dominant contribution to the adult population growth rate, contributing around 65% to the adult population growth rate when λ_i^2 was high ($1{\cdot}3\ \text{year}^{-1}$) and around 79% when λ_i^2 was low ($0{\cdot}9\ \text{year}^{-1}$) (Fig. 3). Recruitment of resident yearling-aged animals (γ_i^{21}) made a minor contribution

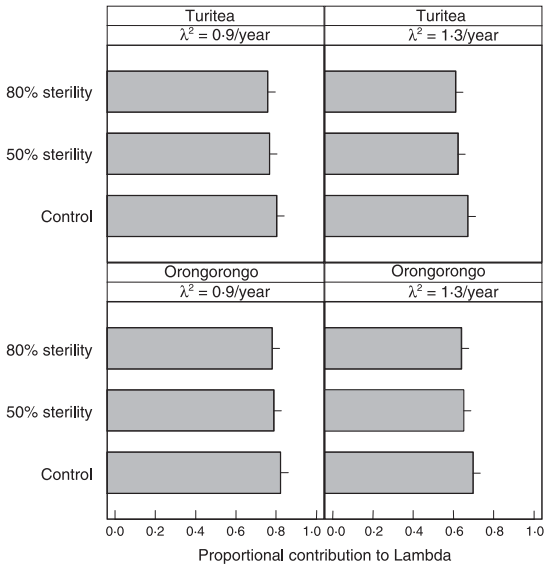

Fig. 3. Predicted values from a logistic regression model of the effects of area (Orongorongo and Turitea), adult population growth rate (λ_i^2) and sterility treatment on the proportional contribution of adult survivors to the adult population growth rate (γ_{i+1}^{22}). Predicted values are for each level for each categorical variable (area, sterility treatment) and for the upper and lower quartile of the observed values for λ_i^2. Error bars are the standard error.

to the growth rate of adults, especially on sites in the Orongorongo Valley (Fig. 4).

The relative contributions to the yearling population growth rate of recruitment of locally born young (γ_i^{10}) and yearling immigrants ($1 - \gamma_i^{10}$) and their bootstrap standard errors in each year are given in Appendix 1. Logistic regression analysis of the contribution of local recruits to the yearling population growth rate revealed that γ_i^{10} differed significantly because of the additive effects of area, λ_i^1 and sterility treatments (Table 4). Local recruitment made the dominant contribution to the yearling growth rate on control sites, predicted to contribute 51% to the growth rate of yearlings when λ_i^1 was low (0·5 year^{-1}) and 41% when λ_i^1 was high (2·5 year^{-1}) (Fig. 5). In comparison, local recruitment on 50% and 80% sterility sites was predicted to contribute only 21% and 19%, respectively, when λ_i^1 was low, and 14% and 13%, respectively, when λ_i^1 was high (Fig. 5).

Because of the significant reductions in γ_i^{10} as a result of sterility treatments, estimates of *per capita* local recruitment $\hat{B}_i$ were also reduced by sterility treatments. The number of offspring surviving until yearling age per adult female averaged 0·13 and 0·17 on control (0% sterility) sites in the Orongorongo Valley and Turitea, respectively, but only 0·03 and 0·05, respectively, on 80% sterility sites (Fig. 6). Estimates of $\hat{B}_i$ and their standard errors in each year are given in Appendix 1.

Model selection results for CJS models fitted to estimate survival rates of sterilized and fertile females revealed that models of capture probability that included the interactive effects of site, sterility treatment and time (year) received the most support, as judged by ΔAIC_c values. Using this best model of capture probability, four survival rate models that included either the additive or interactive effects of site and sterility, and an additive effect of time, received the most support as judged by ΔAIC_c values (Table 5). Although average

Table 5. Model selection results for CJS models fitted to estimate apparent annual survival (ϕ) for adult fertile and sterile female possums. *S*, site effect; *St*, sterility effect; *t*, time (year) effect. Models are ranked according to differences between the model AIC_c and the model with the lowest AIC*c* (ΔAIC_c). w_i indicates the relative support (Akaike weights) for each model. The capture probability component of all models includes the interactive effects of all factors (e.g. $S \times St \times t$)

Predicted values are for each level for each categorical variable (area, sterility treatment) and for the upper and lower quartile of the observed values for λ_i^2. Error bars are the standard error.

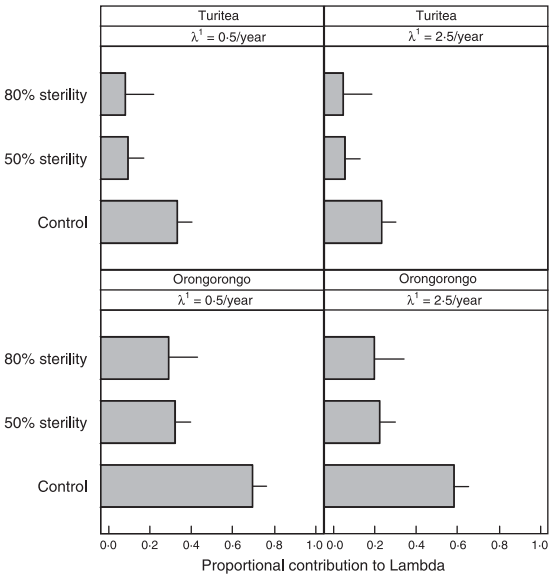

Fig. 5. Predicted values from a logistic regression model of the effects of area (Orongorongo or Turitea), yearling population growth rate (λ_i^1) and sterility treatment on the proportional contribution of local recruitment to the yearling population growth rate (γ_{i+1}^{10}). Predicted values are for each level for each categorical variable (area, sterility treatment) and for the upper and lower quartile of the observed values for λ_i^1. Error bars are the standard error.

survival rates of sterile females were higher than fertile females at the same site (Fig. 7), the 95% confidence intervals (CI) for the sterility term in the model with the most support ($S + St$) overlapped 0 ($\hat{\beta}_{sterility} = 0{\cdot}65$; 95% CI = −0·03, 1·32 on a logit scale). A likelihood ratio test between this model and the more restricted model without the sterility term indicated a marginal level of significance ($P = 0{\cdot}09$).

Discussion

The methods presented here for decomposing contributions to λ from different age classes differ slightly from the robust design approach given in Nichols *et al.* (2000). They advocate calculating age-specific capture probabilities using the ratio of the number caught to an estimate of population size using a closed capture estimator, for example:

$$\hat{p}_i^a = \frac{n_i^a}{\hat{N}_i^a}$$

where $\hat{p}_i^a$, n_i^a and $\hat{N}_i^a$ are the capture probability estimate, total number caught and population size estimate, respectively, for age class a in primary capture session i. Unfortunately, this estimator did not prove to be very efficient when applied to the possum capture data, with imprecision in estimates of $\hat{N}_i^a$ leading to many estimates of γ greater than 1 (and estimates of 1 − γ less than 0). Applying conventional age-structured CJS models in forward time for the estimation of the p_i^a greatly ameliorated this problem, as model selection procedures could be employed. This analysis suggested that capture probabilities for yearling- and adult-aged possums could be adequately modelled using estimates of p_i^a that were constant across time and age classes. An alternative approach using joint likelihoods and multistate models under the robust design also allows the construction of reduced parameter models (Nichols *et al.* 2000). However, because of the complications of estimating capture probability and population size of pouch young (which was dependent on the capture probability, population size and breeding rate of their mothers), this was not attempted for the possum data set.

Permanent sterilization of a proportion of females successfully suppressed breeding rates, regardless of whether the population was a notionally spring breeding population or not. In both the Orongorongo Valley (no spring breeding) and Turitea (spring breeding), fertile females on sterility sites did not breed earlier and did not have an increased breeding rate compared with females on control sites. Levels of spring breeding were also similar between sterility treatments. Hence, there was no evidence that fertile females on sterility sites attempted to compensate for reduced productivity caused by sterilization treatments.

Population abundance exhibited no significant upward or downward trend over the duration of the study, with the exception of the control site at Turitea, which exhibited an average 20% annual increase. Thus, reductions in the birth rate because of sterility treatments did not result in population declines over the course of the study. Examining the contribution of population

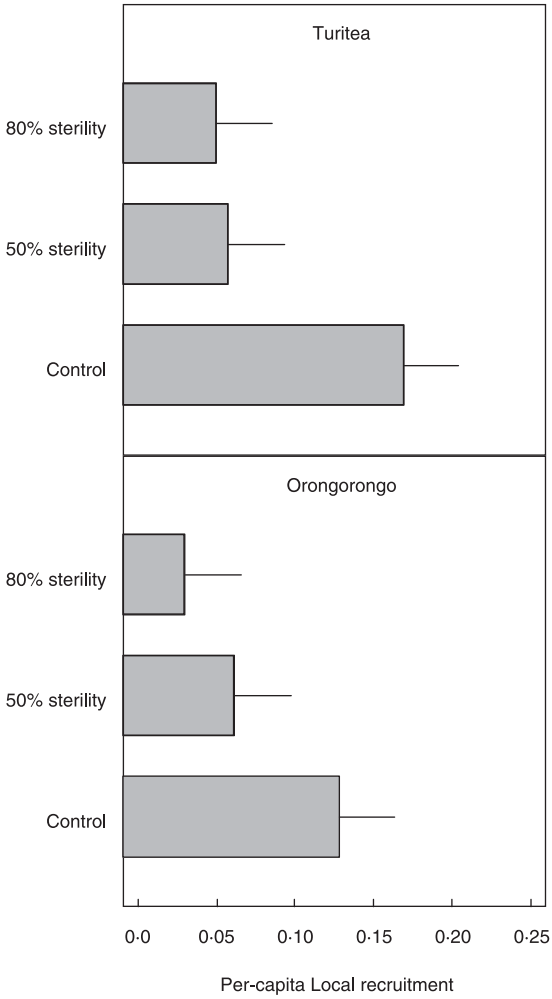

Fig. 6. Mean *per capita* local recruitment rates ($\hat{B}$) for each sterility treatment site in the Orongorongo Valley and Turitea. Error bars are the standard error of the mean ($n = 4$).

vital rates (births, survival and immigration) to annual population growth at each site revealed the contribution of underlying demographic processes driving annual population change.

Overall, sterility treatments suppressed *per capita* rates of local recruitment. In this context, local recruitment refers to both male and female young born *in situ* that survived until the late yearling stage (i.e. 20 months old) per adult female. Averaged over areas, the reduction in the *per capita* rate of local recruitment was 60% and 74% on 50% and 80% sterility treatments, respectively. The contribution of local recruitment to the population growth rate of yearlings was similarly reduced, but was dependent on the magnitude of the yearling population growth rate and differed among areas. The population growth rate of yearlings in year i (λ_i^1) that would have occurred through local recruitment only can be calculated as $\lambda_i^1 \gamma_{i+1}^{10}$. These calculations show that local recruitment only would be inadequate to replace the disappearance of yearling-aged possums through death, emigration or recruitment to the adult age class on any site (Table 6). However, average population growth rates revealed that the yearling subpopulation was increasing, on average, over the course of the study on all sites (Table 6). On sterility treatment sites, immigration made the dominant contribution to the population growth rate of yearlings, compared with that made by local recruitment. On control sites, local recruitment made the dominant contribution to the population growth rate of yearlings on one site only (Orongorongo Valley). At Turitea, the contribution to the yearling population growth rate was dominated by immigration on all sites. However, the contribution by local recruitment to the yearling population growth rate on sterility treatment sites was reduced compared

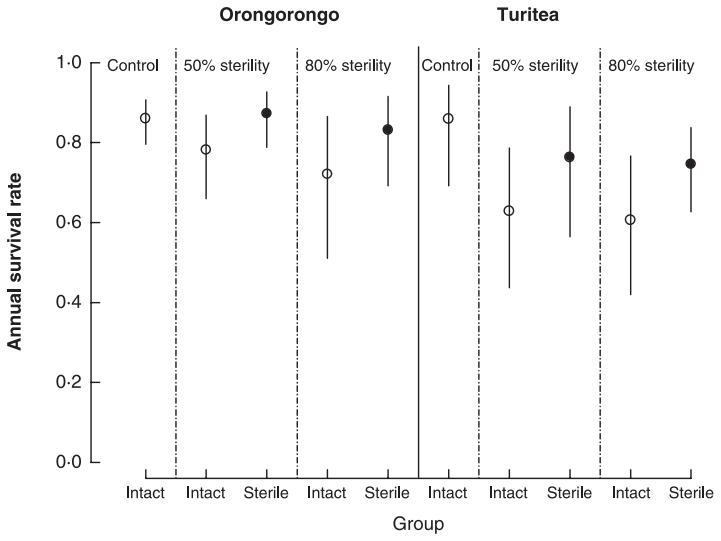

Fig. 7. Estimates of the mean annual apparent survival rates of intact (fertile) adult females (open circles) and sterile adult females (closed circles) for each sterility treatment site in the Orongorongo Valley and Turitea. Estimates are from model including the additive effects of site and sterility [$\phi(S + St)p(S \times St \times t)$] (see text for details).

© 2005 British Ecological Society,

Table 6. The average population growth rate of yearlings on control and sterility treatment sites predicted from local recruitment only ($\lambda_i^1\gamma_{i+1}^{10}$) compared with the average population growth rate because of both local recruitment and immigration (λ_i^1)

	Orongorongo		Turitea	
	Local recruitment only	Including immigration	Local recruitment only	Including immigration
Control	0·94	1·51	0·25	1·60
50% sterility	0·39	1·63	0·13	3·11
80% sterility	0·09	1·96	0·12	1·20

with that on the control site, because of the reduction in *per capita* rates of local recruitment by sterility treatments.

This suppression of local recruitment indicates that the apparent survival rate of pouch young did not compensate for reductions in the birth rate because of sterility treatments. Hence, it is expected that the percentage suppression of local recruitment would be approximately linear with the percentage suppression of the birth rate as a result of sterility. The greater than expected suppression on 50% sterility sites, and the Turitea 50% sterility site in particular, was mainly because of the sterility rate on this site being higher than the nominal 50% over most of the study period (Fig. 1a). In addition, there were no compensatory increases in either the yearling recruitment to the adult population or the annual apparent survival rates of adults in terms of their contribution to the adult population growth rate. Hence, the only demographic response to artificial reductions in fertility has been compensatory increases in the immigration rate of yearling-aged possums, resulting in stable population trajectories ($\lambda = 1$). These results are in contrast to the studies of Twigg & Williams (1999) and Twigg *et al*. (2000) on the effect of sterility on wild rabbit populations in Australia, who found that local recruitment rates compensated for reductions in the birth rate as a result of sterility. One caveat to our conclusion, however, is that densities of possums on most sites have been relatively constant, because of the stabilizing effect of immigration. Hence, density-dependent compensation in local recruitment or adult apparent survival was unlikely to be observed.

The compensatory yearling immigration observed in this study suggests that yearling dispersers may be tuned to the local density of resident yearlings. Hence, a decision to 'settle' in a particular area may be partially based on an assessment of the number of resident yearlings, as an indication of the number of potential 'vacancies'. This makes sense for a species with high adult survival, where existing resident yearlings could rapidly fill any vacancies caused by turnover in the adult subpopulation. However, the rules governing settlement decisions by dispersing possums remain speculative (Efford 1996; Efford 1998). However, if true, this mechanism governing settlement by dispersing yearlings could have direct implications for the operational success of fertility control, as spatial variation in fecundity (i.e. spatial variation in the proportion sterilized) is likely to be inversely related to the settlement patterns of dispersing yearling possums that will limit the overall effectiveness of fertility control. Spatial variation in the proportion sterilized is likely where vectored immunocontraception is used (Barlow 1994) and there is spatial aggregation of the vector. Likewise, fertility control applied at too small a spatial scale would be nullified by immigration.

Comparisons of the survival rates of fertile and sterile females suggested that sterile females had higher survival rates. Such a finding is expected if there are significant costs to reproduction, and is similar to the results observed for the effect of sterility on female rabbit survival (Twigg *et al*. 2000). Theoretical studies of fertility control have explored the potential for changes in a population's vital rates to compensate for reductions in the birth rate (Bomford 1990; Caughley, Pech & Grice 1992; Barlow, Kean & Briggs 1997; Sinclair 1997; Hobbs, Bowden & Baker 2000; Hood, Chesson & Pech 2000; Davis & Pech 2002). Generic stage-structured modelling undertaken by Davis & Pech (2002) suggested the overall response of populations to fertility control was critically dependent on the role of sterilized females in density-dependent processes. If sterile females are not involved in any density-dependent process then they accumulate in the population without (negatively) influencing the population growth rate. Such a scenario can lead to fertility control, resulting in higher populations than uncontrolled populations (Davis & Pech 2002). However, such a scenario is unlikely for brushtail possums as the existing evidence suggests possums are regulated primarily by extrinsic rather than intrinsic mechanisms (i.e. competition for food resources) (Thomas *et al*. 1993; Ramsey *et al*. 2002). Thus, sterile females are expected to play a role in any exploitative competition for food and therefore should contribute to any density-dependent response.

Presently, there are no data on the probable magnitude of compensatory responses to fertility control in brushtail possums at reduced population density. As the most likely scenario for practical application of fertility control is following an initial population reduction using conventional control (Cowan 1996; Bayliss & Choquenot 1999), additional studies will need to be undertaken to determine the operational nature and magnitude of any density-dependent compensatory responses. This will be necessary so that the potential of fertility control for inhibiting population recovery

© 2005 British Ecological Society,

can be predicted. Future studies will need to reduce population density experimentally on sites with imposed sterility to determine the effect of reduced density on both recruitment and mortality, and attempt to determine the strength and nature of any compensatory responses.

In summary, the results to date suggest sterility rates of 50% or greater can result in at least a 50% reduction in *per capita* recruitment when populations are close to carrying capacity (K). However, moderate levels of immigration can ameliorate this reduction. It is not known to what extent density-dependent compensation in recruitment rates will impair the effectiveness of fertility control. The high contribution of adult survival to the annual population growth rate of adults, and the higher survivorship of sterile females compared with fertile females, suggests the benefits of fertility control would be enhanced if integrated with conventional control to provide rapid initial population reduction. However, population models will need data on the nature and strength of compensatory responses at reduced density to improve predictions on the rate of recovery of possum populations following application of integrated conventional and fertility control strategies.

Acknowledgements

This study could not have been undertaken without the co-operation of many people. In particular, thanks are due to Warwick Baldwin, Scott Akin-Sellars, Kathryn Knightbridge, Amelia Pascoe, Dave Hurst, Grant Smith, Ruth Fleeson and Aaron Miller for help with the implementation and running of the possum mark–recapture fieldwork. Thanks also to Terry Fletcher for assistance with possum sterilizations and to Greg Arnold for statistical advice. Many thanks to Murray Efford for access to the long-term possum population data used for the Orongorongo control site and for much helpful advice on mark–recapture analysis. Many thanks also to Phil Cowan who provided thoughtful advice, suggestions and support at various times. Peter Caley and Tony Arthur made helpful suggestions and comments on a draft manuscript, which was edited by Anne Austin. This work was funded by the New Zealand Government through the Ministry of Agriculture and Forestry, Policy division.

BioOne (www.bioone.org) is a nonprofit, online aggregation of core research in the biological, ecological, and environmental sciences. BioOne provides a sustainable online platform for over 170 journals and books published by nonprofit societies, associations, museums, institutions, and presses.

Your use of this PDF, the BioOne Web site, and all posted and associated content indicates your acceptance of BioOne's Terms of Use, available at www.bioone.org/page/terms_of_use.

Usage of BioOne content is strictly limited to personal, educational, and non-commercial use. Commercial inquiries or rights and permissions requests should be directed to the individual publisher as copyright holder.

BioOne sees sustainable scholarly publishing as an inherently collaborative enterprise connecting authors, nonprofit publishers, academic institutions, research libraries, and research funders in the common goal of maximizing access to critical research.

Research Article

Effects of Fertility Control on Behavior and Disease Transmission in Brushtail Possums

DAVE RAMSEY,[1] *Landcare Research, Private Bag 11052, Palmerston North, 4442, New Zealand*

ABSTRACT Fertility control is currently under development for the control of brushtail possums (*Trichosurus vulpecula*), one of New Zealand's most serious vertebrate pests. Despite intensive research into various methods for achieving infertility, including immunocontraception and disrupting endocrine control of reproduction, researchers know little about the potential effects of these methods on the behavior of wild possums. We assessed the effects of surgically imposed sterility, either to block fertilization (tubal ligation) or to disrupt endocrine control of fertility (gonadectomy), by using radiotelemetry on the movement patterns and site fidelity of wild brushtail possums. In addition, we assessed the effect of gonadectomy on the transmission rate of a commonly occurring, directly transmitted pathogen in possums, *Leptospira interrogans* serovar *balcanica* (hereafter *L. balcanica*), to determine the effect of any behavioral changes on possum contact rates. Both tubal ligation and gonadectomy of females did not appear to have any appreciable effect on behavior, with sterilized females having space-use patterns and fidelity to seasonal breeding ranges similar to those of fertile females. However, gonadectomy of male possums resulted in a significant reduction of 42% and 47% in the 95% and 70% isopleth seasonal breeding ranges, respectively. Furthermore, the transmission rate of *L. balcanica* in gonadectomized male and female possums was reduced by 88% and 63%, respectively, compared with that in fertile male and female possums. Overall, these results suggest that fertility control, either by blocking fertilization (e.g., immunocontraception) or by disrupting endocrine control of reproduction (e.g., gonadotropin-releasing hormone vaccines), is unlikely to have an impact on social organization and behavior of brushtail possums in ways that may compromise the efficacy of fertility control for reducing population density. However, the reduction in the transmission rate of *L. balcanica* indicates that fertility control that interferes with endocrine control of reproduction is likely to reduce the contact rate between possums. This could have implications for the control of other wildlife diseases requiring direct contact for transmission. (JOURNAL OF WILDLIFE MANAGEMENT 71(1):109–116; 2007)

DOI: 10.2193.2005-699

KEY WORDS disease transmission, fertility control, home range, *Leptospira interrogans* serovar *balcanica,* leptospirosis, *Trichosurus vulpecula*.

Brushtail possums (*Trichosurus vulpecula*) are a serious vertebrate pest in New Zealand, and research into methods of fertility control of brushtail possums was initiated to develop techniques for environmentally acceptable, humane, and cost-effective population control (Cowan 1996, Roger 1997). Current research has focused on developing immunological blocks to fertilization by immunizing possums against proteins specific to the zona pellucida or sperm (i.e., immunocontraception; Roger 1997, Cowan 2000) or by interfering with central endocrine control of reproduction, such as immunization against gonadotropin-releasing hormone (GnRH) or using GnRH-toxin conjugates that disrupt pituitary gonadotropes (Herbert and Trigg 2005). Recent work has documented the effect of induced sterility on the population dynamics of brushtail possums (Ramsey 2005), but an important issue remains about the potential effects of fertility control on possum behavior. Methods of fertility control that interfere with endocrine control of reproduction may have adverse behavioral repercussions, such as effects on dominance hierarchies that may lead to higher fertility rates in subordinate individuals (Caughley et al. 1992). In contrast, methods of fertility control that block fertilization, such as immunocontraception, should leave the individual hormonally intact and should not significantly interfere with any established social structure.

Brushtail possums are essentially solitary and spend less than 1% of their time directly interacting, except during the breeding season (Day et al. 2000). In New Zealand populations, possums have widely overlapping ranges and do not appear to defend a territory, but at low density they may have an exclusive area that is defended (Day et al. 2000). Male possums generally have a larger range size than females, and male ranges are larger in summer and autumn during the breeding season than in other months, apparently to maximize their access to reproductive females (Cowan and Clout 2000, Ramsey et al. 2002). Although no studies have directly examined the effects of fertility control on the social organization of wild possums, disruption of sex steroid hormone levels in dominant male and female possums in captive populations did not appear to alter the existing dominance status of individuals (Jolly and Spurr 1996, Jolly et al. 1996). However, if the larger range size in male possums is dictated largely by the need to gain access to reproductive females, then it is predicted that hormonally compromised male possums should have a reduced range size compared with that of intact males.

The indirect effects of fertility control on behavior in wild populations have received some attention; the transmission rate of a common, directly transmitted pathogen of possums, *Leptospira interrogans* serovar *balcanica* (hereafter *L. balcanica*), increased by 28% in populations in which approximately 80% of adult females were surgically sterilized by tubal ligation compared with untreated populations. Although the overall effect was statistically weak ($P = 0.16$), the observed increase in the transmission rate was hypothesized to be due to sterile but hormonally intact females having a higher contact rate due to an increased frequency of estrous cycles during the breeding season

[1] *E-mail: ramseyd@landcareresearch.co.nz*

(Caley and Ramsey 2001). An increase in estrous activity due to tubal ligation has been demonstrated in both wild (Ji et al. 2000) and captive individuals (Rekha 1997). Caley and Ramsey (2001) also postulated that methods of fertility control that disrupt endocrine control of reproduction could have the reverse effect, with a reduction in the transmission rate of directly transmitted pathogens due to a decrease in the contact rate associated with mating.

We assessed the effects of both disrupting endocrine control of fertility (gonadectomy of M and F) and blocking fertilization (tubal ligation of females) on patterns of space use and site fidelity. In addition, we assessed the effect of disrupting endocrine control of fertility on contact rates between possums by comparing the transmission rate of *L. balcanica* between gonadectomized and intact possums.

STUDY AREA

We conducted the study on a population inhabiting a remnant patch of native forest on farmland near Porewa, Manawatu, New Zealand (40°01′N, 175°29′E). The site encompassed 3 closely spaced patches of native forest totaling about 14 ha, was surrounded by dairy pasture, and contained a population of approximately 100 possums. The forest canopy was dominated by tawa (*Beilschmiedia tawa*) and northern rata (*Metrosideros robusta*) as emergents, with mahoe (*Melicytus ramiflorus*), titoki (*Alectryon excelsus*), and kaikomako (*Pennantia corymbosa*) as subdominants. The understory was dominated by *Coprosma areolata* and ongaonga (*Urtica ferox*), with a sparse ground layer of ferns (predominantly *Blechnum* spp.), grasses, and forbs. Cattle periodically grazed in the forest.

METHODS

We placed 60 cage traps on the ground throughout the forest on a grid at 30-m spacing and we trapped for 4 consecutive nights, 3 times per year, in January, June, and September from September 1996 until January 2000. Thereafter, trapping occurred bimonthly until August 2001. We anaesthetized all captured possums with ether and gave each a unique tattoo and ear tag for identification. Capture rates of possums were high (60–80% over a 4-night session), ensuring that we recaptured individuals relatively frequently. We judged maturity in females from the presence of a fully formed pouch and evidence of past or existing lactation, and in males from the presence of testes >13 mm in diameter. We scored age from tooth wear following Cowan and White (1989).

Sterility Treatments

We artificially imposed 2 alternative methods of fertility control on individual possums to determine their potential effects on behavior. The first method was surgical ligation of female oviducts as a model for methods of fertility control that would potentially not interfere with hormonal regulation of fertility (e.g., immunocontraception targeting the zona pellucida). The second method was surgical removal of the gonads in both male (testes) and female possums (ovaries) as a model for methods of fertility control that block endocrine control of reproduction (e.g., immunization against GnRH).

We transported possums selected for sterilization to the laboratory in burlap sacks, where we performed surgery under aseptic conditions. We gonadectomized males transscrotally and we performed ovariectomy or tubal ligation in females through ventral midline incision. We did not perform any sham operations on control animals, as previous research in possums has shown that similar surgical procedures had no detectable effect on either possum body condition (Ji et al. 2000) or survival (Ramsey 2005). We placed possums in sacks in a quiet, warm room overnight to recover before being released at their point of capture. There was no evidence, based on trapping records postsurgery, that we displaced treated possums from their previous range. We performed all surgical procedures with approval from Landcare Research's Animal Ethics Committee (AEC No. 00/5/3).

Effect of Fertility Control on Seasonal Breeding Ranges and Movements

We examined the effects of fertility control treatments on the seasonal breeding range and movements of possums using radiotelemetry. Between January 1997 and January 2001, we fitted possums with radiocollars (Sirtrack Ltd., Havelock North, New Zealand) and tracked their movements from 2 fixed stations using twin-element Yagi null-peak antennas operated manually. We determined locations by triangulation of the bearings obtained from each station. Operators maintained radio contact, ensuring that we obtained bearings for each animal nearly simultaneously. We located possums 6 times per night over a 6-hour period beginning from sunset for 2 nights per week during the main breeding period (e.g., between Mar and May). The nightly schedule covered the period of greatest activity by possums (Ward 1978, Efford et al. 2000). We applied surgical sterilization to a random selection of male and female possums in January each year from 1998 to 2001.

We estimated the accuracy (bias and precision) of the radiotelemetry system by triangulating locations of radiocollars placed at known locations within the forest. During January 1997, we estimated the locations of a sample of trap sites in the forest using a differential Global Positioning System (GPS) using a mobile receiver unit placed on a 10-m pole to gain access above the canopy. We estimated locations recorded with this GPS system to within ±1 m. Those trap sites that could not have their location estimated using GPS (due to canopy ht and cover) had their location estimated using distance and bearing measurements taken from the nearest known trap location (i.e., within 30–60 m). During May, July, August, and December 1997, we estimated between 28 and 56 trap site locations within the forest by triangulation by placing radiocollars near ground level (<30 cm above ground), with operators asked to obtain bearings simultaneously. Operators had no knowledge about the whereabouts of each collar, only that it was somewhere in the forest. We estimated the bias of each receiving station by obtaining the mean difference between the estimated

bearing and true bearing for each known location, with precision given by the standard deviation of the bearing errors. We obtained an additional estimate of telemetry error by calculating the mean linear distance between the estimated and true locations. The mean linear distance between estimated and true locations is regarded as the best estimate of telemetry error as it takes into account both angular error and distance between the receiving stations and the transmitter (Zimmerman and Powell 1995).

We analyzed the distribution of the difference between estimated and true bearings between each receiving station and known locations for normality. Quantile plots revealed significant deviation from a normal distribution due to the presence of a few outlying values in both bearing errors and linear distances. Therefore, summary statistics used the median and median absolute deviation (MAD) to describe the location and scale of these distributions. We then used the average of the bearing error scale estimates to calculate error polygons for each location estimate (White and Garrott 1990).

We estimated seasonal breeding ranges for individual possums using a fixed bivariate normal kernel density surface (Worton 1989) estimated on a 10-m grid. Kernel density surfaces using fixed bandwidths are considered the most reliable method for estimating range size from radiotelemetry data (Powell 2000, Hemson et al. 2005). We estimated the bandwidth of the Gaussian kernel separately in the X (easting) and Y (northing) directions using the direct plug-in method (Sheather and Jones 1991, Wand and Jones 1995). This method of selecting the bandwidth from data is considered more optimal than older methods such as least-squares cross validation (LSCV; Wand and Jones 1995). In addition, recent studies have cast doubt on the reliability of LSCV for estimating the bandwidth from radiotelemetry data (Hemson et al. 2005). Once we fitted a density surface, we calculated the home range as the area that encompassed 95% of the probability density surface using bilinear interpolation. In addition, we calculated a core area as the area that encompassed 70% of the probability density surface. We considered core area ranges a more stable estimate of range size as a greater number of observations are used to fit the contour (i.e., the contour is less influenced by 1 or 2 extreme locations). We calculated all home range estimation procedures using the R statistical package (R Development Core Team 2005) using the KernSmooth package.

Disease Transmission

Leptospira balcanica (Kmety and Dikken 1993) is a commonly occurring pathogen in possums that is spread largely by possum-to-possum contact during affiliative or sexual interactions (Day et al. 1997*b*, 2000). Clinical disease due to *L. balcanica* infection in possums is rare (Day et al. 1997*a*) and point prevalence of the disease in wild populations is high, between 40% and 70% (Caley and Ramsey 2001). *Leptospira balcanica* appears to be transmitted primarily through sexual contact, and it was considered to be a useful model for determining the effect of fertility control on disease transmission.

From January 2000, we trapped at bimonthly intervals until August 2001. At each bimonthly trapping occasion, captured possums had approximately 5 ml of blood drawn from a tail vein. We determined the presence of *L. balcanica* infection in each sample using a serological microagglutination test (MAT), using doubling dilutions of serum beginning at 1:50, to determine the presence of leptospiral antigens (Horner et al. 1996). If we saw no reaction in the 1:50 dilution, we scored the result as negative (e.g., Caley and Ramsey 2001). Between January and September 2000, we surgically removed the gonads of a random sample of adult possums that were sero-negative for *L. balcanica*. A random sample of non-treated adult possums, also sero-negative for *L. balcanica,* served as controls.

Analysis

Seasonal breeding ranges and movements.—The number of years (breeding seasons) that we tracked a particular possum varied among individuals, as some individuals provided range estimates as both control and treatment individuals in consecutive years, while others provided home range estimates as just control or treatment in a single year. However, range estimates for individuals in multiple years were likely to be serially correlated. To account for this nonindependence of observations, we analyzed range estimates using linear mixed-effect models (Pinheiro et al. 2005). We fitted possum identification number as a random effect with the added effects of year and sterility treatment fitted as fixed effects. We modeled serial correlation among range estimates for individual possums by assuming the correlation structure followed a first-order autoregressive process. Models, fitted separately for males and females, included the fixed effects sterility treatment and year and their interaction. We assessed the significance of terms in the model using F-ratio tests calculated using marginal sums of squares. We natural log–transformed all estimates of range size before analysis to stabilize the variance.

As a further test of the effect of sterility treatment on seasonal breeding range size, we selected possums that had both pre- and posttreatment range estimates in consecutive years. We used paired t-tests to test for differences in range size pre- and posttreatment for each sex. We performed similar paired t-tests on possum range size in consecutive years for possums that did not receive a sterilization treatment. In addition to changes in range size, we compared the distance between centers of activity, defined as the point of highest probability density, derived from the kernel density surface, pre- and posttreatment to determine the extent of range fidelity between years among both intact and sterility-treatment individuals.

Transmission of L. balcanica.—The statistic of interest was the force of infection or instantaneous incidence, defined as the per capita rate that susceptible individuals become infected (McCallum et al. 2001). We obtained estimates of the force of infection (λ) by fitting exponential (constant force of infection) models to the disease incidence

data or failure times, recorded in discrete 2-month intervals, using maximum likelihood. We defined the failure time as the interval between the possum entering the study and the time of infection or censoring. We used right censoring to indicate the possum was either lost to follow-up (disappeared) or survived (and was seen) at the end of the study without record of infection. Hence, a right-censored time indicated that a possum was at risk of infection between entering the study and the time of censoring. For *L. balcanica*, we recorded a positive MAT for a possum at any point following its entry in the study as an infection event. We compared estimates of the force of infection between sterility treatments (gonadectomy/intact) and sex. We fitted main effects and the 2-way interaction sequentially and estimated their statistical significance by analysis of deviance (Collett 1991). We estimated mean times to infection events using the Kaplan–Meier product-limit estimator. We undertook all statistical analyses in R (R Development Core Team 2005).

RESULTS

The median difference between estimated and true bearings revealed that bearing errors were approximately unbiased for receiving station A (mean angular error of +0.2°). However, estimates for receiving station B revealed a negative bias of approximately 4° during the May, July, and August samples, indicating the presence of a misaligned compass rose. We corrected this, and the estimates we obtained during the December sample were approximately unbiased (mean angular error of +1.4°). We adjusted all bearings from the B receiving station taken during the 1997 breeding season by +3.9° to remove this bias.

Estimates of the median linear distance between estimated and true locations revealed that the effect of bearing errors was highest during the May, July, and August samples when the bias in the B receiving station was present (mean linear error of 44 m) and lowest in the December sample, following the correction of the bias (mean linear error of 28 m). Hence, following correction we expected that the median linear error would be in the order of 30 m. The mean of the MAD estimates of scale for receiving stations A and B were 2.3° and 2.1°, respectively. Therefore, we used 2.2° as the estimate of bearing precision to calculate error polygons for each location. We used only locations with error polygons <2 ha in area in further analyses.

Effect of Fertility Control on Seasonal Breeding Ranges and Movements

The numbers of possums in each treatment group in each year varied throughout the study (Table 1). For males, there were 81 estimates of seasonal breeding range size for 41 individual radiocollared possums, whereas for females there were 74 estimates of seasonal breeding range size for 41 individually collared females. The number of locations having error polygons ≤2 ha in area, used to calculate each seasonal range, ranged from a minimum of 15 to a maximum of 153, with the average number of locations per range being 73. The average size of the error polygons for this reduced data set was 0.5 ha.

Table 1. Numbers of radiocollared brushtail possums in each treatment group present in each year of the study, between 1997 and 2001 at Porewa, Manawatu, New Zealand.

		Yr				
Sex	**Group[a]**	**1997**	**1998**	**1999**	**2000**	**2001**
F	Intact	12	5	7	11	2
	Tubal	0	7	4	0	0
	Ovx	0	0	4	5	8
M	Intact	16	21	7	13	3
	Castrate	0	0	4	5	8

[a] Intact = non-treated possums, tubal = female possums sterilized by ligation of the oviducts, ovx = females sterilized by surgical removal of the ovaries, castrate = males sterilized by surgical removal of the testes.

The linear mixed modeling undertaken for both males and females indicated no significant interaction between year and sterility treatment for both 95% and 70% isopleth ranges (likelihood ratio tests $P > 0.29$). Therefore, we removed the interaction term from these models. For males, *F*-statistics calculated using marginal sums of squares indicated no significant effect due to year (95% isopleth: $F_{1,38} = 1.83$, $P = 0.18$; 70% isopleth: $F_{1,38} = 2.62$, $P = 0.11$) and a marginal level of significance for sterility treatment (95% isopleth: $F_{1,38} = 3.14$, $P = 0.08$; 70% isopleth: $F_{1,38} = 2.94$, $P = 0.09$; Figure 1). However, 2 outlying observations had a large influence on this result (1 intact M and 1 gonadectomized M; Fig. 1), and when removed, the effect of sterility treatment was highly significant (95% isopleth: $F_{1,36} = 6.88$, $P = 0.01$; 70% isopleth: $F_{1,36} = 7.09$, $P = 0.01$). For females, the equivalent *F*-statistics indicated no significant effect due to year (95% isopleth: $F_{1,30} = 2.1$, $P = 0.16$; 70% isopleth: $F_{1,30} = 0.34$, $P = 0.56$) or sterility treatments (95% isopleth: $F_{2,30} = 1.36$, $P = 0.27$; 70% isopleth: $F_{2,30} = 1.66$, $P = 0.21$) on seasonal breeding range size (Fig. 2). Removal of 2 outlying observations (1 intact F and 1 ovariectomized F; Fig. 2) made no difference to this analysis (sterility treatment effect: 95% isopleth: $P = 0.27$; 70% isopleth: $P = 0.21$).

We further tested the effect of sterility treatment using the subset of possums that had both pre- and posttreatment seasonal breeding range estimates in consecutive years. Paired *t*-tests indicated that males that were gonadectomized had a significant reduction in both their 95% and 70% isopleth ranges in the year following their treatment application, with a mean reduction in range size of 42% in the 95% isopleth ($t = 2.5$, df = 6, $P = 0.04$) and a 47% reduction in the 70% isopleth ($t = 3.1$, df = 6, $P = 0.02$). This compares with the sample of intact males, whose range size did not significantly change in the following year when we applied no treatment, with a 10% reduction recorded in the 95% isopleth ($t = 0.51$, df = 8, $P = 0.62$) and an 18% reduction in the 70% isopleth ($t = 1.05$, df = 8, $P = 0.32$). Comparisons of distance between centers of activity indicated that intact males had a mean shift in their centers of activity of 53 m between years. This compares with a

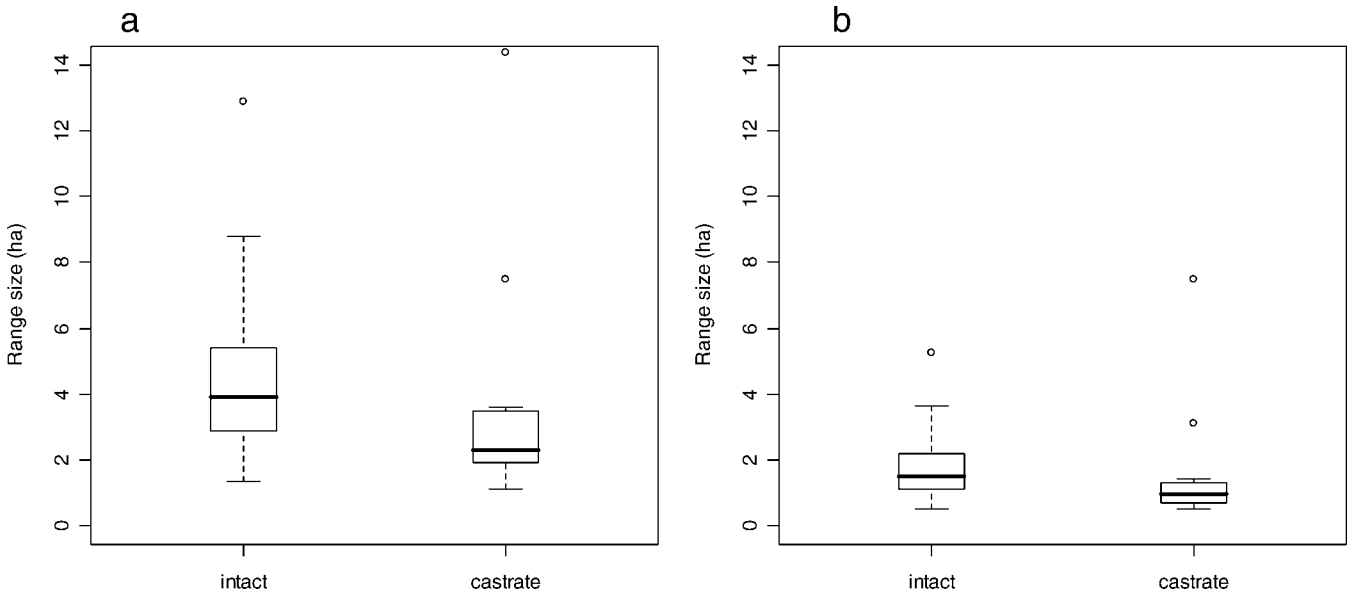

Figure 1. Box and whisker plots of the (a) 95% isopleth and (b) 70% isopleth seasonal breeding range size of intact and castrated male brushtail possums between 1997 and 2001 at Porewa, Manawatu, New Zealand. The length of the box represents the inter-quartile range; the thick horizontal line represents the median, and the whiskers reach to the most extreme data points within 1.5× the inter-quartile range from ends of the box. Circles represent data points outside this range (outliers).

mean range shift of 63 m for castrated males. These were not significantly different ($t = 0.54$, df = 13.5, $P = 0.6$ using Welch's approximation).

For females, paired *t*-tests indicated that females that were ovariectomized had a significant reduction in their 95%, but not in their 70% isopleth range size in the year following the application of the sterility treatment, with a mean reduction of 53% in the 95% isopleth ($t = 2.6$, df = 5, $P = 0.05$) and 44% in the 70% isopleth ($t = 1.8$, df = 5, $P = 0.13$). However, analysis of a similar sample of untreated females indicated that their range size also reduced in the same consecutive years with a mean reduction of 56% in the 95% isopleth ($t = 2.5$, df = 3, $P = 0.09$) and 55% in the 70% isopleth ($t = 2.2$, df = 3, $P = 0.11$), casting doubt about whether there was a true treatment effect. We did not conduct similar analysis on females that were given tubal ligations as there were insufficient numbers of non-treated female possums tracked in the same consecutive years for valid comparisons. Comparison of distance between centers of activity indicated that intact females had a mean shift in their centers of activity of 47 m between years. This compares with a mean range shift of 41 m for ovariectom-

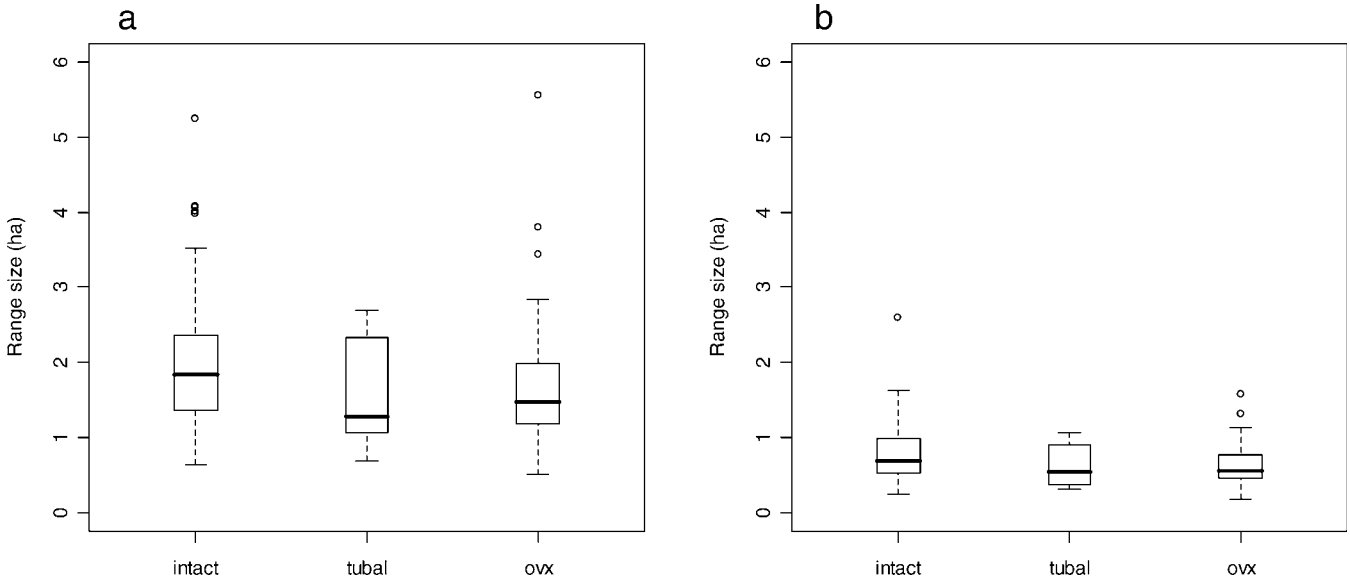

Figure 2. Box and whisker plots of the (a) 95% isopleth and (b) 70% isopleth seasonal breeding range size of intact female, tubally ligated female (tubal), and ovariectomized female (ovx) brushtail possums between 1997 and 2001 at Porewa, Manawatu, New Zealand. The length of the box represents the inter-quartile range; the thick horizontal line represents the median, and the whiskers reach to the most extreme data points within 1.5× the inter-quartile range from ends of the box. Circles represent data points outside this range (outliers).

ized females. As for males, these were not significantly different ($t = 0.21$, df = 8.3, $P = 0.84$ using Welch's approximation).

Disease Transmission

We randomly selected 26 possums to receive gonadectomies (12 M and 14 F) and 33 sexually intact possums served as controls (17 M and 16 F). Of the gonadectomized possums, 3 had sero-converted by the end of the study (2 M and 1 F). This compares with 10 control possums that had sero-converted over the same period (5 M and 5 F). The mean times to infection were 13.2 months (SE = 1.18) for intact possums and 18.7 months (SE = 0.72) for sterilized possums. Comparisons of the force of infection estimates between treatments and sex revealed that only the effect of treatment was significant ($P = 0.01$; Fig. 3). The estimated force of infection in gonadectomized possums was reduced by 88% in males and by 63% in females, compared with that in intact control possums.

DISCUSSION

Results from this study suggest that methods of fertility control that interfere with endocrine control of reproduction may significantly alter the behavior of brushtail possums. Although there is no convincing evidence of a direct effect of tubal ligation or ovariectomy on the behavior of females, castration of males significantly reduced their seasonal breeding range size compared with that of intact males in terms of their space-use patterns or range fidelity. Previous research has investigated the effect of surgical sterilization (tubal ligation) and hormonal sterilization of rats (*Rattus argentiventer*) on home range size and fidelity (Jacob et al. 2004). In contrast to this study, female rats receiving tubal ligations had significantly larger ranges than either hormonally sterilized or fertile rats. Studies in territorial species, such as foxes, have shown that surgically sterilized (but hormonally competent) females maintained similar-sized territories as intact females (Saunders et al. 2002). In pen trials, sterilized females did not appear to lose their dominance following sterilization (Newsome 1995). However, the effect of sterilization by endocrine disruption on the behavior of wild foxes is unknown.

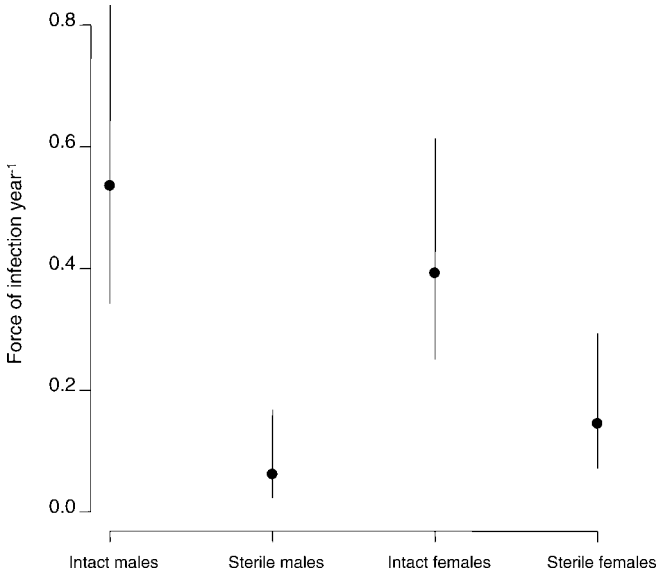

Figure 3. Estimates of the force of infection (λ ± SE) of *Leptospira interrogans* serovar *balcanica* for intact and sterilized (by gonadectomy) male and female brushtail possums between 2000 and 2001 at Porewa, Manawatu, New Zealand.

One potential negative outcome of sterilization by endocrine disruption of fertility of females in wild populations is that animals will lose their status and be forced to vacate their current territory. This could lead to compensatory immigration of fertile females into the area previously occupied by sterilized females, potentially negating the effect of fertility control (Jacob et al. 2004). Studies in captive possum populations have indicated that ovariectomy of the dominant female did not change her dominance status (Jolly and Spurr 1996, Jolly et al. 1996). In the present study, both 95% and 70% isopleth seasonal breeding ranges of ovariectomized females were similar to both intact and tubally ligated females. In addition, ovariectomized females were no more likely to shift their ranges than intact females. This suggests that female possums in wild populations that are sterilized by endocrine disruption of fertility would not lose their dominance status and hence are likely to maintain the same fidelity to their ranges following sterilization as fertile females.

In addition, gonadectomy of both males and females significantly reduced the incidence of *L. balcanica* infection compared with that in intact possums. These results support the hypothesis of Caley and Ramsey (2001), who suggested that methods of fertility control that interfere with hormonal control of reproduction would result in a reduction in the horizontal transmission rate of directly transmitted pathogens, due to a reduction in the contact rate. A study of contacts between male and female brushtail possums in the wild using proximity data loggers revealed that contacts were primarily sexual in nature, occurring more frequently in the breeding season with individual females interacting with up to 4 males (Ji et al. 2005). In addition, a study by Ramsey et al. (2002) found that male, but not female, home range size increased during the breeding season when population density was artificially reduced. The result of this range enlargement was that the male contact rate with females did not reduce in proportion to the reduction in density. This suggested that males were attempting to maintain their contact rate with females following the density reduction (Ramsey et al. 2002). Hence, the reduction in the transmission rate of *L. balcanica* in gonadectomized possums observed in this study was probably due primarily to a reduction in the contact rate associated with mating. Numerous studies have illustrated the effects of male castration on reduction in sexual behavior (Larsson 1978, McGill 1978, Lisk and Heimann 1980, Knol and Egberlink-Alink 1989*b*). In general, castration is followed by a decline or absence in copulatory behavior, declines in agonistic interactions with other males, as well as reductions in movements or roaming behavior (Knol and

Egberlink-Alink 1989*a*,*b*). For males, the reduction in the range size of castrated males would result in a reduction in the number and the extent of overlap with female ranges, reducing their contact rate. In addition, agonistic interactions with other males would also be reduced. For females, we assume that ovariectomized female possums would not be undergoing estrous behavior (Rekha 1997) and would not be sexually receptive. All non-primate mammals studied (with the exception of the rabbit) copulate only when the ovaries are present and undergoing follicle maturation (Lisk 1978). This suggests that the lower transmission rate of *L. balcanica* observed in ovariectomized female possums is driven largely by a significant reduction in their rate of contact with breeding males, without needing to invoke any changes in their movement patterns.

MANAGEMENT IMPLICATIONS

Overall, these results suggest that fertility control, either by immunocontraception or disruption of endocrine control of reproduction, are unlikely to have an impact on social organization and behavior of brushtail possums in ways that may compromise the efficacy of fertility control for reducing population density. Indeed, the results from this study suggest that disrupting endocrine control of reproduction is likely to have an additional benefit of reducing the transmission rate of directly transmitted pathogens. This finding may have important implications for the use of fertility control for other wildlife diseases, providing an additional benefit over and above that achieved through reductions in population density by also reducing contact rates between individuals.

ACKNOWLEDGMENTS

I thank K. Knightbridge, W. Baldwin, S. Akins-Sellars, G. Smith, A. Pascoe, A. Miller, and R. Fleeson for providing assistance with the trapping and radiotracking. G. Arnold provided statistical advice, D. Tompkins and 4 anonymous reviewers provided valuable feedback on a draft, and A. Austin assisted with editing. The New Zealand Ministry of Agriculture and Fisheries and the Cooperative Research Centre for Conservation and Management of Marsupials funded this work.

Quantifying Equid Behavior—A Research Ethogram for Free-Roaming Feral Horses

By Jason I. Ransom and Brian S. Cade

Introduction

Feral horses (*Equus caballus*) are globally distributed in free-roaming populations on all continents except Antarctica and occupy a wide range of habitats including forest, grassland, desert, and montane environments. The largest populations occur in Australia and North America and have been the subject of scientific study for decades, yet guidelines and ethograms for feral horse behavioral research are largely absent in the scientific literature. The U.S. Geological Survey (USGS) Fort Collins Science Center conducted research on the influences of the immunocontraceptive porcine zona pellucida (PZP) on feral horse behavior from 2003–2006 in three discrete populations in the American west (see Ransom and others, 2007; Ransom, 2009). These populations were the Little Book Cliffs Wild Horse Range in Colorado, McCullough Peaks Herd Management Area in Wyoming, and Pryor Mountain Wild Horse Range in Montana; the research effort included over 1,800 hours of behavioral observations of 317 adult free-roaming feral horses. The following ethogram was developed during the course of this study to facilitate accurate scientific data collection on feral horse behavior, which is often challenging to quantify. By developing this set of discrete behavioral definitions and a set of strict research protocols, scientists were better able to address both applied questions, such as behavioral changes related to fertility control, and theoretical questions, such as understanding social networks and dominance hierarchies within social groups of equids.

Background

Feral horses in North America are descendents of animals that escaped domesticity or were intentionally released by settlers, explorers, and military personnel, and because of their highly adaptive nature were able to thrive in a multitude of environments. In the United States most feral horses are federally protected by the Wild Free-Roaming Horses and Burros Act of 1971, which refers to them as "living symbols of the historic and pioneer spirit of the West," stating that "they contribute to the diversity of life forms within the Nation and enrich the lives of the American people" (Public Law 92-195, 85 Stat. 649, as amended). Roughly 30,000 feral horses are distributed across 10 western States in the United States on 21.4 million ha of federally designated horse range. With annual population growth rates reported at 15–25 percent (Eberhardt and others, 1982; Wolfe and others, 1989; Garrott and Taylor, 1990; Garrott and others, 1991) and very limited natural depredation, the influence of feral horses on native flora, fauna, and ecosystem processes varies greatly (see Smith, 1986; Fahnestock and Detling, 1999; Coughenour, 2002; Levin and others, 2002; Beever and Herrick, 2006; Beever and others, 2008). Understanding animal behavior can be an important tool in addressing a species' influences and roles in an ecosystem and can lead to better management and conservation practices (Sutherland, 1998; Buchholz, 2007). Additionally, when management practices such as fertility control alter natural biological processes, it is important to consider the ethical implications, such as influences on animal behavior and social structure (Nettles, 1997; Asa and others, 2005; Porton, 2005).

Social Organization

Feral horses arrange themselves in family groups known as bands, which range in size from 2 to 20 or more animals. Band size is variable and may be a response to both the environment the horses inhabit and population density. Animals can reduce risk of predation by living in groups (Pusey and Packer, 1997), and in open habitats without cover in which to hide, animals may form larger groups (Molvar and Bower, 1994). The latter was found to be true in the USGS study,

where mean band size in the sage steppe habitat found at McCullough Peaks was 8.01 ± 0.38 (SE) horses, while habitats with trees and dense vegetation had smaller mean band sizes—4.45 ± 0.16 horses at Little Book Cliffs and 4.16 ± 0.17 horses at Pryor Mountain.

Feral horse bands typically consist of a single polygynous stallion, adult females, foals of the year, and yearling males and females. Bands with multiple stallions do occur and were first reported by Denniston (1979) and Miller (1979). Miller (1979) found that multiple stallions were present only in bands consisting of greater than 9.3 horses. This finding was supported by the USGS study, during which multiple-stallion bands were recorded only at McCullough Peaks; multiple stallions occurred in five bands of horses consisting of 9–18 animals each. At 2 years of age, subordinate males typically disperse the band into bachelor groups of two to several horses, but occasionally 2- and 3-year-old males remain with the band if the stallion does not drive them away. Rutberg and Keiper (1993) found that the age at which male horse dispersal occurs is strongly correlated with the number of peers in the natal group.

Feral horse bands are not geographically territorial and home ranges overlap with those of other bands in the population. This geographically non-territorial, harem-type social structure is known as Type I organization and also is used by the Przewalski horse (*Equus ferus przewalskii*), Plains zebra (*Equus burchellii*), and Mountain zebra (*Equus zebra*) (Klingel, 1975; Rubenstein, 1989). The other organizational structure found in equids, Type II organization, involves adult males establishing geographic territories and females moving between them. Type II organization is used by the Grevy's zebra (*Equus grevyi*), African wild ass (*Equus africanus*), and Asiatic wild ass (*Equus hemionus*). While feral horses do not exhibit geographic territoriality, the USGS study did document resource-oriented territoriality whereby stallions (with the entire band present) defended mineral sources repeatedly and often with elevated agonistic interactions when other bands approached.

Ethological organization within horse bands is characterized by a dominance hierarchy, but the literature has conflicting functional explanations for hierarchical structures in equids. Houpt and others (1978) found that body weight affected social rank but age did not; however, other researchers (Keiper and Sambraus, 1986; Rho and others, 2004; Heitor and others, 2006) found age to be linearly correlated with social rank. Reproductive status of females has been shown to influence their social dominance in a band, as well as their rate of interchange between bands (van Dierendonck and others, 2004). Most studies, however, indicate that agonism is strongly correlated with dominance rank among females (Houpt and others, 1978; Waring, 1983; Keiper and Receveur, 1992; Weeks and others, 2000). The USGS study found that the most dominant members of feral horse bands were female, and stallion rank varied by band. This ethological structure is reported in much of the existing literature (Houpt and Keiper, 1982; McCort, 1984; Keiper and Sambraus, 1986; Klimov, 1988; and Keiper and Receveur, 1992). Lack of stallion dominance has been attributed to the amount of time stallions spend away from the band while recruiting new females or engaging in agonistic interactions with other stallions; females in a band, however, can establish stronger hierarchical relationships because they continuously remain in close proximity to one another (Keiper and Receveur, 1992). Social rank in bachelor groups, which are often unstable, has only been attributed to individual temperament (Tilson and others, 1988).

Ethological Data Collection and Analyses

It is possible to quantify behavior through the systematic enumeration of discretely defined categorical behaviors in terms of counts of occurrence or proportions of time exhibited. Collection of ethological data may be accomplished through several techniques, and the ultimate decision rests on the precisely defined research objectives. The reader is referred to Altmann (1974) for a definitive overview of sampling methodology for observational data. In the last 30 years, many insights have contributed to refining these methods, such as how to determine the appropriate time period between sampling when using the instantaneous scan sampling method and a better research design to capture infrequent behavioral expressions. In sampling feral horse behavior, the USGS study found that instantaneous scan sampling (the method of recording the categorical behavior of each focal animal at precise moments in time) at 1-min intervals was ideal for quantifying time budget data. Continuous sampling is an alternative to this technique and involves recording a focal animal's behavior continuously and noting the point in time that a new behavior begins. Continuous sampling was impractical for our study due to the number of animals and observers involved. Mitlohner and others (2001) found no significant difference between behavioral data recorded with instantaneous scan sampling versus continuous sampling when intervals were 15 minutes or less, and found a high correlation between the techniques when using 1-min intervals.

Collecting data on time budgets using instantaneous scan sampling is fairly straightforward, but behaviors that are infrequent and expressed briefly are not likely to be captured adequately (Houpt, 1991; Doran, 1992). Two relatively good options exist for collection of such data: the all-occurrence method and focal sampling. All-occurrence data collection records every behavior every time it is observed (Altmann, 1974) and can be a good technique when the number of animals in the focal band is not too large and the behaviors of interest are easy to detect. Although less efficient in terms of data collection, the focal sample method may be more reliable since the observer's focus is directed at only one animal (Altmann, 1974; Houpt, 1991). This method involves randomly selecting one individual in the band and continuously observing and recording all behavioral expressions. In feral

horse research, capturing briefly occurring expressions is most important for reproductive, social, and agonistic behaviors. Feeding, resting, and locomotion typically occur in periods long enough to be captured by most techniques.

Ethological protocols must be established prior to data collection and should be defined by research objectives. The discrete behavioral categories presented in this ethogram do not preclude the exhibition of simultaneous behaviors. For example, it is typical in feral horses for a comfort behavior such as masturbation to occur while the animal is feeding, so a protocol should be explicitly defined stating which behavior takes precedence in the data record. If the objective of your research is to determine the amount of time horses are feeding in relation to some covariate, then feeding is the appropriate category, and if expression of comfort behavior is the focus, then it should be recorded as such (or in this case, one might wish to subdivide comfort into several behaviors, since comfort is generally a short-duration behavior with many specific expressions). Regardless of the approach, notations of simultaneous occurrences are invaluable in retrospect.

Simultaneous behavioral expressions are not the only observational data collection pitfall. Some behaviors, such as olfactory investigation, can be ascribed to several categories. This behavior may fall under comfort, reproduction, or harem social behavior, but the correct categorization of such expressions is not subjective: each expression does have an absolute definition. In such cases, the context of the behavior will define its true characterization. When such potentially confusing behaviors are prevalent, they are addressed specifically in the ethogram.

Considerably more in-depth analyses of behavior are possible when covariates associated with individual focal subjects are collected reliably. Many factors may influence behavior, such as age, body condition, dominance rank, presence of dependent foal, climate, and habitat. Fortunately, many feral horses have unique natural markings, making identification of individual animals possible without the use of radio-collars or numbered tags. Pelage color; facial patterns such as snips, strips, blazes, and stars; and leg markings such as coronet bands, socks, and stockings collectively make cataloging and referencing study animals feasible (Sponenberg and Beaver, 1992; Gower, 2000; Green 2001). Properly cataloging and identifying individual horses in a research effort can provide the foundation from which to build in-depth covariate data and thus lead to a better understanding of animal behavior.

Analyses of behavioral data may incorporate many traditional statistical methods, but time budget data presents a particularly challenging dilemma. These analyses must consider the compositional nature of a time budget: models exhibiting strong support for one behavioral category must also be considered for each other category. Proportions of time spent in behavioral categories are compositional dependent variables because the sum of the proportions in all behavioral categories sum to 1. In other words, there is a unit sum constraint (Aitchison, 1986) by which more time spent in one or more behavioral categories must be associated with less time spent in one or more other behavioral categories. These compensatory shifts in estimates are absolute, leading to a dependent relationship among behaviors constituting the time budget being analyzed (Elston and others, 1996). Many compositional data-analysis procedures have been developed (for example, log-ratio procedures; Aitchison, 1986, 1992), but few are appropriate for data that exhibit real values of 0 or 1. It may be important that the amount of time an animal exhibits a given behavior is truly 0 percent or 100 percent. Many methods, such as log-ratio analysis, require data transformations that eliminate values of 0 and 1 by assigning very small or very large values (greater than 0 or less than 1) (Bakeman and others, 1992; Clark and Messina, 1998). This process ultimately alters the distribution of data and may adversely affect conclusions drawn about individual behaviors in the composition (Bingham and Brennan, 2004). Once transformed, the common method of log-ratio analysis also produces only quantitative statements about the overall distribution of the composition in comparison to another and the sampling distribution of the difference; it does not specify explicit contributions of each piece of the composition to those differences (Aitchison, 1986). If your data are not composed of real values of 0 and 1, log-ratio analyses may be appropriate. It is best suited for compositions with only two elements since conclusions about the change in allocation may be drawn easily (Elston and others, 1996), but most behavioral studies aim to address multiple behaviors. Some extensions of the algebra of log-ratio compositional measures have been made by Billheimer and others (2001), but currently these procedures are limited to three-part compositions and still suffer the restriction of not allowing zero proportions.

One solution to the problem of comparing time-budget compositions with several behaviors and true values of 0 and 1 is the use of a multi-response permutation procedure (MRPP; Mielke and Berry, 2007). This method does not require data-transformation and analyzes compositional differences by approximating probabilities of a test statistic based on average Euclidean distances for detecting distributional differences. In other words, the test is focused on differences in multivariate cumulative distributions rather than means. This approach may yield useful results for drawing conclusions about how different animals or treatment groups allocate their time, but it still does not provide insightful conclusions about specific behaviors within the composition of interest. No standardized way to approach this problem currently exists, but one solution is simply to model each behavior to query further covariates and relationships of interest: analyze each part of the behavioral composition as a univariate dependent variable. For such results to be interpretable, however, the same models must be applied and presented for all individual behaviors in the composition.

In simple compositions with few behaviors, the trade-off in time allocation may be evident. It is likely, however, that such clear trade-offs will not always be evident and multiple models must be presented for each behavior. For example, consider a simple composition of three horse behaviors

(Y_f = feeding, Y_r = resting, and Y_l = locomotion, where $Y_f + Y_r + Y_l = 1.0$). If Y_f has a strong linear increase with the predictor variable X_1 (for example, 0/1 indicator variable of sex) and a weak linear increase with predictor variable X_2 (for example, herd size), then Y_r, Y_l, or both must decrease with X_1, but the actual magnitude of that decrease will depend on both behaviors and the degree to which they also are influenced by X_2 (model 1 is $Y = f(X_1 + X_2)$). It could easily be that the strongest model for Y_r might include X_2 and another predictor (say X_3, and model 2 is $Y = f(X_1 + X_3)$). Thus, it is possible for model 1 to be strongly selected for analyzing the Y_f part of the Y compositional vector of behaviors but model 2 to be strongly selected for the Y_r part of the composition. Likewise, one model may be strongly supported for several behaviors and a complement model may be strongly supported for the remaining behaviors in the composition (see Ransom, 2009); however, because the behavioral composition really induces a relationship among the parts of the composition, statistical model results will be uninterpretable if a selected model is not considered to apply to all parts of the behavioral composition (for example, Y_f, Y_r, and Y_l).

The increasing use of maximum-likelihood and Bayesian approaches for solving complex problems may ultimately lead to the development of more lucid guidelines for many problems indicative of behavioral data. These methods can provide powerful tools for analyzing scientific data and can lead to a deeper understanding of the processes and errors involved (Hobbs and Hilborn, 2006). Regardless of the statistical approach, the path toward proper model selection for individual dependent behaviors in a composition has not been described in the literature. The use of model weights and model averaging may assist in drawing coherent conclusions about parameters of interest (Burnham and Anderson, 2002), but all supported models must be considered simultaneously for all dependent compositional variables to avoid violating the inherent statistical assumptions. A reasonable approach to assessing strength of evidence for compositional models, without violating assumptions of dependence, is to sum the minimum Akaike's Information Criteria (AIC: Burnham and Anderson, 2002) scores for the individually-modeled constituent behaviors in a composition; subsequently, each sum then forms an aggregate AIC score for each compositional model. The strength of evidence for the overall composition may then be assessed using AIC weights as Burnham and Anderson (2002) describe for individual models.

Ethogram

This ethogram was developed to investigate the influences of fertility control on feral horse behavior; thus, the behavioral groupings are broad in some contexts, such as feeding behavior, and much more detailed in areas of specific interest to the research objectives, such as agonism. Behavioral researchers often consolidate an array of behavioral expressions into broad categories since data collection on every specific behavior expressed is usually impractical and makes analyses excessively difficult. Therefore, this ethogram divides behavioral expressions into 13 discrete categories that cover the range of expressions a feral horse may exhibit in free-roaming conditions. Two additional categories (human awareness and out-of-sight) are used to account for biased observations. These 13 categories can easily be further aggregated *a posteriori* if desired, but categorizing these behaviors separately *a priori* allows for a wider range of possible analyses while still being practical for data collection. An example of a broader aggregation of these categories is the consolidation of grooming, comfort, standing attentive, and elimination into *maintenance*; herding, reproduction, harem tending, harem social, agonism, and submission into *social*; and human awareness and out-of-sight (unavailable to the observer) into *unknown* (fig. 1). At any given time during the course of observation, a focal animal will be exhibiting behavior that can be described by one of these categories. Developing a research ethogram from the several hundred behavioral expressions documented in equids can be a daunting task; therefore, this basic ethogram for feral horses is presented as a starting point for behavioral studies. For an excellent ethogram resource detailing complete equid behavior expressions, the reader is referred to McDonnell (2003). For a comprehensive work on equine behavior, the reader should also see Waring (1983).

Feeding

Feeding behavior occupies roughly half of the daily time budget of feral horses (fig. 1) and usually entails grazing. Grazing occurs as a horse bites off and ingests grasses and forbs close to the ground (fig. 2). The feeding category also includes browsing on woody plants and trees, eating snow, drinking, mineral licking, coprophagy (eating feces), and pawing at food resources. The latter is critical in defining feeding as a mutually exclusive category in that a horse may be pawing at soil, plants, or snow, but if the action is directly related to acquiring and ingesting a food resource, then it should be considered as feeding behavior. Also, horses move as they graze; therefore, as long as the horse is feeding while it is moving, it should be considered as feeding rather than locomotion.

Resting

The second largest amount of time in the daily time budget of feral horses is allocated to resting, which may occur during 25–35 percent of the daylight hours (fig. 1). Resting behavior is characterized by a general lack of attention and relaxed state and may occur in a standing position or in recumbency (fig. 3). This includes both relaxation and sleeping. Horses are able to sleep standing up due to the stay apparatus that allows their body to be supported without active muscular control (Dallaire, 1986). This behavior is typically observed

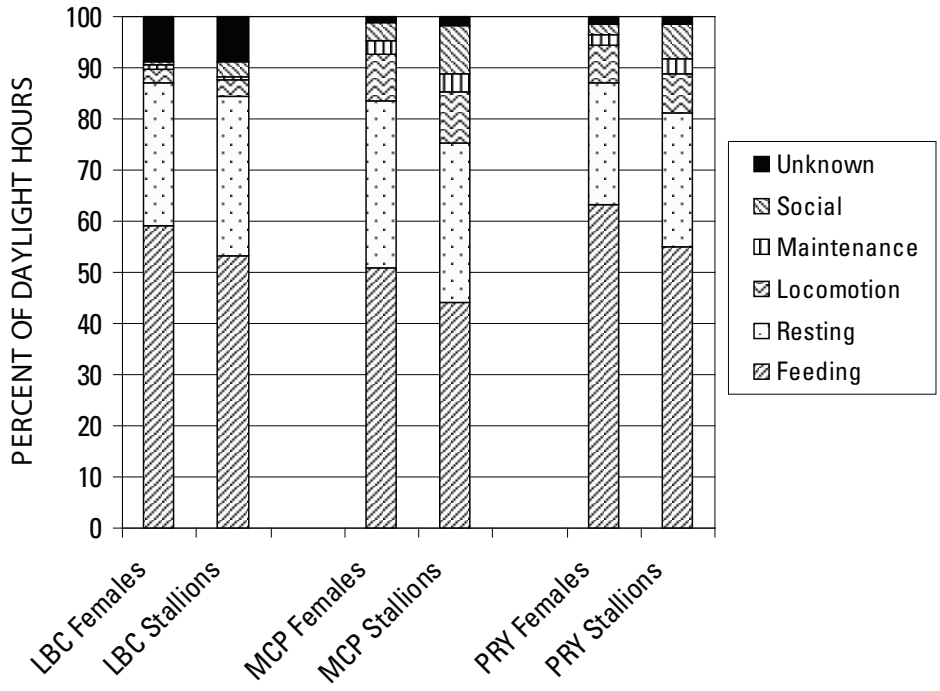

Figure 1. Observed daytime activity budgets of adult control female feral horses (n = 207, mean age = 7.79 yrs ± 0.33 SE, range = 2–21 yrs) and harem stallions (n = 110, mean age = 11.63 yrs ± 0.43 SE, range = 5–26 yrs) at Little Book Cliffs Wild Horse Range in Colorado (LBC), McCullough Peaks Herd Management Area in Wyoming (MCP), and Pryor Mountain Wild Horse Range in Montana (PRY), 2003–2006.

Figure 2. Feral horses grazing, the most typical *feeding* behavior.

Figure 3. *Resting* behavior in a band of feral horses is often characterized by huddling. Aside from the physical protection received by this behavior, the head-to-tail orientation of band members in this type of resting behavior also facilitates grooming. This allows for insect control around the head by the tail-swishing effect of neighbors.

as a body position with the head lowered, eyes closed, and one rear foot slightly elevated. Resting behavior in a band is often characterized by huddling, which facilitates insect control by the tail-swishing of close neighbors. Recumbent rest can be sternal or lateral. The comfort behavior of sun-basking is expressed in a laterally recumbent state, so a protocol must be defined *a priori* characterizing this state as rest or comfort, based on research objectives.

Locomotion

The third largest amount of the daily time budget is spent on locomotion. This behavior includes walking, trotting, cantering, galloping, jumping, and swimming and in feral horses is typically used for moving from one resource to another (fig. 4). Since most feral horse populations in North America occupy arid or semi-arid environments, movement to the few and scattered water sources is often the impetus for daily occurrences of extended locomotion (typically every 12 to 24 hrs). Otherwise, feral horses do not expend vast amounts of energy in locomotion, with the exceptions of brief social interactions between bands, stallion agonistic expressions, and female recruitment efforts by stallions. In this ethogram, locomotion integral to reproductive, harem tending, or comfort behaviors is considered part of its respective behavioral expression and not recorded as locomotion.

Maintenance

Grooming

Grooming behavior occupies a relatively small but important part of the daily time budget of feral horses and is often observed as rolling. Rolling occurs both on land and in water and is thought to assist with pelage health and insect control (fig. 5) (Waring, 1983). Other grooming behaviors include shaking, nibbling or licking on self, tail-swishing, rubbing, and periodic stomping to displace flies and biting insects. Allogrooming (also known as mutual grooming) in this ethogram is not considered categorically as a grooming behavior since it is also a social interaction that involves more than one animal. Depending on the nature of the research, it may be appropriate to consider allogrooming as part of the grooming category.

Figure 4. *Locomotion* is most typically expressed as walking from one place to another, as seen in this feral horse stallion. The higher energy-expense gaits of trotting, cantering, and galloping are observed far less frequently.

Figure 5. *Rolling* by this feral horse mare is a grooming behavior associated with pelage hygiene and insect control.

Comfort

Comfort behavior takes on a wide variety of forms in feral horses and includes any type of self-enjoyment expression, such as play, investigation, and stimulation (fig. 6). Some examples of comfort behavior are sun-basking, shelter seeking, masturbation, sexual play, object play, locomotor play, play fighting, and some olfactory investigations. Olfactory investigations also may be indicative of reproductive behavior or social behavior and should be included in the appropriate category for data collection based on specific research objectives. This ethogram also includes yawning and stretching as comfort behaviors, though it would not be inappropriate to include those expressions as a form of resting behavior.

Standing Attentive

When horses receive a stimulus that causes alertness, they react by exhibiting a rigid body posture with head upright, ears pointed forward, and eyes open and alert (fig. 7). This may be momentary in the case of a sound or smell causing alertness, but such standing attentive behavior also occurs for extended periods of time when a female is standing guard over a sleeping foal or a predator is nearby. In this ethogram, standing attentive does not include instances when the behavior is a result of human presence (fig. 8). In those cases, human awareness is considered its own category so that the biased data may be properly addressed during analyses.

Elimination

Elimination in horses is expressed as urination or defecation (fig. 9), though depending on research objectives, it should be determined whether any such expression will be included in this category or whether elimination with social implications is considered elsewhere. Socially, feral horse stallions create fecal middens known as stud piles and repeatedly defecate on them. These middens are thought to facilitate communication or ownership status of certain resources (Feist and McCullough, 1976; Rubenstein and Hack, 1992). When female feral horses urinate or defecate, it is common for the harem stallion to cover it with his urine for similar reasons. It has been reported that female horses do not cover the urine of other females in this fashion (McDonnell, 2003), though this was documented periodically during our study and may have implications in the female dominance hierarchy.

Figure 6. A typical *comfort* behavior for feral horse males is masturbation, which is expressed when a horse flexes his erect penis against his abdomen. This behavior is not expressed in conjunction with a nearby female and should not be confused with the penis drop observed when a male is reproductively tending a female.

Figure 7. Feral horse mares are focused on an external stimulus (in this case, a foal distress vocalization in the distance) and are exhibiting *standing attentive* behavior. Note the directionally pointed ears, rigid body position, and focused eyes characteristic of this expression. This behavior should not be confused with *human awareness*.

Figure 8. *Human awareness* is an important behavior to record when conducting any behavioral research so that biased data can be properly omitted from analyses of naturally occurring behaviors. Here, an entire band has paused because they noticed the photographer in the distance.

Figure 9. A female feral horse is exhibiting *elimination* by urination. Urination behavior in horses is sexually dimorphic: female horses urinate in a posterior direction and male horses urinate in an anterior direction.

In this ethogram, random urination and defecation are considered elimination, whereas systematic covering of urine or feces from the female by a harem stallion is considered as a harem tending behavior. The systematic covering of urine from a female by a female in the same harem is considered harem social behavior.

Social

Harem Social

Harem social behavior is considered to be social interaction among band members that is not specifically indicative of reproductive, harem tending, or agonistic behavior. Allogrooming is considered a harem social behavior in this ethogram (fig. 10), as is olfactory investigation (from one horse to another, fig. 11, or the systematic smelling of urine deposits among band members) and pair-bonding among juveniles (fig. 12).

Herding

When a feral horse stallion actively drives females of his harem together, it is considered herding behavior. This involves the stallion moving systematically behind the females, posturing with his head held low and ears laid back, and controlling the direction and movement of the band members (fig. 13). Waring (1983) termed this motion with the stallion's head moving side-to-side as snaking. Some researchers may choose to consider this as an agonistic behavior, but it is considered here as its own category since the function of the behavior is maintaining the harem rather than aggression toward specific females.

Harem Tending

Harem tending consists of stallion behaviors that are directed at maintaining the harem and include the defense and recruitment of females. The defense of females is expressed as a stallion positioning himself between his harem females and a perceived threat (typically another stallion) (fig. 14). It is also expressed by covering a female's urine or feces with his own, or by depositing feces on a stud pile (fig. 15). Recruitment, or stealing, of females by a harem stallion from another stallion is also considered harem tending behavior in this ethogram.

Reproduction

Reproductive behavior in feral horses is characterized by a series of stallion-initiated behaviors and a series of mare-initiated behaviors. The stallion reproductive sequence often

Figure 10. One of the most common *harem social* behaviors is allogrooming (also known as mutual grooming). It is expressed by the lateral parallel body position of two horses that allows for nibbling along the back or withers of each horse. While this behavior can be considered grooming, it is also thought to facilitate pair-bonding and dominance structure between band mates (Waring, 1983).

Figure 11. Olfactory investigation in the *harem social* behavior context is often observed as prolonged olfactory engagement of a female and her foal in a bonding regimen. This also may include licking and nudging.

Figure 12. Pair-bonding among juveniles within a band is also a common *harem social* behavior. In this example, female foals are closely engaging each other, which is thought to facilitate development of the female-female ethological relationships critical to band structure and stability later experienced as reproductive members of a family group (Crowell-Davis and others, 1986).

Figure 13. A feral horse stallion (leftmost horse) is *herding* females in his band by posturing and actively driving his females back into a cohesive group. Herding is the most common social behavior expressed by the dominant male toward females in his harem.

Figure 14. The blue roan stallion (foremost) is *harem tending* by expressing a posturing behavior and positioning himself between his harem females (several additional females out of the photo to the left) and an intruding male (right). Depending on the persistence and signals of the intruder, this behavior may develop into *agonism*.

Figure 15. Male feral horses also express *harem tending* by maintaining fecal middens, or stud piles, in which feces are aggregated at strategically located positions within the band's home range.

(but not always) begins with herding or reproductive tending behavior. Reproductive tending is the close following of a female by the male, without the directional driving observed in herding behavior. Following this tending behavior, the stallion often vocalizes and exhibits the olfactory response known as flehmen (fig. 16) (Stahlbaum and Houpt, 1989). He then proceeds by rubbing his head on the female's flanks and (or) resting his chin on her back, and extends his penis out of the prepuce (fig. 17). Some of these behaviors out of sequence are not necessarily associated with a stallion reproductive sequence; therefore, protocols to determine how to categorize the observed behavior are specified in figure 18.

Female reproductive behavior is signified by estrous, which can sometimes be challenging to detect from typical field observation distances. A mare initiates her reproductive sequence by presenting herself facing away from the stallion, lifting her tail, and vocalizing (though sometimes the female faces the stallion first). These behaviors alone do not necessarily signify estrous, since the female could simply be vocalizing and preparing to defecate. If in estrous, it is typically accompanied by posturing her body with hind legs slightly apart (an apparent squat) and often turning her head toward her posterior. The mare also will frequently emit small streams of urine, a behaviour that is often concurrent with rhythmic 'winking' of her vulva: winking can be observed by the periodic flashes of pink from the inner coloration of her vaginal membranes (McDonnell, 2003). These contrasting pigments can be seen in the rolling female in figure 5, simply because of her posture. The urine emitted from female horses in estrous consists of specific variations of urinary volatile compounds that may facilitate chemical communication during reproductive behavior (Ma and Klemm, 1997). Female horses may express estrous behavior during the anovulatory period (typically winter) as well as during pregnancy (Crowell-Davis, 2007). Such anomalies to our conventional understanding may lead to misinterpretation of estrous behavior in the field and care should be taken to correctly and systematically identify this behavior.

Once both male and female are exhibiting reproductive behaviors, copulation may occur with the stallion mounting the female from behind, neck arched over her back and forelegs resting on her sides (fig. 19). Several events could occur in this situation and should be categorized separately if reproductive behavior is a focus of the research. These include successful copulation, unsuccessful copulation (the stallion cannot adequately mount the female for some reason), mare acceptance, mare rejection (the mare kicks and moves away from the stallion), and forced copulation (the mare is not presenting or accepting the stallion's advance, but he relentlessly mounts her anyway).

Figure 16. Flehmen response in this feral horse stallion is displayed by the elevated head, and raised, inverted upper lip. This posture is a response to particularly exciting chemicals and olfactory signals that are detected by the main olfactory epithelium and concentrated directly into the vomeronasal organ, which in part controls sexual activity (Estes, 1972; Mills and Nankervis, 1999).

Figure 17. A feral horse stallion is exhibiting penis extension and rubbing of the female's flanks as part of the male reproductive behavior sequence.

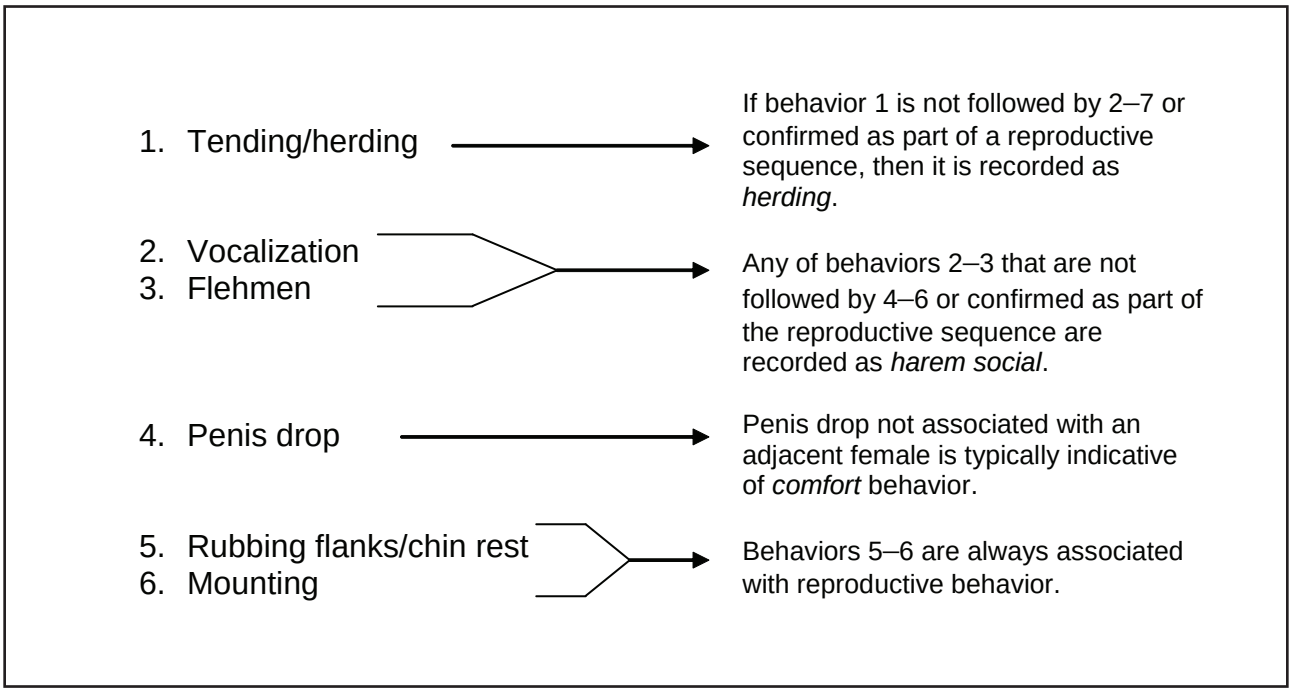

Figure 18. Basic guidelines for distinguishing reproductive and non-reproductive behaviors in stallions.

Figure 19. *Successful copulation* is occurring between this feral horse male and female. This reproductive behavior is characterized by a maintained mounting position on the female for the male and a relatively stationary, relaxed position for the female. *Unsuccessful copulation* is often a result of *mare rejection*, with the female expressing *agonistic* behaviors such as kicking toward the male and a brief mounting position for the male.

Parturition may also be included in the reproductive category or designated as its own behavioral category, depending on research focus.

Agonism

Agonism in feral horses is exhibited by a wide range of behaviors and in this ethogram is put into seven categories arranged by increasing intensity of the interaction. Note that any or all of the following behaviors may be exhibited in play by young animals, in which case they should be considered comfort behavior rather than agonism. The first four categories of agonism may occur between males only, females only, or between males and females, but the remaining levels of agonism are typically observed only between males.

1. The most common and least intense form of agonism is the threat. Threats are characterized by laterally pinned back ears, arched neck, and (or) a movement of the head toward the opposing horse, but with no physical contact (fig. 20). Most conflicts and dominance interactions among feral horses are resolved by these gestures alone.

2. The next agonistic expression is the bump or push, which is expressed by the aggressor making forceful contact with another horse using its head, neck, or shoulder (fig. 21).

3. As agonism escalates, the aggressor may chase its adversary at a gallop to displace the animal from the immediate area or with the intent of engaging the animal in more agonistic behavior (fig. 22). Chasing behavior is typically brief (seconds) or may last several minutes; however, the USGS study documented this behavior occasionally persisting over long time periods (greater than 1 hour) and great distances (greater than 3 km).

4. The fourth level of agonism involves biting an opponent or kicking with the hind legs (fig. 23). This level involves physical contact, though serious injury is rare.

5. Rearing occurs when the horse lifts its forelegs off the ground and elevates its body into a more vertical position, thus looking larger to the opponent (fig. 24). While technically only a threat, this body position typically signifies a more intense agonistic interaction and provides the initial position for commencement of stomping, striking, boxing, and dancing behaviors.

Figure 20. *Agonism* is expressed by both of these feral horses in the form of a *threat*. This is the most common form of agonism between feral horses and is most easily recognized by the laterally positioned, posterior pointing direction of the ears (shown in both animals here).

Figure 21. *Pushing* is an agonistic expression shown here by the foremost horse pushing toward the more distant horse.

Figure 22. *Chasing* is a moderately intense form of agonism and is shown here along with an expression of imminent biting behavior.

Figure 23. *Biting* is a common expression of agonism in equids and is expressed here between feral horse females to assert dominance.

Figure 24. *Rearing* is an expression often signifying a potentially intense agonistic interaction, typically between feral horse stallions.

Figure 25. *Striking* or *stomping* is being expressed by the feral horse stallion on the left. This behavior is typically indicative of highly agonistic expression and is expressed by the directed extension and downward motion of one or both front feet.

6. Stomping and striking occur when a horse uses one or both front feet to attack an opponent by extending the legs out and downward. This behavior has the potential to seriously injure the recipient (fig. 25).

7. The most intense form of agonism between feral horse stallions is boxing and dancing. These behaviors involve the engagement of the agonists in vertical body positions and the use of the front legs in striking (boxing) or closer engagement that results in head and neck biting (dancing) (fig. 26). On very rare occasions, feral horse stallions have been observed engaging in prolonged fights resulting in considerable injury and sometimes fatal outcomes.

Submission

Submission is exhibited by the loser of the agonistic encounter. This may be expressed by simply running away, but also may be expressed with laid down ears (distally or posteriorly), lowered head posture, lowering of the hindquarters, and sometimes jaw snapping (especially in juveniles) (fig. 27).

Acknowledgments

Thanks to Linda Coates-Markle, the late Dr. Francis J. Singer, and the many field technicians who voiced their opinions on how to aggregate these behaviors in the most meaningful way for its original research purpose. Many thanks to Hanem Abouelezz, Laura Caldwell, Melissa Esser, Marty Felix, Kayla Grams, Patti Grigsby, Susan Hahn, Billie Hutchings, Georgia Manus, Jane Nibler, Christina Petrandis, Phyllis Preator, Jennifer Severude, and Gerald Thygerson for the thorough notes and explanations in the margins of datasheets, which inevitably became as valuable for understanding equid behavior as did the rigidly collected and analyzed data points. J. Roelle, J. MacLeay, L. Zeigenfuss, and A. Kane provided useful and critical insights in their reviews of this manuscript. Thank you to S. McDonnell for expertise in helping us accurately define stallion reproductive behaviors. All photographs are courtesy of Jason I. Ransom. The National Park Service, U.S. Bureau of Land Management, and U.S. Department of Agriculture Animal and Plant Health Inspection Service provided administrative support and oversight during all USGS feral horse research efforts.

Figure 26. *Boxing* and *dancing* between these two stallions is illustrative of the highest level of agonism that feral horses typically express.

Figure 27. *Submission* is being expressed by a young male horse (grullo [dark grey] horse in center) and directed toward the larger, dominant male (foremost), who is displaying *threat* behavior associated with dominance.

ABSTRACT

Wildlife management actions can alter fundamental behaviors of individuals and groups, which may directly impact their life history parameters in unforeseen ways. This is especially true for highly social animals because changes in one individual's behavior can cascade throughout its social network. When resources to support populations of social animals are limited and populations become locally overabundant, managers are faced with the daunting challenge of decreasing population size without disrupting core behavioral processes. Increasingly, managers are turning to fertility control technologies to supplement culling in efforts to suppress population growth, but little is quantitatively known about how either of these management tools affects behavior. Gonadotropin releasing hormone (GnRH) is a small neuropeptide that performs an obligatory role in mammalian reproduction and has been formulated into the immunocontraceptive GonaCon-B™. We investigated the influences of this vaccine on behavior of feral horses (*Equus caballus*) at Theodore Roosevelt National Park, North Dakota, USA, for a year preceding and a year following nonlethal culling and GnRH-vaccine treatment. We observed horses during the breeding season and found only minimal differences in time budget behaviors of free-ranging female feral horses treated with GnRH and those treated with saline. The differences observed were consistent with the metabolic demands of pregnancy and lactation. We observed similar social behaviors between treatment groups, reflecting limited reproductive behavior among control females due to high rates of pregnancy and suppressed reproductive behavior among treated females due to GnRH-inhibited ovarian activity. In the treatment year, band stallion age was the only supported factor influencing herding behavior ($P < 0.001$), harem-tending behavior ($P < 0.001$), and agonistic behavior ($P = 0.02$). There was no difference between the mean body condition of control females (4.9 (95% CI = 4.7–5.1)) and treated females (4.8 (95% CI = 4.7–4.9)). Band fidelity among all females increased 25.7% in the year following vaccination and culling, despite the social perturbation associated with removal of conspecifics. Herding behavior by stallions decreased 50.7% following treatment and culling ($P < 0.001$), while harem-tending behavior increased 195.0% ($P < 0.001$). The amount of available forage influenced harem-tending, reproductive, and agonistic behavior in the year following culling and treatment ($P < 0.04$). These changes reflected the expected nexus

between a species with polygynous social structure and strong group fidelity and the large instantaneous change in population density and demography coincident with culling. Behavioral responses to such perturbation may be synergistic in reducing grazing pressure by decreasing energetically expensive competitive behaviors, but further investigation is needed to explicitly test this hypothesis.

1. Introduction

Gregarious relationships can impart individual benefits such as decreased depredation, increased foraging efficiency, and increased fecundity (Pusey and Packer, 1997). When resources to support populations of social animals are limited and populations become locally overabundant, managers are faced with the daunting challenge of decreasing population size without disrupting core behavioral processes. For example, the limited contiguous habitat and finite resources found on public wildlands cannot sustain overabundant populations of large ungulates, and managers continuously seek innovative and publically-acceptable tools for managing these species (Powers et al., 2011). Historically, such populations have been reduced by culling, using either lethal methods such as hunting, or non-lethal methods such as capture and translocation. Limiting fecundity through the use of immunocontraceptives is becoming a more commonly considered tool for controlling wildlife abundance. However, these tools can be accompanied by physiological changes that may alter behavior and ultimately influence population dynamics in unforeseen ways (Ransom et al., 2014). The paucity of quantitative data on natural behavior of wild free-roaming fauna, especially pertaining to those treated with fertility control agents, impairs our ability to understand species' influences and roles in ecosystems and thus our ability to effectively manage populations.

Elk (*Cervus canadensis*) and feral horses (*Equus caballus*) are increasingly targeted for fertility control management in the United States and both species exhibit complex social behavior and polygynous mating systems. Whereas elk congregate seasonally into mating groups (Geist, 1982), feral horses form bands that persist year-round with distinct associations of individuals sometimes lasting a decade or more (Klingel, 1982). These bands are largely maintained by reproductive, herding, agonistic, and defensive behaviors initiated by the polygynous male in the band, as well as hierarchical relationships among females (Ransom and Cade, 2009). Culling can result in discrete changes to population density and demography, which could perturb social organization. Likewise, effective fertility control agents lead to discrete changes in presence of offspring in the population, and thus may influence social behavior.

Approximately 33,000 feral horses roam 13 million ha of public lands in the western United States and managers have historically relied on nonlethal culling through a process of capture, removal, and public adoption to regulate animal abundance (Garrott and Oli, 2013). This process is unsustainable because demand in the U.S. for feral horses as domestic stock is less than half the number of animals removed, which has left as many horses in federally-subsidized pastures as persist in the wild. Several fertility control techniques have been investigated for use in feral horses, but most of these efforts resulted in tools that were publicly unacceptable, expensive to use, or impractical on a large scale. Among the most promising techniques are immunocontraceptive vaccines such as porcine zona pellucida (PZP) and gonadotropin-releasing hormone (GnRH). These agents are relatively easy to apply, are reasonably efficacious, and are not expected to be accompanied by serious contraindications (Kirkpatrick et al., 2011).

Gonadotropin releasing hormone is a small neuropeptide that performs an obligatory role in mammalian reproduction. When combined with a potent adjuvant, the GnRH vaccine stimulates a persistent immune response resulting in prolonged antibody production against GnRH, the carrier protein, and the adjuvant (Miller et al., 2008). The most compelling hypothesis of vaccine effectiveness suggests that antibodies to GnRH likely induce transient infertility by binding to endogenous GnRH, thus preventing attachment to receptors on gonadotropes and suppression of pulsatile luteinizing hormone (LH) secretion (Molenaar et al., 1993). Gonadotropin releasing hormone antibody titers are correlated with suppression of the reproductive system and infertility in a variety of species (Fagerstone et al., 2010). As anti-GnRH antibodies decline over time, concentrations of available endogenous GnRH increase and treated animals usually regain fertility (Powers et al., 2011).

This immunocontraceptive vaccine, known by the trade name as GonaCon-B^{TM}, has been shown to provide multiple years of infertility in several wild ungulate species including horses (Killian et al., 2008; Gray et al., 2010), bison (*Bison bison*) (Miller et al., 2004), elk (Powers et al., 2011), and white-tailed deer (*Odocoileus virginianus*) (Gionfriddo et al., 2009). Given the physiological mechanism of action, GnRH immunocontraception has the potential to reduce fertility and suppress the reproductive behaviors typically associated with copulation; however, in GnRH-vaccinated elk, such behaviors were not entirely diminished likely due to incomplete suppression of the hypothalamic pituitary gonadal (HPG) axis (Powers et al., 2011). Similar to elk, feral horses are polyestrous and fertility control agents that do not suppress these social behaviors can lead to females exhibiting frequent reproductive behaviors that can cascade into altered behaviors from associated band members and nearby males (Nuñez et al., 2009; Ransom et al., 2010).

Rigorous quantitative investigation into the potential effects of GnRH treatment on feral horse behavior is missing from the assessment of this immunocontraceptive as a potential management tool. Such data are

Table 1
Population metrics for feral horses (*Equus caballus*) at Theodore Roosevelt National Park, North Dakota, USA, 2009 and 2010. Normalized Difference Vegetation Index (NDVI) is shown for only the behavior observation period in each year.

	2009	2010
Number of males	64	26
Number of females	74	59
Number of foals	27	31
Mean male age ± SE (range)	5.0 ± 0.45 (1–15)	7.7 ± 0.68 (1–16)
Mean female age ± SE (range)	5.3 ± 0.50 (1–20)	6.4 ± 0.45 (1–18)
Number of bands	19	16
Mean band size ± SE (range)	8.3 ± 0.07 (3–14)	8.7 ± 0.07 (3–19)
Total population size	165	116
Mean NDVI (95% CI)	0.44 (0.324–0.548)	0.43 (0.346–0.504)
Density (number of horses/ha)	0.009	0.006

also absent in regard to culling, which is arguably the most common feral horse management practice worldwide. We investigated the influences of GnRH treatment on behavior of feral horses at Theodore Roosevelt National Park, North Dakota, for a year proceeding and a year following GnRH vaccination and culling. Our objectives were to quantify effects of these two management tools on time budgets of individuals and social interactions between individuals. Based on the assumed mechanism of action of GnRH vaccine, we posited that inoculation would suppress reproductive behaviors in treated females compared to controls and that the sudden decrease in density and social perturbation caused by population reduction would measurably influence social behaviors of all horses.

2. Materials and methods

2.1. Study area

Theodore Roosevelt National Park is located in southwestern North Dakota, USA (45°55′N/103°31′W). The South Unit of the park, where this study was conducted, comprised approximately 19,000 ha and consisted of eroded badlands with gullies and ravines separated by large upland plateaus, and small buttes. The mixed-grass prairie vegetation was predominantly comprised of needle and thread (*Hesperostipa comata*), threadleaf sedge (*Carex filifolia*), western wheatgrass (*Pascopyrum smithia*), blue grama (*Bouteloua gracilis*) and little bluestem (*Andropogen scoparius*) (Butler et al., 1986). Sympatric ungulates included feral horses, pronghorn (*Antilocapra americana*), bison, mule deer (*Odocoileus hemionus*) and elk. Feral horses were confined to the South Unit by a 1.8–2.4 m high woven wire boundary fence and no other feral horse populations were nearby. All individual horses in this population were previously identified and assigned individual identity numbers by managers, and age and reproductive data for each animal have been maintained since 1993 (National Park Service, unpublished data).

2.2. Treatments and study subjects

In spring/summer 2009, when pre-treatment data were collected, 165 horses occupied the park and were organized into 19 bands (Table 1). All bands contained a single adult stallion and adult females and their offspring, with the exception of one band that also contained a second stallion. No females persisted outside of bands; whereas, bachelor males were distributed across the landscape individually or sometimes in small ephemeral bands.

Horses were gathered into permanent corrals and handling facilities using a helicopter during a scheduled management capture in October 2009. Managers attempted to gather all horses in the population at that time, and removed 78 horses based on the agency's specific management needs. Eighty-one percent of the culled animals were foals, yearlings, and 2- and 3-year olds, and 14% were bachelor males not associated with any band. The remaining individuals removed included three females age ≥16 years, and one 6-year old female; none of which were part of our experimental group. These removals inherently skewed the sex ratio of the population between years because so many bachelor males were removed; however, paternity attributed to bachelor males is thought to be low (Bowling and Touchberry, 1990) and all study bands were subjected to competition pressure equally in each year at the population level. Post-treatment data were collected in spring/summer 2010, when 116 horses (including those born in 2010) occupied the park (Table 1).

We selected 58 adult females (2–17 years of age) using a randomized complete block design consisting of a GnRH-vaccinated treatment group and a saline control group. The resulting experimental female population consisted of 29 GnRH-vaccinated females (treatment) and 28 saline-treated (control) females, with one mature female remaining in the population that could not be captured. Females that were not in either treatment group were excluded from behavior analyses. The GnRH vaccine ultimately did not prevent conception in all inoculated horses (Baker et al., 2013); therefore, to more clearly separate the effects of infertility on behavior, we also excluded from analysis observations of 14 treatment females that became pregnant in 2010 and produced offspring in 2011. Females of both treatment groups were dispersed randomly across 16 bands with no difference in proportion of treated and control females between bands (paired t-test for unequal means: $t = 0.116$, $P = 0.909$). The same adults and bands observed in 2009 were observed in 2010, with none of the research cohort or band stallions removed during the culling operation.

Veterinarians blinded to treatment status assessed the general health, pregnancy, and body condition of each

animal at the time of capture. Pregnancy status and approximate stage of gestation were determined using rectal palpation of the reproductive tract and transrectal ultrasound imaging (Bucca et al., 2005). We visually assessed body condition of all females and scored condition using a numerical index that increased 1–9 with increasing fatness (Henneke et al., 1983). Females in the treatment group received an intramuscular injection in the gluteus muscle, by hand-syringe, containing 2000 μg of GnRH vaccine (2 mL, GonaCon-B™ (National Wildlife Research Center, Fort Collins, CO, USA)). Females in the control group were injected in a similar manner with an equal volume of saline solution. All data for this study were collected in accordance with Colorado State University Animal Care and Use Committee standards (protocol 12-3197A).

2.3. Behavioral sampling

Behavioral observations were conducted during three daylight time periods (08:00–12:00 h, 12:01–16:00 h, and 16:01–20:00 h) from April 18, 2009–July 16, 2009 and April 8, 2010–August 19, 2010. Each observation session included collection of a 20 min instantaneous scan sample of time budgets at 1 min intervals for each adult band member (≥1 years old), and all-occurrence data collection for social interactions, exactly as implemented by a synonymous study of PZP in horses (Ransom et al., 2010). We used a feral horse ethogram that categorized specific behaviors into 15 discrete time budget categories; agonism, comfort, elimination, feeding, grooming, harem-social (e.g., allogrooming, pair-bonding, female-female urine marking), harem-tending (e.g. stallion defense of a band female or recruitment of a new female into the band), herding (e.g., driving or snaking behavior by the stallion), interaction-with-humans, locomotion, out-of-sight, reproduction, resting, standing attentive, and submission (Ransom and Cade, 2009). The infrequency and similar nature of several behaviors in the instantaneous scan samples led us to aggregate them into broader categories for time budget analyses. Grooming, comfort, standing attentive, and elimination were combined into *maintenance*; reproductive, harem-tending, harem-social, agonism, submission, and herding were combined into *social*; and interaction-with-humans and out-of-sight were combined into *unknown*. The time spent in the category *unknown* ultimately did not differ between treatment groups or between years.

We also collected social behavior data at every occurrence throughout each observation session because instantaneous scan sampling has the potential to underestimate rare events (Ransom and Cade, 2009). These all-occurrence behaviors included intraband social behaviors associated with herding, reproduction, agonism, and harem-tending and were retained as discrete categories for social behavior analyses. We observed all horses from the nearest distance that did not elicit attention of horses to the presence of the observer, typically 50–300 m. All observations were conducted using a 15–45 × 600 mm spotting scope or 10 × 42 mm binoculars when the distance between horses and observers was too far to allow unassisted detailed observation.

2.4. Statistical analyses

We modeled the frequency of each behavior using mixed-effects linear regression, where individual female identity and sampling time period (time of day) were included as random effects on the intercept term of each model. This accounted for variation that may have been present among individuals who were sampled repeatedly, though not always equally over time, and for temporal variation in behavior when samples were not equally collected across all times of day. We used the lme4 package of R version 2.14.1 (The R Foundation for Statistical Computing 2011) and SYSTAT 12.02.00 (SYSTAT Software, Inc. 2007) to calculate descriptive statistics and obtain mixed-effects model estimates using restricted maximum likelihood (Harville, 1977).

We fitted separate models for each year to assess the fixed effects of treatment (x_1, pre-treatment or pre-control in 2009, treatment or control in 2010), foal presence (x_2, dependent foal < 1 year of age present with the female, or no foal present with the female), female age (x_3), band size (x_4, total number of animals in the group), and band fidelity (x_5, number of times a female changed bands within the sampling year) on time budget behaviors. In the notation of Gelman and Hill (2007), models took the form of $y_{jk[i]} = \alpha_{0j[i]} + \alpha_{1k[i]} + \beta_0 + \beta_{x_1}x_{1[i]} + \beta_{x_2}x_{2[i]} + \beta_{x_3}x_{3[i]} + \beta_{x_4}x_{4[i]} + \beta_{x_5}x_{5[i]} + \varepsilon_{jk[i]}$, where the random effect intercept of $\alpha_{0j[i]} \sim N(\mu = 0, \sigma_j^2)$ represents time period j (08:00–12:00 h, 12:01–16:00 h, 16:01–20:00 h), for $i = 1,\ldots,n$ observations, and the random effect intercept $\alpha_{1k[i]} \sim N(\mu = 0, \sigma_k^2)$ represents $k = 1,\ldots,n$ individual horses for $i = 1,\ldots,n$ observations. This equation identifies the fixed effect intercept as β_0, x = independent variable with parameter β_x, ε = statistical error, and y = dependent variable. All-occurrence social behavior was modeled in the same framework, but because those data involved a given stallion directing a behavior toward a given female, we also included the additional variable of stallion age as a fixed effect.

In order to gain insight into the effects of removal versus fertility control, we also modeled time budget and all occurrence behavior across both years, replacing treatment status with observation year as a fixed effect. This allowed us to look at the broad paradigm change, independent of trying to separate the inherently related aspects of changing sex ratio, density, and competition. We included Normalized Difference Vegetation Index (NDVI) as a fixed effect in this model in order to estimate the temporal influence of forage availability on behavior that could have varied between years. The NDVI data were obtained from the National Aeronautics and Space Administration (http://modis.gsfc.nasa.gov) and reconciled using ArcGIS software (ESRI, Redlands, California). We also included sex as a fixed effect in this model to gain insight into both male and female time budgets in concert with the culling perturbation.

3. Results

The 2009 pregnancy assessment indicated that 89% of the control group and 86% of the treatment group were pregnant at the time of saline- or GnRH vaccine-injection. In the following year, 71% (95% CI = 53.9–89.3%) of control females and 72% (95% CI = 55.1–89.7) of treated females were observed with a dependent offspring. Mean body condition of pre-control females was 5.1 (95% CI = 4.8–5.4) and of pre-treatment females was 4.9 (95% CI = 4.7–5.2) in 2009. Likewise, mean body condition of control females was 4.9 (95% CI = 4.7–5.1) and of treated females was 4.8 (95% CI = 4.7–4.9) in 2010.

We collected behavioral data on 93 feral horses (23 males, 29 pre-treatment females, 27 pre-control females, 14 other females) for 582.4 h in 2009. The median age of observed stallions was 7 years (range = 3–14 years), median age of observed females was 5 years (range = 2–17), and median band size was 8 horses (range = 3–17). In 2010, approximately 5 months after treatment and culling, we observed 77 of the same feral horses (18 males, 29 treated females, 28 control females, two other females) for 1263.90 h. The median age of observed stallions was 9 years old (range 5–15), median age of observed females was 5 years old (range = 3–18), and median band size was eight horses (range = 3–19). The final data used for GnRH treatment analyses arose from 1331 observations of 29 pre-treated and 29-pre-control females in 2009 and 2299 observations of 15 treated and 28 control females in 2010. The final data used for culling analyses arose from 2115 observations of 23 males, 27 pre-control females and 29 pre-treatment females in 2009, and 3274 observations of 18 males, 28 control and 29 treatment females in 2010.

3.1. Time budgets

Band size and foal presence were influential in how females allocated their time during 2009, but there were no differences in behaviors between pre-treatment and pre-control females (Table 2). However, treated and control females spent their time differently in the year following inoculation. Treated females fed more and moved more than control females, and reciprocated by reducing time in resting and maintenance behaviors (Fig. 1). There were no changes in time spent engaging in social behaviors between treated or control females and their conspecifics (Table 2). Band size influenced feeding time, increasing 0.9 ± 0.40 (SE)% with each additional horse in the band in 2009. This effect was not evident in 2010 after the population was reduced. Time of day influenced feeding behavior in both years. Horses fed an estimated 7.3 ± 4.69% (2009) and 7.5 ± 5.01% (2010) less in the morning, as compared to 7.4 ± 5.00% (2009) and 9.0 ± 5.04% (2010) more in the afternoon.

Time spent feeding was largely reciprocated by time resting among both treated and control groups (Fig. 1). There were no differences between pre-treatment and pre-control females in time spent resting ($t_{1270} = 0.459$, $P = 0.646$), but like feeding, this relationship changed after inoculation, and treated females rested less than their control counterparts (Table 2). Foal presence influenced

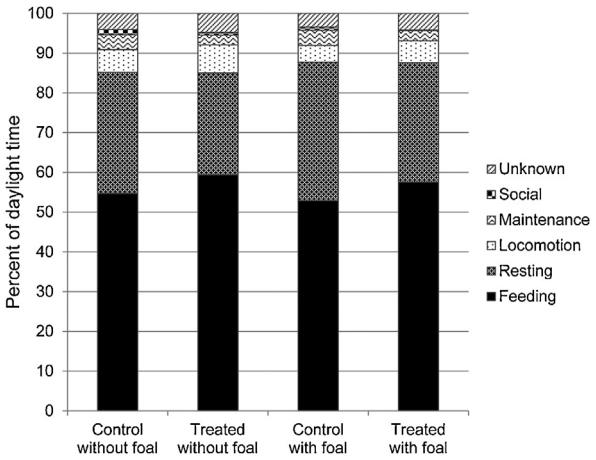

Fig. 1. Mean allocations of daylight time budget behaviors for feral horse (*Equus caballus*) females at median age (5 years old) and median band size (eight horses). Estimates are shown from mixed-effects linear regression considering individual identity and time of day as random effects. Data consisted of 2299 observations of 28 control and 15 treatment females in 2010 at Theodore Roosevelt National Park, USA. Foal presence was defined as a dependent born during the observation year.

resting in both years with independent females resting 4.4 ± 2.27% (2009) and 4.4 ± 1.83% (2010) less than females with a dependent foal (Table 2). Resting occurred temporally opposite of feeding activity, with 7.0 ± 4.43% (2009) and 6.5 ± 4.18% (2010) more resting in the morning and 6.8 ± 4.72% (2009) and 7.2 ± 4.22% (2010) less in the afternoon.

The remainder of horses' time was occupied by locomotion (about 5% of their time), maintenance (about 3% of their time), and social behavior (about 1% of their time) (Fig. 1). Treated females spent less time moving than controls and reciprocated with increased maintenance behavior (Table 2). Age was a statistically significant effect in modeling locomotion in 2010, but because time in locomotion only differed by 0.12% per year of age, this is unlikely to be biologically significant. Foal presence, however, was a strongly supported effect and females with a dependent were on the move 1.5 ± 0.35% more than independent females (Table 2). Maintenance behavior was influenced by band fidelity in 2010 and time spent exhibiting this behavior increased 1.6 ± 0.44% per band change. Six of 43 females (14%) were observed changing bands one to three times during 2010. In contrast, 23 of 58 females (40%) changed bands one to four times in 2009. The decreased band size in 2010 appears to have influenced time spent performing maintenance behavior (Table 2). Like age and locomotion, this effect was statistically significant but with an increase of only 0.1 ± 0.06% per additional band member it is unlikely to have biological meaning. Locomotion, maintenance, and social time budget behaviors were influenced minimally by time of day or individual variation (Table 2).

3.2. Social behaviors

All-occurrence social behaviors associated with herding, harem-tending, reproduction, and agonism from stallions toward females were observed 57% of the time

Table 2

($n = 331$) during 2009 and 51% of the time ($n = 650$) during 2010. Herding by stallions was the most frequently observed social behavior. Band size influenced this behavior in 2009, with herding increasing 0.16 ± 0.56 times per hour (tph) per additional horse in the band (Table 3). In 2010, however, age of the stallion was the only important fixed effect on this behavior and herding increased 0.18 ± 0.038 tph per year of age. At median stallion age, median female age, and median band size, pre-treatment females received herding behavior 2.24 ± 0.743 tph and pre-control females received this behavior 1.98 ± 0.694 tph ($t_{274} = -0.892$, $P = 0.373$); likewise, treated females received herding behavior 1.06 ± 0.415 tph and control females received this behavior 0.99 ± 0.454 tph ($t_{602} = -0.271$, $P = 0.787$). Time of day was not an important influence on herding in either year and variance of this random effect was similar in both years (Table 3).

Harem-tending occurred less frequently than herding in 2009, but at a similar rate as herding in 2010. The supported fixed-effects in models of harem-tending were band size in 2009 and age of stallion in 2010 (Table 3). As band size increased per horse, harem-tending decreased 0.05 ± 0.020 tph in 2009, and as stallion age increased per year, harem-tending decreased 0.11 ± 0.026 tph in 2010. As with herding behavior, time of day did not influence harem-tending occurrence in either year and there was little individual variance in 2009.

Contrary to our prediction that reproductive behaviors would be reduced in GnRH-treated mares compared to controls, we observed almost exactly the same frequency in both years and between treatment groups. At median stallion age, median female age, and median band size pre-treatment females received reproductive behaviors 0.57 ± 0.374 tph and pre-control females received reproductive behaviors 0.40 ± 0.349 tph ($t_{274} = -1.054$, $P = 0.293$); likewise, treatment females received reproductive behaviors 0.59 ± 0.270 tph and control females received reproductive behaviors 0.56 ± 0.297 tph ($t_{602} = -0.177$, $P = 0.860$). The only supported fixed-effect in either year was female age in 2009, which estimated a 0.05 ± 0.024 tph decrease in reproductive behavior per year of age.

Agonism occurred at similar rates as reproductive behaviors in both years and was influenced by stallion age in both years (Table 3). Agonism from males toward females increased 0.03 ± 0.019 tph per year of male age in 2009 and 0.04 ± 0.017 tph per year of male age in 2010. At

median stallion age, median female age, and median band size pre-treatment females received agonistic behaviors 0.26 ± 0.251 tph and pre-control female received agonistic behaviors 0.44 ± 0.234 tph ($t_{274} = 1.744$, $P = 0.082$); likewise, treatment females received agonistic behaviors 0.19 ± 0.184 tph and control females received agonistic behaviors 0.36 ± 0.203 tph ($t_{602} = 1.627$, $P = 0.104$). Band fidelity also influenced the 2010 estimate and agonism increased with number of band changes (Table 3). Neither time of day nor individual variance influenced agonism occurrence in either year.

3.3. Population reduction

Horses allocated time differently by sex and by year (Table 4). Males fed less, rested more, moved more and engaged in social interactions more often than females, but all horses fed less, rested more, moved more, and performed less maintenance behavior and engaged in more social behavior in 2010 as compared to 2009 (Fig. 2). Normalized Difference Vegetation Index was highly correlated between years ($R^2 = 0.90$). The finer scale all-occurrence behavioral data revealed that herding by stallions decreased 50.71% from 2009 to 2010, and appeared to increase in frequency concurrent with the seasonal green-up period (and concurrent reproductive season) (Fig. 3A). Harem-tending behavior increased 195.0% from 2009 to 2010, when both were estimated at median stallion age, median female age, median band size, and mean NDVI. Harem-tending also occurred in concert with forage production, but this relationship was more pronounced in 2010, when the frequency of occurrence was markedly escalated (Fig. 3B). Time of day and individual identity contributed little to variance in these models (Table 4).

4. Discussion

There were no differences in any behaviors between treatment groups before GnRH vaccination and culling. Females vaccinated against GnRH managed their time differently than controls. They fed less, rested more, traveled less, and performed more maintenance behaviors than their control counterparts, but engaged in the same amount of social behavior. The estimates across years, however, indicated that pronounced behavioral changes occurred in how stallions engaged with females in social behaviors. Stallions herded all females less and harem-tended more following the changes in population density, demography, and social perturbation that resulted from culling. The date of observation in relation to forage availability explained some differences between years, while the increased mean age of stallions as well as the decreased band size in 2010 also explained some of the differences. None of the models indicated that herding or harem-tending varied due to the treatment status of females, but rather implied that the paradigm shift in competition influenced how band stallions managed their family groups. Because the same stallions were observed in both years, the effect of age potentially reflected the additional year of experience each male possessed, in the context of competition pressure.

The similarity in female social behavior between treatment groups likely related to estrous behavior, a catalyst of other social behavior. Estrous behavior is influenced by the concentration and timing of progesterone and estradiol, the steroid hormones that fluctuate with occurrence of pregnancy (Katz, 2007). During pregnancy, high concentrations of progesterone usually inhibit estrous behavior (Crowell-Davis, 2007; Fabre-Nys and Gelez, 2007). The GnRH-antibodies stimulated by GnRH vaccination should have interrupted the hormonal cascade in females and ultimately suppressed pulsatile luteinizing hormone (LH) secretion, and thus ovulation (Powers et al., 2011). Consequently, we might expect that similar social behavioral expressions (albeit for different reasons) between pregnant females and GnRH-treated females would be observed. However, a similar study in elk concluded that GnRH was not completely suppressed in vaccinated females and thus some LH stimulation occurred and likely allowed limited production of estradiol (Powers et al., 2011). This permitted reproductive behaviors, at a reduced level, in GnRH-treated individuals. It should also be noted that estrous behavior has been observed with low frequency among both pregnant female and anovulatory female horses (Asa et al., 1983; Crowell-Davis, 2007). This is thought to be a bonding mechanism that assists in the maintenance of stable social groups of horses year-round, rather than ephemeral reproductive groups, such as those observed in elk. Also, the complex social behaviors among feral horses do not entirely center on reproductive receptivity, and other behaviors associated with dominance hierarchies, leadership, and gregarious lifestyles may or may not be as directly influenced by fluctuations in progesterone and estradiol.

Regardless of the similarity in social behaviors between treatment groups, treated females still allocated their time budgets differently than controls in 2010. Most GnRH-vaccinated females in the final dataset were likely not pregnant in 2010 because we categorically omitted the treated females that demonstrated unsuccessful response to vaccination by producing offspring in 2011. Pregnancy influences time spent feeding and resting simply due to the metabolic needs of barren females as compared to pregnant females (National Research Council, 2007). The composite nature of time budget behaviors requires that if any one behavior changes, then other behaviors such as locomotion or maintenance must also change; thus, the small differences between treatment groups were unsurprising.

The estimates of time spent per behavior for all horses in our study fell well within the ranges previously reported for daylight time budgets of horses (Mayes and Duncan, 1986; Boyd, 1998; Berger et al., 1999; Ransom et al., 2010). Ultimately, body condition scores of control and treated females were at parity in 2010. This may indicate that the metabolic demands of pregnant and non-pregnant females were compensated for behaviorally, that the body condition scoring system was not sensitive enough to detect finer-scale differences, or that forage abundance was high enough to obfuscate the effects of behavior on body condition. Foal presence influenced resting in both years with independent females resting less than females with a

dependent foal. Band size was also an important effect on some behaviors; most notably, herding and harem-tending behavior in 2009 were significantly related to band size, but this was not the case in 2010. This effect on social behaviors was replaced with stallion age in 2010. These contradictions may be in part due to the change in population size that occurred between years or due to changes in band composition. Even though band size did not change notably between years, some young animals were removed from bands.

Density of bachelor males in the population was likely influential in the large changes in herding and harem-tending behaviors observed between years: the number of bands and band size did not differ greatly between

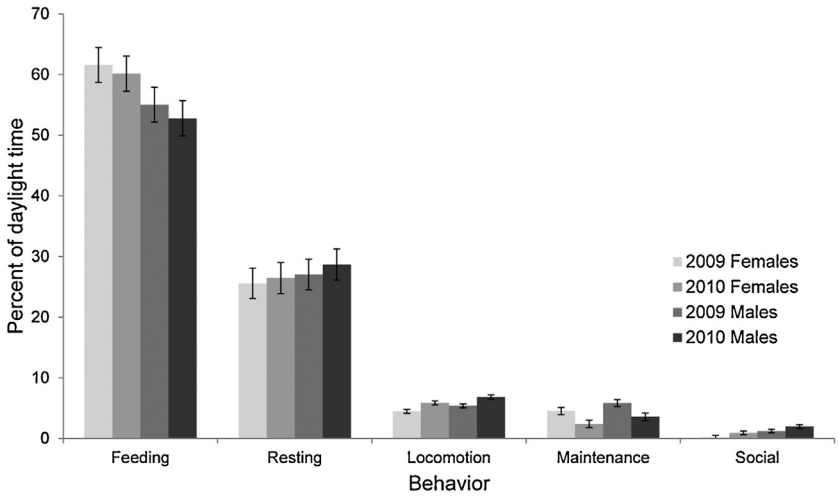

Fig. 2. Comparison of mean ± SE daylight time budget behaviors of feral horses (*Equus caballus*) before (2009) and after (2010) culling and GnRH treatment at Theodore Roosevelt National Park, USA. Estimates are shown at median age, median band size, and mean Normalized Difference Vegetation Index (NDVI) and arose from mixed-effects linear regressions considering individual identity and time of day as random effects.

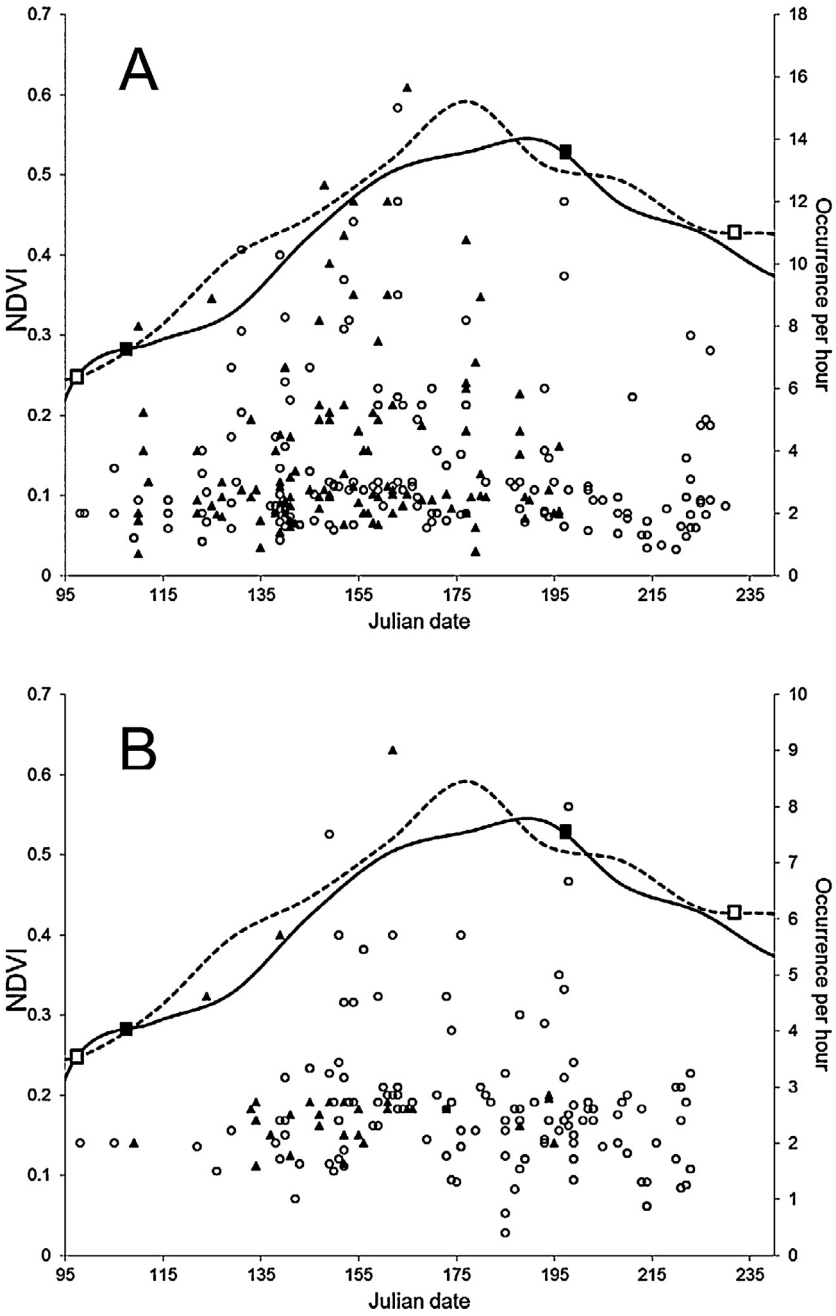

Fig. 3. Temporal occurrence and rate of feral horse (*Equus caballus*) herding (A) and harem-tending (B) behaviors in relation to seasonal trend in forage availability using Normalized Difference Vegetation Index (NDVI) as an index of greenness. NDVI for the pre-treatment year of 2009 is shown as a solid line with behaviors as solid triangles and NDVI for the post-treatment year of 2010 is shown as a dashed line with behaviors as hollow circles. Boxes on the NDVI trend lines designate the beginning and end of each behavior observation season.

years, but the number of available males in the population decreased 41% between years and the mean age of males in the population increased by nearly 3 years or 36%. This combination of effects presents compelling evidence that quickly and non-randomly reducing population density has behavioral implications for individuals and how bands function in the social dynamics of the population.

Herding and harem-tending behavior are important behaviors used by band stallions to maintain bands, but also represent an energetic cost for both the male and female(s) involved. Such costs may have biological meaning in terms of body condition and fidelity of females to the band (Ransom et al., 2010). The decline in herding behavior detected between years is not surprising given the decreased presence of competing males in the

population, which is often what prompts a stallion to actively herd females together (Waring, 2003). This decrease in potential energetic expense lends support for the practice of culling because while it decreases grazing impact by removing animals, it also leads to the remaining animals expending less energy (that would have to be replaced by grazing) by decreasing frequency of behaviors that arise from competition. Consequently, 2.2% less feeding behavior was estimated for stallions in 2010 as compared to 2009 in our study. This is supported by the observed increase in harem-tending behaviors in our study, most of which are likely driven by instinctual behavioral mechanisms more than active presence of a competitor. Such behaviors include stallions marking urine deposits of band members and constructing fecal middens that relate to reproductive status, communication, and band identification (Feist and McCullough, 1976; Rubenstein and Hack, 1992).

Little has been studied on the effects of culling in feral horse populations, and what has been presented in the literature focuses on stress and its effects on reproduction (Hansen and Mosley, 2000; Ashley and Holcombe, 2001). A short term study did collect data on percent of time horses spent feeding, resting, vigilant, traveling, and engaged in agonistic encounters and found no difference between control (horses not gathered or pursued) and simulated (horses that were pursued but evaded capture) groups (Hansen and Mosley, 2000). That study did not investigate the broader effects relating to density and sex ratio changes. We could find no other studies that investigated behavior before and after population removals of feral horses. There are some comparable studies of feral horse behavior in relation to immunocontraception however.

Porcine zona pellucida is the most extensively investigated immunocontraceptive for feral horses, and recent studies have found PZP-treated females exhibit more frequent reproductive behaviors and seasonally prolonged reproductive behaviors than their control counterparts. In a comparable study of three feral horse populations, 54.5% more reproductive behaviors were received by PZP-treated females than by control animals during the breeding season (Ransom et al., 2010). Likewise, in another feral horse population, more frequent reproductive behaviors among PZP-treated females were observed in the non-breeding season (Nuñez et al., 2010). Elevated rates of estrus have been reported in PZP-treated females of other species as compared to control females, which likely explains this increase in observed reproductive behavior (Mahi-Brown et al., 1985; Shumake and Wilhelm, 1995; Heilmann et al., 1998; Curtis et al., 2002). Seasonality of estrus in horses may not be as constrained by abiotic factors as previously thought, so it is possible that any contraceptive that does not completely suppress estrus could be associated with seasonally atypical expressions of reproductive behavior (Ransom et al., 2013). Decreased band fidelity has also been reported among PZP-treated female horses (Nuñez et al., 2009; Madosky et al., 2010), and in our GnRH study the per capita female interchange rate decreased 25.7% from 2009 to 2010. Given that some social reorganization was expected following the culling perturbation, the observed decrease in interchange provides additional evidence that GnRH-vaccinated females were not expressing the frequent reproductive behavior that appears to be coincident with decreased band fidelity.

Studies of the effects of GnRH immunocontraceptive vaccines on behavior of female horses are limited; nevertheless, a few small studies do illustrate some general patterns in responsiveness. In the only other feral horse study reported in the literature, no differences were observed between treatment groups in time spent feeding, resting, or traveling in either the breeding or non-breeding season (Gray et al., 2010). Of the 25 copulations observed in that study, only one was a GnRH-vaccinated female and it occurred during the non-breeding season. Both treated and control females demonstrated reproductive behavior roughly once every 2 h in our study. Our results concur with observations of reproductive behaviors in controlled experiments where captive mares were treated with GnRH vaccine. In those studies, treated mares showed suppressed ovarian activity and ovulation after immunization but continued to show evidence of estrous behavior at irregular intervals and duration (Dalin et al., 2002; Imboden et al., 2006). Similar behavioral responses to contraception induced by GnRH vaccine and GnRH agonist have been reported in other ungulate species as well (Baker et al., 2002, 2004; Conner et al., 2007; Powers et al., 2011). The parity we observed between treatment groups therefore simply reflects the limited reproductive behavior among control females due to high rates of pregnancy and suppressed reproductive behavior among treated females due to GnRH-inhibited ovarian activity. Since GnRH is highly conserved across mammalian species, fertility control technology founded on this hormone may suppress reproduction but does not always prevent the occurrence of sexual behaviors.

Our study was limited to only a pre-treatment and treatment year, and as such inferences should only be extended to the individual level in the short term. Both pregnancy and birth rates between treatment groups in our study were the same, but variation in birth interval among individuals can make longer term trends less certain in terms of births, dependent foals, physiology, and associated behaviors. While some studies have demonstrated females may be less likely to foal in consecutive years, as opposed to alternate years, others have found no differences (Roelle et al., 2010). Probability of foaling can also be strongly related to band size (Roelle et al., 2010), which was equitable between years in our study but may trend downward with effective fertility control over long time periods. For these reasons, the short duration of our study provides some relatively clear inference toward short-term effects of GnRH and culling on individual behaviors; however, long term effects of fertility control on behavior may manifest to all individuals as a population paradigm shifts to lower fecundity, and variable and unknown effects on social structure and dynamics emerge.

5. Conclusion

Our study found only minimal differences in behavior of free-ranging female feral horses treated with GnRH

and those treated with saline. Those differences could be physiologically explained and body condition between the two treatment groups was at parity. Following the same methodological protocols as a similar study of PZP-treatment on behavior of feral horses (Ransom et al., 2010), GnRH appears to lead to fewer behavioral modifications than PZP in this species in the short term. Long term influences of GnRH remain uncertain. The ultimate assessment of any fertility control agent must include the scope and magnitude of all potential contraindications, vaccine efficacy, and weighing the known effects against the benefit of reducing population growth. The differences in how band stallions socially interacted with all females between years provided strong evidence related to the effects of culling. These behavioral responses shed light on the effects of reducing competition and density in a social polygynous species with strong group fidelity. Such perturbation may be synergistic in reducing grazing pressure by decreasing energetically expensive competitive behaviors, but further investigation is needed to explicitly test this hypothesis.

Conflict of interest

We declare no conflict of interest among financial, personal, or other relationships with other people or organizations that could inappropriately influence, or be perceived to influence, our work.

Acknowledgments

Special thanks to Lindsey Eby, Alanna Kirby, Al and Jennifer Schaeffer, Marylu and Henry Weber, and Jan Peterson for enduring the elements to collect these data. Kathy Fagerstone, James Gionfriddo, and Lowell Miller graciously provided GonaCon for treatments. Thanks to Valerie Naylor and Bill Whitworth for their support, assistance, and funding from Theodore Roosevelt National Park. Thanks to Alicia Niery for data entry assistance. This research was funded by the Morris Animal Foundation, Merck-Merial Veterinary Scholars Program, Theodore Roosevelt National Park, U.S. Geological Survey Fort Collins Science Center, and the National Park Service Biological Resource Management Division. No agency administration or funding program had a role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. REVIEW

Ecological feedbacks can reduce population-level efficacy of wildlife fertility control

Summary

1. Anthropogenic stress on natural systems, particularly the fragmentation of landscapes and the extirpation of predators from food webs, has intensified the need to regulate abundance of wildlife populations with management. Controlling population growth using fertility control has been considered for almost four decades, but nearly all research has focused on understanding effects of fertility control agents on individual animals. Questions about the efficacy of fertility control as a way to control populations remain largely unanswered.

2. Collateral consequences of contraception can produce unexpected changes in birth rates, survival, immigration and emigration that may reduce the effectiveness of regulating animal abundance. The magnitude and frequency of such effects vary with species-specific social and reproductive systems, as well as connectivity of populations. Developing models that incorporate static demographic parameters from populations not controlled by contraception may bias predictions of fertility control efficacy.

3. Many population-level studies demonstrate that changes in survival and immigration induced by fertility control can compensate for the reduction in births caused by contraception. The most successful cases of regulating populations using fertility control come from applications of contraceptives to small, closed populations of gregarious and easily accessed species.

4. Fertility control can result in artificial selection pressures on the population and may lead to long-term unintentional genetic consequences. The magnitude of such selection is dependent on individual heritability and behavioural traits, as well as environmental variation.

5. *Synthesis and applications*. Understanding species' life-history strategies, biology, behavioural ecology and ecological context is critical to developing realistic expectations of regulating populations using fertility control. Before time, effort and funding are invested in wildlife contraception, managers may need to consider the possibility that many species and populations can compensate for reduction in fecundity, and this could minimize any reduction in population growth rate.

Key-words: behaviour, demography, ecological process, fertility control, fitness, immunocontraception, population dynamics, population ecology, wildlife contraception, wildlife management

Controlling reproductive capacity of wildlife

Humans have been attempting to control the abundance of animals for over 13,000 years (Diamond 2002). Although regulating the herd size of domestic animals has been a feature of human economies for millennia, people have also sought to regulate populations of wild animals using hunting and culling techniques. Recent societal trends have motivated wildlife managers to seek nonlethal strategies of regulating births using fertility control (Hobbs, Bowden & Baker 2000; Porton 2005). This trend may be attributed to an increasingly mutualistic societal view arising from abundance of wildlife in suburban and urban areas (Teel & Manfredo 2009). In such circumstances, perception of wildlife species may focus less on

their role as a natural resource and more on how they are part of our social environment (Leong 2010). This may lead humans to be more aware of, and concerned about, the welfare of these species. The balance of human perception and wildlife abundance is precarious because as highly adaptive species increase in density, wildlife–human conflicts increase, and society can then be confounded with the dichotomy of desire for wildlife protection and relief from wildlife conflict (Knuth *et al.* 2001; Lauber & Knuth 2004; Lauber *et al.* 2007; Hadidian 2009).

The practice of using fertility control to manage reproduction in wildlife emerged over 40 years ago (Asa & Porton 2005). Wildlife managers have been attracted to fertility control as a means to regulate overabundant wildlife when animals threaten people's lives, livelihoods or property; when they cause declines in more desirable species; and when their densities are high enough to increase disease transmission or disrupt ecosystem function (Caughley 1981; Hone 2007). The vast majority of empirical knowledge about wildlife fertility control comes from individual-level studies of drug safety and efficacy (Garrott 1995; Kirkpatrick, Lyda & Frank 2011). As a consequence, we know relatively little about how fertility control influences population ecology. It remains uncertain whether findings of research on the efficacy of fertility control at the individual level can allow inferences to populations. There may be compensation in vital rates that allow individuals to maintain fitness, thus offsetting the effects of fertility control agents. If such compensation occurs, then it may be infeasible to control some wildlife populations using fertility control.

Types of fertility control applied to wildlife include products that disturb normal reproductive hormone cascades or interfere with conception, such as immunocontraceptive vaccines, pharmaceuticals, hormone derivatives, agonists, antagonists, mechanical devices and surgical techniques (Asa 2005). All of these methods may prevent births, but they also may induce unintended changes to behaviour and physiology (Nettles 1997; Gray & Cameron 2010). It is not surprising that hormonal derivatives such as melengestrol and levonorgestrel affect behaviour (Gray & Cameron 2010), but it is surprisingly uncertain how variable such behavioural changes can be, even within similar taxa. Stump-tailed macaque *Macaca arctoides* females, for example, can become markedly more aggressive towards conspecifics when treated with a synthetic progestin (Linn & Steklis 1990), but hamadryas baboon *Papio hamadryas* females can become more passive when treated with a similar progestin (Portugal & Asa 1995).

Any fertility control application that changes the reproductive capacity of an individual has the potential to induce individual behavioural changes that can alter family group structure, influence interspecific and intraspecific interactions and ultimately shape population dynamics in unforeseen ways. Fertility control in free-roaming wildlife populations has been associated with changes in immigration (Ramsey 2005; Merrill, Cooch & Curtis 2006), decreased group fidelity (Nuñez *et al.* 2009; Madosky *et al.* 2010), increased survival (Caughley, Pech & Grice 1992; Kirkpatrick & Turner 2007; Williams *et al.* 2007), altered reproductive behaviour (Nuñez, Adelman & Rubenstein 2010; Ransom, Cade & Hobbs 2010) and shifted phenology (Ransom, Hobbs & Bruemmer 2013). Understanding and predicting these sometimes subtle and incremental shifts is difficult, and the challenge of separating the influences of multiple population growth controls can be daunting (Sibly & Hone 2002). To exacerbate these problems, the longitudinal studies needed to detect and quantify long-term population-level effects of fertility control treatments are expensive and time-consuming.

Insights into population-level effects of fertility control have largely been accomplished through efforts that simulate population dynamics (Caughley, Pech & Grice 1992; Hone 1992; Hobbs, Bowden & Baker 2000; Davis & Pech 2002; Merrill, Cooch & Curtis 2006). Simulation models can be useful tools for screening management alternatives; however, widespread behavioural and demographic changes induced by fertility control may subvert the underlying assumptions of demographic parameters in models that fail to consider these changes. The assumptions of many fertility control population models could be wrong if the vital rates informing them are based on the wealth of *a priori* ecological knowledge about species and systems before fertility control was applied.

Here, we synthesize findings from studies on population-level effects of wildlife fertility control and compare some of those outcomes with those from individual-level studies. We specifically investigate the demographic and behavioural components from wildlife fertility control studies, seeking to understand feedbacks that might be influencing population-level outcomes of fertility control strategies. We attempt to identify some of the underlying processes to help inform modelling efforts and future design for empirical population-level fertility control studies, and ultimately try to determine whether, in fact, nature can overcome control efforts at a scale that makes fertility control ineffective as a wildlife management tool.

The feedback dilemma

Considering animal behaviour in broad ecological and conservation contexts is critical to understanding population ecology (Sutherland 1998; Buchholz 2007); yet, a lack of rigorously quantified behaviour data often inhibits our ability to assess the magnitude of its importance. At the individual level, wildlife contraceptive studies have illuminated a wide array of behavioural changes attributed to fertility control applications (Nettles 1997; Gray & Cameron 2010). Studies on captive animals incorporate more experimental control than is usually possible with free-ranging wildlife, but the artificial environments inherent in captive studies often preclude the insights towards ecological feedbacks that studies of free-ranging wildlife

contribute. Consideration of results from both types of studies is needed to understand the potential population-level effects of fertility control acting through birth, survival, immigration and emigration. Feedbacks on population growth may be negative or positive, and the nature of feedback direction may vary with the ecology of the species in question.

Fertility control is designed to reduce the probability that an individual gives birth, so it should be expected that fecundity of treated animals will be less than that of untreated animals; however, indirect effects make the broader influence of treatment on birth rates less clear. Unintentionally protracted contraception has been attributed to physiological changes in ovarian function after fertility control treatments (Kirkpatrick *et al*. 1995; McShea *et al*. 1997; Nettles 1997; Powell & Monfort 2001; Stoops *et al*. 2006). Such residual infertility was observed in feral horses *Equus caballus* and Przewalski horses *E. ferus przewalskii* repeatedly treated with porcine zona pellucida (PZP) and was further complicated by shifts in the seasonal birth pulse when fertility resumed (Nuñez 2009; Feh 2012; Ransom, Hobbs & Bruemmer 2013). Increased frequency of reproductive behaviour has been observed in females treated with PZP vaccines and has the potential to focus attention of breeding males away from fertile females and towards the attractive, but sterile, females (Shumake & Wilhelm 1995; McShea *et al*. 1997; Heilmann *et al*. 1998; Nuñez, Adelman & Rubenstein 2010; Ransom, Cade & Hobbs 2010). Similarly, both elk *Cervus elaphus* and mule deer *Odocoileus hemionus* males demonstrated increased reproductive behaviour towards females treated with gonadotropin-releasing hormone vaccine (GnRH) or leuprolide (a GnRH agonist) after the untreated cohort became pregnant (Baker *et al*. 2002, 2004; Conner *et al*. 2007; Powers *et al*. 2011). All of these studies represent a potential mechanism for decreased fitness in males and could result in a higher net contraceptive effect at the population level (Ransom 2012).

In contrast, fecundity of untreated female mice *Mus domesticus* increased when fertility-controlled females were present, attenuating the contraceptive effect (Chambers, Singleton & Hinds 1999). Many species have been reported exhibiting a compensatory reproduction response when a subset of the population has been perturbed, such as might be the case with large-scale fertility control application (Swenson 1985; Kirkpatrick & Turner 1991; Boyce, Sinclair & White 1999; Williams 1999). How such effects originate through changes in social networks is unknown. Likewise, the effects of fertility control on biochemical and olfactory communication are virtually unknown, but have been implicated in disrupting intraspecific interactions in a primate (Crawford, Boulet & Drea 2010) and could lead to greater uncertainty about fecundity at the population level.

Fidelity to family groups has decreased in conjunction with fertility control applications (Fayrer-Hosken *et al*. 2000; Nuñez *et al*. 2009; Madosky *et al*. 2010), and time spent with conspecifics or potential mates has also changed (Bertrand *et al*. 1996; Poiani *et al*. 2002; Harrenstien *et al*. 2004). Territoriality increased for pikas *Ochotona curzoniae*, and the increase was related to decreased litter size (Liu *et al*. 2012). These types of changes can affect time budgets such that basic maintenance behaviours of feeding and resting decrease, resulting in lower body condition in animals receiving contraception (see Ji, Clout & Sarre 2000; for example). Similarly, female elk treated with leuprolide had comparable maintenance behaviours as untreated elk, but retained less body fat than untreated, pregnant females, possibly due to decreased anabolic hormone exposure during their infertile year (Conner *et al*. 2007).

Increased or decreased agonism between conspecifics has also been attributed to some contraceptive applications (Linn & Steklis 1990; Portugal & Asa 1995; Penfold, Patton & Jochle 2005; Snape, Hinds & Miller 2011). These behaviours can alter dominance hierarchies and thus access to resources (Dublin 1983; Schulte *et al*. 2000; Creel 2001). More directly, some deer treated with hormonal applications lost body condition or stopped eating altogether (Bell & Peterle 1975; White, Warren & Fayrer-Hosken 1994). Low body condition arising from any of these processes can enhance the fertility control effect by changing the ability of individuals to meet the nutritional requirements needed to support pregnancy and lactation (Cook *et al*. 2004; Rhind 2004).

Apart from the many potential direct and indirect effects of fertility control on births, some applications may also influence survival. Body condition and longevity can increase when the costs associated with reproduction decrease. For example, feral horses treated with a PZP vaccine had higher survival probability than untreated controls (Turner & Kirkpatrick 2002; Ransom 2012). Similarly, survival was higher among fertility-controlled rabbits *Oryctolagus cuniculus* (Twigg *et al*. 2000; Williams *et al*. 2007), coyotes *Canis latrans* (Bromley & Gese 2001) and foxes *Vulpes vulpes* (Saunders *et al*. 2002). These results show that reductions in recruitment caused by fertility control can be offset at least in part by enhanced survival of females, thereby attenuating the effect of fertility control on population growth rate.

Feedbacks amplifying the effect of fertility control can also occur. Disease transmission was 28% higher in populations of possums *Trichosurus vulpecula* with sterile females, illustrating the potential for decreased survival in fertility-controlled populations (Caley & Ramsey 2001). Phenological shifts in birth patterns among females that formerly received contraception may also have implications for survival of both females and their neonates if births occur asynchronously with forage resources (Ransom, Hobbs & Bruemmer 2013).

Perhaps, the most challenging impediment to predicting population-level effects of fertility control occurs when populations are open to immigration and emigration, processes that can be accelerated by feedbacks from the

application of fertility control. Male possums, for example, increased in frequency at sites where females received contraception (Ji, Clout & Sarre 2000), and in one study, the rate of immigration equalled the rate of reduction in births attributed to fertility control (Ramsey 2005). A similar feedback was also observed in deer (Merrill, Cooch & Curtis 2006). Home ranges of fertility-controlled female rats *Rattus argentiventer*, koalas *Phascolarctos cinereus* and white-tailed deer were larger than those of fertile females (Jacob, Matulessy & Sudarmaji, 2004; Gilman *et al*. 2010; Hynes *et al*. 2011). This was explained by an absence of range-limiting dependent young, and in deer, this larger home range was positively correlated with increased mortality rates (Gilman *et al*. 2010).

For nearly all of the collateral effects discussed here, there are almost as many cases where no collateral effects were detected when a different fertility control method was used or a different species was studied (Gray & Cameron 2010: Fig. 2). Such variation in individual and species responses emphasizes the need for careful consideration of species biology, reproductive system, physiology, behavioural ecology, population biology and ecological context when considering fertility control management for a population.

Population-level effects of fertility control

Scientific progress towards understanding population-level effects of fertility control has been slow despite an articulate call for population-level research of wildlife contraception nearly two decades ago (Garrott 1995). We reviewed 479 papers in the scientific literature on wildlife fertility control from 1980 to 2011 and found that 90% focused on individual-level effects (Fig. 1). Half of the papers were published in the last decade, reflecting an increasing interest in wildlife fertility control. There was an increasing trend in population-level studies, but still only 10% of the papers reviewed addressed population-level effects.

Only 6·5% of all papers we reviewed considered behavioural or indirect demographic effects in population-level assessment of fertility control (Table 1), and only half of those quantitatively considered such effects in modelling population dynamics with fertility control (Table 2). This is surprising given that such a large number of individual-level studies describe the potential for indirect effects to influence fertility control efficacy at the population level (Nettles 1997; Gray & Cameron 2010). The number of studies that empirically tested fertility control management for achieving long-term reduction in population size was too small for us to conduct a meaningful quantitative meta-analysis. It is worth noting, however, that the studies evaluating fertility control in open populations of promiscuous breeders did not sufficiently reduce population size for long time horizons (Twigg *et al*. 2000; Ramsey 2005; Jacob, Singleton & Hinds 2008), and a study of an open population of deer had mixed results (Merrill, Cooch & Curtis 2006). Efforts to manage relatively small, closed populations of feral horses, deer, elephants and feral cats using fertility control were much more successful (Rudolph, Porter & Underwood 2000; Delsink *et al*. 2006; Rutberg & Naugle 2007; Kirkpatrick & Turner 2008; Mendes-de-Almeida *et al*. 2011; Ransom 2012).

A broad consensus among both empirical and simulated studies is that in most free-roaming wildlife populations, a majority of the individuals in one or both sexes must be infertile to realize meaningful reduction in population growth. Reduction in abundance can require aggressively maintained treatment for long periods of time (Hobbs, Bowden & Baker 2000). This can mean that >50% of females must be treated in closed populations of long-lived, low-fecundity species to achieve moderate reduction in growth (Hone 1992; Hobbs, Bowden &

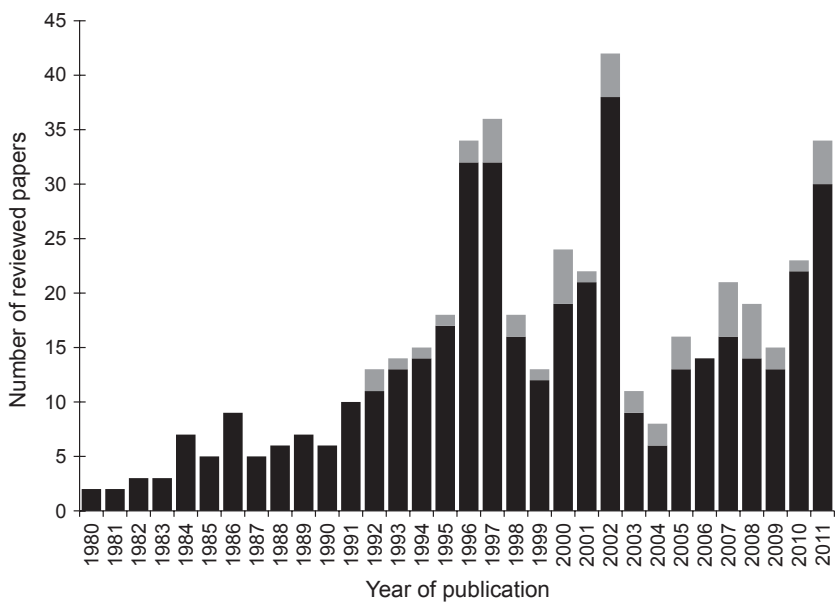

Fig. 1. Trends in publication (n = 479 papers) for research on fertility control in wild and feral fauna from 1980 to 2011. Proportion of each bar in grey depicts investigations that included empirical or simulated population-level effects.

Table 1. Number of reviewed scientific publications from 1980 to 2011 that included population-level effects of fertility control on wild or feral animals in theoretical, simulation or empirical contexts and the number of those publications that considered behavioural or indirect demographic feedbacks on population-level effectiveness of the application

	Type of study			Feedback on fertility control efficacy		
Fauna type	Theoretical	Simulation	Empirical	Negative	Positive	Not considered
Ungulate	1	10	6	4	0	13
Rodent	2	2	6	6	1	3
Marsupial	0	1	3	4	0	0
Pachyderm	2	2	1	2	0	3
Carnivore	0	3	1	0	0	4
Fish	1	0	0	1	0	0
Non-specific	4	3	0	4	0	3
Total	10	21	17	21	1	26

Baker 2000), and perhaps, >90% of females must be treated in open populations where immigration can compensate for birth reductions (Merrill, Cooch & Curtis 2006). Controlling populations of short-lived, high-fecundity animals is even more daunting because the high recruitment rates require fertility control treatments to be applied frequently (Singleton *et al*. 2002; Williams *et al*. 2007; Jacob, Singleton & Hinds 2008). In some applications, the lag time between treatment and effect on birth rates can result in too many new fertile females being recruited into the population for treatment strategies to be efficiently applied, even in long-lived, low-fecundity species (Nielsen, Porter & Underwood 1997; Whyte, van Aarde & Pimm 1998). Achieving population goals using fertility control for highly promiscuous breeders may not be feasible (Caughley, Pech & Grice 1992).

Some simulations have concluded that the response of a population to fertility control is nonlinear, and if survival increases as fecundity declines, then the survival is more influential on population growth than births (Hone 1992; Sinclair 1997; Hobbs, Bowden & Baker 2000; Merrill, Cooch & Curtis 2003). The logical conclusion to this is that fertility control is generally more effective at maintaining populations than actually reducing them, and thus, effective use of fertility control to maintain a population at reduced abundance may require culling to get the population to the desired level within a manageable time frame (Hone 1992; Barlow, Kean & Briggs 1997; Hobbs, Bowden & Baker 2000). Perhaps, most alarming is that many of these simulations assume 100% sterility, which is generally only achieved using surgical applications. Physically treating such large numbers of animals may be prohibitive due to the labour, time and expense necessary for capture, handling and application.

In contrast to these discouraging results, there is some evidence that fertility control can reduce and maintain populations at desired targets for abundance. Female feral horses have a long lifespan and can potentially produce offspring annually for up to 20 years of their life. A fertility control study at Assateague Island, the USA, reported zero population growth in only 2 years, with 42–76% of adult female feral horses treated annually with PZP (Kirkpatrick & Turner 2008). Population decline began 8 years after treatment began, and by year 11, the population had decreased nearly 23%. This sharply contrasts most simulation predictions, but may be explained by the indirect effects of treatment, the population parameters, life-history strategies of the species and the continual accessibility to individuals for treatment. This example reflects a relatively small, closed population of a polygynous species with strong social hierarchies. Thus, the lack of immigration and potentially reduced fecundity in subordinate females may act to supplement the effects of fertility control at the population level. Residual effects of treatment and decreased birth rate among untreated females contributed to a 33% difference in expected and realized births in another study of PZP in feral horses (Ransom 2012). Survival, however, appears to have increased in older females in both studies, which partially offsets the effects of fertility control. This complex system of feedbacks demands a deeper understanding of the influences acting on vital rates in populations proposed for control, and before we categorically dismiss the use of fertility control to functionally reduce populations, we must carefully consider how those feedbacks are operating.

Implications towards fitness

The genetic consequences of controlling any individual's fertility could have long-term effects on population fitness. Such artificial selection can theoretically occur in two ways. First, by purposeful or inadvertent non-random selection of animals targeted for contraception, managers may prevent reproduction in wildlife in ways that change gene flow in a population. This would have genetic effects similar to those that may arise from traditional means of wildlife management, such as non-random lethal removal of individuals from the gene pool. The second and far more uncertain mechanism is that inferred by the animal itself. Behavioural decisions unique to individuals shape their fitness, especially among males (Smith & Blumstein 2008). Such may be the case when polygynous males divert reproductive behaviour or when agonism increases or decreases in response to fertility control in the

Table 2. Population-level effects of fertility control in simulated (S) and empirical (E) studies that explicitly incorporated demographic feedbacks into analyses

Source	Taxa	Data	Individual treatment efficacy	Percent of population treated	Population effect	Feedback	Mechanism
Caughley, Pech & Grice (1992)	Gregarious, stratified by dominance structure	S	Non-specific: 100%	0–100% in social groups of up to 5 females	If female loses dominance at treatment, productivity increases	Negative	Increased births from subordinate females
Hone (1992)	a: long-lived, low fecundity b: short-lived, high fecundity	S	Non-specific: 100%	20–100% of original fecundity of females	Curvilinear response: for b, 80% fertility reduction ≈ 50% abundance reduction	Negative	Increased survival
Seagle & Close (1996)	White-tailed deer (*Odocoileus virginianus*)	S	Non-specific: 100%	0–100% of females	No reduction at <50% of females treated in open population	Negative	Increased immigration
Barlow, Kean & Briggs (1997)	a: monogamous and, b: polygamous	S	Non-specific: 100%	0–100% of females and/or 0–100% of males	Greatest effect in (a) with both sexes treated; less effect in (b)	Negative	Increased survival; increased births in b
Twigg *et al.* (2000); Williams *et al.* (2007)	European rabbit (*Oryctolagus cuniculus*)	E	Tubal ligation: 100%	0%, 40%, 60%, 80% of females	After 4 years, no difference in population size between treatments	Negative	Increased survival, increased immigration, decreased emigration
Singleton *et al.* (2002)	House mouse (*Mus domesticus*)	E, S	Tubal ligation & ovariectomy: 100%	67% of females	75% density reduction after 11 weeks, but compensation by 20–24 weeks	Negative	Increased births per female
Davis & Pech (2002)	Based on red fox (*Vulpes vulpes*)	S	Non-specific: 100%	0–100% of females	Absent density dependence, density increased with up to ~50% treatment	Negative	Increased survival
Merrill, Cooch & Curtis (2006)	White-tailed deer (*Odocoileus virginianus*)	S	Non-specific: 100%	30%, 45%, 60% of females	No population reduction if movement rates were >25% of observed and treatment was <45%	Negative	Increased immigration

Table 2. (continued)

Source	Taxa	Data	Individual treatment efficacy	Percent of population treated	Population effect	Feedback	Mechanism
Ramsey (2005)	Brushtail possum (*Trichosurus vulpecula*)	E	Tubal ligation: 100%	0%, 50%, 80% of females	60% recruitment for 50% treated/74% for 80% treated: no population effect	Negative	Increased immigration, increased survival
Kirkpatrick & Turner (2008)	Feral horse (*Equus caballus*)	E	PZP: 0–8% birth rate in females	42–76% of females	Population decreased 22·8% in 11 years	Negative	Increased survival
Jacob, Singleton & Hinds (2008)	Ricefield rat (*Rattus argentiventer*)	E	Tubal ligation, progesterone: 100%	Up to 76% of females	No population effect in open population	Negative	Increased births, increased survival
Budke & Slater (2009)	Feral cat (*Felis catus*), closed population	S	Surgical or contraception: 100%	0–30% of females	91% of adult females need to be sterile to stop population growth	Negative	Increased survival

population. The age of individuals also interacts with demographic parameters of the population, as well as environmental variation, to influence fitness (Gaillard *et al*. 2000).

Individual physiology introduces a special consideration in the case of immunocontraceptives, and some authors have questioned the soundness of using a wild animal's immune system to select for the ability to reproduce (Nettles 1997; Cooper & Herbert 2001; Cooper 2004; Cooper & Larsen 2006). Immunocontraceptives are typically <100% effective at preventing pregnancy because they impose their effects through stimulation of the immune system. Depending on the magnitude of heritability, it is possible to select for decreased immune function and likely decreased fitness in relatively few generations. For example, if 10% of females in a population fail to mount a significant antibody response to an immunocontraceptive vaccine, and that phenotype has 80% heritability, then approximately 20% of female progeny will likewise not respond (Cooper & Larsen 2006). Thus, the trait has doubled in a single generation, assuming all females within the population were vaccinated. This has the potential to lead to immune incompetence and resistance to immunocontraception in the population. If immune responses responsible for contraception are mediated through the same or similar genetic pathways as those responsible for responding to pathogens and disease states, it is possible and even likely to select for decreased population fitness.

Alternatively, if a large proportion of the variation in contraceptive response is attributable to the environment, then even intense selection will have little effect on the phenotype of future generations (Magiafoglou *et al*. 2003). Difficulties in estimating heritability and finding reliable, accurate and sensitive indicators of changes in phenotype of immune function, given multigene effects on the system, pose significant challenges to resolve this question. However, there is evidence from studies with mice, chickens and pigs that strongly suggest that antibody production, delayed type hypersensitivity and phagocytic activity are heritable traits (Mouton, Sant'Anna & Biozzi 1988; Sarker *et al*. 1999; Wilkie & Mallard 1999; Pinard-van der Laan 2002). Significant changes in both humoral and cell-mediated immune responses can be achieved in as few as three generations in controlled environments (Sarker *et al*. 1999). Genetic variability in phenotype can change in response to environmental conditions (Hoffman 1999). This emphasizes the need for both laboratory and field studies of immunocontraceptives when investigating variance in immune response.

The proportion of the population targeted for fertility control will also influence selection pressure applied by non-response. From a practical standpoint, managers are likely to treat as many animals as possible when beginning a fertility control programme, particularly in extensively managed populations that are above management objectives. This will maximize non-response selection

pressure (Garrott 1995). Targeting for contraception may be more discriminating in intensively managed feral horse herds by selecting only a proportion of the population and ensuring that each female contributes an offspring to the population prior to contraception (Nuñez, Adelman & Rubenstein 2010). This strategy would result in decreased selection for non-response. Additionally, immigration and emigration will affect gene flow in the population and dilute the selection pressure. Treatment application intensity, non-response rate, change in fitness and migration will all influence the strength of artificial selection. This is one aspect of fertility control that wildlife managers have little, if any, valid data with which to make an informed decision. A cross-disciplinary approach involving immunologists, reproductive scientists, population or conservation geneticists and wildlife biologists may begin to answer these questions.

CONCLUSION

Study of individual effects of fertility control applications is an important step towards technology development of potential tools for managing wildlife, but understanding their ecological effects is a critical prerequisite for using them. Natural systems and processes are strained under anthropogenic pressures and ever-fragmenting landscapes, and resources to address these challenges are often lacking. Actions such as population-level fertility control demand that practitioners weigh not only the biological and ecological costs, but also the economic, political and regulatory costs involved for implementation.

Definitive generalizations about the biological and ecological conclusions of fertility control across taxa and biomes remain elusive. Primary empirical studies are still needed to evaluate population-level effects of fertility control on large wildlife populations over long time periods. Given the resources necessary to conduct such studies, it is likely that most future insight will arise from adaptive management applications. As such, fertility control as a management tool must be applied in thoughtful, calculated ways to achieve the greatest likelihood of success at reducing or maintaining population numbers. Current evidence suggests that population-level management of wildlife using fertility control is more likely to be successful if it is applied to populations (i) that are relatively small, (ii) that have little or no opportunity for an influx of new animals, (iii) that are comprised of a species that exhibits a relatively long gestation period and (iv) where a large proportion of individual animals can be accessed and aggressively treated. Fertility control management of non-native species might be more successful than management of native species because non-natives have not evolved in the ecosystem of concern, and the system is not dependent upon the species for natural function. For these reasons, alterations to life history, natural selection or behaviour may be also more publically acceptable, as long as they do not affect the conservation of native wildlife species. This hypothesis has not been tested to date. Likewise, applications to wildlife species occupying highly disturbed ecosystems may be effective because there may be disproportionately large influences from anthropogenic sources (i.e. where ecosystem drivers are more dependent on human actions than on natural processes), and the effects of fertility control on natural processes may be relatively minor in comparison.

If the necessary biological and ecological conditions can be met for effective use of fertility control to regulate wildlife populations, it is critical to address regulatory, political and economic concerns through public discourse and debate between agency, academic, political and public stakeholders who value their common wildlife resources for a wide variety of reasons. This includes transparent consideration of laws and regulations governing label and off-label use of drugs and vaccines; the welfare of animals subjected to capture, handling and treatment; and public acknowledgement that the targeted population effect and the ability of a management tool to reach such goals are not absolute. Rigorous economic analysis of the cost-effectiveness of fertility control relative to other management options is necessary to economically justify investing in the control actions (sensu Sebastián-González *et al.* 2011). This requires quantitative evaluation of the population-level and ecosystem-level benefits of the proposed actions.

Robust quantitative tools are necessary for modelling outcomes due to the disparate responses observed across species, populations and control options. Feedbacks from fertility control application vary widely and can produce quite unexpected results. In some cases, unintended changes to births, survival, immigration or emigration could provide a formidable barrier to effective management of populations using fertility control. Scientists, managers and practitioners are thus faced with understanding the often confounding nature of the actions implemented to achieve goals for populations. Fertility control can lead to complex population-level effects on the target species as well as cascading impacts on ecosystems. Both population-level and ecosystem-level impacts can and should be explored using a range of tools including empirical studies and simulation modelling. Expanding the prevailing birth-centric research theme to more thoughtful data collection and modelling that considers births, deaths, immigration, emigration, gene flow and ecological interactions will improve the quality and utility of fertility control studies.

What is known about the topic of this paper

- It is well known that neutering of bitches may lead to a change in coat quality, although the nature of the change has never been described in detail.
- The gonadotropin concentrations of spayed untreated bitches were several times higher than concentrations found in intact or spayed female dogs treated with gonadotropin-releasing hormone (GnRH).
- Side effects of neutering of bitches, for example, urinary incontinence, may be treated with GnRH analogues.

What this paper adds to the field of veterinary dermatology

- After spaying, more follicles were in anagen and fewer in telogen compared with intact bitches.
- Spaying resulted in coat changes in 20% of the bitches.
- GnRH treatment resulted in a temporary improvement of coat changes in 79% of patients; however, the anagen : telogen ratio did not change after treatment.

Abstract

Although spaying can result in qualitative hair coat changes in dogs, the influence of spaying on the hair growth cycle has never been described. The study aims were to examine the effect of spaying and gonadotropin-releasing hormone (GnRH) treatment on canine hair coat, cycle stages of hair follicles, plasma gonadotropin concentrations and mRNA transcription of luteinizing hormone (LH) and GnRH receptors in hair follicles. Fifteen female dogs were examined before and 1 year after spaying and 24 spayed dogs before and after GnRH treatment. Spaying resulted in increased plasma gonadotropin concentrations and increased anagen : telogen ratio of hair follicles, but only 20% of the dogs developed coat changes. No differences were found in mRNA transcription of LH and GnRH receptors. GnRH treatment resulted in reduced plasma gonadotropin concentrations and improvement of coat changes in 79% of patients. This was associated with an increase in catagen hair follicles without changes in the anagen : telogen ratio. The present study demonstrated that spaying had an effect on the anagen : telogen ratio of hair follicles. Spaying-induced coat changes did not correlate with the anagen : telogen ratio. GnRH treatment reduced gonadotropin concentrations and reversed coat changes in some dogs, but had no effect on the hair growth cycle other than increasing the number of catagen hair follicles. A weak positive correlation between the plasma LH concentration and the anagen : telogen ratio was noted; however, our data did not suggest a direct receptor-mediated hormonal effect on the hair follicle. The present study did not identify the pathomechanism of spaying-induced coat changes.

Accepted 10 January 2008

Introduction

The factors influencing hair growth and quality are diverse. Apart from genetic causes, environment and diet, cytokines and hormones influence hair growth.[1,2] It is generally accepted that in addition to many others hormones, androgens, oestrogens and prolactin are involved in the control of the normal hair cycle.[2–8]

Certain breeds, such as Irish setter, cocker spaniel, long-haired dachshund, Eurasier, chow-chow, golden retriever, Newfoundland and Landseer, have a predisposition for coat changes after spaying.[9] Affected dogs have a significant increase of wool hair and decrease in hair colour intensity. The coat resembles that of young dogs and is called 'puppy coat'.[9,10] These may be so severe that breeders advise against spaying. However, it is unknown to what extent reproductive hormones influence hair growth.

Until recently, side effects of spaying – namely, changes in the hair coat and urinary incontinence – were believed to be largely the result of oestrogen deficiency after ovariectomy. Short-acting oestrogens, administered daily to weekly, can successfully treat the 'puppy coat' condition observed after spaying.[10] Some reports, however, do not support oestrogen deficiency as the underlying cause.[11]

Iris Margaret Reichler and Monika Welle contributed equally to this work.

Dogs are treated with depot-gestagens for the long-term postponement of oestrus which results in ovarian quiescence.[12] These gestagen-treated dogs have similar basal oestrogen values as spayed dogs; however, the type of incontinence seen in spayed dogs has not been reported in gestagen-treated dogs and coat changes rarely occur. Furthermore, although oestrogen receptors have been demonstrated immunohistochemically in various locations of the hair follicle, no difference was detected between intact and spayed dogs.[3]

After ovariectomy, not only the gonadal secretion of oestrogen and progesterone is lacking, but also the feedback of these hormones to the hypothalamus and pituitary gland is interrupted. As a result, plasma concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in spayed dogs are several fold higher than that of sexually intact dogs during anoestrus.[11,13–15] Besides the reproductive integrity, body weight, breed and time point of ovariectomy influence plasma gonadotropin concentrations.[11] The gonadotropin secretion is under the control of gonadotropin-releasing hormone (GnRH), a decapeptide from the hypothalamus. Many forms of GnRH analogues with varying potencies and persistence of action have been synthesized.[16] Repeated administrations or continuous release of GnRH analogues suppresses the secretion of FSH and LH by desensitizing the pituitary gland and thus the gonadal function. In dogs, they were used for hormonal ablation of the gonads,[17–21] for the treatment of mammary tumours,[18] prostatic hyperplasia[22] and urinary incontinence after spaying.[23,24] After treatment of incontinent dogs with depot preparations of GnRH analogues owners reported an improved coat quality.[23,24] Furthermore, receptors for FSH, LH and GnRH have been demonstrated in various epithelial structures in the canine skin.[25] The authors therefore hypothesized that the increased secretion of gonadotropins after ovariectomy may play a role in the development of the so-called 'puppy coat' observed in certain breeds of dog after spaying.

The main goals of this study were to examine the effect of spaying and GnRH treatment on the hair coat, cycle stages of the hair follicle, plasma gonadotropin concentrations and mRNA transcription of LH and GnRH receptors in canine hair follicles. Female dogs before and 1 year after spaying and spayed dogs before and after GnRH treatment were examined.

Materials and methods

Dogs

All procedures dealing with animal care, handling and treatment in this study were reviewed, approved and monitored by the Canton of Zurich Veterinary Office.

All dogs included in the study were examined at the Veterinary Teaching Hospital in Zurich. Fifteen dogs were presented for spaying (ovariectomy or ovariohysterectomy) and 1 year thereafter. Four of these dogs were spayed in spring, two in summer, five in autumn and four in winter. These 15 dogs were evaluated exactly 1 year after spaying, eliminating any potential impact of season in the parameters investigated.

Twenty-four spayed dogs were presented for GnRH treatment and were re-examined 8–16 weeks after a single subcutaneous injection of GnRH analogue (Deslorelin acetate, Peptech Animal Health Australia, North Ryde, NSW, Australia). Dogs weighing less than 30 kg received 4.7 mg of GnRH analogue and dogs over 30 kg received 9.4 mg.[21] The dogs treated with GnRH were presented because they showed side effects of spaying. Seven dogs had urinary incontinence due to urethral sphincter incompetence and two had increased aggressiveness towards other bitches, which occurred after spaying. One of these dogs as well as 13 other dogs showed coat changes after spaying. Furthermore, two dogs that did not show side effects of spaying (including coat or behavioural changes) participated in the study. Three of these 24 dogs were presented for treatment in spring, 11 in summer, four in autumn and six in winter.

Clinical examination

At each visit, the dogs had a complete physical examination performed. The hair coat was evaluated empirically and categorized as 'unchanged' or 'changed' after spaying or before GnRH treatment. The coat was classified as 'unchanged' if it had the breed-specific features. The coat was assessed as 'changed' if loss of colour intensity, excessive wool hair, loss of guard hair, or increased curling were observed. The hair coat assessment after GnRH treatment was performed only in dogs with at least one of the above changes before treatment. The dogs whose coat quality improved after GnRH treatment were placed in the category of 'clinical effect'. The dogs with no improvement were classified as 'no clinical effect'.

The sexual cycle phase of the intact dogs was determined by the interval since the last oestrus, inspection of the external genitalia and the plasma progesterone value. Anoestrus was diagnosed if the external genitalia were inconspicuous and the progesterone concentration was below 2 ng mL^{-1}. Prooestrus was defined as the period from onset of vulvar swelling and sanguineous vaginal discharge to the first signs of accepting the male dog (standing behaviour). Metoestrus was diagnosed if oestrus behaviour was not present and the progesterone values were above 2 ng mL^{-1}.

Hormone analysis

At the initial presentation, 5 mL of blood was collected from the jugular vein for hormone analysis, either during clinical examination of the dogs presented for GnRH treatment ($n = 24$) or induction of anaesthesia in the dogs presented for spaying ($n = 15$). To determine the effects of spaying and GnRH treatment on FSH and LH concentrations, all dogs had plasma concentrations of FSH and LH measured before and after spaying or GnRH treatment. In addition, the 15 dogs presented for spaying had plasma progesterone concentrations measured before spaying to determine the phase of the oestrus cycle. For hormone analysis, blood samples were transferred immediately after collection into NH4-heparinized tubes and centrifuged within 15 min for 10 min at 1500 RCF (relative centrifugation forces). The plasma was transferred into polysterol tubes and stored at –20 °C until analysis. Canine LH was determined using a specific canine LH radioimmunoassay (Biocode canine LH kit, No. AH C002, DispoLab AG, Dielsdorf, Switzerland) with the lowest limit of detection of 0.2 ng mL^{-1}. According to the manufacturer, the assay is species specific although LH from other species can partially cross-react with canine LH. Weak cross-reactivity with other canine pituitary hormones was noted and was due to contamination of the hormonal preparation as verified by a receptor assay (data not shown). Reproducibility data for this assay were as follows: intra-assay coefficient of variation (CV) of 5.35%, 4.67% and 7.21% (three samples, 18 replicates; 4.39, 23.33 and 62.10 ng mL^{-1}) and interassay CV of 5.13%, 6.47% and 18.9% (same sample, eight separate assays).

Canine FSH was determined using a canine-specific FSH immunoradiometric assay (Biocode canine FSH kit, No. AH C001; DispoLab AG) with the lowest limit of detection of 0.2 ng mL^{-1}. The specificity of this test was the same as that of the LH test. The intra-assay reproducibility (18 replicates) for this test was as follows: using 2.24, 9.18 and 34.46 ng mL^{-1}, the CV was 4.07%, 1.81% and 1.69%. The interassay (same samples, eight separate assays) CV was 9.91%, 5.46% and 4.03%. For assay purposes the reported limit was set at the lowest supplied standard concentration. For LH and FSH, this was 1.0 and 1.5 ng mL^{-1}, respectively. Plasma progesterone concentrations were measured by radioimmunoassay using a commercial kit (Coat-A-Count® Progesterone, Bühlmann Laboratories AG; Schönenbuch,

© 2008 The Authors. Journal compilation © 2008 ESVD and ACVD.

Switzerland) previously validated for dogs.[26] The intra- and interassay CV were 5.1% and 8.8%, respectively. For assay purposes the reported limit was set at the lowest and highest supplied standard concentration, this was 0.32 and 127.2 nmol L^{-1}, respectively.

Skin biopsies

To evaluate the effect of spaying and GnRH treatment on hair follicle cycle stages and mRNA transcription of LH and GnRH receptors, skin biopsies were performed before and after spaying or GnRH treatment. Skin biopsies were taken from the flank under full anaesthesia in the 15 dogs that presented for spaying. In 10 of these dogs an additional skin biopsy was taken from the abdomen to determine if body site influenced the anagen : telogen ratio. One year after spaying as well as before and after GnRH treatment, skin biopsies were taken under local anaesthesia using 2% lidocaine. In all 24 dogs treated with GnRH, biopsies were taken from the flank at the cranial-ventral border of the wing of the ilium. The first biopsy sample was taken from the left flank and the second from the right flank to avoid potential scar tissue from the first biopsy. Eight millimetre punch biopsy instruments were used to collect all samples and the biopsy sites were closed with single sutures (Supramid 4/0). One-half of each biopsy was fixed in 4% buffered formalin at room temperature for 24 h for evaluation of the hair follicle cycle stages. The other half of the biopsy was placed into 1 mL RNAlater (RNAlater™, Qiagen AG, Hombrechtikon, Switzerland) and stored at 4 °C until polymerase chain reaction (PCR) analysis of mRNA transcription of LH and GnRH receptors.

Histological examination for determination of hair follicle cycle stages

After embedding in paraffin wax, 4-μm sections were cut from each tissue block and stained with haematoxylin and eosin. A blinded histological examination was performed by one of the authors. The cycle stages of all hair follicles present in the vertically embedded biopsies were assessed. The follicles were defined to be in anagen if either a bulb or an inner sheath was visible. The follicles were defined to be in telogen if the inner sheath cornification was completely replaced by trichilemmal cornification. Hairless telogen follicles were telogen follicles where no hair shaft was present.[27] Catagen was characterized by having no bulb, increased numbers of apoptotic cells and partial replacement of the inner sheath by trichilemmal cornification. Hair follicle cycle stages were evaluated before and after spaying (n = 15 dogs) and before and after GnRH treatment (n = 24 dogs).

Real-time RT-PCR for mRNA transcription of LH and GnRH receptors

Skin biopsy specimens preserved for mRNA extraction were further processed as previously described.[25] Real-time RT-PCR for mRNA transcription of LH and GnRH receptors was performed using TaqMan Universal PCR Master Mix (Invitrogen AG, Basel, Switzerland). Mean values (± SE) of triplicate determinations of LH and GnRH mRNA were assessed and expression levels of the genes were given as values in arbitrary units relative to the amount of the constitutively expressed 'house-keeping' gene r18S.

Real-time RT-PCR was not performed in the present study to quantify the mRNA transcription of FSH receptors, as the results of preliminary examinations gave very low values and a high mean variation in biopsy duplicates.

Data analysis

Microsoft Excel 97 was used to record data and statistical analyses were performed using StatView 5.01 (SAS Institute Inc., Cary, NC, USA). Plasma FSH and LH concentrations and mRNA transcription of LH and GnRH receptors were analysed with histograms in order to evaluate the distribution of the values. Transcription values for LH and GnRH receptors were transformed for statistical analysis because the distribution was skewed. The effects of spaying (n = 15) or GnRH treatment (n = 24) on mRNA transcription of LH and GnRH receptors and on hair follicle cycle stages were analysed by paired Student's t-test and paired sign test. These tests were also used to analyse if the body location had an impact on the above-mentioned parameters for the 10 dogs in which skin biopsies from the flank and the abdominal wall were taken before spaying.

The coat categories 'changed' or 'unchanged' after spaying, and whether the GnRH treatment had 'clinical effect' or 'no clinical effect' on coat quality were summarized by proportions and the corresponding 95% confidence intervals (CI). For the evaluation of differences between the groups ('changed'/'unchanged'; 'clinical effect'/'no clinical effect'), the Mann–Whitney U-test for two independent spot checks was used. Additionally, a simple analysis of variance was used for the transformed data and a post-hoc analysis, according to Bonferroni, was performed to confirm differences between single groups.

In order to demonstrate possible relationships between the different parameters (body weight, age, season, plasma gonadotropin concentrations, percentage distribution of the follicular cycle stage, mRNA values of LH and GnRH receptors), Pearson correlation coefficients (r) on the log transformed values and the corresponding 95% CI were calculated. Linear regressions were also performed to show the possible influence of single parameters on the percentage distribution of the follicular cycle stage and on the mRNA values of LH and GnRH receptors.

Throughout the study, statistical tests with P-values less than 0.05 were considered significant.

Results

The effects of spaying and GnRH treatment on hair coat were evaluated in 15 and 24 dogs, respectively, by examining each dog twice. Compared to the dogs presented for GnRH treatment (n = 24) the dogs presented for spaying (n = 15) were significantly younger and had a lower body weight at the time of spaying and 1 year later (mean age at the time of GnRH treatment 6 years vs. 2 years at the time of spaying (P = 0.0020) and 3 years 1 year later (P = 0.0098); mean body weight at the time of GnRH treatment 24 kg vs. 14 kg both at the time of spaying and 1 year later (P = 0.0074 and P = 0.0110, respectively).

Effects of spaying on coat change, cycle stages of hair follicles, plasma FSH and LH concentrations and mRNA transcription of LH and GnRH receptors

The effect of spaying on coat appearance, cycle stages of the hair follicles, plasma FSH and LH concentrations, and mRNA transcription of LH and GnRH receptors was examined in 15 female dogs before and 1 year after spaying. At the time of spaying, 12 dogs were in anoestrus, two in prooestrus and one in metoestrus (Table 1).

Coat changes 1 year after spaying were observed in 2 of 12 dogs (16.7%) spayed during anoestrus. A Hovawart dog had increased wool hair at the caudal aspect of the thighs and a beagle dog had a lighter coat colour. Additionally, a cocker spaniel spayed during metoestrus had a lighter coat colour and increased wool hair on the trunk and caudal aspects of the thighs. No coat changes were noted in the two dogs in prooestrus. Therefore, 3 of the 15 dogs (20%) developed coat changes 1 year after spaying.

Skin biopsies from the flank of nine anoestrous dogs and of the dogs spayed in prooestrus (two) and metoestrus (one) were analysed histologically before and after spaying. The histological sections of the remaining three dogs were of insufficient quality. Statistical analysis was only performed for the dogs spayed in anoestrus (n = 9). Before spaying, 67% of the hair follicles were in telogen and only 29.2% in anagen (median anagen : telogen ratio = 0.4). One year after spaying, significantly fewer follicles were in telogen (40.5%) and significantly more in

LH flank skin	61.0 (11.3, 168.4)	29.8 (11.2, 167.9)	0.8
GnRH flank skin	1.2 (0.5, 5.2)	3.5 (1.4, 7.1)	0.1242

Results are presented as median values with the 1st and 3rd quartile (Q1, Q3) in parentheses. *Unclear follicle cycle stages were taken into account in regards to the total number, but were not assigned to a cycle phase. †All telogen follicles including hairless telogen.

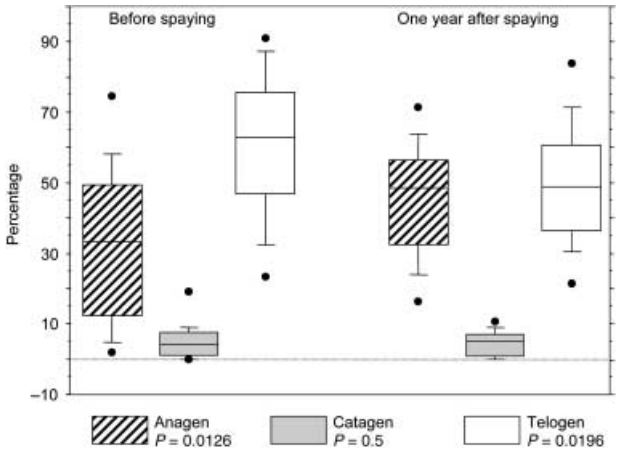

Figure 1. Percentage of anagen, catagen and telogen hair follicles in skin biopsies from the flank of nine dogs in anoestrus before spaying and 1 year after spaying. Values in the box plots reflect the 25th, 50th (median) and 75th percentiles. The whiskers represent approximately 90–95% of the values. Outliers are represented by dots.

anagen (50.8%, median anagen : telogen ratio = 1.2) (Fig. 1; Table 2). This increase of the anagen : telogen ratio was shown in eight of nine dogs (P = 0.0391).

No difference in the anagen : telogen ratio between dogs with and without coat changes after spaying could be observed (anagen : telogen ratio: 0.9 vs. 1.1, respectively; P = 0.9).

One year after spaying, the body weight as well as plasma LH and FSH concentrations of the 12 female dogs spayed during anoestrus were significantly increased. Although the median mRNA value of LH receptors was twice as low in spayed dogs and of GnRH receptor was nearly three times higher, these findings were not statistically significant. The data are shown in Table 2.

Effects of GnRH treatment on coat change, cycle stages of hair follicles, plasma FSH and LH concentrations and mRNA transcription of LH and GnRH receptors

The effect of GnRH treatment on coat quality as well as on the cycle stages of the hair follicles, plasma FSH and LH

© 2008 The Authors. Journal compilation © 2008 ESVD and ACVD.

concentrations and mRNA transcription of LH and GnRH receptors was examined in 24 spayed dogs before and 8–16 weeks after treatment. Fourteen spayed dogs were presented for GnRH treatment because they had developed coat changes after spaying (Table 3). According to the owners, most dogs (n = 13) had significantly more wool hair especially on the trunk, caudal aspect of the thighs and the abdomen. In three dogs the coat was curlier after spaying. At re-examination 8–16 weeks after GnRH treatment, the coats of three dogs remained unchanged whereas in 11 dogs the coat quality improved. Two dogs had a 10- to 15-cm-wide stripe of a shinier, smoother and intensively coloured hair on the dorsum from the shoulder down to the sacral region (Fig. 2). The effect of duration of treatment varied considerably. In one dog, the improvement of coat quality lasted only 4 months, whereas in the majority of dogs, it lasted at least 6 months. Consistent with previous reports, all 24 female dogs tolerated the GnRH treatment and no systemic or local side effects were observed.[19,21,23,24,28,29] The body weight of the dogs before and after treatment was similar (Table 4).

The analysis of the follicular stages before and after treatment was performed only in 21 dogs because the histological sections of three dogs were of insufficient quality. Before GnRH treatment, spayed dogs with coat changes (n = 14) had a higher anagen : telogen ratio than spayed dogs with unchanged coats (n = 7) (median = 0.6 (1st and 3rd quartiles = 0.2, 1.2) vs. 0.2 (0.1, 05); P = 0.0560). Furthermore, higher plasma FSH concentrations before treatment were observed in dogs presented with coat changes compared to dogs with breed-specific coats, but this difference was not significant (median = 66.2 ng mL^{-1} (1st and 3rd quartiles = 54.4, 83.9) vs. 36.6 ng mL^{-1} (28.4, 70.0); P = 0.0862). Plasma LH concentrations and mRNA transcriptions of LH and GnRH receptors were similar in both groups before treatment. After GnRH treatment, the anagen : telogen ratio did not change significantly; however, a significant increase in the percentage of catagen follicles was observed. Plasma FSH and LH concentrations of all 24 dogs treated with GnRH decreased after treatment. The mRNA values for LH and GnRH receptors were similar before and after GnRH treatment. Data are shown in Table 4.

After GnRH treatment, no differences in mRNA transcriptions of LH and GnRH receptors, percentage of follicles in different cycle stages, and plasma FSH and LH concentrations were observed between dogs showing clinically improved coat quality (n = 11) and nonresponders (n = 3) (data not shown).

Influence of body weight, age, season, and plasma gonadotropin concentrations on the percentage distribution of the follicular cycle stages and on the mRNA transcription of LH and GnRH receptors

A weak relationship between the anagen : telogen ratio and the plasma LH concentrations in spayed dogs could be demonstrated (r = 0.324, P = 0.0705). Spayed dogs with high plasma concentrations of LH had higher percentages of anagen follicles than dogs with low LH plasma concentrations. A relationship between hair cycle stages and gonadotropin concentrations was not found in dogs in anoestrus or in spayed GnRH-treated dogs. No associations

Figure 2. Picture of a male dog not evaluated in the present study demonstrating the effect of neutering and gonadotropin-releasing hormone (GnRH) treatment on the hair coat. This dog had coat changes similar to those observed in the Malinois dog and cocker spaniel in the present study. (a) Cocker spaniel with the breed-specific coat before neutering. (b) The same dog 6 months after neutering. Note the marked wool hair, the dull coat colour and the increased hair curvature. (c) The same dog 12 weeks after GnRH treatment: the coat is darker, shinier and smoother on a 10-cm stripe at the dorsal midline from the shoulder to the sacral region. (d) The same dog 16 weeks after GnRH treatment: the hair on the dorsal midline is woollier and has a dull appearance.

Table 4. Plasma gonadotropin concentration, cycle stage of hair follicles and mRNA values of LH and GnRH receptors in skin biopsies from the flank of spayed dogs before and 8–16 weeks after GnRH treatment

	Before GnRH treatment	After GnRH treatment	*P*-value
Age (years)	5.7 (3.4, 9.7)	6.2 (3.9, 10.0)	< 0.0001
Bodyweight (kg)	23.0 (19.8, 31.7)	23.5 (20.3, 31.3)	0.3
Gonadotropins (n = 24)			
LH (ng mL^{-1})	5.7 (3.4, 7.0)	1.0 (0.75, 1.0)	< 0.0001
FSH (ng mL^{-1})	59.1 (39.8, 81.4)	1.0 (0.6, 2.2)	< 0.0001
Percentage of follicles in cycle stage* (n = 21)			
Anagen	30.1 (17.2, 43.4)	40.1 (24.8, 48.7)	0.2
Catagen	0.6 (0.0, 3.7)	4.0 (1.7, 7.0)	0.0302
Telogen†	67.9 (45.6, 81.2)	55.9 (49.6, 71.8)	0.1191
Hairless telogen	24.6 (18.8, 34.6)	26.6 (15.9, 32.7)	> 0.9
Anagen : telogen ratio	0.4 (0.2, 1.1)	0.7 (0.4,1.0)	> 0.9
Receptors (n = 24)			
LH flank skin	12.0 (8.0, 27.9)	20.6 (7.8, 45.2)	0.3
GnRH flank skin	0.7 (0.2, 1.9)	0.8 (0.3, 1.6)	0.3

Results are presented as median values with the 1st and 3rd quartile (Q1, Q3) in parenthesis. *Unclear follicle cycle stages were taken into account in regards to the total number, but were not assigned to a cycle phase. †All telogen follicles including hairless telogen.

were observed between the anagen : telogen ratio and body weight, age and season, respectively, in dogs that are in anoestrus, spayed, or spayed and GnRH treated (data not shown).

Plasma gonadotropin concentrations were significantly lower in spayed dogs with a higher body weight (LH r = –0.421, P = 0.0147, FSH r = –0.473, P = 0.0038). Age and season at the time of examination had no effect on plasma LH or FSH concentrations (data not shown).

A significant influence of body weight on mRNA values of LH receptors in skin biopsies of the flank of intact and spayed untreated dogs was demonstrated. The higher the body weight, the lower the mRNA transcription of LH receptors (intact: r = –0.530, P = 0.0062; and spayed: r = –0.373, P = 0.0350). This effect was not observed on mRNA values of GnRH receptors. After GnRH treatment, no associations were found between mRNA values of LH and GnRH receptors and body weight. There was no relationship between mRNA transcriptions of LH or GnRH receptors and plasma gonadotropin concentrations, age or season at the time biopsies were taken, respectively (data not shown).

Influence of biopsy site

Biopsies from the flank and from the abdominal wall could be evaluated in 10 of the 15 intact dogs. A higher anagen : telogen ratio in the biopsies of the flank compared to the abdominal wall was noted in samples from the same individual; however, the difference was not significant (P = 0.0673). This was due to a higher percentage of hairless telogen follicles in the abdominal wall (flank: median 22.3 (1st and 3rd quartiles = 11.5, 31.0) vs. abdominal wall: 35.6 (25.0, 44.0), P = 0.0135). The mRNA transcription of LH and GnRH receptors was similar in biopsies of the flank and abdominal wall in intact anoestrous dogs (median 50 (1st and 3rd quartiles = 9198) vs. 249 (17, 1130) P = 0.2; and median = 1.1 (0.4, 4.9) vs. 1.6 (1.3, 4.8) P = 0.3, respectively).

Discussion

Although it is frequently observed that in dogs of certain breeds spaying results in changes of the hair coat quality, to the authors' knowledge, the influence of spaying on the hair cycle and mRNA transcription levels of gonadotropin receptors has never been described.

In this study, 3 of 15 (20%) female dogs exhibited coat changes 1 year after spaying. The changes occurred in a Hovawart and a beagle dog in anoestrus and a cocker spaniel in metoestrous.

The anagen : telogen ratio was significantly increased 1 year after spaying independent of coat changes. A similar effect has also been demonstrated in rats where ovariectomy caused a profound and rapid telogen to anagen transition, with accompanying full hair growth.[30] The percentage of the different follicle stages may be influenced by body location, breed and season.[31–34] However, in the present study, it was possible to exclude these influences since the same dogs were reinvestigated at the same time of the year and biopsies from the same body location were taken. The only influence on the hair follicle cycle phases that could not be excluded entirely was age and body weight, although no significant relationship between these parameters could be demonstrated in this study.

Spayed dogs that were presented with coat changes for GnRH treatment had a higher anagen : telogen ratio compared to dogs with unchanged coats. The abnormal coat quality noted after spaying is called 'puppy coat'. After birth all hair follicles in dogs are in late stage of morphogenesis, similar to anagen, and the hair is of fairly constant diameter and curvature. At the age of 3–6 months, dogs 'lose' their puppy coat and develop the breed-specific adult coat. It is justifiable therefore to relate the changes in hair follicle cycle and coat quality observed in spayed dogs with the coat of puppies. The result of the present study may also explain the successful empirical oestrogen therapy in dogs with 'puppy coat'. Estrogens delay the initiation of the anagen hair follicle phase[35] and, thus, counteract the described spaying effect.

Subjectively, GnRH treatment was highly effective on the hair coat quality. At re-examination 8–16 weeks after treatment, nearly 80% of the dogs had less wool hair and a shinier and more intensively coloured coat. GnRH analogues are also given successfully to human patients with excessive hair growth.[36] It remains unclear why in the

© 2008 The Authors. Journal compilation © 2008 ESVD and ACVD.

present study the response to GnRH therapy ranged from ineffective to long lasting. In dogs and other species, the required dose and duration effect of GnRH therapy are individually variable.[21,23,24]

Before and after GnRH treatment a large variability in the percentage distribution of hair cycle stages was observed. Although the same dog was examined before and after treatment, biopsies were taken from different breeds at various times of the year and these factors could also have affected the hair follicle stages. After GnRH treatment no significant difference in the anagen : telogen ratio was found. However, a significantly higher percentage of catagen follicles after treatment was observed, which may indicate that GnRH terminates the anagen phase and initiates the catagen phase, and thus has a similar effect to androgens. However, these data have to be considered with precaution since dogs were re-evaluated 8–16 weeks after GnRH treatment; therefore, at a different time of the year.

No difference in the percentages of follicular cycle stages was observed between dogs that had clinically improved coat quality after GnRH treatment and non-responders. This was unexpected as the owner's observation that the wool hair was easier to comb after GnRH treatment suggested that more telogen hair follicles was present. These findings could be the result of seasonal influences, since the repeated skin biopsies were taken 2 to 3 months apart; therefore, at a different season of the year. It has been shown in intact male dogs with same hair type but of different breeds that the time of the year influences hair growth individually.[33] A study including a greater number of treated dogs evaluated at the same season before and after treatment would be necessary to obtain more reliable data.

After spaying, plasma gonadotropin concentrations increased significantly. A weak positive relationship between plasma LH concentrations and the percentage of anagen follicles in spayed dogs could be demonstrated. A relationship between LH concentrations and hair growth is also known in humans. Women with polycystic ovarian syndrome have increased hair growth and abnormally high LH concentrations.[37] This finding supports a role for LH on the hair cycle.

In spayed dogs with coat changes, a tendency towards higher plasma FSH concentrations was observed compared to dogs without coat changes. This finding is supported, to some extent, by a study in postmenopausal women who complained about hair and skin changes.[38] Increased FSH values were seen in those women mostly bothered by such postmenopausal problems.[38] However, the possible role of FSH in the pathophysiology of spay-induced coat changes is unclear.

The plasma gonadotropin concentrations of all dogs treated with GnRH decreased significantly as previously reported.[23,24] Although most treated dogs showed an improvement of the hair coat quality, no relationship with lower plasma gonadotropin concentrations could be shown.

The influence of the sexual cycle on hair growth has been described in a large number of studies.[34,39–43] A direct receptor-mediated effect of oestrogens and androgens on the hair follicle is unlikely because the removal of the gonads does not seem to have an effect on these receptors.[3] Based on the present results, the same seems to be true for LH and GnRH receptors, since no significant changes could be shown after spaying or GnRH treatment.

Body weight seems to influence the mRNA transcription of LH receptors with lower levels noted in heavier dogs. It can be suggested that there is an association between the lower plasma gonadotropin concentrations in heavy dogs observed in another study,[11] and the lower receptor expression found in this study. However, in this study we could not find a significant correlation between body weight and gonadotropin concentrations. It is possible that receptor expression is not only influenced by body weight but also by other factors such as breed and season. However, studies need to be conducted to test this hypothesis.

Although FSH receptors were demonstrated in the canine skin by immunohistochemistry, and indirectly through the presence of low levels of FSH receptors mRNA by PCR,[25] a quantitative assessment of mRNA transcription of FSH receptors in the skin was not performed in the present study as preliminary results gave very low values and a high mean variation in biopsy duplicates.

The mRNA transcription of LH and GnRH receptors in the flank and abdominal skin was similar, although the percentage of the different follicle phases was significantly different. Therefore, a direct role of gonadotropins and GnRH influencing the hair cycle is not very likely. However, receptor protein is responsible for hormone binding in a target tissue and thus necessary for hormone action. A quantitative demonstration of receptor protein, and simultaneous evaluation of the plasma gonadotropin concentrations and the anagen : telogen ratio in dogs of the same breed before and after spaying would lead to more conclusive results about the role of FSH, LH and GnRH on the hair cycle.

It is likely that there is an indirect relationship between LH plasma concentrations and the percentage of anagen follicles. The LH secretion in intact animals is not only influenced by the feedback mechanism of oestradiol, but also by prolactin which suppresses the LH secretion. After gonadectomy, the prolactin concentration in rats significantly decreases, but can again increase with oestrogen treatment.[44,45] If the same endocrinological mechanisms occur in the dog, a causal role of prolactin would be conceivable. In addition, this might also explain the positive effect of oestrogen treatment seen in spayed dogs with a 'puppy coat'. Furthermore, after treatment with prolactin-suppressing substances a change of the coat colour was observed,[46] which would also be in agreement with a key role of prolactin. The absolute deficiency of prolactin in prolactin knockout mice results in slightly longer and coarser hair than in wild-type mice.[5] Because prolactin induces the catagen stage,[5,47,48] a deficiency of prolactin in spayed dogs could explain the shift in favour of anagen follicles as was observed in the present study. Prolactin and its receptor are expressed in hair follicle epithelium and show hair cycle-dependent expression in mice and mares.[47,48] Future studies are needed to clarify if prolactin plays a causative role in the pathomechanism of spaying-induced coat changes.

In summary, the present study clearly shows an increased anagen : telogen ratio in dogs after spaying independent

© 2008 The Authors. Journal compilation © 2008 ESVD and ACVD.

of coat changes. Additionally, coat changes after spaying could be successfully treated with GnRH. However, GnRH treatment did not influence the anagen : telogen ratio and no changes in mRNA transcription of LH or GnRH receptors were found after spaying or after GnRH treatment. Thus, a direct receptor-mediated hormonal effect of the pituitary and hypothalamic hormones on the follicle is unlikely and the results of this study cannot clarify the underlying pathomechanisms of coat changes after spaying.

Résumé Bien que la stérilisation puisse être responsible de modifications de la qualité du pelage chez le chien, son influence sur la pousse pilaire n'a pas été rapportée. Cette étude s'est intéressée à examiner les effets de la stérilisation et d'un traitement à la GnRH sur le pelage, le cycle folliculaire, les concentrations en gonadotropines plasmatiques et la transcription de l'ARNm des récepteurs à la LH et la GnRH dans les follicules pileux. Quinze chiennes ont été examinées avant et un an après une stérilisation et 24 chiens mâles castrés avant et après traitement à la GnRH. La stérilisation a provoqué une augmentation des concentrations plasmatiques en gonadotropines et une augmentation du rapport anagène/télogène, mais seulement 20% des chiens ont présenté des modifications du pelage. Aucune différence n'a été observée pour la transcription d'ARNm des récepteurs LH et GnRH. Le traitement à la GnRH a provoqué une diminution des concentrations en gonadotropine plasmatique, et une amélioration du pelage chez 79% des chiens. Ceci était associé avec une augmentation des follicules en phase catagène sans modification du rapport anagène:télogène. Cette étude démontre que la stérilisation a un effet sur le rapport anagène:télogène des follicules pileux. Les modifications pilaires ne corrèlent pas avec le ration anagène:télogène. Le traitement à la GnRH a diminué les concentrations en gonadotropines et a permis d'améliorer le pelage chez certains chiens, mais n'a pas eu d'effet sur le cycle pilaire, hormis une augmentation du nombre de follicules en catagène. Une corrélation faible entre les concentrations plasmatiques en LH et le rapport anagène:télogène a été observée, cependant nos données n'ont pas suggéré un effet direct médié par les hormones sur le follicule pileux. Cette étude n'a pas permis d'identifier le mécanisme pathogénique des modifications du pelages observées après stérilisation.

Resumen Aunque la esterilización puede resultar en cambios cualitativos en el pelaje de los perros, las influencia de la esterilización en el ciclo de crecimiento del pelo nunca ha sido descrita. Este estudio trata de examinar el efecto de la esterilización y del tratamiento con GnRH en el pelaje canino, los estadíos del ciclo de los folículos pilosos, las concentraciones de gonadotropina en el plasma y la transcripción del mRNA de los receptores LH y GnRH. Se examinarion quince hembras antes y después de un año del tratamiento de esterilización y 24 perros esterilizados antes y después del tratamiento con GnRH. La esterilización resultó en un aumento de la concentración de gonadotropina y un aumento de la relación anágena:telógena de los folículos pilosos, pero sólo un 20% de los perros presentaron cambios en el pelaje. No se observaron diferencias en el nivel de transcripción de los receptores de LH y GnRH. El tratamiento con GnRH resultó en una reducción de la concentración de gonadotropina y en una mejora de la calidad del pelaje en un 79% de los pacientes. Esto se relacionó con un aumento de los folículos en fase catágena sin cambios en la relación anágena:telógena. Este estudio demuestra que la esterilización tuvo un efecto en la relación anágena:catágena de los folículos pilosos. Los cambios en el pelaje inducidos por la esterilización no se asociaron con la relación anágena:telógena de los folículos pilosos. El tratamiento con GnRH redujo las concentrationes de gonadotropina e invirtió los cambios en el pelaje en algunos perros, pero no tuvo efecto el el ciclo de crecimiento del pelo, excepto por un incremento del número de folículos en fase catágena. Se observó una pequeña correlación entre la concentración de LH en plasma y la relación anágena:telógena; aunque nuestros datos no sugerían un efecto directo hormonal mediado por receptores en los folículos pilosos. Este estudio no identificó el mecanismo patogénico de los cambios en el pelaje inducidos por la esterilización.

Zusammenfassung Obwohl die Ovariohysterektomie bei Hunden eine qualitative Veränderung des Haarkleides bewirken kann, wurde der Einfluss der Ovariohysterektomie auf den Haarwachstumszyklus nie beschrieben. Die Ziele dieser Studie bestanden darin, die Wirkung der Kastration und der GnRH-Behandlung auf das Haarkleid des Hundes, auf die Zyklusstadien der Haarfollikel, auf die Gonadotropinkonzentrationen im Plasma und auf die mRNA Transkription der LH und GnRH Rezeptoren in Haarfollikeln zu untersuchen. Es wurden fünfzehn Hündinnen vor und ein Jahr nach der Kastration, sowie 24 kastrierte Hündinnen vor und nach Behandlung mit GnRH untersucht. Die Kastration resultierte in erhöhten Gonadotropinkonzentrationen im Plasma und einem erhöhten Anagen-Telogen-Verhältnis der Haarfollikel, obwohl nur 20% der Hunde eine Veränderung des Haarkleides entwickelten. Bei der mRNA Transkription der LH und GnRH Rezeptoren wurden keine Unterschiede festgestellt. Die Behandlung mit GnRH ergab niedrigere Gonadotropinkonzentrationen im Plasma und eine Verbesserung der Fellveränderungen bei 79% der Patienten. Dies wurde im Zusammenhang mit einer Zunahme der katagenen Haarfollikel ohne Veränderungen des Anagen-Telogen-Verhältnisses gesehen. Die vorliegende Studie zeigte, dass die Kastration eine Auswirkung auf das Anagen-Telogen-Verhältnis der Haarfollikel hatte. Die durch die Kastration bedingten Veränderungen des Haarkleides korrelierten nicht mit dem Anagen-Telogen-Verhältnis. Die Behandlung mit GnRH reduzierte die Gonadotropinkonzentrationen und machte die Haarkleidveränderungen bei manchen Hunden rückgängig, hatte aber außer einer Zunahme an katagenen Haarfollikeln keinen Einfluss auf den Haarwachstumszyklus. Eine schwach positive Korrelation zwischen der LH Konzentration im Plasma und dem Anagen-Telogen-Verhältnis wurde beobachtet; unsere Daten wiesen jedoch nicht auf eine direkte, durch den Rezeptor vermittelte, hormonale Wirkung auf den Haarfollikel hin. Die gegenwärtige Studie konnte den Pathomechanismus der durch die Ovariohysterektomie bedingten Veränderungen des Haarkleides nicht identifizieren.

Sexual behavior in geldings

Jaume Fatjo i Rios, Katherine Houpt

Animal Behavior Clinic, College of Veterinary Medicine, Cornell University, Ithaca, NY 14853, USA

Abstract

In response to a request published in *Equus*, a magazine for those interested in horses, 85 owners of older geldings exhibiting sexual behavior completed history forms. The mean age of geldings was 16 ± 5 years. Only 39 of the owners had had the gelding for at least a year before the behavior was noted. These cases could be used to determine the true age of onset of the problem. When log survivorship was used to determine whether there were one or two different populations, a break or change in the slope at age 16 indicated that there are two populations. One population shows the behavior from the time of castration and the other first exhibits the behavior in old age, possibly in response to an ACTH secreting pituitary adenoma. A total of 40% of the horses were Quarterhorses, the most numerous breed in the US; 78% of the horses were purebreds. Fewer than half the owners knew the age at which their horse had been castrated because they did not own the horse at the time. The mean age at castration, when known, was 3.3 ± 2.5 years. The reason for contacting us was sexual behavior (70%), aggression (24%), or some other problem (1%). Whether or not aggression was the presenting problem, most of the horses showed aggression (95%), particularly towards other geldings (88%), but also towards people (31%). Copulatory behavior (mounting) was shown by 69% of the geldings and half of those were able to intromit. These findings indicate that the sexual behavior of geldings is a problem for owners and that aggression usually accompanies sexual behavior. The owners were encouraged to send serum samples taken before and after human chorionic gonadotropin (HCG) administration for testosterone and estrone sulfate analysis to determine whether residual testicular tissue was responsible for the horse's behavior. Of the 14 horses tested, only one had elevated levels of testosterone indicating that there was residual testicular tissue. A total of six of the owners agreed to treat their horses with cyproheptadine at a dose of 8 mg day^{-1} gradually increased to 88 mg day^{-1} per horse. A total of three of the horses showed a decline in sexual and aggressive behavior, one got worse and two had side effects and treatment was withdrawn.

Unilateral and Bilateral Laparoscopic Ovariectomy in 157 Mares: A Retrospective Multicenter Study

Objective: To evaluate surgical techniques, perioperative complications and outcome of laparoscopic surgery for unilateral and bilateral ovariectomy in mares.
Study Design: Retrospective multicenter case series.
Animals: Mares (n = 157).
Methods: Indications for surgery were neutering, fertility problems, elimination of hormone-related abnormal behavior, ovarian tumors as well as nonregressive ovarian hematomas or cysts. Ovariectomy (n = 206) were performed by a standard laparoscopic procedure in 157 standing sedated mares. Dissection and hemostasis were achieved by using either (1) a linear stapling device, (2) bipolar electrosurgical instruments, with or without a modified Roeder knot, (3) a vessel-sealing system, or (4) a diode-laser with ligation. For some larger ovarian masses (>20 cm diameter), a 2-step surgical procedure was used with standing flank laparoscopic ovariectomy followed by ovarian retrieval through a median celiotomy. Surgical techniques, outcome, and perioperative complications of each method were recorded and analyzed.
Results: Laparoscopic dissection of the ovary was accomplished in all mares. Because of the size of the ovarian tumor (n = 7) or in 1 mare with behavioral problems (n = 1), the dissected ovary was removed through a median celiotomy under general anesthesia. Seventeen mares (10.8%) developed postoperative complications (eg, incisional drainage, incisional infection, seroma formation, dehiscence, transient fever and mild abdominal discomfort). All mares with flank incisional problems had ovarian size >12 cm and in 15 (88%) of these mares electrosurgical instruments were used for mesovarial dissection.
Conclusions: Laparoscopic ovariectomy in standing sedated mares provides good surgical access and is associated with low morbidity.

INTRODUCTION

Different conventional surgical procedures[1–5] and minimally invasive techniques[6–11] have been reported for unilateral and bilateral ovariectomy in mares. Ovariectomy seems to be associated with a higher frequency of perioperative complications than other elective surgical procedures.[12,13] Ovariectomy by laparotomy or colpotomy is associated with serious perioperative complications, including hemorrhage, myopathy and neuropathy, wound infection and dehiscence, eventration, peritonitis, adhesions, postoperative colic and ileus.[14,15] Minimal invasive surgery is considered to result in fewer complications and has become more popular in the last few years. In comparison to colpotomy and laparotomy, laparoscopic procedures offer the advantages of good intraoperative visibility, secure hemostasis, less invasiveness, reduced surgical morbidity, and shortened hospitalization.[8,16] According to individual surgeon preference, laparoscopic intervention can be in the standing sedated horse[9,17–25] or in dorsal recumbency.[10,11,26–28] Most authors favor surgery in standing sedated mares because of the normal anatomic orientation, increased operative visibility, and avoidance of the risks and complications associated with general anesthesia.

We report findings from a retrospective multicenter clinical study to evaluate the surgical techniques, intra- and perioperative complications, and outcome of laparoscopic surgery for unilateral and bilateral ovariectomy in mares.

MATERIALS AND METHODS

Horses

Medical records (1996–2009) of 157 mares that had either unilateral or bilateral ovariectomy at the Veterinary Clinic Starnberg, Germany, the Department of Equine Surgery, School of Veterinary Medicine, Justus-Liebig University, Giessen, Germany, and the Faculty of Veterinary Medicine, Department of Equine Sciences, Utrecht University, Netherlands, were selected. Clinical indications were neutering, fertility problems, elimination of hormone-related abnormal behavior, ovarian tumors as well as non-regressive ovarian hematomas or cysts.

A complete physical examination, a hematologic and serum biochemical profile and a gynecologic examination, including abdominal palpation per rectum with ultrasonographic evaluation of the reproductive tract were performed in all mares presented for ovariectomy, regardless of the reason.

Depending on the clinical indication, the behavior of the mare, the size of the ovary, and the surgeon's preference, ovariectomy was performed as a standing laparoscopic surgical procedure or a 2-step surgical procedure. For the 2-step procedure, in the 1st step, transection of the ovarian pedicle was carried out laparoscopically in the standing sedated mare and in the 2nd step, the dissected ovarian tumor was extracted through a median celiotomy in dorsal recumbency under general anesthesia.

Mares were provided free choice of water but fed only mash and pellets for 36–48 hours before surgery or had food withheld for 48 hours. Cefquinomsulfate (1.0 mg/kg intramuscularly [IM]), procaine penicillin G (22,000 U/kg, IM) or sodium benzylpenicilline (30,000 U/kg, IM) in combination with gentamicin (6.6 mg/kg intravenously [IV]), and flunixin meglumine (1.1 mg/kg, IV) or meloxicam (0.6 mg/kg, IV) were administered preoperatively. In 119 mares, butylscopolamine (0.2 mg/kg, IV) was administered preoperatively to achieve spasmoanalgesia.

Surgical Technique

Sedation and analgesia was achieved with detomidine (0.01 mg/kg, IV) and butorphanol (0.01 mg/kg, IV). Throughout the surgical procedure, sedation was adjusted as needed by administration of detomidine and butorphanol (each in a dosage of 0.005–0.01 mg/kg, IV).

According to the diagnosis, one or both paralumbar fossae were shaved and aseptically prepared. Local analgesia was achieved by a paravertebral anesthesia and or an infiltration anesthesia subcutaneously, intramuscularly and subperitoneally with 20 mL 2% lidocaine (with or without 2% adrenalin) each at the surgical sites: the paralumbar fossa and the 17th intercostal space at the level of the tuber coxae.

Laparoscopic ovariectomy was achieved through 2 ipsilateral instrument portals in the flank and 1 optic portal in the 17th intercostal space or just caudal to the last rib. After exposure of the ovary, infiltration anesthesia of the ovarian pedicle was performed using 10–20 mL 2% lidocaine (with or without 2% adrenalin). Before transection, the size of the ovary was reduced by suction of fluid, when possible. Dissection and secure hemostasis of the mesovarium was achieved using either (1) a linear stapling device (35 mm or 45 mm, Endo-GIA, Covidien, Service Center S.A., Elancourt, France); (2) bipolar electrosurgical instruments, with or without ligation; (3) a vessel-sealing system (LigaSure® Force Triad™, Tyco Healthcare Deutschland GmbH, Soltau, Germany); or (4) a diode-laser (Dornier MediLas D®, Dornier Medizinlaser GmbH, Wessling, Germany) with ligation. In 13 mares, the ovarian tumor was contained within in an intraabdominal sterile plastic bag, cut into pieces and then retrieved within the bag. In the mares, the ovaries were removed intact, when necessary by enlarging 1 of the instrument portals or by connecting the 2 instrument portals up to a length of 15 cm using a modified grid technique. After removal of the ovary, portals and flank incisions were sutured. In bilateral interventions, the same procedure was performed through the opposite paralumbar fossa to remove the contralateral ovary. In 1 mare, the dissected left ovary was moved from the left to the right side, and both ovaries were exteriorized through the same right-sided incision at the end of the procedure.

For ovarian tumors with a diameter >20 cm or if the mare displayed aggressive behavior, ovariectomy was accomplished in a 2-step procedure.

Surgical techniques for dissection and hemostasis, the diameter of the tumor (measured with a ruler after removal) and intra- and perioperative complications (bleeding of the mesovarium, wound healing problems, fever and abdominal discomfort) were evaluated. In 30 mares, surgical time was measured to evaluate the influence of the dissection technique (linear stapling, bipolar electrosurgery and vessel-sealing); these procedures were performed by 1 surgeon in horses with an ovarian tumor <12 cm diameter.

Postoperative Care and Follow-up

Cefquinomsulfate (1.0 mg/kg intramuscularly, IM), procaine penicillin G (22,000 U/kg, IM every 12 hours), or sodium benzylpenicillin (30,000 U/kg, IM) in combination with gentamicin (6.6 mg/kg, IV) and flunixin meglumine (1.1 mg/kg, IV) or meloxicam (0.6 mg/kg, IV) were administered according to the initial administration for 2–6 days. During hospitalization, a clinical examination and white blood cell count were performed the first 3 days postoperatively. Horses were discharged with a recommendation of stall rest for 10–14 days after laparoscopic intervention and for 6 weeks after a 2-step surgical procedure with hand-walking twice daily before resuming normal use. Short-term results (6–8 weeks) were determined by telephone questionnaire of owners, trainers or referring veterinarians in 72 mares.

RESULTS

Ovariectomy (n = 206) was performed in 157 mares. Laparoscopic ovariectomy was bilateral in 49 mares and unilateral in 108 mares. Clinical indications for bilateral ovariectomy were neutering (24 mares), nymphomania, hormone-induced abnormal behavior as well as estrus-related reduced athletic performance (24 mares), and bilateral ovarian tumor (1 mare). Unilateral ovariectomy was performed for granulosa-theca-cell tumor (GCT) in 103 mares, an ovarian cyst in 1 mare, and nonregressive ovarian hematoma in 4 mares. The diameter of the GCT in 68 mares was <12 cm (66%), in 23, between 12 – 20 cm (22%) and in 12, > 20 cm (12%).

Complete laparoscopic ovariectomy was achieved in 149 standing sedated mares. In 7 mares, laparoscopic dissection was followed by removal of the ovary through median celiotomy in dorsal recumbency because the ovarian tissue was > 20 cm diameter. In only 1 mare was conversion to celiotomy necessary after laparoscopic dissection of the ovarian pedicle because of inability to control behavioral problems in the standing mare.

Hemostasis and dissection of the ovarian pedicle was performed using either a 35 mm or 45 mm linear stapling device (n = 66), by vessel-sealing system LigaSure® (n = 49) or by using bipolar electrosurgical instruments as a single technique (n = 49) or in combination with a circular ligature around the main vessels (n = 38), knotted extracorporeally using a modified Roeder knot. In 2 mares, hemostasis was initially performed with a diode-laser and in 2 mares with a single modified Roeder knot. In these 4 mares, hemostasis was incomplete and bipolar electrocoagulation was necessary to occlude the bleeding vessels.

Use of linear stapling devices (Endo-GIA) was technically easy and created very precise cut edges. Mean ± SD surgical time was 40.2 ± 10.2 minutes. Two cartridges were necessary to completely divide the mesovarium of a normal ovary, whereas 3–4 cartridge units were needed for ovarian tumors.

Using the 10-mm bipolar vessel-sealing system, (LigaSure®) the ovarian pedicle was progressively coagulated and cut in a single-step process. The main vessels were sealed twice at a distance of 1 cm before cutting. The device allowed very efficient and safe sectioning of the mesovarium and created a smooth coagulated wound surface at the resection site. By using this system, smoke evacuation was minimal and hemostasis was secure. Mean surgical time was 46.2 ± 8.2 minutes.

Electrocoagulation was performed using a bipolar forceps with a mechanical cutting blade, which allowed tissue coagulation and division over a length of 5 mm. Because the cranial and caudal part of the mesovarium is less vascularized, a single coagulation was sufficient to achieve secure hemostasis. In the middle part, including the main vessels, multistage tissue coagulation was performed before dissection. At the resection site, a coagulated and carbonized wound surface was created. This technique turned out to be a time-consuming procedure before a secure hemostasis was achieved. Mean surgical time was 60 ± 15.4 minutes.

In 13 mares, the ovarian tumor was intraabdominally placed in a sterile plastic bag, cut into pieces with a scalpel blade (# 11 or 22) and then extracted in pieces. In the other mares, the ovaries were removed intact, when necessary by enlarging 1 instrument portal or by connecting 2 instrument portals.

No major intraoperative complications occurred. Seventeen mares (10.8%) developed postoperative complications, such as postoperative dehydration (n = 1), extensive subcutaneous emphysema (n = 1), wound swelling, and seroma formation followed by infection and dehiscence of the flank incision (n = 15). In 4 of these 15 mares, transient fever up to 39.2° C was observed over 3–5 days, starting on the 2nd postoperative day. Two of these mares had mild postoperative depression and colic signs on the 1st and 2nd postoperative day. In 1 of these mares, a fist-sized hematoma at the resection site was diagnosed by rectal palpation and ultrasonography. In the other mare, an adhesion between the resected ovarian pedicle and the base of the cecum was detected, which was easily released by transrectal manipulation. All postoperative complications occurred in mares with an ovarian tumor size >12 cm (in 15 of 27 mares where the tumor was removed by flank incision). No incisional problems occurred in the celiotomy wounds.

Transection of the mesovarium was carried out with the bipolar electrosurgical forceps in 10 of 15 mares with incisional problems, in 2 mares with a combination of bipolar electrocoagulation and circular ligature, in 1 mare where a linear stapling device was used and in 2 mares where the vessel-sealing system was used. The hematoma as well as the intraabdominal adhesion occurred in mares in which hemostasis and dissection of the ovarian pedicle was carried out with the bipolar electrosurgical forceps.

All postoperative complications responded to conservative treatment and all 157 mares were discharged from the clinic. Mares that had laparoscopic surgery had an overall postoperative morbidity of 10.8% and mortality of 0%.

In the follow-up questionnaire, a slight depression of the musculature was reported for 8 mares at the site of the enlarged flank-incision. No further complications were reported.

DISCUSSION

We report laparoscopic ovariectomy in 157 mares (46 bilateral, 97 unilateral) for removal of normal (48 mares) and pathologic (109 mares) ovaries, using different techniques for mesovarial dissection and transection, with no mortality and 10.8% morbidity that is substantially lower than is reported for conventional surgical ovariectomy techniques (mortality, 4.5–7.7%[14]; morbidity, 24.4–26.6%[29]).

Incisional problems were the predominant complications (15 mares) and only occurred in mares with ovarian

diameter > 12 cm. In 12 of these mares, mesovarial dissection was by electrosurgery (10 electrosurgery alone, 2 electrosurgery in combination with ligation). Others have reported incisional complications being statistically associated with ovarian tumor size[30,31], particularly when ovarian diameter is > 18 cm. Six to 8 weeks after surgery, 8 mares in our study had a depression at the flank incision site. We did not suture the internal abdominal oblique and transverse abdominal muscles in the mares in this study. It is possible that closure of the muscle layers may have prevented this cosmetic defect; however, suturing these layers is technically difficult because of the small wound size. Nevertheless avoiding cosmetic defects is important in mares used for competition or those intended for sale.

Different techniques were used for removal of the transected ovaries. After mesovarial dissection, complete ovaries < 15 cm diameter were removed by enlarging the instrument portals exclusively, using forceps and wound-retractors. Hand-assisted procedures[32], were not used. In 13 mares, we used an intraabdominal retrieval bag and fragmented the ovary to minimize the size of the mass being exteriorized. Other reported techniques include placing the mobilized ovary in a sterile plastic disposable surgical drape and, after intraabdominal transection into pieces with a scalpel or a morcellator[33], removal of the contained ovarian tissue through a smaller incision.[32,34,35] This technique offers also the advantages of decreasing the risks of losing the ovary and avoiding wound contamination by the tumor during removal. In an effort to prevent incisional complications and to optimize cosmetic outcome in 7 mares with a tumor diameter >15 cm, even after size-reduction by suction, we used a 2-step procedure with ovariectomy performed standing and ovarian exteriorization performed under general anesthesia through a median celiotomy.

We used different primary methods to achieve hemostasis of the mesovarium before or during transection: linear stapling (66 ovaries), vessel sealing (49 ovaries), electrosurgical dissection (49 ovaries), electrosurgery in combination with ligation (38 ovaries); diode laser and ligation (2 ovaries) and ligation followed by electrocoagulation (2 ovaries). Measured in 30 mares with the same surgeon, time to accomplish mesovarial separation of an ovary (<12 cm diameter), was comparable (stapling, 40.2 ± 10.2 minutes: vessel sealing, 46.2 ± 8.2 minutes) although slightly longer with the electrosurgical method (60 ± 15.4 minutes). Other reported techniques include use of a modified Roeder knot[32] or by diode-laser.[20] Use of a modified Roeder knot or endoloop ligature are reportedly more economical[36]; however, a disadvantage of these techniques is the potential for ligature slippage and bleeding during dissection especially with enlarged ovaries,[30] and which we also experienced in 2 mares. A combination of bipolar electrosurgical dissection of the cranial and caudal part of the mesovarium with a circular ligature around the main vessels was reliable in our hands for removal of normal and enlarged ovaries. Surgical lasers (eg, diode- or Nd:YAG) should only be used in addition to one of the techniques already described.[20] The coagulative abilities of these lasers are insufficient to achieve reliable hemostasis as the sole method. We had this experience in 2 mares and had to use electrocoagulation to achieve hemostasis. During laser-dissection, there is also risk of thermal damage to adjacent structures.[37]

A safe, effective, but expensive, technique for laparoscopic ovariectomy is use of a vessel-sealing system (LigaSure®).[35] We found this to be a quick, safe method for hemostasis of the mesovarial vasculature. Although vessel size may limit effective use of the LigaSure® especially in pathologic ovaries,[38] we did not encounter any difficulty in its effective use. Perhaps this is because we sealed the main vessels twice before cutting. Compared with monopolar or bipolar electrosurgical instruments,[39,40] surgical time is less with the Ligasure and thermal damage is confined to the target tissue.[41] The main disadvantage of electrosurgical instruments for ovariectomy in mares is the small-sized jaws (5 mm) of the bipolar forceps. Multistage tissue coagulation was needed in our mares to achieve reliable hemostasis causing a circumscribed thermal soft tissue necrosis with carbonization of the target tissue. As a consequence, in 1 mare a fist-sized hematoma occurred at the resection site and in another mare, an adhesion occurred between the resected ovarian pedicle and the base of the cecum. It seems that, the risk of postoperative adhesions might be higher when using electrosurgical instruments for coagulation of the ovarian vasculature.

Laparoscopic ovariectomy in the standing sedated mare has many advantages compared with conventional surgical ovariectomy through a median celiotomy. These include superior viewing, normal anatomic orientation, easier intraabdominal manipulation, and avoidance of the risks of general anesthesia.[9,42] In dorsal recumbency using conventional surgical technique, tension-free and secure ligation of the mesovarium under visual control cannot be guaranteed.[14,15,29] Excessive traction on the ovarian pedicle can result in intraoperative hypotension, which is believed to contribute to myopathy and neuropathy.[14,15,43] Using stapling devices for dissection of the mesovarium makes this surgical step technically easier. But even then, application of staples and ligatures tightened under tension may result in inadequate hemostasis.[44,45]

In our study, except for 8 mares, laparoscopic ovariectomy was completed in the standing position. Based on our favorable experiences with standing laparoscopic ovariectomy, recumbent ovariectomy should be limited to horses that exhibit behavioral problems during standing surgery. Laparoscopic ovariectomy in dorsal recumbency and 30° head down position has, from the technical point of view, no distinct advantages. Indeed, there is the potential disadvantage of cardiopulmonary derangement during laparoscopic surgery in the Trendelenburg position.[9,11,25,46]

Each surgical technique for ovariectomy in the mare has offered distinct advantages and disadvantages. Comparison of the different surgical techniques should be interpreted cautiously because treatments in this multicenter case series study were not conducted in a blind or random manner. Nevertheless, in our clinical experience laparoscopic ovariectomy in standing sedated mares has

been proven to be the preferred method for ovariectomy and avoids the risks of general anesthesia. It can be performed safely and reliably for removal of normal and enlarged ovaries and, compared with conventional surgical techniques, is less invasive[47,48] and is associated with substantially lower perioperative morbidity and mortality.

Potential Demographic and Genetic Effects of a Sterilant Applied to Wild Horse Mares

By James E. Roelle and Sara J. Oyler-McCance

Abstract

Wild horse populations on western ranges can increase rapidly, resulting in the need for the Bureau of Land Management (BLM) to remove animals in order to protect the habitat that horses share with numerous other species. As an alternative to removals, BLM has sought to develop a long-term, perhaps even permanent, contraceptive to aid in reducing population growth rates. With long-term (perhaps even permanent) efficacy of contraception, however, comes increased concern about the genetic health of populations and about the potential for local extirpation. We used simulation modeling to examine the potential demographic and genetic consequences of applying a mare sterilant to wild horse populations. Using the VORTEX software package, we modeled the potential effects of a sterilant on 70 simulated populations having different initial sizes (7 values), growth rates (5 values), and genetic diversity (2 values). For each population, we varied the treatment rate of mares from 0 to 100 percent in increments of 10 percent. For each combination of these treatment levels, we ran 100 stochastic simulations, and we present the results in the form of tables and graphs showing mean population size after 20 years, mean number of removals after 20 years, mean probability of extirpation after 50 years, and mean heterozygosity after 50 years. By choosing one or two combinations of initial population size, population growth rate, and genetic diversity that best represent a herd of interest, a manager can assess the likely effects of a contraceptive program by examining the output tables and graphs representing the selected conditions.

Introduction

As the primary agency responsible for management of wild horses (*Equus caballus*) on public lands in the United States (U.S.), the Bureau of Land Management (BLM) has a need for a long-lasting, non-lethal method to control population growth rates. Given the protection afforded by The Wild Free-Roaming Horses and Burros Act of 1971 (P.L. 92–195 as amended) and general lack of natural predators, wild horse populations commonly increase at rates of 15–25 percent per year (Eberhardt and others, 1982; Garrott and others, 1991a) and quickly exceed the carrying capacity of their ranges. In the past, BLM has managed excess horses through a gather, removal, and adoption program, with unadopted horses held in short- and long-term holding facilities until the end of their natural lives. The sustainability of this strategy has recently been called into question, however (U.S. Government Accountability Office, 2008; Garrott and Oli, 2013; National Research Council, 2013). Therefore, BLM has increased efforts to develop a contraceptive that will reduce population growth rates in wild horse herds and thus reduce the number of excess animals that must be removed and cared for.

The contraceptive SpayVac has recently demonstrated the potential for long-lasting efficacy (at least 4 years) in wild horses (Killian and others, 2008). Maximizing the duration of contraceptive effectiveness is especially important in managing wild horses, which in most cases must be captured in order to successfully administer the drug. With extended efficacy (or perhaps even permanent sterility), however, comes increased concern for both the genetic health of a horse herd and the possibility of extirpation. Simulation modeling can be a useful tool in understanding the likely consequences of alternative management actions. We used the VORTEX software package (Lacy and others, 2014; Lacy and Pollak, 2014) to simulate the effects of treating various proportions of mares with a permanent sterilant. Response variables included population size, number of animals removed, average heterozygosity, and probability of local extirpation. (The VORTEX manual (Lacy and others, 2014) uses the term "extinction" rather than "extirpation." We believe that extirpation is more appropriate in this case, as we are simulating local populations, not the entire species.) We chose the VORTEX software because it can be used to simulate both demographic and genetic effects, and because it has been useful in simulating management of the horse population on Assateague Island (Ballou and others, 2008).

VORTEX is an individual-based model in which events happen or fail to happen on the basis of probabilities for each modeled individual. For example, if 100 females are of breeding age, each of which can produce at most one offspring, and fecundity is set to 80 percent, there is no guarantee that exactly 80 offspring will be born. Rather, for each female of breeding age, a random number chosen from a uniform distribution between 0 and 1 is compared to the probability of producing an offspring (in this example, 0.8). If the random number is less than 0.8, then the female is tagged in the model to give birth but otherwise does not. Thus, no two simulations are identical even when they use the same demographic parameters, and multiple iterations must be run in order to examine the possible range of outcomes. In general, we present results in the form of mean values for the multiple simulations; however, it is important to remember that extreme values can also be of interest. In addition, it is important to note that these simulations represent the results of management prescriptions applied consistently through time, without adaptation based on monitoring of results. In the real world, there would be many opportunities to adjust management strategies based on previous results.

Model Parameters

Parameter values and VORTEX options used in our simulations are summarized in table 1 and described in some detail in the sections that follow. Our knowledge of the biology and demography of horse populations and the efficacy of SpayVac and other forms of contraception is incomplete; what is applicable to one herd may not be applicable to all herds. In light of that fact, in cases where specific parameter values were in question, we tried to select the value or option that would have the largest effect on one or more of the response variables. For example, we don't know that SpayVac is a sterilant, but it may be. Furthermore, BLM is considering the use of other techniques (for instance, ovariectomy) that definitely will be permanent. So, for modeling purposes, we assume a permanent sterilant; once a mare is treated and the treatment works, she is infertile for life. This assumption is likely to minimize the number of animals tagged for removal during a simulation, while at the same time maximizing any decline in heterozygosity. We were similarly conservative in our choice of other parameter values and options, always choosing those that were likely to have the most detrimental effect on population demography and genetics.

Table 1. Parameter values and options used in simulations of the effects of a mare sterilant applied to wild horses.

[H_o, observed heterozygosity; ≥, equal to or greater than; BLM, Bureau of Land Management]

Parameter or option	Value selected for simulations
Mating system	Long-term polygyny
Age of first reproduction	Females = 3 years, males = 5 years
Maximum age (life span)	25 years
Maximum age of reproduction	20 years
Basic time cycle	1 year
Maximum litters per year	1
Maximum progeny per litter	1
Density-dependent reproduction	Not used
Reproductive rates	See tables 2 and 3
Mortality or survival rates	See tables 2 and 3
Sex ratio at birth	50 percent males
Mate monopolization	Mean of 3.0 mates per successful sire
Initial population size	100, 250, 500, 750, 1,000, 1,250, or 1,500
Initial age distribution	Stable age distribution calculated from age-specific schedules in table 2 and 3
Carrying capacity	Arbitrarily set at 5× the initial population size, but the contraception and removal programs prevent carrying capacity from having any effect
Initial heterozygosity	Actual allele frequencies at 13 microsatellite loci from the Lost Creek herd in Wyoming (high diversity, $H_o = 0.78$) or the Cibola-Trigo herd in Arizona (low diversity, $H_o = 0.49$)
Removals	When the simulated population reaches ≥150 percent of the initial population size, try to remove enough animals to get back to the initial population size. BLM's age-class removal criteria are used, but are constrained such that no more than 90 percent of any age and sex class are removed.
Efficacy of treatment	Treatment is efficacious in 90 percent of all newly treated mares
Duration of efficacy	If treatment is efficacious, female remains contracepted for life
Proportion of females treated	0 percent–100 percent, in 10 percent increments
Standard deviation due to environmental variability	$S_{EV} = 0.12$ for fecundity; $S_{EV} = 0.06$ for mortality
Concordance	Yes. Breeding and mortality are affected simultaneously.
Probability of catastrophe	10 percent annually
Impact of catastrophe	Reduce reproduction to 50 percent of normal; reduce survival to 75 percent of normal
Distribution of litter sizes	Not used; litter size in horses is virtually always 1
Number of iterations per simulation	100
Number of years per iteration	20 years for population size and removals; 50 years for heterozygosity and probability of extirpation
Number of populations in each simulation	1
Definition of extirpation	The population is considered to be extirpated when it no longer has individuals of both sexes.

Demographic Parameters

Mating System

VORTEX models breeding systems as monogamous or polygamous and short-term or long-term. With monogamous breeding, a male is needed for every breeding female; males may therefore become a limiting factor restricting breeding. In polygamous models, only one male is needed for all females to have an opportunity to breed. However, another parameter (see the section Mate Monopolization) can specify that only a subset of males has an opportunity to breed. For example, a polygynous system can be created in which successful males control harems of, say, five females on average, while the remaining males are excluded from breeding.

If a short-term option is chosen, then VORTEX assumes that mates are randomly reshuffled each year and that all available individuals have an equal probability of breeding. If a long-term option is chosen, then once harem relationships between stallions and mares are formed, those relationships remain intact across years of the simulation until a member dies or disperses to a different population. Demographically, it does not matter whether long-term relationships or rearrangement of harems each year is chosen. Genetically, there may be a small effect on the rate of loss of genetic diversity from the population, with greater loss of diversity expected in populations with higher harem fidelity.

We realize that wild horses do not necessarily mate for life (mares do move between harems) but, of the two choices available in VORTEX, long-term polygyny comes closer to representing the mating system of wild horses. We therefore used long-term polygyny as the mating system in all of our simulations. This is a conservative assumption, in the sense that it represents the greatest opportunity for loss of genetic diversity. Any additional interchange that does occur in the real world will tend to ameliorate effects and result in higher genetic diversity than predicted by our models.

Age of First Reproduction

VORTEX describes reproduction in terms of the age when the first offspring are born, not the age at onset of sexual maturity or the age at first conception. The program also assumes that breeding (and, for that matter, all other events) takes place at discrete intervals, usually years. Thus, age at first reproduction is entered as an integer value. The value used should represent something like the median age of first reproduction, not the earliest age ever observed, because the earliest observed age may not be typical of the population. We therefore used 3 years as the age of first reproduction in females and 5 years as the age of first reproduction in males (Garrott and Taylor, 1990; Garrott and others, 1991b; Roelle and others, 2010).

Maximum Age and Maximum Age of Reproduction

If the species being modeled does not reproduce throughout its entire adult life, the age when the species ceases to reproduce must be specified. For example, humans typically reach reproductive senescence before they die. If the typical life expectancy is 70 years but reproduction ceases at 50 years, then 50 years would be the maximum age of reproduction. VORTEX requires that the maximum age be the same for both sexes, but allows the maximum age of reproduction to vary by sex. Establishing the maximum age of reproduction is difficult because old animals are hard to age (unless they were marked or identified in the year of birth) and because sample sizes of old animals are typically small. Garrott and others (1991b) present information showing that some mares can reproduce at greater than 20 years

of age, whereas Roelle and others (2010) found no evidence of reproduction by females older than 16 years. Roelle and others (2010) also found that very few harems are held by stallions older than age 20. On the basis of available evidence, we used 20 years as the maximum age of reproduction and 25 years as the maximum age.

Maximum Number of Progeny per Year

VORTEX provides a great deal of flexibility in specifying the maximum number of progeny that can be born to a given female in a year (or other time interval), thus allowing species that produce multiple clutches or litters to be modeled. However, most of this flexibility is not needed for modeling a horse population. Given that horses produce only a single litter per year (the average gestation period is 335–342 days; Card and Hillman, 1993) and that twins are virtually unknown, we used 1 for the maximum number of litters per year, 1 for the maximum number of progeny per litter, and a year (365 days) as the basic time cycle.

Density-Dependent Reproduction

VORTEX allows the reproductive rate of the population being modeled to change with changing population size. For example, reproduction could be low when the population is small owing to a difficulty in finding mates (Allee effect) or, conversely, reproduction could drop off when the population is large (more specifically, at high density) owing to limited resources or territories, intraspecific competition, crowding, or stress.

Density-dependent reproduction, also known as compensatory reproduction, has been reported for wild horses (Kirkpatrick and Turner, 1991; Jenkins, 2000; Roelle and others, 2010), but quantifying the magnitude of the effect is difficult, and the information available is insufficient to allow generalization or calculation of some average function. In addition, many of our simulated populations differed only about 50 percent (that is, between N and 1.5 × N) because of the way we implemented the removal function (see section Removal and Contraception Programs). In our estimation, reproductive rates are not likely to change substantially owing to density in that relatively small range. We therefore did not use density-dependent reproduction in our simulations.

Reproductive and Mortality Rates

VORTEX models reproductive rate as the proportion of adult females giving birth each year (or other time interval), where an adult female is defined by the age of first reproduction (see previous discussion). Similarly, mortality rates are modeled as the proportion of animals dying in each age and sex class. From age 0 to the age of first reproduction, each age and sex class can have a different mortality rate; after the age of first reproduction, all animals are considered adults, and the mortality rate can vary only by sex.

While these parameters are fundamental to modeling population dynamics, values are well known for perhaps only a handful of wild horse populations. In our estimation, however, wild horse managers are more likely to have at least some idea of the annual population growth rate multiplier for a herd (λ, lambda), which is just a different way of expressing the growth rate itself. We therefore modeled a set of scenarios in which $\lambda = 1.05$, 1.10, 1.15, 1.20, or 1.25 (that is, annual growth rates of 5 percent, 10 percent, 15 percent, 20 percent, or 25 percent in the absence of contraception). To produce these growth rates, we used reproductive and survival rates (table 2) derived largely from Garrott

(1991a). We arrived at the values for λ = 1.25 by experimenting with parameters in the model. Table 3 provides an example of how we translated these parameters into VORTEX.

Table 2. Annual survival and reproductive rates used to simulate various annual population growth rates.

Population growth rate (percent)	Juvenile survival rate (percent)	Adult survival rate (percent)	Mares foaling (percent)
5	80	91	50
10	80	92	65
15	80	97	65
20	80	99	80
25	90	99	92

Table 3. Translation of the annual rates shown in table 1 into VORTEX parameter values for an annual population growth rate of 20 percent (λ = 1.20).

[λ, annual population growth rate multiplier for a herd; <, less than; ≥, equal to or greater than]

Reproduction		Female Mortality		Male Mortality	
Mare age (years)	Mares foaling (percent)	Age (years)	Rate (percent)	Age (years)	Rate (percent)
1	0	<1	20	<1	20
2	0	1 to <2	1	1 to <2	1
≥3	80	≥2	1	2 to <3	1
				3 to <4	1
				4 to <5	1
				≥5	1

We believe that, in the absence of contraception, growth rates of most wild horse herds will fall within the range shown in table 2. Rather than having to specify reproductive and mortality rates, a manager will need only to choose one or perhaps two values for the annual population growth rate to use the output from the model.

Sex Ratio at Birth

While foal sex ratio can differ from 50:50 in small herds in a given year (Roelle and others, 2010), over time the ratio tends to be fairly even in most herds. For example, Garrott (1991b) found that for a 12-year period 65 of 74 (88 percent) herds sampled in Nevada, Oregon, and Wyoming had a foal sex ratio that did not differ from 50:50. We therefore used 50 percent males in the foal crop in our simulations.

Mate Monopolization

As noted in the previous section, we ran our simulations using a polygynous breeding system. In order to do so, VORTEX requires that one of the following three parameters be specified: percentage of males in the breeding pool, percentage of males successfully siring offspring, or mean number of mates per successful sire. The remaining two parameter values are calculated from the one that is supplied based on the assumptions that some males are excluded from the breeding pool and that breeding

success among males in the pool of available breeders is described by a Poisson distribution. Only the first parameter (percentage of males in the breeding pool) is used by VORTEX.

Of the three ways in which mate monopolization can be described in VORTEX, mean number of mates per successful sire is the one most commonly discussed in the literature on feral horses, but comparisons among studies are hampered by inconsistencies in defining what constitutes a potential mate (that is, the age classes of mares). Roelle and others (2010) defined potential mates as all mares 2 years of age and older, and found a mean harem size of 2.2 mares (range 1.9 to 2.7) during 12 years. Using the same age criteria, Kaseda and Khalil (1996) found average harem sizes of 1.8 to 5.3 mares in many years.

Potential effects of using different values for the mean number of mates per successful sire are not intuitive; to a first approximation, however, one might expect that varying this parameter would affect genetics more than demography. We explored sensitivity of model results to mean number of mates per successful sire in a series of simulations with initial population size = 500, proportion of mares treated = 0.5, lambda = 1.05 (in the absence of contraception and removals), and initial heterozygosity = 0.77. We varied mean number of mates per successful sire systematically between 1.5 and 5.0. The fairly low growth rate and fairly high proportion of mares treated consistently kept the simulated population after 50 years at 200–250 animals; however, final heterozygosity ranged only from 0.74 to 0.75. Given the apparent lack of sensitivity of the model, we decided to set the value of mean number of mates per successful sire to 3.0 for all simulations.

Initial Population Size

Horse herds managed by BLM vary considerably in size, and the size of the herd is potentially very important relative to demographic and genetic results of contraception. We approached this problem by simulating herds with initial populations of 100, 250, 500, 750, 1,000, 1,250, and 1,500 animals. These initial populations should encompass the appropriate management level (AML; population goal) for many herds. We recommend a more detailed, site-specific analysis before a sterilant is applied to any herd with fewer than 100 animals. In addition, we implicitly assume that a herd is at its appropriate size before the results of these simulations can be used to evaluate a fertility control program. For example, the results of the simulations having an initial population and appropriate management level of 500 animals cannot be used if the population in fact contains, say, 1,000 animals.

Initial Age Distribution

VORTEX allows two options for specifying the initial age distribution used in a simulation. A specific age distribution (the number of individuals in each sex and age class) can be entered, or VORTEX can calculate the stable age distribution (proportion of animals) that would result from the age-specific schedules of reproduction and mortality described previously. We used the latter option, and the proportions were applied to the initial population size to determine the number of animals initially in each sex and age class.

Carrying Capacity

Carrying capacity (K) describes a theoretical upper limit to the size of a population. In VORTEX, if the actual population, N, exceeds K at the end of a particular year, then additional mortality is applied equally across all age and sex classes to reduce the population such that N = K. While carrying capacity is an important theoretical construct, values for K are difficult to estimate. We

somewhat arbitrarily set the value for K at 5 times the initial population size. With the contraception and removal programs specified as described in subsequent sections, simulated populations never reach carrying capacity.

Genetic Parameters

VORTEX allows inbreeding depression to be incorporated into the population model as a reduction in first-year survival among inbred individuals. Although some diploid species that have been studied show depressed fitness when inbred (O'Brien and Evermann, 1988; Quattro and Vrijenhoek, 1989), the rate at which inbreeding affects survival and reproduction is not well understood for most species. Therefore, we elected not to use this function in the wild horse model. A better approach for investigating the potential genetic consequences of contraception and gathers (round-ups) is to track the degree of genetic diversity, which can be loosely linked to fitness and an ability to adapt to environmental change.

VORTEX tracks changes in genetic diversity using heterozygosity (the frequency of two different alleles at a given gene) as a metric. Heterozygosity ranges from 0 (all individuals are homozygous and the same at all genes) to 1 (all individuals are heterozygous with different alleles at all genes). It is generally believed that higher levels of heterozygosity are associated with more genetic variation and lower probability of inbreeding depression.

VORTEX can track heterozygosity in two ways. Because VORTEX includes a detailed simulation of genetic change in the populations, one way to measure changes in heterozygosity is to start with maximum heterozygosity (1) by assigning each founder individual two unique alleles at a number of loci (genes). Each offspring is randomly assigned one of the two alleles from each parent at each locus. This method tracks relative loss of heterozygosity through time. Perhaps a more realistic way to examine loss of heterozygosity is to mimic real populations by starting with individuals that have a known level of heterozygosity. VORTEX allows this option by allowing real allele frequencies to be used as a starting point for model simulations. Thus, if we know the level of heterozygosity for a population, we can enter real allele frequencies such that the starting point of the simulations will have exactly that level of heterozygosity. We used the latter of these two approaches and ran the simulations for two different initial levels of heterozygosity (high and low) as reported for two real-world herds (Gus Cothran, Texas A&M University, unpublished reports prepared for BLM). Actual allele frequencies at 13 microsatellite loci were taken from the Lost Creek herd in Wyoming (high genetic diversity, $H_o = 0.78$; report prepared in 2010) and the Cibola-Trigo herd in Arizona (low genetic diversity, $H_o = 0.49$; report prepared in 2008). Absent site-specific information, we typically expect larger herds to have higher genetic diversity.

Removal and Contraception Programs

Removals

Given the limitations of available contraceptive methods, and facing population sizes that greatly exceed the desired number of animals in many herd management areas, BLM currently views contraception as a means of reducing the number of animals that must be removed, and perhaps increasing the interval between gathers, rather than as a replacement for gathers. We therefore simulated a gather-and-removal program that is as similar as possible to the program that BLM uses in the field. We modeled a gather-and-removal event in any year in which the simulated population was 150 percent or more of the initial population, and we attempted to remove sufficient animals to return the population

to its initial size. We removed animals from age classes according to BLM's removal criteria, which specify the following order: ages 4 and under, followed by ages 11–19, followed by ages 5–10. We constrained the number of animals removed, however, such that no more than 90 percent of any group was taken (because it would rarely be possible or desirable to remove every animal from a given age class). Our response variable is the total number of animals removed in 20 years averaged for 100 iterations.

Contraception

We implemented a simulated contraception program using capabilities in VORTEX called "population state" variables and "individual state" variables. Briefly, we used these variables to define the proportion of previously untreated females that are treated in each application and the probability that the treatment works if it is given (efficacy). In most cases, animals in BLM herds need to be gathered in order to apply a fertility control agent; we therefore treated mares following every gather and removal. Killian and others (2008) found that 17 percent of mares treated with SpayVac were pregnant in years 2 through 4 of their study, which implies efficacy of 83 percent. The most aggressive assumption would be that the treatment is 100 percent efficacious. However, it is probably also fair to assume that some mares will not respond to an immunocontraceptive such as SpayVac. We therefore assumed efficacy of 90 percent for all simulations. We also assumed that once a mare is successfully contracepted, she remains contracepted for life without further treatment (we assumed permanent sterility). We varied the proportion of mares treated from 0 to 100 percent in increments of 10 percent to illustrate the range of possible contraceptive effects. For example, when the proportion of mares treated is set at 20 percent, each mare not successfully treated in the past has a 20 percent chance of being caught and treated, and there is a 90 percent chance that the treatment will be effective. Note that high treatment rates (90–100 percent, for example) would likely be very difficult to achieve in the real world because some animals are difficult or impossible to gather.

Random Variation

Environmental Variation in Breeding and Mortality

In addition to the variability inherent in an individual-based model, VORTEX allows specification of variability (standard deviation) in the proportion of females breeding and in the proportion of both sexes dying due to factors external to the population (such as weather, predation, parasite loads). Estimates of variability in these parameters are generally not available for wild horse herds, but sufficient information was available to calculate standard deviations in fecundity and mortality for the Pryor Mountain herd (Roelle and others, 2010).

The standard deviation due to environmental variability, s_{ev}, for either fecundity or mortality, can be expressed as $s_{ev} = \sqrt{s_{tot}^2 - s_{ds}^2}$, where s_{tot}^2 is the total variance in the parameter for all years and s_{ds}^2 is the sampling (binomial) variance for all individual rates. From the Pryor Mountain data set (Roelle and others, 2010), we calculated $s_{ev} = 0.12$ for fecundity and $s_{ev} = 0.06$ for mortality. We combined ages and sexes for both of these calculations and used the resulting values in all simulations.

Concordance of Environmental Variation in Breeding and Mortality

Factors such as those already described (weather, predation, parasite loads) can affect reproduction and survival independently or simultaneously. Simultaneously means that good years for

reproduction are also good years for survival. We know of no information that can be brought to bear on this subject in regard to wild horse demography, but it seems logical that demographic effects would be most pronounced if these parameters vary simultaneously. We therefore opted for concordance in environmental variation.

Number and Types of Catastrophes

The VORTEX software allows specification of catastrophes (floods, forest fires, epidemic diseases) through particular effects on reproduction and survival. Perhaps the most common such event on western ranges is drought, and although droughts occur fairly frequently, we know of no specific information relating drought to reproduction and survival in wild horses. Nevertheless, we felt that it was important to include some form of catastrophe in our simulations. We therefore specified that drought would have a 10 percent probability in any year and that it would reduce reproduction to 50 percent of the normal level and survival to 75 percent of the normal level.

Distribution of Litter Sizes

VORTEX allows for one additional form of random variation if females can produce litters of different sizes. Because wild horses almost never produce more than one offspring, we did not use this parameter.

Simulation Control

Number of Iterations

As noted in the previous section, VORTEX uses a random number generator to simulate random events in an organism's life cycle. Therefore, no two runs or iterations of the model are identical even with a single set of input data. To obtain a more complete picture of demographic behavior, multiple iterations are required. We explored changes in the standard deviation of both mean population size and heterozygosity after 50 years while varying the number of iterations from 25 to 1,000. Because of the complexity of the removal and contraception functions, no consistent pattern emerged in the standard deviations of these parameters. More particularly, increasing the number of iterations to more than 100 did not consistently lead to lower variance about the mean. We therefore chose 100 iterations for all of our simulations.

Number of Years per Iteration

Initial simulations with some basic data indicated that significant changes in heterozygosity are rare in less than 50 years. On the other hand, significant demographic changes can occur in as little as 20 years. We therefore evaluated mean population size and removals at the end of 20 years of simulation, but we used 50 years to evaluate heterozygosity and probability of extirpation.

Number of Populations

VORTEX can be used to model a single, isolated population or a complex metapopulation composed of as many as 50 populations with interchange of animals between them. Although it is clear that some animals move between certain populations of wild horses, we know of no information on

rates of such movement. We therefore modeled only a single population without introduction of animals from outside, which is the worst case from the perspective of genetic diversity.

Extirpation Definition

VORTEX offers several methods for defining extirpation of a population. We used the definition that says a population is extirpated when it no longer contains individuals of both sexes.

Interpreting Model Output

Appendix A contains output from 70 sets of simulations representing two levels of genetic diversity (low or high), seven initial population sizes (100, 250, 500, 750, 1,000, 1,250, or 1,500 animals), and five population growth multipliers (1.05, 1.10, 1.15, 1.20, or 1.25). Each set of simulations is represented by a figure, and each figure contains five graphs and a table of supporting data. The order of the figures varies first by annual growth rate, then by population size, and then by genetic diversity. Thus, figure 1 has low genetic diversity, an initial population size of 100, and a growth multiplier of 1.05, and is followed by figure 2 with low genetic diversity, an initial population size of 100, and a growth multiplier of 1.10, and so on. In each figure, the first four (black and white) graphs and the table represent the same set of simulations, and the graphs and table have identical values. Due to a nuance in the way VORTEX operates, however, the final (color) graph represents a different set of simulations having the same parameter values but differing slightly due to random variation as already discussed. Thus, the value for average population size at 20 years on the color graph will not in general be identical to that in the table, but the two values will usually be very similar.

The black and white graphs present mean values (that is, averaged for 100 iterations) of four response variables on the vertical axes: mean population size after 20 years, mean number of removals after 20 years, mean probability of extirpation after 50 years, and mean heterozygosity in the herd after 50 years. In all cases, the horizontal axis is the percentage of previously untreated mares that are treated following each gather, varying from 0 percent to 100 percent. The colored graph represents the mean trajectory of the population size for a subset of the treatment levels (0 percent, 20 percent, 40 percent, and so on) depicted as lines of different color. It is very important to understand that there is some information that cannot be conveyed by mean values. For example, there are many cases where the table and black and white graphs show that animals were removed, but the colored graph lines never plot higher than 1.5 × the initial population. The appropriate interpretation is that on average the population stayed below the threshold (1.5 × the initial population), but in some individual iterations the population grew sufficiently to trigger a removal.

As an example application of model results, suppose a manager wants to know what proportion of mares can be treated with a sterilant in a herd having low genetic diversity, an initial population size of about 750, and a population growth multiplier of 1.15. This set of conditions is represented by figure 18 in appendix A. The first thing to notice about figure 18 is that no treatment level has any real effect on either mean probability of extirpation after 50 years or mean heterozygosity after 50 years. The graph of mean population size after 20 years, however, shows that treatment levels greater than 50 percent of the mares result in populations somewhat less than 750. We also see that if 50 percent of the mares are treated, the mean number of removals after 20 years is around 900, or about 500 fewer than in the scenario where no mares are treated. The number of removals can be further reduced by treating a higher proportion of mares, but only if average population levels below 750 are acceptable. The average trajectory of the population size through time can be examined by looking at the last (color) graph in the

figure 18, which also shows that treatment rates more than about 50 percent will result in populations that are commonly below the starting point of 750 animals.

Finally, uncertainties about level of genetic diversity, population size, or growth rate can be addressed by examining figures representing nearby values in the parameter space. Thus, in the example in the preceding paragraph, a manager might also wish to look at the figures representing 500 and 1,000 animals in the population and growth multipliers of 1.10 and 1.20 to gain some understanding of how sensitive model results are to these assumptions.

Conclusions

We believe that simulation results presented herein represent a useful starting point for evaluating a management program involving a contraceptive technique that is permanent (or nearly so). In particular, the results show that only in the most extreme circumstances (such as low initial genetic diversity, low population growth rate, high proportion of mares treated, no change in management for 50 years) would there likely be any noticeable effect on genetic diversity or a significant probability of extirpation of a herd. Monitoring and adaptive management would reduce the probability of unacceptable results even further. For example, a simple exchange program in which an animal or two were moved between herds periodically would help to maintain genetic diversity, and the contraceptive program could always be modified or discontinued in the event that the reduction of population was greater than anticipated. In short, we see nothing in our results that should steer wild horse managers away from permanent contraceptive techniques, as long as results are monitored and adjustments are made if necessary.

Demography of the Pryor Mountain Wild Horses, 1993–2007

By James E. Roelle,[1] Francis J. Singer,[1,2] Linda C. Zeigenfuss,[1] Jason I. Ransom,[1] Linda Coates-Markle,[3] and Kathryn A. Schoenecker[1]

Abstract

Wild horses (*Equus caballus*) at Pryor Mountain were studied by direct observation from 1993 through 2007. All horses present were individually identifiable on the basis of coat coloration, head and leg markings, gender, and band associations. Of the 609 horses either present prior to foaling in 1993 or born since, ages were precisely known for 491 (observed as a foal). Ages for 52 horses were estimated through tooth eruption and wear patterns, and for the remaining 66 horses through body size, morphology, and anecdotal evidence concerning when they were present on the range. At varying intensities, never less than 30 days per year, all horses were inventoried and their band associations noted. Foals were paired with dams based on observations of attachment during the early days and weeks of life. Year of death was determined by identification of the carcass where possible. In the absence of finding a carcass, an animal that was not observed for 2 years was considered to have died in the year that it went missing. Animals that were removed from the herd and mares that were part of a contraception study were excluded from calculations of survival and foaling rates, respectively, as appropriate.

The average prefoaling population over the 15 years of the study was 148.8 animals (range = 120–187), and the annual foal crop averaged 32.1 (range = 23–40). Large removals (19–60 animals) in four years helped maintain the herd at this level; apparent growth rate (calculated as though removals had not occurred) was 9.6 percent annually ($\lambda = 1.096$, range = 0.977–1.220). This annual growth rate is relatively low compared to that for many western horse herds, at least in part because of a decline in foal survival. Sex ratio of the foal crop varied widely among years, but pooled across years did not differ from 50:50. Sex ratio in the herd changed mostly as a result of removals. The average age of both males and females in the herd increased during the course of the study. Annual survival of males did not differ from that of females, nor did gender affect annual survival of foals. Pooled across years, ages, and sexes, the annual survival rate was 0.899. Annual foal survival rate was 0.697 and declined through time, with a tendency toward recovery in 2005–2007. Foal survival was higher in larger bands, but did not differ between foals born to primiparous and multiparous mares. A few 2-year-old mares produced foals; foaling rate (excluding contracepted mares and foals they produced) increased through age 10, remained high through age 15, and declined thereafter. Overall foaling rate for mares ≥3 years of age was 0.576 foals per mare, with no apparent trend during the period of our study. Foaling rate in years following gathers was somewhat lower than in other years. There was a positive relation between foaling rate and band size. Primiparous mares were somewhat less likely to foal in the following year than were multiparous mares. Most stallions that acquired a harem did so at age 5 or 6, and the average age of harem stallions increased during our study. Most harems had 1–3 mares ≥2 years of age, but harem size varied with age of the stallion, increasing through about age 11 and declining thereafter. About 6 percent of bands had a satellite stallion (≥5 years of age), but the mean number of mares did not differ between single- and multistallion bands. Most stallions left their natal band at age 2 or 3, but 17 percent remained with their natal band until age 4 or 5.

Foal survival rate was positively related to precipitation, suggesting a possible link to forage production and availability mediated through mare fitness. There also was evidence for density-dependent population regulation, as both population growth rate and survival rate were negatively correlated with population size from the previous year. These and other factors were not sufficient to stabilize the population during our period of study, however, as evidenced by the necessity for large removals in several years.

Introduction

The Pryor Mountain Wild Horse Range was created in 1968 by order of the Secretary, U.S. Department of the Interior, who directed that wild horses (*Equus caballus*) be managed in "a balanced program which considers all public values and without impairment of the productivity of the land" (Federal Register, Document 68-11056, Sept. 11, 1969;

[1] U.S. Geological Survey, Fort Collins, Colorado.

[2] Deceased.

[3] Bureau of Land Management, Wheat Ridge, Colorado.

Bureau of Land Management, 2006, p. 5). The Bureau of Land Management (BLM) was designated as the lead agency for management of wild horses, though the range also contains lands administered by the U.S. Forest Service (FS; Custer National Forest) and the National Park Service (NPS; Bighorn Canyon National Recreation Area). The Wild Free-Roaming Horses and Burros Act of 1971 (P.L. 92-195) further directed the FS and BLM to manage wild horses at Pryor Mountain and wild horses and burros (*Equus asinus*) wherever they occur "in a manner that is designed to achieve a thriving natural ecological balance on the public lands."

While laudable as general management goals, the conditions implied by phrases such as "a balanced program which considers all public values without impairment of the productivity of the land" and "a thriving natural ecological balance" have proven difficult to achieve for many wild horse herds. With the protection afforded by the Act and a dearth of natural predators, many wild horse herds can increase at annual rates of 15–25 percent (Eberhardt and others, 1982; Garrott and Taylor, 1990; Garrott and others, 1991b; Singer and others, 2000), thus threatening to exceed the carrying capacity of their ranges. BLM has addressed this problem largely through a gather and removal program in which excess horses are removed from the range and offered to the general public for adoption or sale to good homes. While hugely successful by some measures (BLM has adopted out more than 220,000 horses since 1971; *http://www.blm.gov/wo/st/en/prog/wild_horse_and_burro/wh_b_information_center/Fact_Sheet.html*), supply has exceeded demand, leaving nearly 32,000 horses in BLM corrals and long-term holding pastures. This approach is not embraced by all members of the public. Wild horse advocacy groups often favor a policy of minimum disturbance and intervention, arguing that there are too few, rather than too many, wild horses and that the gather and removal process is detrimental to horse health and well-being. On the other hand, ranchers and conservationists often see wild horses as competing with domestic cattle (*Bos taurus*) and native wildlife for forage, and would thus prefer that BLM reduce the size of many horse herds.

Given the contentious nature of the issues involved, BLM has a continuing need for the best scientific information available on the ecology and demography of wild horse herds. Since creation of the range in 1968, information on wild horses has been gathered nearly continuously by trained investigators and volunteers, making the Pryor Mountain horses perhaps the most studied herd in the Western United States. Furthermore, all of the horses at Pryor Mountain are individually identifiable (unique color markings), and many are of known (observed as a foal) or closely estimated (tooth eruption and wear patterns) age, making the resulting data dependable. The first study of horses at Pryor Mountain was initiated in 1970 by J.D. Feist, who focused largely on behavior (Feist, 1971), but also gathered some information on demography of the population (Feist and McCullough, 1975). Shortly thereafter, Hall (1972) performed an assessment of the herd and possible management alternatives. Perkins and others (1979) studied population dynamics, age distribution, and band composition in the Pryor Mountain herd from 1974 through 1978. Garrott and Taylor (1990), using information gathered by BLM personnel, reported on many aspects of herd demography from 1972 through 1986. F.J. Singer and several colleagues began studies at Pryor Mountain in the early 1990s, broadening their scope to include vegetation dynamics and conservation genetics as well as demography (Singer and Schoenecker, 2000). Prior to his untimely death in 2005, Singer also participated in work at Pryor Mountain on contraception and population estimation.

Here we report on the demographics of the Pryor Mountain wild horse herd from 1993 to 2007. The results contained herein represent a more detailed analysis of the data presented by Singer and others (2000) and an extension covering the next decade. While specific to the Pryor Mountain herd, and thus not necessarily representative of the other 180 Herd Management Areas (HMAs) overseen by BLM, we hope that our results will provide wild horse managers with useful insights as they continue to meet the challenges of managing wild horse herds in the Western United States.

Study Area

During the period of our study, horses actually used an area larger than the Pryor Mountain Wild Horse Range as originally designated. The northwestern and northern boundaries of our study area are not well defined, as there are no natural or manmade barriers to horse movement in that direction. As shown in figure 1, however, the study area encompasses about 22,300 hectares (ha). The following description of the area largely follows Singer and others (2000) and Ricketts (2004).

The study area lies along the Montana-Wyoming border at approximately latitude 45°4'N and longitude 108°19'W, 76 kilometers (km) south of Billings, Mont., and 14 km north of Lovell, Wyo. (fig. 1). The area is topographically diverse, dominated by narrow canyons and steep cliff faces. Elevations range approximately from 1,175 to 2,670 meters (m), with corresponding variation in climate and vegetation. Temperatures range from 40 ºC in the summer to -34 ºC in the winter. Mean annual precipitation ranges from 15 centimeters (cm) at lower elevations to nearly 70 cm at higher elevations, with much of the annual total falling in April–June. Midelevation ridges and plateaus often remain snow free or accumulate <10 cm of snow as a result of winds and southern and western exposures. Higher elevations often have winter snow accumulations of 1 m or more. In water years 1993–1998 (water year 1993, for example, runs from October 1992 through September 1993), mean annual precipitation at Lovell, Wyo. (*http://www.wrcc.dri.edu/summary/climsmwy.html*), was 17.2 cm, essentially identical to the 30-year average (Bureau of Land Management and others, 2008). From 1999 to 2004, however, severe drought conditions prevailed (mean annual precipitation = 12.3 cm). Prolonged drought can decrease plant health

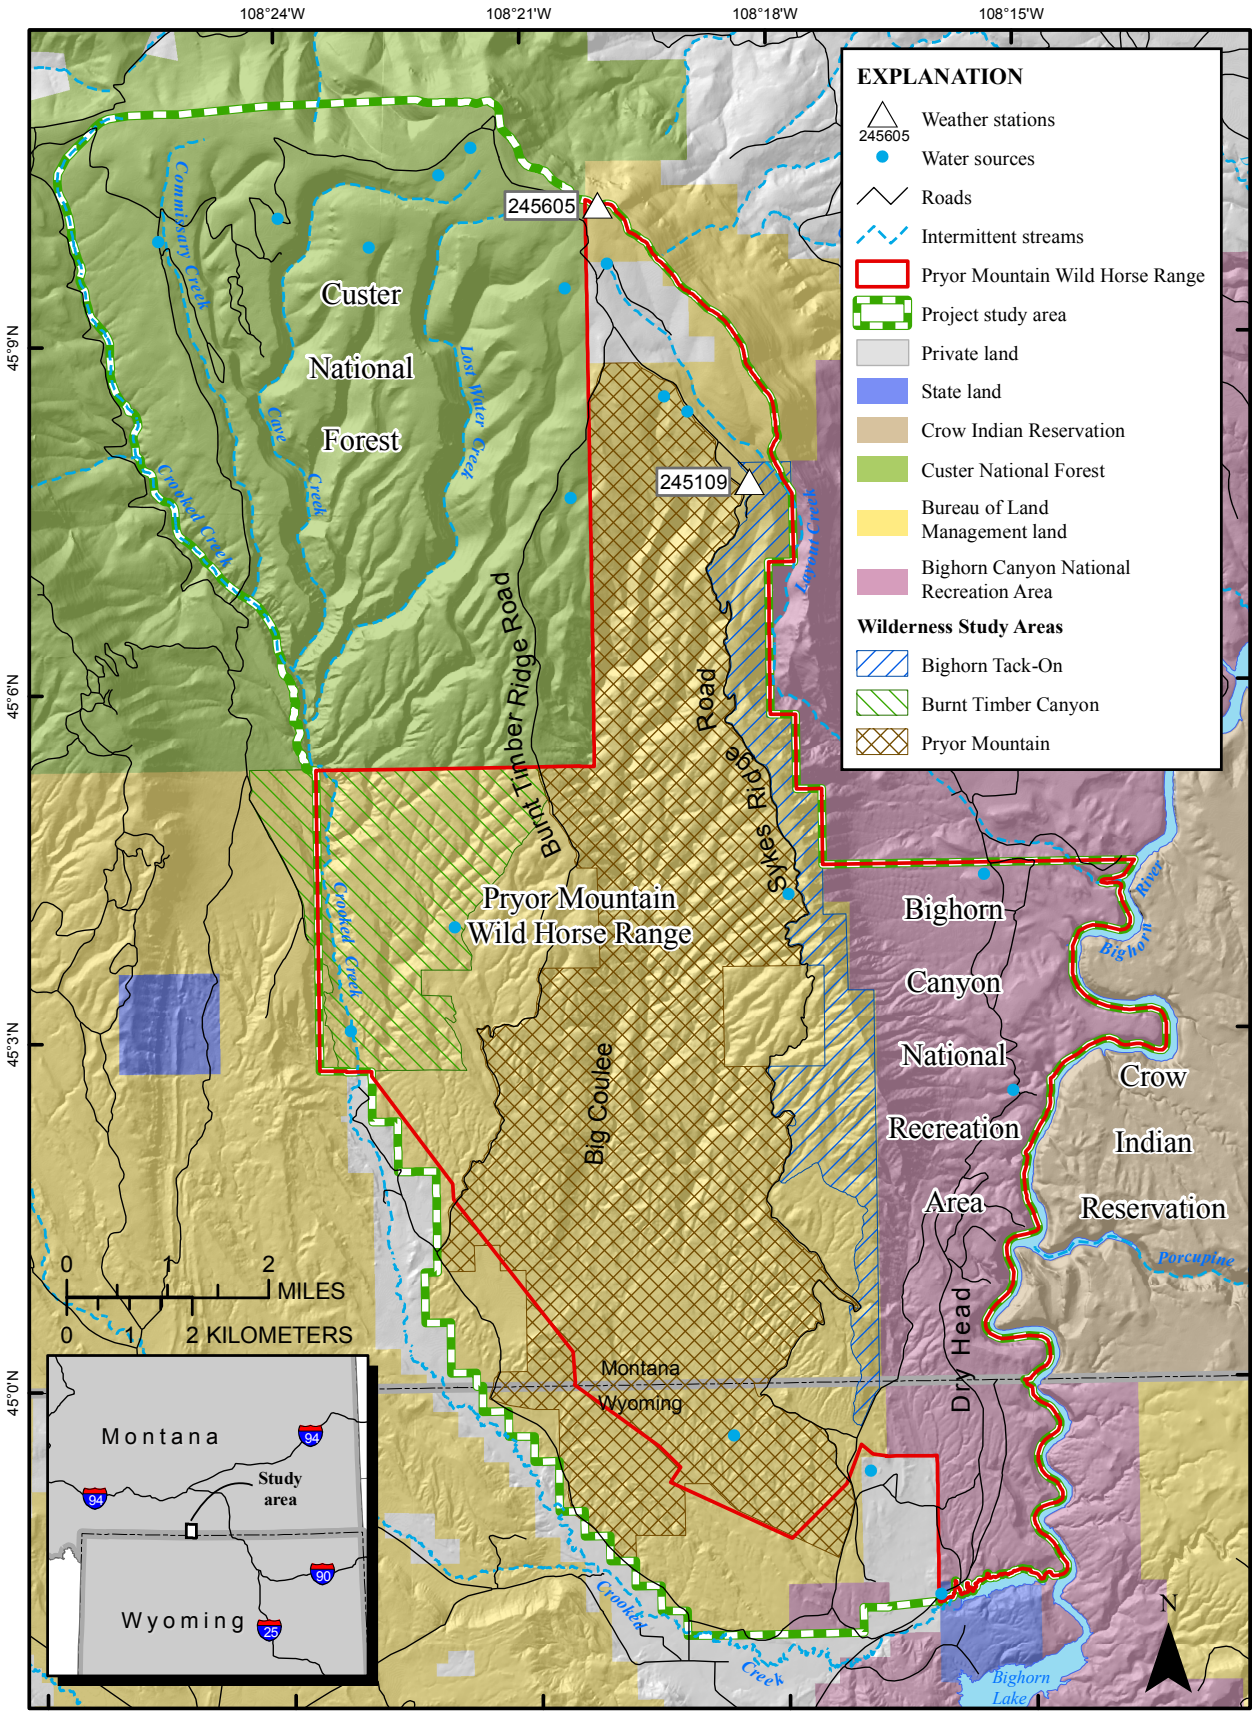

Figure 1. Location of the Pryor Mountain Wild Horse Range and study area.

and vigor and forage production. Temporary relief from the drought occurred in 2005 (annual precipitation = 21.2 cm) and 2007 (annual precipitation = 14.3 cm for 11 months, data missing for June) At least in 2005, greater precipitation probably resulted in improved forage production (Bureau of Land Management, 2006).

Vegetation in the study area changes dramatically with elevation. At the highest elevations, subalpine meadows (Idaho fescue, *Festuca idahoensis*; alpine timothy, *Phleum alpinum*; alpine bluegrass, *Poa alpina*; Ross sedge, *Carex rossii*; silky lupine, *Lupinus sericeus*) are interspersed with stands of subalpine fir (*Abies lasiocarpa*) and Engelmann spruce (*Picea engelmannii*). At somewhat lower elevations, Douglas fir (*Pseudotsuga menziesii*) occurs with an understory of snowberry (*Symphoricarpos* spp.). Still lower is a shrub community dominated by big sagebrush (*Artemisia tridentata*), rubber rabbitbrush (*Ericameria nauseosus*), shrubby cinquefoil (*Dasiphora fruticosa*), Utah juniper (*Juniperus osteosperma*), and curl-leaf mountain mahogany (*Cercocarpus ledifolius*) and a variety of grasses and forbs such as bluebunch wheatgrass (*Pseudoroegnaria spicata*), threeawn (*Aristida purpurea*), needle-and-thread (*Hesperostipa comata*), and blue grama (*Bouteloua gracilis*). For a more complete description of vegetation communities on the Pryor Mountain Wild Horse Range, see Ricketts (2004).

Herd Behavior and Management

The social structure of the Pryor Mountain wild horse population consists of bands that include a harem stallion, occasionally along with a satellite stallion, plus adult mares and yearlings and foals of both sexes. In general, we use the term band to refer to all members of the group and harem to refer to mares ≥2 years of age. Males older than yearlings that have not acquired a band usually are found in bachelor groups. Distribution and movements of the bands largely are restricted by topography to the west (Crooked Creek drainage) and east (Bighorn Canyon), and fences of varying integrity to the north and south (fig. 1). The wild horses occur in three more or less discrete subpopulations (Burnt Timber Ridge, Sykes Ridge, and Dryhead). These areas are separated by Big Coulee (a deep canyon) and a long, nearly vertical cliff face. However, the horses are able to move between these areas at high elevations and below Big Coulee, as well as occasionally by way of trails on the cliff face. Varying numbers of horses also use U.S. Forest Service land to the north and west of the original horse range boundary. Interchange of horses between subpopulations occurs regularly, but not with high frequency. The horses move with the seasons, spending winters at low and middle elevations where snow is less deep and summering at higher elevations. Distribution is restricted by available water in summer, when the horses tend to congregate near water sources. Water has less effect on distribution in winter, when the horses use snow to meet their water needs.

In the past, the herd has been managed consistent with national selective removal policy for the BLM Wild Horse and Burro Program, removing mostly young animals and conserving the core breeding component of the population. In general, BLM defines Appropriate Management Level (AML) as the number of adult wild horses (6 months and older) determined through the agency planning process to be consistent with the objective of achieving and maintaining a thriving natural ecological balance and multiple-use relation (Bureau of Land Management, 2006). Initially, the AML for the Pryor Mountain herd was set at 115–127, but was revised to 85–105 horses in 1992. However, based on genetic research (Cothran and Singer, 2000; Gross, 2000a,b), from 1996 to 2006 BLM attempted to manage the herd at an average of 140 adult horses to help conserve genetic diversity (Bureau of Land Management, 2006). More recently, BLM has determined that management at an AML of 90–120 adult horses is necessary to protect and improve rangeland health (Bureau of Land Management, 2009).

The BLM has managed the size of the Pryor Mountain herd primarily through a gather, removal, and adoption program. In 1994, wranglers on horseback attempted to capture the entire herd by moving horses into corral traps. In 1997 and 2001, a helicopter was used to move most of the family bands (individual bachelors typically were not gathered) into corral traps; approximately 125 animals were gathered in each of these years. Smaller gathers aimed at removing excess bachelor stallions and yearling females were conducted in 2003 and 2006. The 2003 gather involved a helicopter to move groups containing target horses into a corral trap. The 2006 gather was conducted using bait trapping to lure the horses into a trap, after which they were transported by vehicle to a holding corral.

Since 2001, some mares in the Pryor Mountain herd have received fertility control treatments using the contraceptive porcine zona pellucida [PZP; see Kirkpatrick and Frank (2005) for a recent review of contraception in equids and other free-ranging animals] as part of a cooperative research project between BLM, the U.S. Geological Survey (USGS), and the U.S. Department of Agriculture, Animal and Plant Health Inspection Service (APHIS). In 2001, six mares (age 1–2) that had not yet reached breeding status were treated with PZP by hand injection during the gather. A booster inoculation was administered to three of these females in August 2002; the remainder had either died or could not be located to deliver the booster. Fertility control was subsequently applied to younger mares (age 1–2, 2002–2004) and older mares (>14 years, 2002–2004; >10 years after 2004) that had already contributed to the genetics of the population. After 2001, all inoculations (both primers and boosters) were delivered remotely by darting. Because of the timing of booster inoculations relative to the breeding season, the first contraceptive effects were expected in 2004. From 2004 through 2007, 20.0, 29.0, 10.8, and 30.8 percent of the mares (≥3 years old) in the herd were presumptively contracepted.

BLM also has attempted to manage the herd to adjust the sex ratio in favor of males (Bureau of Land Management, 2006) and occasionally has introduced a limited number of horses (both mares and stallions) from outside herds in order to supplement the herd genetically. Introduction of outside horses was discontinued in 1994.

Methods

Field Data Collection

All data reported in this study were gathered through direct observations of the herd by trained BLM and USGS employees and volunteers. From 1995 to 1997, efforts were focused on the peak foaling season, May 1 to June 30. From 1998 to 2007, daily observations were made during the peak foaling and breeding period, May 1 to August 30. This effort totaled approximately 100 hours of observation per week during 1995–1997 and 100–150 hours per week during 1998–2007. Semi-weekly to weekly observations were made March–April and September–November. Fewer observations were made during midwinter, and they were limited to accessible areas of the range, which varied from year to year. Observations were made from the ground during systematic surveys along roads and trails that traverse the study area. Ground observations were augmented with two helicopter flights each fall or winter, 1995–2001, and one flight in late 2006, as well as 20–25 days of horseback surveys throughout each year, 1995–2005.

Greater than 90 percent of the bands were located at least twice per week during the May–July period, and all bands usually were located at least once per week from April to mid-May and August to mid-October. Reduced effort in the remainder of the year resulted in less than one observation per week per band. Observers collaborated during the peak observation season to develop a weekly list of band composition and foal presence.

Wild horses were approached within 100–250 m and could be observed for periods of 2–6 hours with no apparent effect on their behaviors. All horses were identified individually based on color, markings, gender, and band associations since 1993. All stallions, mares, yearlings, and foals observed in bands, bachelor groups, or alone were recorded. Lead harem stallions were identified based on behavior as described in Feist and McCullough (1975), Oom and Santos-Reis (1986), and Berger (1986). Interchanges between bands by mares and stallions were recorded, as were returns to the original band.

Each horse in the population was assigned a unique number during data compilation. Of the 609 animals in the population from 1993 to 2007, horses whose birth year was known from foal records included 480 of the 481 foals born during 1993–2007 and 11 horses born prior to 1993. Ages of an additional 52 animals were estimated by a veterinarian based on tooth eruption and wear patterns (American Association of Equine Practitioners, 2002). Ages of the remaining 66 animals were based on body size and morphology and anecdotal evidence of years the animals were on the range. Death year was determined by identification of the carcass of the deceased individual or, if an individual was not observed for two consecutive years, the animal was considered to have died in the year it went missing. Number of foals produced was determined by observation as described above. It is possible that some foals were born and died without being seen; however, given the intensity of the observations, we believe that this was rare. Identification of an individual's dam was based on observations of attachment of foal to mare during the early days and weeks of the foal's life.

Analysis

We conducted all of our analyses on the basis of biological years, which we defined as just prior to foaling in one year to the same time the next year. Thus, the biological year 1993 encompasses the period from spring 1993 to spring 1994. Because we defined the biological year in this way, because we made no attempt to pinpoint when during a year a horse was born or died, and because we have the benefit of hindsight (other reported data were often projections), our data will in some cases not match exactly those presented elsewhere (for example, various Environmental Assessments prepared by BLM).

We calculated annual population growth using the expression $\lambda_t = N_t / (N_{t-1} - R_{t-1})$, where λ_t is the growth multiplier from year $t-1$ to year t, N is the population size, and R_{t-1} is the number of animals removed in the period $t-1$ to t. In this formulation, λ represents the apparent growth rate of the population had horses not been removed (Garrott and Taylor, 1990).

Survival rates were calculated as the number of animals present at the end of a year divided by the number present at the beginning of that year. Animals that were removed from the herd were excluded from survival calculations in the year they were removed. Foaling rates were calculated as the number of foals born (regardless of how long they lived) divided by the number of mares present. Mares that were presumptively contracepted and foals that they produced were excluded from calculations of foaling rate.

Band composition has been recorded on "horse lists" regularly (usually weekly) since 1996. These are lists of all the harem stallions present and all the members of their bands, plus lists of bachelor males and animals in transit between bands. To derive information on harem stallions and band composition, we used two of these lists for each year from 1996 through 2007, one from the breeding season (usually early June) and one from fall (September–November, usually the last list available for the calendar year). For each harem stallion present, we calculated the number of mares ≥2 years of age in the band for each of the two time periods and then

took the maximum of those two values as the number of mares held in the harem in that year. We calculated total band size in an analogous manner, and we used these same lists to derive information on bachelors and satellite stallions, which we defined as ≥5 years of age. We defined a satellite stallion in this way in an effort to distinguish true multistallion bands from cases in which a male simply remained with his natal band longer than usual.

We looked for evidence of density dependence in foaling rate, herd survival, foal survival, and population growth rate in the Pryor Mountain wild horse population using stepwise multiple regression with the current year's postfoaling population and the previous year's postfoaling population as independent variables. For these analyses, we used data from Garrott and Taylor (1990) for 1976–1986 (foaling rate, herd survival, and population growth rate), as well as data from our study for 1993–2007. We excluded data from the winter of 1977–1978, during which 51 percent of the population died as a result of heavy snow and ice accumulations (Garrott and Taylor, 1990), from the analyses of density dependence in herd survival and growth rate. We also excluded data from 2004, when 96 percent of the foal crop was lost, from the analysis of foal survival. Foal losses in 2004 are suspected to have been the result of predation by mountain lions (*Puma concolor*). We believe that these exclusions are justified because the biological processes operating in these years were clearly different from those operating in other years.

It would be desirable to have consistent, long-term data on annual forage production for comparison with demographic parameters, but we are unaware of such data for the study area. As a possible surrogate, we examined weather records from a number of stations in the area, reasoning that forage production in this semiarid environment likely is related to precipitation, even though large elevation differences across the study area make it unlikely that any single station will be representative of the entire area. In terms of location, the best available data are from a Remote Automated Weather Station (RAWS; Wild Horse Montana, NWS ID #245605, elevation 2,675 m), which was operated in the study area from October 1991 to July 1997 (*http://raws.dri.edu/wraws/emtF.html*) (fig. 1). Unfortunately, overlap between this period of record and the period of our study is minimal. A National Climatic Data Center Station (NCDC #484770, elevation 1,170 m) at Lovell, Wyo., has a much longer period of record (1948–present; *http://www.wrcc.dri.edu/summary/climsmwy.html*), but its lower elevation caused us to question its relevance to higher elevations in the study area. For the 7 years of data in common, however, there was a strong correlation between the two stations for both total annual precipitation ($R^2 = 0.921$, $P = 0.0006$) and the minimum of the monthly average minimum temperatures ($R^2 = 0.763$, $P = 0.01$). We therefore used data from the Lovell station and stepwise multiple linear regression to analyze relations between weather and herd survival rate, foal survival rate, and foaling rate (mares ≥3 years of age). Data on annual herd survival and foaling rate were available from both our study and the work of Garrott and Taylor (1990), but data on annual foal survival were available only from our study. For the reasons cited above, we again excluded 2004 from the analysis of foal survival.

Other investigators (Heitschmidt and others, 2005; Smart, 2005) showed that spring precipitation (April–June) is related to annual forage production in the Great Plains. We therefore divided precipitation data into spring (April–June), summer (July–September), and winter (October–March). For each year, we also calculated the mean of the monthly average minimum temperatures (December–February) and the mean of the monthly average maximum temperatures (April–September) as indices of winter cold and summer heat.

For herd survival, we used the covariates winter precipitation in the previous year, spring precipitation in the current year, and summer precipitation in the current year (hypothesizing that all might have a positive relation with forage production in the current year), winter precipitation in the current year (potential negative effect of snow accumulation on forage availability in the current year), and average monthly minimum temperature in the current year (potential negative effect on ability to meet energy demands). For foal survival, we used the same set of covariates and added average monthly maximum temperature (possible effect of heat stress on more susceptible foals). For foaling rate, we used the covariates summer precipitation in the previous year (potential positive relation with forage production during early pregnancy), winter precipitation in the previous year (potential negative effect of snow accumulation on forage availability), average monthly minimum temperature (potential negative effect on ability to meet energy demands), and spring precipitation in the current year (possible positive relation with forage production during late pregnancy).

All data were entered into Microsoft Excel® spreadsheets (Microsoft Corporation, Redmond, Wash.). Analyses were conducted in SAS® v. 9.1 (SAS Institute, Cary, N.C.) using standard statistical techniques as noted in the Results section.

Results

Population Size and Growth

Prior to foaling in spring 1993, there were 128 horses ≥1 year of age in the study area. From 1993 to 2007, 481 horses were born; thus, our study encompasses 609 individual animals. During the period of study, the prefoaling population averaged 148.8 animals (range = 120–187), the foal crop (number born) averaged 32.1 (range = 23–40), and the postfoaling population averaged 180.9 animals (range = 149–227) (table 1). As we calculated it, the postfoaling population represents the maximum number of animals that could have been present at any time during the year, as it assumes no mortality of foals or adults during the foaling period. The number of deaths per year apparently increased during 1999–2006, while the foal crop remained relatively constant throughout

Table 1. Size and growth rate of the Pryor Mountain wild horse (*Equus caballus*) herd, 1993–2007.

[Growth rate (λ) is calculated based on the postfoaling population. —, not applicable; SE, standard error of the mean.]

the period of study. The mean annual apparent growth rate, calculated as though removals had not occurred, was 9.6 percent (λ = 1.096, range = 0.977–1.220), or 10.5 percent if the year (2004) of heavy foal loss is excluded. Although the growth rate rebounded somewhat in 2006 and 2007, there was a significant (R^2 = 0.514, P = 0.004) overall decline during the period of study as determined by linear least squares regression (fig. 2).

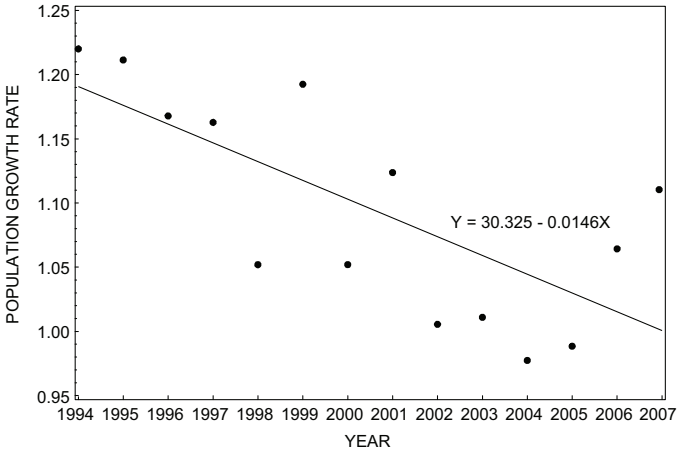

Figure 2. Trend in growth rate of the Pryor Mountain wild horse (*Equus caballus*) population, 1993–2007.

Removals

Major removals of wild horses occurred in 1994, 1997, 2001, and 2006, with smaller numbers of horses removed in four other years (table 2). For the entire period, adults (≥2 years of age) were removed most often (62.6 percent; n = 182), followed by yearlings (28.6 percent) and foals (8.8 percent). Across all age classes, slightly more males (56.6 percent; n = 182) were removed than females.

Sex and Age Structure

During the period 1993–2007, 477 foals of known sex were born; four foals disappeared before sex could be ascertained. Slightly more males (243) were born than females (234), but this difference was not statistically significant (χ^2 = 0.170, P = 0.68). On an annual basis, however, the proportion of males in the foal crop varied widely (range = 34.8–71.9 percent) (fig. 3). The proportion of males produced also varied by age of mare, declining from age 3 through about age 10, and then increasing in older mares (fig. 4).

The sex ratio of animals ≥1 year of age varied only moderately during the period of study, ranging from a high of 55.2 percent males in 1997 to a low of 44.2 percent males in 2000 and 2007 (fig. 5). The largest interannual changes in sex ratio occurred as a result of removals in 1994 (27 males, 33 females

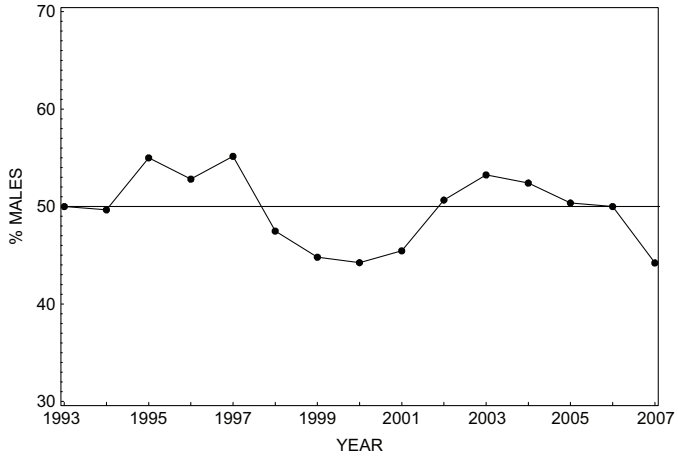

Figure 5. Annual sex ratio of adult (≥1 year old) wild horses (*Equus caballus*) in the Pryor Mountain herd, 1993–2007.

removed), 1997 (33 males, 13 females), 2001 (18 males, 28 females), and 2006 (14 males, 5 females).

The age structure of the Pryor Mountain wild horse herd, on the other hand, changed markedly between 1993 and 2007 (fig. 6*A*,*B*). In 1993, males in the herd averaged 4.4 years of age and females averaged 4.2 years. In 2007, the comparable values were 8.1 and 6.8 years, respectively. Both of these trends are statistically significant as judged by linear least squares regression (males, $P < 0.0001$, $R^2 = 0.911$; females, $P < 0.0001$, $R^2 = 0.832$).

Survival

Pooled across years, ages, and sexes ($n = 2{,}531$), the annual survival rate of horses on the study area was 0.899. Excluding four foals that disappeared before sex could be ascertained, survival of males (0.896, $n = 1{,}246$) did not differ from that of females (0.905, $n = 1{,}281$) ($\chi^2 = 0.486$,

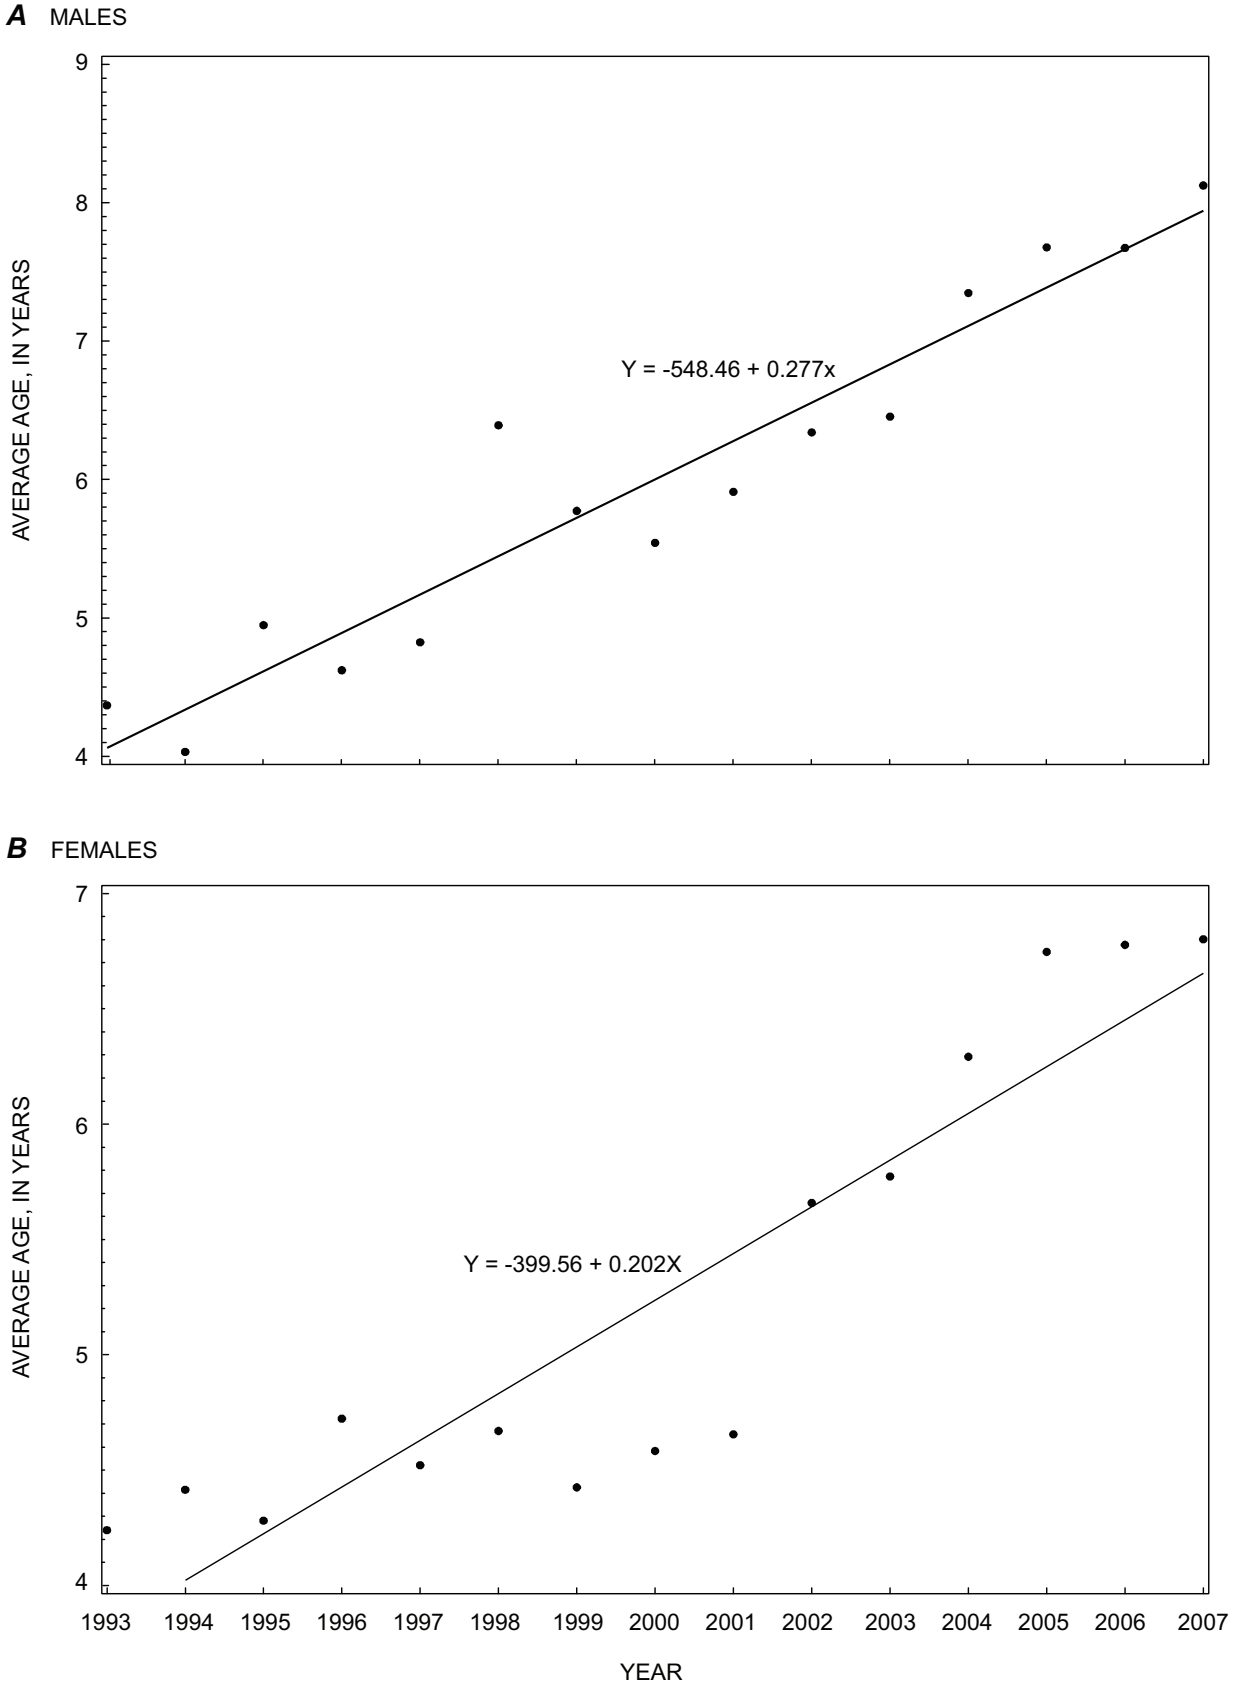

Figure 6. Average age of (*A*) male and (*B*) female wild horses (*Equus caballus*) in the Pryor Mountain herd, 1993–2007.

$P = 0.486$), nor was the difference between the sexes significant for foals ($\chi^2 = 2.500$, $P = 0.114$, $n = 461$). Data from both sexes were therefore pooled for calculations of survival by year.

Survival by year varied from a high of 0.993 in 1993 to a low of 0.780 in 2004 (table 3), when 27 of 28 foals were lost, with predation by mountain lions suspected as the cause (Bureau of Land Management, 2006). For the period of our study, there was a trend toward decreasing foal survival (fig. 7; $P = 0.020$, $R^2 = 0.353$), but there was no trend in survival of animals ≥1 year old ($P = 0.282$, $R^2 = 0.088$). Foal survival increased in the most recent three years of our study, however.

More than one half of the horses that died from 1993 to 2007 were foals, and annual foal survival pooled across years was 0.697 (table 4). Survival increased gradually from age 0 to age 3, remained high through age 15, and then declined gradually. Horses ≥18 years of age were pooled for this analysis because of small sample sizes in these age classes. The oldest animal recorded during the period of study was a male that died at age 26 in 2005. Nine horses lived to be 20 years of age or older, seven of which were males. Four horses (3 males, 1 female) age 20 and 21 were present on the range at the end of our study.

As judged by logistic regression, there was a positive relation between the probability of a foal surviving and the mean (average of summer and fall in a given year) number of members in the band ($n = 393$ foals in 1996–2007; Wald $\chi^2 = 14.964$, odds ratio = 1.244 with 95 percent CI = 1.114–1.390, $P = 0.0001$). Thus, for example, the regression yields a predicted foal survival rate of 0.457 (95 percent CI = 0.351–0.567) for a band size of two, and a predicted survival rate of 0.757 (95 percent CI = 0.688–0.815) for a band size of eight.

We also examined survival of foals in relation to parity of their dams—primiparous (those giving birth to their first foal) compared to multiparous (those that had given birth one or more times). For this analysis, we excluded all mares born before 1993 (since parity could not be determined with certainty) and any foals they produced. We also excluded mares that were presumptively contracepted or were present postcontraception (hereafter referred to as treated and posttreated) and foals that they produced. For the remaining subset of foals, there was no difference in survival based on parity of the dam ($n = 189$, $\chi^2 = 0.957$, $P = 0.328$).

Foaling Rates

For ease of comparison with other studies, we calculated foaling rates of mares ≥2 years of age, ≥3 years of age, and ≥4 years of age. Treated and posttreated mares were excluded from these calculations, as were foals born to unknown dams. Pooled across years, productivity was 0.501 foals/mare (range = 0.254–0.705) for mares ≥2 years of age, 0.576 foals/mare (range = 0.300–0.795) for mares ≥3 years of age, and 0.597 foals/mare (range = 0.311–0.795) for mares ≥4 years of age (table 5). Regression analysis showed a slight increase in foaling rate of mares over time (for mares ≥3 years of age, $P = 0.088$), but variability was high ($R^2 = 0.208$).

From 1993 to 2007, 464 of the 481 foals produced in the study area were born to 118 known or highly probable dams (table 6), an average of 3.93 foals per mare. Many of the dams represented in table 6 are still producing foals; thus, the data represent only a single point in time. Twenty-seven dams that each produced seven or more foals accounted for a total of 237 foals, or 51.1 percent of the production by known dams. Of the 54 dams that have been monitored since birth (that is, those born in 1993 or later) and have not been contracepted, 6 (11.1 percent) first produced a foal at age 2, 29 (53.7 percent) at age 3, 14 (25.9 percent) at age 4, 3 (5.6 percent) at age 5, and 2 (3.7 percent) at age 7. The average age at first foaling for these dams was 3.4 years. Age-specific fecundity was 0.048 foals per mare for 2-year-old mares, increased nearly monotonically through age 10, remained high through age 15, and dropped rapidly thereafter (table 7). The maximum age at which any mare gave birth during the study period was 17 years, although that mare was presumptively contracepted and thus is not represented in table 7. A single set of twin foals (both females) was born during the period of our study, to a 6-year-old mare in 1994.

We used logistic regression to examine the probability of foaling in years following a gather as compared to other years for three age groups of mares: 2 years old, 3 years old, and ≥4 years old. Foal production (yes or no) was the dependent variable and year was the independent variable, and we used a specific hypothesis test (or contrast) to compare the mean probabilities of foaling. For this analysis we considered

only the gathers conducted in 1994, 1997, and 2001 in which most of the family bands were gathered; in 2003, only groups containing animals targeted for removal were gathered, and in 2006 a subset of the herd was captured by bait trapping. For mares 2 or 3 years old, the data were too sparse to allow calculation of the maximum likelihood estimate in the logistic regression (for example, in some years no mares in these age groups produced foals). For mares ≥4 years old the probability of foaling was lower in years following a gather than in other years ($P = 0.03$). The absolute value of this difference was small, however. The mean predicted foaling rate in years following a gather was 0.522 ($n = 3$ years, 134 mares) as opposed to 0.622 ($n = 12$ years, 531 mares) in other years.

We also used logistic regression to examine the probability of a mare foaling as a function of number of members in the band in summer and found a positive relation ($n = 577$ mare-years, Wald $\chi^2 = 24.122$, odds ratio = 1.254 with 95 percent CI = 1.146–1.372, $P < 0.0001$). As an example, the regression yields a predicted probability of foaling of 0.427 (95 percent CI = 0.347–0.511) with a band size of two, as compared to a probability of foaling of 0.743 (95 percent CI = 0.682–0.797) with a band size of eight.

In addition, we compared the probability of foaling in the next year for primiparous and multiparous mares. Primiparous females were less likely to foal ($\chi^2 = 27.29$, $P < 0.0001$) in the year following their first foal (proportion foaling = 0.26, n = 43) than were multiparous females (proportion foaling = 0.72, n = 110). On the other hand, multiparous females were somewhat more likely to foal ($\chi^2 = 2.60$, $P = 0.107$) if they foaled in the previous year (proportion foaling = 0.72, n = 110) than if they did not foal in the previous year (proportion foaling = 0.61, n = 76).

Harem Stallions and Band Composition

During the 12 years (1996–2007) for which information was available, the number of bands varied from 29 to 38 (table 8), with an increasing trend through time (least squares regression, $P = 0.012$, $R^2 = 0.48$). There was no relation, however, between number of bands and band size (least squares regression, $P = 0.88$); that is, band size did not decline significantly as the number of bands increased. Bands were held by 64 different stallions during this period, the youngest being age 3 and the oldest being age 23 (fig. 8). The vast majority of bands, however, were held by stallions aged 5–17 (fig. 8; n = 399). A single stallion gained his first harem at age 3, but 18 of the 29 harem stallions (62.1 percent) for which we have records since birth (born in 1993 or later) acquired their first harem at age 5 or 6 (fig. 9). As might be expected from the increasing age of all males in the herd (fig. 6A), the average age of harem stallions also increased through time (table 8) (least squares regression, $P < 0.0001$, $R^2 = 0.82$).

Harems with as many as six breeding-age females (≥2 years old) were recorded occasionally, but more than 86 percent of the harems contained 1–3 breeding-age females (fig. 10; n = 399). Harem size varied by age of stallion, increasing from age 3 to about age 11 and declining thereafter (fig. 11; n = 399). There were four somewhat anomalous cases in which a male was listed as a harem stallion but the harem size was zero (fig. 10). In two of these cases there were no harem members at all when the observations were recorded. These represent harems in flux, with one or more mares sometimes with the stallion and sometimes not. In the other two cases the only band members were the harem stallion and a yearling female, and we counted only females ≥2 years old in our calculations of harem size.

Of 399 band-year combinations for which we have observations, only 25 (6.3 percent) involved satellite stallions, which we defined as a male ≥5 years old that was associated with a harem stallion. Three pairs of stallions that lived in the same band for 6, 6, and 5 years accounted for 17 of these 25 associations. The remaining eight associations lasted only 1 or 2 years. In only one case were three stallions involved, and that association was maintained for a year or less. Two of the long-term associations (≥5 years) involved stallions that were the same age (7 through 12 years of age) or 1 year apart (harem stallion 5 through 9 years of age; satellite stallion 6 through 10 years of age). The third long-term association included a harem stallion 17 through 22 years of age and a satellite stallion 7 through 12 years of age. The mean number of mares (≥2 years old) did not differ between single- and multistallion bands (2.2 mares in both cases), although 5 of the 25 multistallion bands had 4–6 mares.

Of the 180 male foals born from 1993 through 2003 (those born after 2003 would have been only 3 years old or younger at the end of our study), 124 died or were removed before reaching age 4 and thus had virtually no chance of becoming a harem stallion. An additional 17 died or were removed at age 4 or 5 and thus had a much reduced chance of becoming a harem stallion. Three died at age 6, and two were removed at age 7 without having held a harem. Of the original 180 male foals born, 29 became harem stallions. Of the remaining five animals, two were still bachelors at the end of our study (ages 4 and 6 in 2007), two briefly held harems (at ages 4 and 8) but reverted to bachelor status, and one was a satellite stallion in his natal band (at age 5).

Table 8. Number of wild horse (*Equus caballus*) bands, mean age of harem stallions, mean harem size (mares ≥2 years old), and mean band size (all members) in the Pryor Mountain herd, 1996–2007.

[—, not applicable.]

Year	Number of bands	Mean age of harem stallions	Mean harem size	Mean band size
1996	29	8.76	1.90	5.14
1997	31	9.68	2.06	5.23
1998	31	10.26	1.87	4.90
1999	31	10.71	2.68	5.74
2000	31	11.10	2.68	5.87
2001	38	10.71	2.39	5.24
2002	34	11.06	1.94	4.59
2003	36	10.89	2.06	4.53
2004	34	11.21	2.06	4.03
2005	35	12.11	2.11	4.20
2006	35	13.00	2.20	4.66
2007	34	11.97	2.38	5.18

Bachelors

The number of bachelor males in a wild horse herd changes through the course of a year, as young males are expelled from or leave bands, middle-aged males (formerly bachelors) gain bands, and older males gain and lose bands. In the Pryor Mountain herd, the number of bachelor males in summer (early to mid-June) varied between 16 and 36 during the period of study (fig. 12). The largest interannual change occurred between 1997 and 1998, in part because of the removal of 18 bachelors in fall 1997. In total, 40 bachelors were removed from the herd from 1996 through 2007. Pooled across years, 188 of 328 bachelors (57.3 percent) were 2 through 5 years of age (fig. 13).

To examine the question of when young stallions leave their natal bands and become bachelors, we used a subset of our data that included all males born in 1996 or later (thus ensuring that we had complete information on their band associations since birth). Of the 59 males that were born in 1996 or later and reached bachelor status (many died or were removed before becoming bachelors, others were born too late in the study period to have an opportunity to become bachelors), 4 (6.8 percent) became bachelors at age 1 (though one subsequently returned to his natal band), 32 (54.2 percent) at age 2, 13 (22.0 percent) at age 3, 7 (11.9 percent) at age 4, and 3 (5.1 percent) at age 5.

Population Regulation

Density Dependence

Regression analyses showed no relation between the foaling rate of mares ≥3 years of age and population size in either the current year or the previous year ($P \geq 0.143$). Foaling rate of 2-year-old mares may have declined somewhat with larger population in the previous year ($n = 13$ years, $P = 0.090$), but variability was high ($R^2 = 0.239$). Other young age classes (3–5 years) did not show similar relations, nor did combinations of these age classes.

Overall herd survival was related negatively to the previous year's postfoaling population (fig. 14A) ($n = 23$ years, $P = 0.006$), but there was a great deal of variability ($R^2 = 0.305$). Foal survival, however, was unrelated to population size ($n = 13$ years, $P > 0.15$). There also was a relation between population growth rate and the previous year's postfoaling population (fig. 14B) ($n = 23$ years, $P = 0.002$, $R^2 = 0.382$). This is perhaps not surprising, because survival rate is an important component of population growth rate.

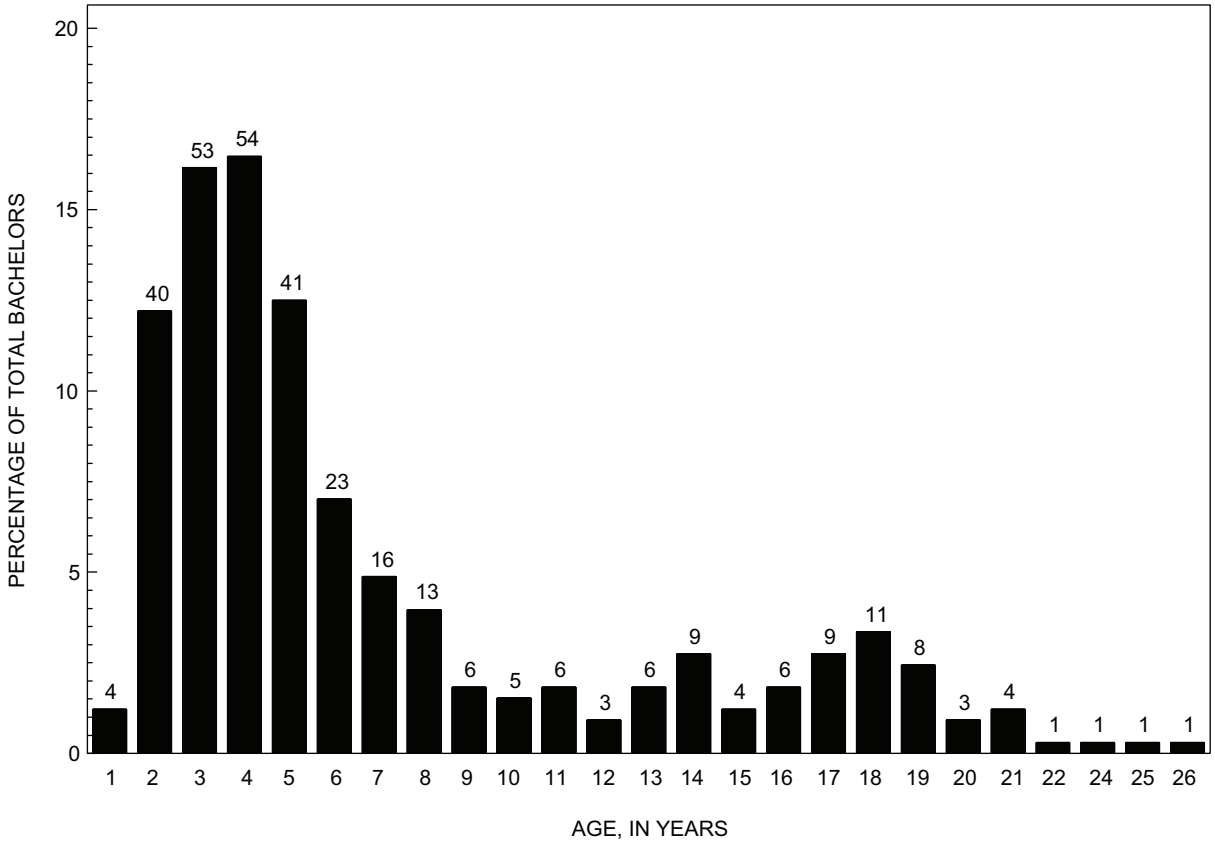

Figure 13. Age distribution of bachelor wild horses (*Equus caballus*) in the Pryor Mountain herd, 1996–2007. Values above the bars are number of bachelors.

Weather

None of the covariates that we used entered the stepwise multiple regression model for herd survival ($P > 0.15$; table 9). For foal survival, both summer and winter precipitation in the current year met the criterion for entry in the model ($P < 0.15$), and both were related positively to foal survival. In the case of winter precipitation in the current year, the positive relation was contradictory to our hypothesis. In combination, these parameters accounted for about 81 percent of the variability in foal survival. In terms of mare foaling rate, only the mean of the monthly average minimum temperature in the previous winter entered the model, and the relation accounted for only about 15 percent of the variability.

Discussion

Population Size and Growth

From 1993 to 2007, the prefoaling (adult) population averaged about 149 animals, only slightly more than the target population of ≈140 adults established on the basis of genetic considerations (Bureau of Land Management, 2006). Removals and a declining survival rate for foals appear to have been the primary factors keeping the population at this level. Contraception also may have played a role if it prevented the birth of any foals. However, it seems likely that the effect of the contraceptive program on population growth was small, given that relatively few mares were treated and that those mares were not in the most productive age classes.

The subject of population growth in wild horse populations has been controversial since early reports (for example, Cook, 1975) of rates as high as 30 percent annually. Other investigators challenged the accuracy of such estimates, and several used simulation modeling in combination with the scant data then available for wild horses and extrapolation of data from other ungulates to show that growth rates of 20–30 percent seemed highly unlikely given apparently reasonable assumptions about model parameters (Conley, 1979; Wolfe, 1980). Frei and others (1979) suggested that the apparently inflated growth rates might be an artifact of improved aerial census techniques and greater experience of observers.

As additional data were accumulated, however, it became apparent that initial assumptions regarding population parameters, particularly survival rates and age of mares at first reproduction, were probably conservative for many wild horse herds (Wolfe, 1986). Eberhardt and others (1982) calculated rates of increase of 20 and 22 percent for two herds

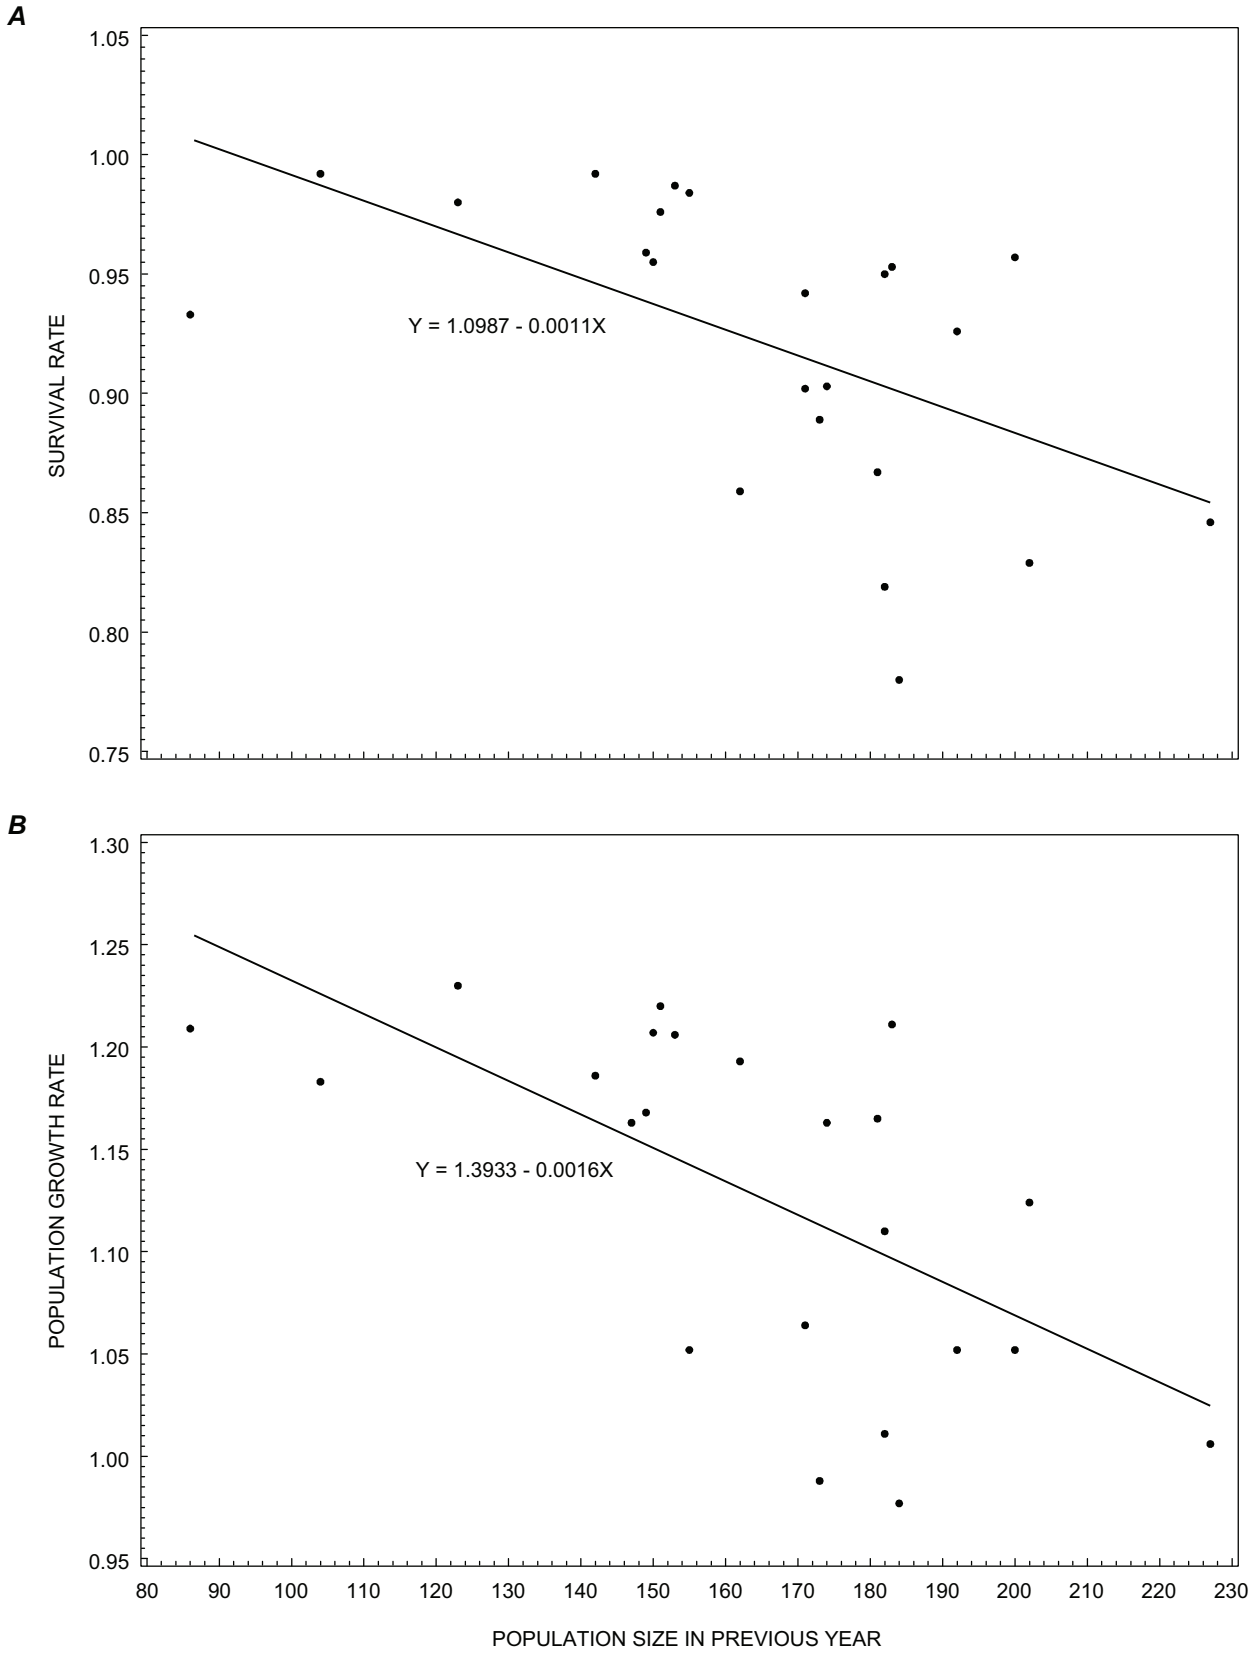

Figure 14. Relation of (*A*) survival and (*B*) population growth rate to the previous year's population for wild horses (*Equus caballus*) in the Pryor Mountain herd. Includes data from this study and from Garrott and Taylor (1990), excepting the abnormally severe winter of 1977–1978.

Table 9. Results of stepwise multiple regressions between wild horse (*Equus caballus*) herd survival, foal survival, and foaling rate (mares ≥3 years of age) and various weather parameters for the Pryor Mountain herd.

Foaling rate	19	LMNT	0.008	0.005	0.15	0.15	0.105

in Oregon and, by comparing pre- and postremoval populations with known removals, showed that the aerial counts used to derive the growth rates must have been reasonably accurate. Berger (1986, p. 76), based on a 5-year study of horses in the Granite Range of Nevada, reported an average annual growth rate of 31 percent. [Note, however, that Berger (1986, p. 77) also reported an exponential growth rate of 0.188, which is equivalent to a finite growth rate of only 20.7 percent annually.] Wolfe (1986), using data from an unspecified number of BLM herds (>40,000 animals), calculated an annual growth rate of 14 percent for the period 1981–1983 and 15 percent for 1983–1985. Garrott and others (1991b) reported an unweighted mean growth rate of 21 percent (range = 15–27 percent) for 12 western herds. High rates of population growth are not limited to western horse populations. Franke Stevens (1990), for example, reported that the horse population at Rachel Carson National Estuary, made up of four small islands off the coast of North Carolina, increased from 44 animals in 1984 to 68 animals in 1986, from which we calculated an annual growth rate of 24.3 percent.

Reported growth rates of wild horse herds have not been universally high, however. Keiper and Houpt (1984), for example, stated that the horse population on Assateague Island National Seashore grew from 42 to 80 animals during the period 1975 to 1982, which represents an average annual growth rate of 9.6 percent. Goodloe and others (2000) found an average annual growth rate of 4.3 percent (range = 3.0–6.8 percent) for horses on Cumberland Island, Georgia, from 1986 to 1990 and suggested that the low rates likely were the result of density-dependent response to limited forage. Greger and Romney (1999), studying a horse population at the Nevada Test Site (now the Nevada Wild Horse Range), found an average growth rate of -7.0 percent, which they attributed to very low foal survival as a result of predation by mountain lions.

The first multiyear study of horses at Pryor Mountain was that of Perkins and others (1979). While they did not calculate population growth rates, they presented information sufficient to do so for two years. Based on information in their table 1, we calculated growth rates of 7.5 and 16.0 percent for 1976 and 1977, respectively, for the postfoaling population. Garrott and Taylor (1990) reported growth rates at Pryor Mountain for 1977–1986 with a mean of 11.9 percent, but 17.8 percent if a year with heavy winter mortality (51 percent of the population died) was excluded. Singer and others (2000) found a mean growth rate of 17.6 percent at Pryor Mountain from 1992–1997.

Our mean annual growth rate (9.6 percent; 10.5 percent if the year of heavy foal loss is excluded) for the period 1993–2007 is thus toward the lower end of the range reported for the Pryor Mountain and other herds. The declining trend in growth rate through time appears to be a result of decreasing survival of foals, though both foal survival (2005–2007) and growth rate (2006–2007) increased in recent years. Contraception also may have played a small role in reducing the average growth rate, though it is difficult to separate the effects of multiple factors.

Sex and Age Ratios

Studies at Pryor Mountain and elsewhere have found foal sex ratios favoring both males and females, with the pattern sometimes switching for the same herd in different time periods. At Pryor Mountain, for example, Feist and McCullough (1975) reported that 54.3 percent of 35 foals were males, Singer and others (2000) found that 58.3 percent of "surviving" foals were males (sample size not given), but Perkins and others (1979) found 48.5 percent males among 103 foals. Similarly, Keiper (1979) reported 52.6 percent males among 190 foals on Assateague Island, but Keiper and Houpt (1984) found 46.6 percent males in 103 foals born at the same location. In many of these studies with relatively small sample sizes, of course, the results did not differ significantly from parity, which also is true of most studies with larger samples, including ours. Speelman and others (1944), for example, found 49.4 percent males in 568 foals born to domestic mares raised under range conditions in Montana. Garrott (1991), who

studied the sex ratio of more than 10,000 foals removed from 74 BLM herds, found no significant difference from parity in 65 of those herds; the foal sex ratio favored females in seven herds and males in two herds. Interestingly, one exception to this pattern is found in the study by Garrott and Taylor (1990) at Pryor Mountain, who reported a sex ratio of 39.7 percent males ($P < 0.001$) in a sample of 330 foals from 1972 to 1986. Garrott and Taylor offered no explanation for this result, but they did comment that other data from their study might suggest low forage availability. Other investigators have hypothesized that females in poor condition (as through low forage availability) should produce fewer male offspring (Trivers and Willard, 1973).

The foal sex ratio did not differ from parity during the course of our study, and there was no overall difference in survival between the sexes. Thus, apart from minor variations resulting from each foal crop entering the population, consistent departures from a 50:50 sex ratio are the result of removals. This is evidenced by the fact that the largest interannual changes in sex ratio occurred following the larger removals. The drop in the proportion of males in the herd in 2007 was because of the removal of 14 males and 5 females in 2006, but also because natural mortality in 2006 consisted of 13 males and only 3 females. The increasing age of the herd also is mostly explained by removals; for all animals removed during the period of study, the average age was 3.2 years for females and 2.7 years for males. This is in keeping with BLM's management strategy of retaining harem stallions and core breeding-age mares (6–10 years) on the range (Bureau of Land Management, 2006). Low survival of foals in 2003 (36.7 percent) and 2004 (3.6 percent) also reduced the proportion of young animals in the herd and thus increased the average age. To the extent that it prevented any mares from foaling, the contraceptive program also would have contributed to increasing age of the herd, but the magnitude of any such effect is unknown.

Survival

The most striking feature of the survival data from our study is the general decline in foal survival in 1993–2004, followed by an apparent increase in the next 3 years. It would be tempting to attribute at least the declining part of this pattern to increased observational effort and hence increased detection of neonatal loss. We do not believe this to be the case, however, because there was no trend in the number of foals produced through time (linear least squares regression, $R^2 = 0.06$, $P = 0.38$), and because all animals present in the herd in 1993 and all foals born since then have been accounted for. Predation by mountain lions is suspected as the cause of low foal survival in 2004 and perhaps in 2003, though only four foals were confirmed to have been taken by mountain lions (Bureau of Land Management, 2006). Three mountain lions were removed from the area by hunters in winter 2004–2005 (Bureau of Land Management, 2006), which might in part explain the increase in foal survival observed in 2005–2007. It also seems possible that predation began on a smaller scale much earlier than 2003, but we know of no evidence to support this hypothesis. Predation by mountain lions has been shown to be an important factor in foal mortality in at least one herd (Turner and Morrison, 2001) and has been implicated in others (Salter, 1979; Greger and Romney, 1999). Wolves (*Canis lupus*), when present, are also suspected of preying on wild horses (Salter, 1979; Oom and Santos-Reis, 1986). Another possible contributor to the observed pattern in foal survival is drought. The drought began in 1999, the same year as the first real drop in foal survival, and was somewhat ameliorated in 2005 and 2007, at which time foal survival increased. The results of our regression analyses between precipitation and foal survival would seem to support this explanation. On the other hand, the initial response to reduced forage availability would likely be a decline in body condition of mares and foals, and such a decline was not observed during the early years of the drought (LC-M).

Overall, survival rates from our study for 1993–2007 are similar to those reported by Perkins and others (1979), but lower than those reported by Garrott and Taylor (1990) and Singer and others (2000) for the same study area (table 10). The foal survival rate reported by Garrott and Taylor, however, probably is an overestimate because it covers the period from midsummer to midsummer; neonatal mortality, which often constitutes the majority of foal mortality (Boyd, 1979; Keiper, 1979; Berger, 1986; Monard and others, 1997; Goodloe and others, 2000), likely was missed. Age of the herd also may account for some of the difference between our survival rate and that calculated by Garrott and Taylor (1990). At the end of their study in 1986, about 22 percent of the herd was ≥11 years of age, whereas the comparable number for 2007 was 39 percent. Perkins and others (1979) and Singer and others (2000) did not provide sufficiently detailed age data to make similar comparisons. Survival rates from our study were also moderate compared to those reported previously for other horse herds in North America (table 10).

Relations between foal survival and band size have not often been reported in the literature on wild horses, and the few available results are equivocal. We found that foals from larger bands tended to survive better than those from smaller bands. Working on Camargue horses in France, Feh (1999) found that there was less foal mortality in bands with an alliance of two stallions (3.2 percent), than in single-stallion bands (22.0 percent). Multiple stallions often are associated with larger bands. Cameron and others (2003), on the other hand, found that among Kaimanawa horses in New Zealand more foals died in multistallion bands (survival = 80 percent, $n = 30$) than in single-stallion bands (survival = 94 percent, $n = 50$), but the difference was not quite significant ($P = 0.056$). Similarly, evidence for a relation between mare age or parity and foal survival is equivocal. We found no relation between foal survival and parity of the mare. Keiper and Houpt (1984) reached the same conclusion, but only 10 foals died in the course of their study. In contrast, Cameron and

Table 10. Survival rates reported for North American wild horse (*Equus caballus*) herds.

[Data are arranged in order of increasing foal survival. Sample size (*n*), when available, is given in parentheses. NA, data not available; PMWHR, Pryor Mountain Wild Horse Range.]

Source and location	Survival rate (*n*)				Comments
	Foals	Yearlings	Adults	Herd	
Greger and Romney (1999), NV	0.12	NA	NA	NA	Foal survival is a mean for 8 years and is a maximum estimate because some neonatal mortality probably went undetected.
Turner and Morrison (2001), CA and NV	0.32	0.88	0.92	NA	All data represent means for 10 years.
Goodloe and others (2000), GA	0.600 (105)	NA	0.923 (263)	NA	Adult rate is for mares only, probably ≥3 years old.
This study, (PMWHR)	0.697 (465)	0.917 (252)	0.949 (1,814)	0.899 (2,531)	
Perkins and others (1979), PMWHR	0.75	NA	NA	0.903 (579)	Foal survival is a mean for 4 years. Herd survival is a weighted mean calculated from Table 1, Perkins and others (1979).
Boyd (1979), WY	0.824 (51)	NA	NA	NA	Data for 1978 only.
Singer and others (2000), PMWHR	0.87	NA	NA	Males, 0.965 Females, 0.975	Not clear that data reported for the herd actually includes all animals.
Siniff and others (1986), Pine Nut, NV	0.875 (40)	NA	0.972 (72)	NA	Adult rate is a weighted mean for 2 years representing only mares, probably ≥2 years old
Siniff and others (1986), Pah Rah, NV	0.877 (73)	NA	0.975 (81)	NA	Adult rate is a weighted mean for 2 years representing only mares, probably ≥2 years old
Keiper and Houpt (1984), MD and VA	0.883 (86)	NA	NA	NA	Foal rate is a weighted mean for 8 years.
Pellegrini (1971), NV	0.905 (21)	NA	NA	NA	Data are for 1969. However, in 1968 no foals were observed, and in 1970 only one foal was observed.
Berger (1986), NV	0.917 (120)	0.969 (64)	0.951 (329)	0.945 (513)	Herd rate calculated from data on the three age groups.
Garrott and Taylor (1990), PMWHR	0.968 (249)	0.977 (173)	0.962 (865)	0.965 (1,287)	Excludes data from a severe winter. Adult and herd rates calculated from Table 2, Garrott and Taylor (1990). Foal rate measured from midsummer to midsummer and may be an overestimate.

others (2000) found significant differences in mortality of foals born to mares 3–5 years old (18 percent mortality), 6–8 years old (3 percent), and ≥9 years old (9 percent).

Foaling Rates

Foaling rates of mares at Pryor Mountain most often have been low to moderate when compared to those reported for other North American herds (table 11). In fact, the rate of 0.432 foals/mare for mares ≥4 years of age calculated from Feist and McCullough (1975) is among the lowest for any herd, although their study was primarily behavioral and lasted only 1 year. In addition, they attempted to classify mares aged 1, 2–3, and ≥4 years without the benefit of examining tooth eruption and wear, and they admit that some classification errors probably occurred. If there was a tendency to misclassify 3-year-old mares as being ≥4 years old, the resulting foaling rate would be biased low. Garrott and Taylor (1990), however, reported similarly low rates, and mares in their study were aged by dental characteristics. As noted above, Garrott and Taylor (1990) reported on foals present in midsummer; some neonatal loss likely was missed, which would tend to bias foaling rates low. Perkins and others (1979) did not report age-specific foaling rates of mares, but for the three years of their study for which data are complete (1975–1977), the foal crop was 15.1 percent of the prefoaling population (weighted average, $n = 411$ animals ≥1 year of age). The comparable value during our study was 21.6 percent (table 1, $n = 2{,}232$ animals). These values, of course, are affected by the sex and age structure of the herd. Similarly, Singer and others (2000) did not report age-specific foaling rates in sufficient detail to be included in table 11. They did, however, show rates of 0.107 foals/mare for mares of age 2, 0.54 for age 3, 0.67 for ages 4–11, and 0.46 for ages ≥12 in the period 1992–1997. Comparable values from our study (1993–2007) were 0.048, 0.414, 0.588, and 0.636, respectively. Thus, it appears that foaling rates at Pryor Mountain have varied considerably through time, with those from our study being intermediate.

Several investigators have suggested that forage availability can affect the condition of feral mares and thus foaling rates (Green and Green, 1977: Nelson, 1978; Berger, 1986; Siniff and others, 1986; Garrott and Taylor, 1990). Hall (1972) described range conditions at Pryor Mountain as being poor to extremely poor through much of the area. Feist and McCullough (1975) reported a low foaling rate in 1971, as did Garrott and Taylor (1990) in the first 3 years (1976–1978) of their study. Furthermore, Garrott and Taylor (1990) suggested that low foaling rates likely were a result of poor forage, also noting that the foaling rate increased markedly in 1979 following loss of 51 percent of the herd in the severe winter of 1977–1978. Singer and others (2000) reported somewhat higher foaling rates than were observed in the earlier studies and also noted that former managers who visited Pryor Mountain in 1997 remarked about the overall improvement in "plant condition." Again, our values for foaling rate appear to be intermediate. It also may be relevant that mean annual precipitation in the biological years covered by the study of Singer and others (17.55 cm; 1992–1997, all years included regardless of missing data) was greater than that for the remainder of our study (13.79 cm; 1998–2007).

In addition to its effects on foaling rates of adult animals, forage availability may affect age of first reproduction by mares. Feist and McCullough (1975), Perkins and others (1979), and Garrott and Taylor (1990) all worked at times when forage production may have been poor at Pryor Mountain and all found that mares first foaled at age 3. Singer and others (2000), on the other hand, at a time when forage production may have been somewhat better, found that 10.7 percent of 2-year-old mares produced foals; the comparable value from our study was 4.8 percent. First foaling at age 2 (Salter and Hudson, 1982; Berger, 1986; Lucas and others, 1991) and age 3 (Boyd, 1979; Keiper and Houpt, 1984; Goodloe and others, 2000) has been reported for other herds, with the rate for 2-year-olds varying both among herds and within herds in different years (Garrott and others, 1991a). In at least two studies, low foaling rates in young mares have been attributed to high rates of fetal and neonatal loss (Lucas and others, 1991; Linklater and others, 2004).

Other factors that have been shown or hypothesized to affect foaling rate include gathers, band stability, and parturition history of the mare. In the case of gathers, we found a small but statistically significant effect, with foaling rate being lower in years following gathers. It must be remembered, however, that we did not design an experiment specifically to test a hypothesis about the effect of gathers. In particular, we had to assume that the majority of mares were affected by the gather (either actually moved into a trap or significantly disturbed by helicopter activity) in each of the three years that we considered to be gather years. Given the nature of the gathers in those three years, we believe that such an assumption is reasonable. Other evidence for an effect of gathers on foaling rate is equivocal. Hansen and Mosley (2000) studied two herds, one in Idaho and one in Wyoming, and found no difference in foaling rate between mares ungathered, gathered and released, or gathered and adopted. The ungathered samples were small, however, consisting of only 14 mares in each herd. Ashley and Holcombe (2001), on the other hand, found that in one of the two years of their study, ungathered mares foaled at a higher rate than did those that were gathered and released or gathered and removed. They found no evidence for an effect of a gather in the other year.

Evidence for an effect of band stability on mare foaling rate is more consistent. Berger (1983) found that mares in bands with resident stallions produced foals at a higher rate than those in bands taken over by a new stallion. Kaseda and others (1995), working on Misaki horses in Japan, reported that mares in "stable consort relationships" had higher reproductive success than those that changed stallions. Similarly, Goodloe and others (2000) found that mares that changed bands had a lower probability of foaling than those that did

Table 11. Foaling rates reported for North American wild horse (*Equus caballus*) herds.

not. Data on mare interchanges are available from the Pryor Mountain herd, but have not yet been analyzed.

The question of whether parturition history of the mare affects foaling rate has been of interest since early investigators reported what they perceived to be a tendency to foal in alternate years (Green and Green, 1977; Nelson, 1978). This question has been addressed in a number of ways and results have varied. Seal and Plotka (1983) found that 68.4 percent (n = 76) of pregnant mares also had a foal at their side or were lactating, and Wolfe and others (1989) found no difference in pregnancy rates for lactating and nonlactating mares in six different populations. Neither of these studies, however, addressed the question of whether lactating and nonlactating mares are equally successful in bringing their pregnancies to term. On Assateague Island, 10.2 percent of 49 mares followed for 4 years foaled in alternate years, whereas 55.1 percent foaled in either 3 or 4 years (Keiper, 1979). Similarly, Keiper and Houpt (1984) could not see any tendency to foal in alternate years among 14 mares followed for 8 years. At Pryor Mountain, in both our study and that of Garrott and Taylor (1990), primiparous mares were less likely to foal in the next year than were multiparous mares. Cameron and Linklater (2000), on the other hand, found that the probability of foaling in a given year was reduced significantly if the mare had a foal in the previous year. Thus, while not universal, it appears that foaling in one year can sometimes reduce the probability of foaling in the subsequent year, particularly in primiparous mares.

Harem Stallions and Band Composition

Comparisons among band or harem sizes reported by various investigators are hampered by inconsistencies in defining what constitutes a harem member, or failure to do so at all. We defined harem members as mares ≥2 years of age, and found that the mean harem size was 2.2 mares with a range of 1.9 to 2.7 over 12 years; the number of bands ranged from 29 to 38. In other studies at Pryor Mountain, Feist and McCullough (1975) reported only average band size (5.0 including all members, not just mares), but they found 44 bands and 106 females ≥2 years of age, so the average harem size was likely somewhere near 2.4 mares. Note that the total population during the single summer of their study was about 225 animals, which probably explains the somewhat larger number of bands. Perkins and others (1979), working on a population that ranged from 95 to 168 animals (1974–1978), found 19–27 bands with a mean size of 4.9 (total animals), but did not report harem size in terms of number of mares. During a period (1992–1997) when the mean population was 161 animals, Singer and others (2000) reported an increase in the number of bands (18 to 31) and a decline in the number of mares (age unspecified) per harem from four to two. They attributed these trends to an increasing proportion of males in the population, death or waning vigor of a number of older males, and removal of members from the bands of several stallions aged 10–15 years. Investigators working on other herds have found similar or perhaps slightly larger average harem sizes. Mean harem size on Cumberland Island was 1.8 mares (Goodloe and others, 2000); the authors did not specify the age of mares included, but only mares ≥3 years old produced foals. Greger and Romney (1999) reported an average harem size of 2.4, which included all females ≥1 year of age, excluding daughters. Berger (1986, p. 130) found an average harem size of 3.1 mares with a range of 2.73–3.67 across years; age of mares was not specified but, because 2-year-old females reproduced, mares ≥2 years old may have been included. In Misaki horses (Japan), the annual average harem size ranged from 1.8 to 5.3 mares ≥2 years old; one stallion in one year had a harem of nine mares, and 55.0 percent of 60 harems (14 harem stallions) observed from 1979 to 1994 had four or more mares (Kaseda and Khalil, 1996).

In our study, 62.1 percent of harem stallions first acquired a harem at age 5 or 6. Other investigators have found comparable results: Berger (1986, p. 142), age 5–6; Kaseda and Khalil (1996), age 4–6; Asa (1999), age 5; Singer and others (2000), mean age = 6 years. In the last two years of our study, the mean age of harem stallions was 13 and 12 years, which is remarkably similar to the mean of 12.8 years reported at Pryor Mountain by Perkins and others (1979). Hall (1972), however, reported a mean age of 7.8 years, which is more similar to the data from the early years of our study. Age structure of removals is undoubtedly an important determinant of such results.

During our study, 6.3 percent of bands had multiple stallions. Feist and McCullough (1975) did not mention whether any of the 44 bands present during their study had multiple stallions. Perkins and others (1979) found only two multistallion bands in the 19–27 bands present during the 4 years of their study; if the mean number of bands present was, say, 23 per year, multistallion bands would have made up about 2.2 percent of the total. These percentages are lower than those reported for other herds: Goodloe and others (2000), 10.7 percent, n = 177; Nelson (1978), 11.8 percent, n = 17; Berger (1986, p. 129), 12 percent, sample size not given; Salter and Hudson (1982), 17.4 percent, n = 23; Asa (1999), 28 percent and 33 percent in 2 years, n = 18 and 9; Miller (1979), 23–45 percent for 3 years, n = 12–18; Bowling and Touchberry (1990), 39.1 percent, n = 69; Franke Stevens (1990), 50 percent, n = 12; Green and Green (1977), 45 percent and 54 percent in 2 years, n = 53 and 67, respectively. Kirkpatrick and Turner (1986) suggested that differences in proportions of bands with multiple stallions may be related to population density and sex ratio, with a greater ratio of males to females tending to lead to multistallion bands, and noted that some of the reported proportions may be high as a result of inaccurate aging of the animals based on body size [for example, Green and Green (1977)].

Bachelors

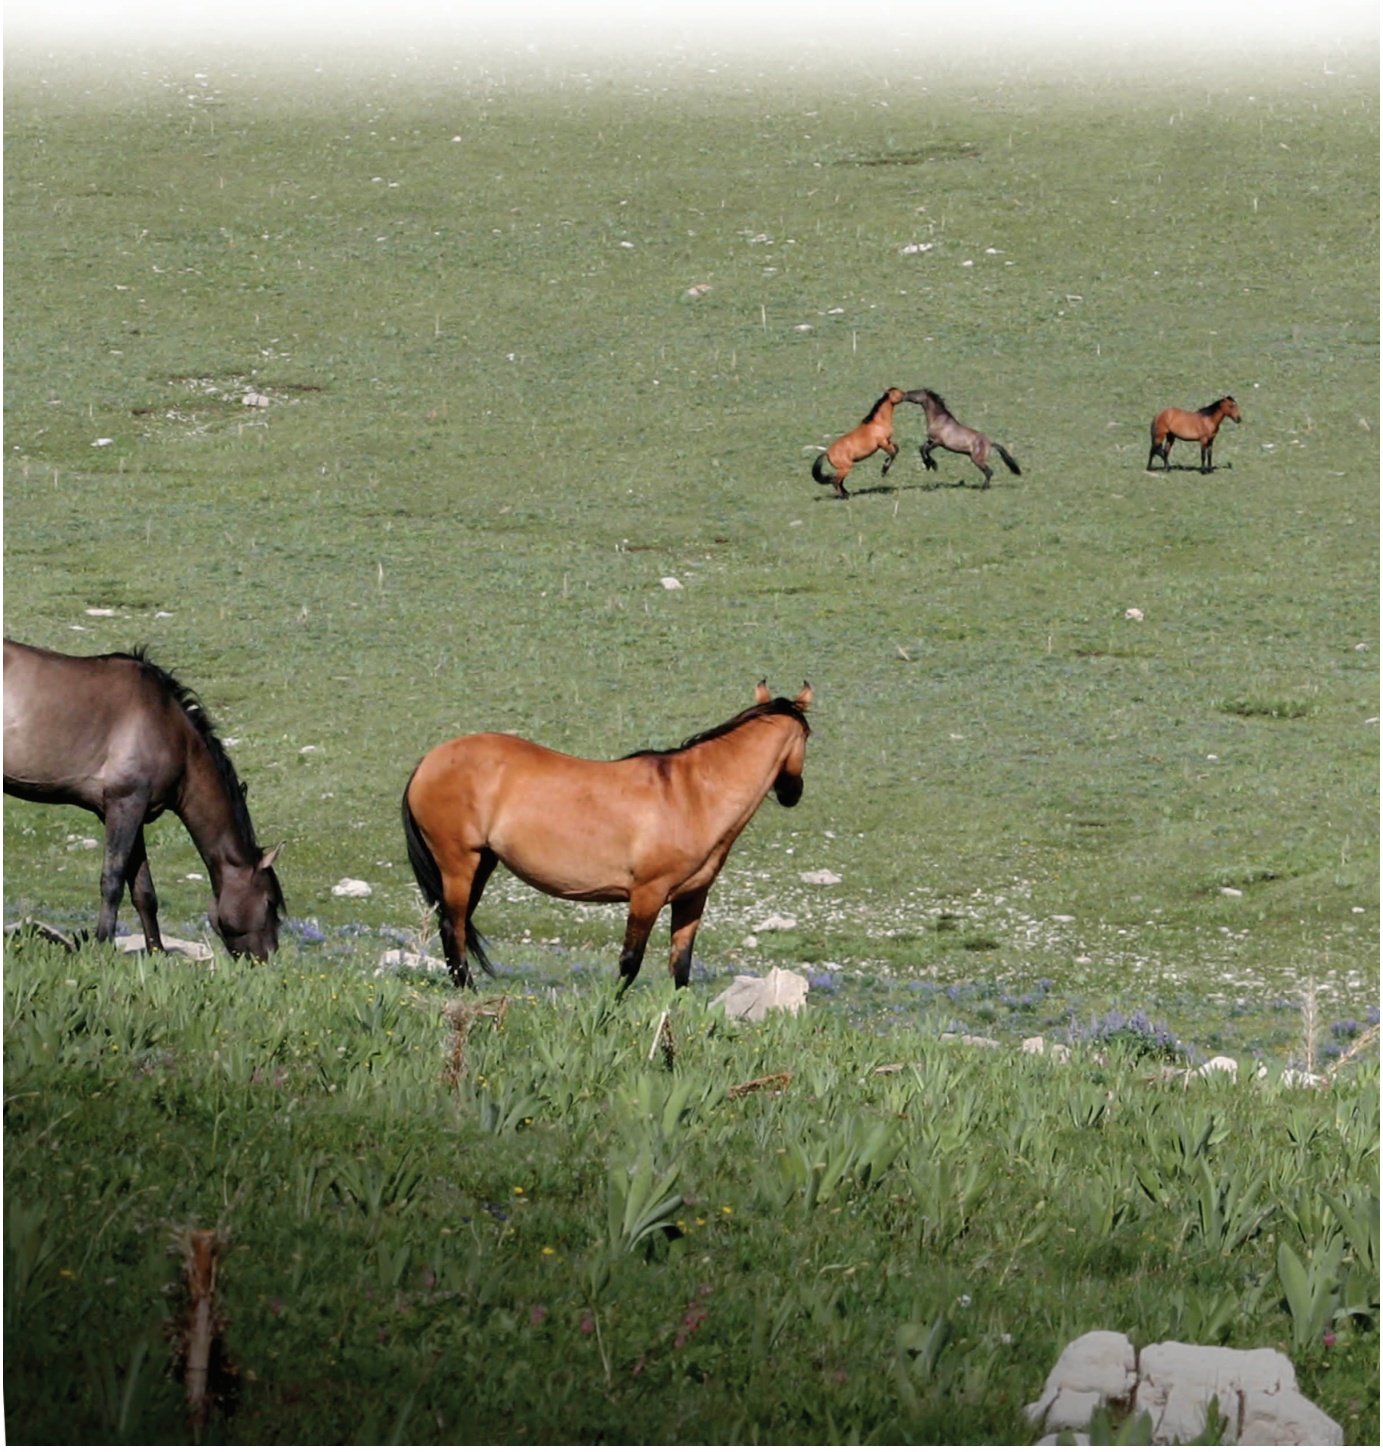
We have information on the total number of bachelors, but not on individual groups, which makes comparisons with other studies at Pryor Mountain difficult. Hall (1972) reported that the average size of bachelor groups was three, with individuals ranging in age from 1 to 5 years, and that older stallions usually lived alone after losing their harems. Feist and McCullough (1975) found 23 bachelor groups with a mean of 1.8 animals per group. Perkins and others (1979) found six bachelor groups, all with 2–3 individuals ranging in age from 3 to 8 years, as well as six older stallions that lived alone. With allowances for varying population size, our results do not appear to be greatly different from those found at other times at Pryor Mountain.

Most evidence suggests that males leave or are expelled from their natal band when they reach sexual maturity, which usually occurs at age 3 and occasionally at age 2 (Angle and others, 1979; Kirkpatrick and Turner, 1986). Our data show a somewhat different pattern. A few males left their natal band at age 1, most (54.2 percent) left at age 2, but 17 percent remained with their natal band until age 4 or 5. Of the three individuals that remained in their natal bands until age 5, two subsequently acquired harems and one was still a bachelor (6 years old) at the end of our study. Interestingly, one of these stallions took over his natal band, at which point his dam left the band for another. It seems possible that instances of stallions remaining with their natal band until age 4 or 5 account for some of the reports in other studies of a high proportion of multistallion bands.

Population Regulation

Several investigators have suggested a relation between forage availability and foaling rate, but few studies have been long enough and had sufficient variation in population size to allow detection of density-dependent effects. Berger (1986, p. 97) found little evidence for density dependence in his data from the Granite Range and suggested that the confounding effects of weather were responsible. He did, however, find some evidence for a decline in foaling rate with increasing population size in data from Keiper and Houpt (1984). Singer and others (2000) found that population growth rate at Pryor Mountain declined with increasing population size, but this result was clearly dominated by data from a single year [Singer and others (2000), fig. 5]. They did not find evidence for a density-dependent effect on either foaling rate or survival rate. Jenkins (2000) examined data from the Granite Range and Pryor Mountain herds, both having individually identified animals, as well as five additional herds where population size was estimated using aerial surveys. In all seven cases, he found that population growth rate decreased with increasing population size, but only one was statistically significant ($P \leq 0.05$). However, his meta-analysis of the entire data set indicated that the probability of the same result through chance alone was only 0.001.

Our results are similar to those of both Singer and others (2000) and Jenkins (2000) in that we also found that population growth rate declined with increasing population size, albeit population size from the preceding year, which suggests that lag effects may be important. Furthermore, we found similar evidence for a negative relation between overall herd survival and population size, and perhaps some weaker evidence that the foaling rate of 2-year-old mares is affected by population size. We did not, however, find evidence for a density-dependent effect on foal survival, perhaps in part because Garrott and Taylor (1990), whose study encompassed a range of population sizes, did not provide annual foal survival rates.



We used population size as a surrogate for population density in these analyses, as did all of the authors cited in this section. In doing so, we made the implicit assumption that the area used by horses did not change significantly through the course of the study. In the case of the Pryor Mountain herd, however, horses probably made increasing seasonal use of Forest Service lands north and west of the original wild horse range. It seems likely that any density-dependent effects would have been more pronounced had this increase in use of Forest Service land not occurred.

In all cases where we found evidence for density dependence, variability was high, suggesting that other factors also may be important in regulating the Pryor Mountain wild horse herd. Assuming that the cause of mortality was correctly identified, mountain lion predation may have had a dramatic effect on foal survival in at least one year. In the latter years of our study, contraception also may have had some effect on foaling rate, though it seems likely that this effect was small given that relatively few mares were treated and that they were not in the most productive age classes. One of the most important regulatory mechanisms appears to be precipitation, which we found to be strongly related to foal survival. Both density dependence and precipitation effects are consistent with an interpretation of forage availability per individual as an important parameter. All of these factors combined, however, were not sufficient to stabilize the population during our period of study, as evidenced by the necessity for large removals in several years.

Acknowledgments

Thanks to the Bureau of Land Management's Billings Field Office for logistical support and making historical data available, and to the National Park Service, Bighorn Canyon National Recreation Area, for providing access and logistical support for field work on NPS lands. The integrity of

long-term data for the Pryor Mountain herd can be partially attributed to the commitment and dedication of the late Reverend Floyd Schwieger, who graciously shared his work and answered many questions before his passing. Special thanks to the BLM and USGS field technicians who spent their summers following horses and accurately collecting the data: Hanem Abouelezz, Genie Amelung, Erin Anderson, Laura Caldwell, Steve Cordts, Kira Donnelly, Darla Dunaway, Jason Dungan, Melissa Esser, Jill Fanning-Rodgers, Don Galvin, Kayla Grams, Patti Grigsby, Susan Hahn, Christine Hardy, Heather Jensen, Martina Keil, Dan Kraemer, Megan Lallier, Samantha Lukas, Ian McCluskey, Sean Mead, Jessica Meredith, Jill Nannenga, Jane Nibler, Christopher Papouchis, Christina Petrandis, Justin Rodgers, Lisa Selner, Jennifer Severude, Aaron Swallow, Nani Teves, and Jamie Wages. Thanks also to Dan Baker, Jared Bybee, Bob Garrott, Al Kane, and Alan Shepherd for providing critical reviews of the manuscript, to Tammy Fancher for preparing the map of the study area, and to Jennifer Shoemaker for assistance with graphics.

Estrus-related behavior

ABSTRACT

Synthetic progestins, including altrenogest, are employed to modify undesirable estrus-related behavior or poor performance in mares. Bilateral laparoscopic ovariectomy (BLO) is another means of management. Our objective was to compare the perceived improvement in mares with estrus-related problems administered altrenogest to BLO. Owners of mares with estrus-related problem(s) that had undergone BLO after altrenogest treatment completed a telephone survey. They rated the behavioral or performance improvements with altrenogest and after BLO on a Likert scale (1 = no response; 5 = complete resolution). They also compared improvement with altrenogest and following BLO (1 = better response with altrenogest; 2 = comparable responses; 3 = better response with BLO). Likert scores for the two treatments were compared using the Wilcoxon signed rank test. The association between altrenogest and BLO scores was compared using Spearman rank-order correlation. Owners or trainers identified a variety of estrus-related problems in 20 mares meeting the inclusion criteria. Median scores for BLO were significantly higher than those for altrenogest ($P = .008$). The association of the perceived response to altrenogest and BLO was positive but relatively weak ($\rho = 0.288$). In a substantial proportion of mares with estrus-related problems, a salutary response to altrenogest was associated with a favorable response to BLO; however, some mares showing limited improvement with the progestagen still responded favorably to BLO. In this series, BLO was perceived by owners or trainers to be at least as effective as altrenogest administration as a means of diminishing a number of estrus-related behavioral and performance problems.

1. Introduction

Trainers involved in a variety of disciplines have observed variation in the athletic performance of some mares that appear related to the estrous cycle [1–3]. Estrus-related behavioral or performance problems include difficulties during riding or training, back or flank pain, aggressiveness to other horses or people, frequent urination, colic signs, and undesirable estrous behavior during competition or training [2–5].

A variety of synthetic progestagens have been used in efforts to control undesirable behavior or impaired performance related to estrus [3,6]. Among the most popular is altrenogest (Regu-Mate; Merck, Whitehouse Station, NJ). Altrenogest is effective in eliminating estrous signs within 2–3 days in mares treated during estrus and will continue to suppress behavioral estrus with daily administration [1,6]. Despite recommendations to the contrary, this progestagen is reputedly used for prolonged periods in athletic mares without ill effects [7]. The associated cumulative expense, the necessity for daily administration, and potential deleterious effects after unintentional percutaneous absorption in women are disadvantages of its use.

Bilateral ovariectomy is regarded by some as a treatment of the last resort for mares with estrus-related problems

http://dx.doi.org/10.1016/j.jevs.2015.01.007

that fail to respond favorably to pharmacologic treatment [3,6]. Complications after conventional open ovariectomy, although uncommon, can be grave and include serious hemorrhage, infection, adhesions, herniation, and evisceration [8,9]. Hooper et al [5] reported the elimination of objectionable estrus-related behavior in 14 of 17 mares ovariectomized via colpotomy. Improved performance after surgery was observed in a subset of 10 of 12 treated mares used for athletic purposes.

It is widely held that morbidity and mortality accompanying surgery are reduced when mares are ovariectomized using laparoscopic techniques [10], and bilateral laparoscopic ovariectomy (BLO) is increasingly popular for treatment estrus-related problems in working mares. The efficacy of BLO to reduce estrus-associated behavior and performance problems has not been firmly established, although favorable results have been reported in 70%–85% of cases where the procedure has been conducted for this purpose [11–16]. Similarly, the value of a favorable response to altrenogest to predict the efficacy of subsequent BLO is unknown. Critics of using the behavior- or performance-modifying effects of progestagen therapy to predict improvements after bilateral ovariectomy indicate that exposure of a mare to progesterone or one of its analogs is not equivalent to removal or absence of an estrogen influence [3,6]. Nonetheless, collective experience has led to the clinical impression that substantial improvements in the behavior and performance of mares with altrenogest administration are mirrored by those after BLO. Thus, the objectives of this study were to compare behavioral improvement in mares with altrenogest therapy to improvement after BLO and to determine if the behavioral or performance improvements realized with altrenogest were predictive of the response to BLO.

2. Materials and Methods

2.1. Case Selection

The medical records of mares that had undergone a BLO for estrus-related behavioral or performance problems were retrieved. Inclusion criteria included (1) mares had to have undergone treatment with altrenogest for a minimum duration of 2 weeks at some time before surgery; (2) at least some reduction in objectionable behavior(s) had to have been observed with altrenogest treatment (supporting the of an estrus-related problem); (3) had to have had grossly normal ovaries; and (4) follow-up was available. Mares that had been treated with other progestagens (e.g., medroxyprogesterone acetate [Depo-Provera; Pfizer, New York, NY]) but not altrenogest were not included.

2.2. Surgery

Bilateral laparoscopic ovariectomy was conducted in a manner previously reported [17]. Briefly, following fasting for 15–18 hours, mares were confined in treatment stocks with cross-ties and sedated with an IV loading dose of 3 μg/kg of detomidine followed by a continuous IV infusion (12 mg detomidine diluted in 250 mL of sterile polyionic fluids) to effect. Both flanks were clipped in a conventional fashion. Local anesthesia was effected using injections of 5–10 mL of 2% mepivacaine at the intended portal sites.

A 10-mm telescope portal was created in the left 17th intercostal space, at the level of the palpable ventral extremity of the tuber coxa and insufflation with carbon dioxide (6–10 mm Hg) was used to augment working space. A pair of 5-mm instrument portals was placed in the paralumbar fossa. The mesovarium was desensitized with 20–30 mL of local anesthetic injected at three to five locations dorsal to the ovary and tip of the uterine horn using an endoscopic injection needle. Subsequently, the mesosalpinx was elevated from its position on the lateral side of the ovary and dissected cranially to the point at which it fuses with the mesovarium using an electromechanical dissector (SonoSurg; Olympus KeyMed, Center Valley, PA). The dissector was used to sever the proper ligament, separating the ovary from the tip of the uterine horn, and dissection was continued craniad until a relatively narrow pedicle of mesovarium remained. A hand-tied ligating loop of one polydioxanone was placed on the pedicle containing the principal vasculature of the ovary. After transection of the remaining pedicle, the left ovary was passed to the right side of the abdomen between the urinary bladder and the body of the uterus. A similar portal arrangement was established on the right side of the mare, and the ovarian pedicle was transected using the technique described previously. Both ovaries were removed by morcellation through the right flank after enlargement of an instrument portal to 1.5 cm (electromechanical morcellator; Rotocut; Karl Storz, Tuttlingen, Germany).

2.3. Follow-up

A questionnaire was prepared that was used to conduct a telephone survey of individuals whose mare(s) had undergone BLO after management of objectionable behavior or impaired performance following one or more courses of daily altrenogest administration for a minimum duration of 2 weeks. Owners were asked to identify the principal behavioral and/or performance problem that had prompted medical and then surgical management, as well as any other perceived behavioral abnormalities. They rated the degree to which each of altrenogest therapy and BLO eliminated the principal behavioral or performance problem on a Likert scale (1 = no response; 5 = complete resolution). They also compared the quality of response to altrenogest and BLO (1 = better response to altrenogest; 2 = comparable response to both; 3 = better response to BLO). Owners were also requested to identify any complications that resulted from BLO.

2.4. Statistics

Likert scores were reported as medians and ranges. Owners' opinions regarding the relative efficacy of the two treatments were compared using the Wilcoxon signed rank test. The association between altrenogest treatment and BLO was assessed using Spearman rank-order correlation.

3. Results

Twenty mares met the four inclusion criteria and were included in the study. Mares ranged in age from 3 to 15 years with an average age of 9.4 years. Principal estrus-related problems, identified by owners or trainers, were some or all of kicking, bucking, or rearing (six mares); colic during estrus or ovulation (four mares); refusal to work during estrus (three mares); aggressiveness to other horses, people, or both (three mares); stallion-like behavior (one mare); undesirable estrus behavior during work (one mare); flank pain during estrus (two mares). Commonly, owners reported that their mares demonstrated additional behaviors to those previously mentioned to a lesser extent than the primary one. Before surgery, the mean duration of altrenogest administration was 4.7 months (range, 2 weeks–12 months). Dosage ranged from the recommended dose (0.044 mg/kg daily) to four times the recommended dose. Five mares underwent treatment with medroxyprogesterone acetate in addition to altrenogest on at least one separate occasion.

The median scores for owners' perception of resolution of the principal problem with altrenogest and BLO were 4 (range, 2–5) and 5 (range, 2–5), respectively. The perceived improvement in undesirable behavior or suboptimal performance after BLO was statistically significantly better than that for altrenogest therapy ($P = .008$). The association of responses to altrenogest and surgery was positive but weak ($\rho = 0.288$). Owners' opinions regarding the effects of both altrenogest and BLO on resolution of secondary problem(s) were virtually identical to those provided for the primary problems.

Of the 20 mares, six (30%) showed estrus signs at least once after surgery; in two mares (both aged 11 years), this was transient and the behavior ultimately disappeared. In the remaining four mares (mean age, 7.3 years [range, 3–10 years]), mild estrus signs persisted.

Complications related to the procedure were rare. Incisional swelling that resolved without treatment was reported for one mare, and two mares experienced mild colic signs shortly after discharge from the hospital. In both these mares, symptoms abated with treatment with nonsteroidal anti-inflammatory drugs.

4. Discussion

The results of this study provide evidence that BLO for the management of a variety of estrus-related behavioral and performance problems compares favorably with altrenogest therapy. Indeed, 95% of owners were of the opinion that BLO resulted in similar (four of 20) or greater (15 of 20) resolution of the primary problem than was achieved with medical therapy. A single mare had a better response to altrenogest than BLO. The principal problem for this 11-year-old mare was kicking and lack of regard for handlers. After surgery, the mare no longer kicked; however, she continued to slam into the wall of her stall. This behavior was not considered sufficiently problematic to resume treatment with altrenogest.

A variety of undesirable behaviors can accompany estrus in mares but clearly establishing a cause–effect relationship is challenging and is often a diagnosis made by exclusion. Obviously, for effective treatment of these problems, it is important to confirm that behavioral or performance problems are associated with estrus or the estrous cycle. Suppression of estrus with altrenogest was used to establish that estrus or ovulation was the source of colic symptoms in two mares [4]. We anticipated that a beneficial effect of progestagen administration on other putative estrus-related abnormalities would aid in establishing an association of undesirable behaviors with estrus and might portend a favorable response to BLO. For this reason, mares that failed to evince improvement in signs with altrenogest therapy, indirect evidence of a problem not related to estrus or cyclicity, were not included. (Parenthetically, four mares with altrenogest scores of 1 [no noticeable improvement] were excluded from the statistical analysis. Their median BLO score was 4.5 [range, 2–5]).

Commonly, owners' assessments of the effects of medical and surgical treatment paralleled one another. Interestingly, although scores for improvements observed with altrenogest and BLO were infrequently widely disparate, a number of owners observed only minor amelioration of signs with progestagen administration and perceived obvious improvement or complete resolution of the primary problem after BLO. The frequency of this phenomenon was sufficient (four of 20 mares) to result in a positive but weak Spearman correlation coefficient; thus, we were unable to strongly support the contention that the response to altrenogest is predictive of that to BLO. A stronger association of perceived improvements with medical and surgical treatment might be evident with a larger sample size.

One inclusion criterion included a course of treatment specifically with altrenogest before surgery. A number of mares that received just medroxyprogesterone acetate before BLO were not included. It has been shown that, like some other synthetic progestagens, medroxyprogesterone is relatively ineffective as a progesterone analog in mares because of weak binding to the progesterone receptor [18]. This purported lack of pharmacologic efficacy for mares given only medroxyprogesterone was considered a potential confounding factor, prompting their exclusion. Parenthetically, with rare exception, owners noted little or no improvement in signs with medroxyprogesterone, and those that had tried both altrenogest and medroxyprogesterone were generally of the view that the response to altrenogest was clearly superior.

It is important to recognize that bilateral ovariectomy does not consistently eliminate behavioral estrus in all mares. In this study, owners reported residual estrous behavior in six mares (30%), paralleling previous reports in which estrous behavior of reduced intensity was observed in 35% of 22 mares [5] and in one of five ovariectomized mares [19]. In this study, persistent estrous behavior appeared not to be age related; the mean age for mares continuing to show some estrous behavior after surgery was 2 years younger than the overall average. Residual estrous behavior in ovariectomized and anestrus mares was hypothesized to be because of an extragonadal source of sex steroids [20]. Another explanation for the phenomenon is that in mares, unlike other species, the absence of

estrous behavior is more closely associated with the presence of progesterone than the absence of estrogen [21]. This latter explanation is supported by the observation of estrous behavior in some seasonally anovulatory mares where both estradiol and progesterone levels are minimal [22]. Regardless of the reason for this phenomenon, it is prudent to advise owners that estrus-like behavior, albeit of a reduced intensity, may be observed in some ovariectomized mares.

Although not a specific objective of the study, the observation of very few complications reported by owners whose mares underwent BLO adds support to the clinical impression that laparoscopic ovariectomy in the standing sedated mare is a safe and reliable procedure associated with limited morbidity [10]. Smaller incisions, avoidance of the risks of general anesthesia, better local anesthesia, and visually monitored control of hemorrhage are widely accepted advantages of the technique and are likely contributory to the recent growth in popularity of this method of ovariectomy in mares.

This study, by virtue of inherent design limitations, is of limited scope. The results are based on the opinions of horse owners and trainers and are subjected to the fidelity of their memories, particularly for mares treated early in the study period. As for any study involving the use of a survey, the possibility of a placebo effect must be acknowledged. Second, establishing the association of objectionable behaviors to estrus or cyclicity is difficult, particularly without concomitant endocrinologic evaluation over the course of one or more estrous cycles. We attempted to establish the association of the behaviors and estrus by careful and repeated questioning of the owner or trainer with respect to the estrus-related nature of the principal problem, in addition to excluding mares that failed to improve with altrenogest therapy. Finally, as mentioned, mares did not uniformly undergo preoperative endocrinologic screening nor were ovaries submitted for histopathologic evaluation. Thus, despite using the inclusion criterion of palpably normally sized ovaries, it is possible some of the mares had an incipient granulosa theca cell tumor, which could have resulted in the observed undesirable behavior(s). Despite these shortcomings, that 95% of this sample of owners or trainers perceived an equal or better response to BLO compared with altrenogest suggests that BLO should be considered for the management of undesirable behavior(s) in mares that can be established to be related to the estrous cycle with some confidence.

5. Conclusions

A substantial proportion of estrus-related behavioral and performance problems that evince a salutary response to altrenogest showed similar or superior behavioral improvements after BLO. In addition, a number of mares demonstrating suboptimal improvement in objectionable behaviors with altrenogest treatment had a favorable response to BLO. These data suggest that for at least some mares with behavioral problems referable to the estrous cycle, BLO appears to be as effective as altrenogest. A clearer statistical association of the responses to the two treatment modalities, enabling clinicians to predict improvement after ovariectomy, might be better established with a larger sample size and the attendant collection of endocrinologic data to more firmly establish the link between undesirable behaviors and hormonal status of affected mares.

Abstract

Objective: To determine the influence of epidural detomidine and morphine on serum corticosteroid concentrations and pain-related behavioral responses in mares during and after ovariectomy via colpotomy.

Study design: Blinded prospective study.

Animals: Nine university-owned mares.

Methods: Five of 9 horses received caudal epidural detomidine hydrochloride (0.01 mg/kg) and morphine sulfate (0.1 mg/kg) prior to surgery. All horses received local anesthetic around the ovarian pedicle, 0.02 mg/kg butorphanol IV at the start of the procedure and after first ovary removal, were sedated as required throughout the procedure, and were monitored for leg lifting, grunting, and abdominal tensing. Horses were monitored hourly for pain postoperatively. Heart rate was recorded every 4 hours, and photographs were taken to assess pain according to the horse grimace scale (HGS). Control group horses (n = 4) were treated with butorphanol (0.02 mg/kg IV) every 4 hours for 24 hours postoperatively. All horses received oral phenylbutazone 18 hours postoperatively. Serum cortisol was measured prior to the procedure, after first and second ovary removal, and 8 and 24 hours postoperatively.

Results: No differences were detected between horses receiving caudal epidural detomidine and morphine and those that received systemic opioids. A decrease in HGS score occurred after phenylbutazone administration.

Conclusion: Administration of caudal epidural detomidine and morphine resulted in similar pain-related behavior and corticosteroid concentrations as did administration of systemic butorphanol every 4 hours for 24 hours postoperatively.

Clinical significance: Caudal epidural detomidine and morphine may mitigate the requirement for frequent systemic opioid administration after a potentially painful procedure.

1 | INTRODUCTION

Ovariectomy is a routine surgery in the mare and can be achieved via colpotomy, median, paramedian, or laparoscopic approaches.[1] Colpotomies have become less common with the advent of laparoscopic surgery; however, ovariectomy via colpotomy offers an economical and practical alternative to the laparoscopic approach. Colpotomies require less surgical

 © 2018 The American College of Veterinary Surgeons

equipment and, in our experience, take less time to perform because of reduced preparation and suturing and lack of external incisions. Postoperative complication rates have been reported to be 4%.[2-4] Because of the small amount of equipment required and lack of external incision requiring care, colpotomies offer a useful method for sterilization of feral or wild equids, especially when facilities are limited. A laparoscopy-assisted colpotomy approach has been described that eliminates the requirement for a large external incision to remove the ovary; however, costly equipment is still required.[5]

During ovariectomy, local anesthetic is routinely applied to the mesovarium or directly to the ovary to mitigate pain.[6] However, this treatment does not completely eliminate sensation in the ovary or caudal tract, nor does it prevent straining, a response that may complicate the procedure.[3] Caudal epidural with anesthetics reduces straining by causing desensitization of the pudendal, middle and caudal rectal, and caudal cutaneous nerves, which are responsible for sensation of the external genitalia.[3,7] However, caudal epidural analgesia has no effect on pain from the ovary and increases the risk of ataxia and recumbency.[3,7] Caudal epidural with analgesics, such as opioids and α-2 agonists, effectively modulates pain during ovariectomy and may also reduce postoperative pain.[3,7] Depending on volume and location of administration, analgesics have been shown to have effects that extend to coccygeal, sacral, lumbar, and thoracic nerves and that may extend as far cranially as thoracic nerves 8-15.[7]

Systemic opioids such as butorphanol have profound analgesic effects but may lead to complications, such as central nervous system excitation, bradycardia, ataxia, and gastrointestinal stasis.[8,9] In addition, clearance of butorphanol is rapid because it has a half-life of 2 hours.[10] In contrast, epidural administration of hydrophilic opioids (such as morphine), when accompanied by α-2 agonists, has a duration of analgesia of up to 24 hours and less systemic absorption, which translates to reduced side effects.[11]

The first objective of this study was to evaluate the effect of the addition of caudal epidural detomidine and morphine during ovariectomy via colpotomy versus systemic sedation and analgesia alone during the procedure. The second objective was to evaluate the effectiveness of caudal epidural detomidine and morphine administered before surgery in controlling pain in the first 24 hours postoperatively vs repeated systemic use of opioids, which is the standard procedure in our hospital after ovariectomy via colpotomy. Drawing on our clinical experience using caudal epidural detomidine and morphine, we hypothesized that there would be a significant reduction in horse pain-related behaviors intraoperatively in the epidural group and no appreciable differences in behavior or corticosteroid concentrations postoperatively between treatment groups.

2 | MATERIALS AND METHODS

Nine university-owned mares (8 mixed quarter horse type breed, 1 African quarter horse) undergoing ovariectomy via colpotomy as part of another study (IACUCs 2012-0237 and 2015-0282) were used. Horses ranged in age from 9 to 30 years (median, 22) and weighed 420-570 kg (median, 500). None of the horses had a history of reproductive illness. A third party randomly assigned the horses to epidural or control groups by denoting group A as the epidural group and then using www.random.org to randomly assign numbers 1 through 9 to 1 of 2 groups, A (epidural) or B (control). Other than the clinician performing the epidural injection, all investigators were blinded to treatment group assignment during the surgery. Five horses (epidural group) received detomidine hydrochloride and morphine sulfate via caudal epidural prior to surgery, and the remaining horses (control group) received postoperative butorphanol injections (every 4 hours, IV).

2.1 | Surgical procedure

Feed was withheld for 12 hours prior to the surgical procedure, but access to water was not restricted. Approximately 30 minutes prior to the start of the procedure, ampicillin sodium (10 mg/kg IV), gentamicin sulfate (6.6 mg/kg IV), and flunixin meglumine (1.1 mg/kg IV) were administered through direct venipuncture. Horses were placed in stocks and sedated with acepromazine (0.05 mg/kg IV) and detomidine (0.006-0.018 mg/kg IV).[12] The epidural site was clipped and aseptically prepared in all horses. In the horses assigned to the epidural group, a board-certified equine surgeon performed a caudal epidural with detomidine (0.01 mg/kg) and morphine (0.1 mg/kg) diluted with saline to a total of 0.03 mL/kg, as previously described.[7] Briefly, the first intercoccygeal vertebral space was identified as the most cranial movable intervertebral space when the tail was lifted. The skin and subcutaneous tissue were then desensitized with local injection of 1-2 mL of 2% lidocaine, after which a 3-inch, 18 gauge Tuohy needle was introduced at a 10-degree forward angle into the epidural space. Location in the space was confirmed by using the "hanging drop" technique. A polyamide epidural catheter (Perifex continuous epidural anesthesia set; Braun Medical, Bethlehem, Pennsylvania) was introduced and advanced 20 cm cranial in the epidural space (measured prior to introduction) to the approximate level of S2-S5, depending on the size of the horse. Analgesia was then administered, and the catheter was withdrawn. In all horses, the prepared area was covered with a sterile gauze bandage so that treatment was not revealed to those blind to treatment. The veterinarian performing the surgery then reentered the room and conducted a standard ovariectomy via

colpotomy as previously described.[3] Butorphanol (0.02 mg/kg IV) was administered to all horses at the beginning of the procedure and again after the first ovary was removed. Regardless of group assignment, each ovarian pedicle was blocked before ovary removal by holding a sponge, soaked in 50 mL of 2% lidocaine, around the ovarian pedicle and applying pressure for 3 minutes. The placement of the ecraseur was started approximately 3 minutes after application of local anesthetic. Horses were additionally sedated as required during the surgery with detomidine or with xylazine at the discretion of the surgeon. Choice and dose of sedative was based on maintaining an appropriate surgical plane of sedation as determined by horse head height and reaction to environmental stimulus, with regard to the expected remaining duration of the procedure. Horse reactions, including leg lifts (any time the hoof left the ground but not associated with adjusting her stance), grunting of any duration, and abdominal tensing were recorded throughout the procedure by a dedicated blinded person who was also assigned to record any other potential complications, such as excessive hemorrhage, inability or reduced ability to perform the procedure as expected, or uncontrolled pain.

2.2 | Postoperative management

Horses were observed postoperatively by hospital personnel every hour for 3 days after surgery for changes in attitude, appetite, and manure production, for signs of pain such as tail swishing, teeth grinding, trembling, flank watching, pawing, obtunded attitude, or persistent recumbency. If at any observation there were signs of pain, the clinician was to be contacted to initiate rescue analgesia. Rescue analgesia was 5 mg butorphanol administered intramuscularly (IM). Heart rate was recorded every 4 hours for the first 24 hours postoperatively. Full physical examinations were performed every 12 hours for 3 days. All horses received procaine penicillin (22,000 IU/kg IM) twice daily, gentamicin (6.6 mg/kg IV) once daily, and phenylbutazone (2.2 mg/kg orally, starting 18 hours postoperatively) twice daily for 3 days postoperatively. Horses in the control group received butorphanol (0.02 mg/kg IV) every 4 hours for the first 24 hours after surgery.

2.3 | Cortisol assay

Blood samples were drawn from the jugular vein prior to the start of the procedure, after each ovary was removed, and at 8 and 24 hours postoperatively. Heparinized samples were centrifuged at 4000 × *g* for 5 minutes, and serum was collected and frozen at −80°C until the cortisol assay could be performed. Serum cortisol levels were later determined by using a solid phase, competitive chemiluminescent enzyme immunoassay as previously described.[13]

2.4 | Facial grimace scoring

The profile of each horse was photographed every 4 hours for 24 hours postoperatively, with t = 0 being the conclusion of surgery. Photographs were randomized and 4 blinded persons individually scored the images by using the horse grimace scale (HGS).[14] The HGS incorporates 6 facial action units: stiffly backward ears, orbital tightening, tension above the eye area, prominent strained chewing muscles, mouth strained and pronounced chin, and strained nostrils and flattening of the profile.[14] Each category is scored from 0-2. The sum of the 6 categories results in the HGS score, with 0 being the least painful and 12 being the most. The 4 individuals who scored the photographs were given detailed instructions on how to use the HGS, and a composite HGS score was made by averaging the results from the 4 scorers. The HGS scores were evaluated over time (at t = 4, 8, 12, 16, 20, and 24 hours) and between treatment groups.

2.5 | Statistical analysis

Commercial statistical software (SAS version 9.4; SAS Institute, Cary, North Carolina) was used. Repeated-measures analysis of variance was used to determine whether each outcome variable differed significantly by treatment group over time, with horse considered a random effect. This analysis was performed in PROC MIXED (SAS Institute) with an autoregressive correlation structure; $P \leq .05$ was considered significant.

3 | RESULTS

All 9 procedures were performed without complication (including no excessive hemorrhage, inability to perform the procedure, or uncontrolled pain during the procedure or in the postoperative period), and all mares were returned to their herd after the 3-day hospitalization. The median duration of surgery was 49 minutes (range, 22-74). There was no significant difference in duration of surgery between the 2 groups (49-68 and 22-74 minutes for control and epidural groups, respectively). The procedure was started immediately after epidural administration or equivalent waiting period in the control group. The total volume administered to the epidural group varied with horse weight but was approximately 15 mL. Time between the 2 intraoperative butorphanol administrations (at the beginning of the procedure and after the first ovary was removed) ranged from 11 to 44 minutes (median, 30). In both treatment groups, additional α-2 agonist sedation was administered as required. Three horses (1 in the control group and 2 in the epidural group) received additional detomidine, with a median dose of 0.004 mg/kg; 6 horses (3 in the control group and 3 in the epidural group) received additional xylazine, with a median dose of 0.2 mg/

TABLE 1 Horse movement and additional sedation administered during ovariectomy via colpotomy for horses in the epidural and control groups

Horses by group	Abdominal tensing episodes, n	Abdominal tensing duration, s	Grunts, n	Leg lifts, n	Additional sedation, mg/kg
Epidural					
1	14	22	7	1	0.3 xylazine
2	7	9	0	2	0.2 xylazine, 0.002 detomidine
3	29	178	0	1	None
4	13	16	0	0	0.3 xylazine, 0.006 detomidine
5	7	45	0	1	None
Control					
6	13	13	0	0	None
7	14	15	0	9	0.2 xylazine
8	15	26	5	3	0.15 xylazine
9	5	13	0	3	0.5 xylazine, 0.004 detomidine

kg (Table 1). The proportion of mares receiving additional sedation and the dosage of additional sedation did not differ between treatment groups.

3.1 | Movement

Frequency of abdominal tensing, leg lifts, or grunts in either group was too low to draw a statistical conclusion (Table 1).

3.2 | Heart rate

One mare in the epidural group was excluded from heart rate analysis after being diagnosed with atrial fibrillation according to results of electrocardiogram in the immediate postoperative period. In the remaining mares, there was no significant difference in heart rate postoperatively between treatment groups (control group median, 50 beats per minute [bpm]; epidural group median, 48 bpm) or over time.

3.3 | Cortisol

There were no significant differences in serum cortisol concentrations between treatment groups, either overall or within time points. There was a significant ($P < .001$) change in serum cortisol concentration over time, with the lowest concentration preoperatively (control median, 6.6 μg/dL; epidural median, 3.8 μg/dL) and the highest concentration 8 hours postoperatively (control median, 8.2 μg/dL; epidural median, 9.0 μg/dL; Figure 1).

3.4 | Facial grimace scoring

There was no significant difference in HGS scores between treatment groups (Figure 2). Across both treatment groups there was a significant effect of time ($P = .01$). Median HGS scores were highest at t = 16, with a median control score of 4.4 and a median epidural score of 4 (control range, 3.3-5.3; epidural range, 2.5-4.3), and lowest at t = 20, with a median control score of 2.5 and a median epidural score of 2.3 (control range, 2-2.8; epidural range, 1.8-3.5). It should be noted that t = 18 is when horses received phenylbutazone.

4 | DISCUSSION

Our findings in this study lead us to conclude that administration of caudal epidural detomidine and morphine in

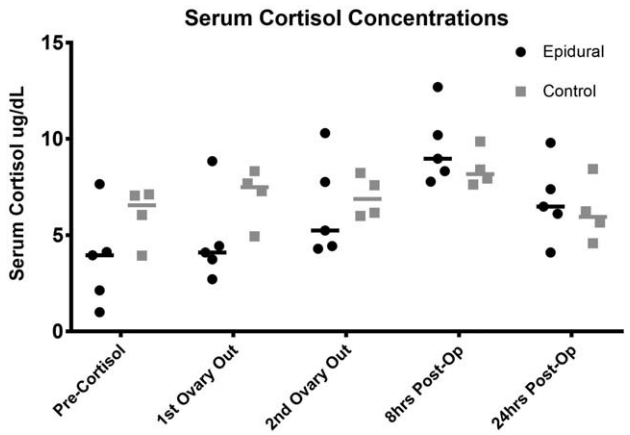

FIGURE 1 Serum cortisol concentrations of horses that did (epidural) or did not (control) receive detomidine and morphine via caudal epidural before ovariectomy via colpotomy. Time points include precortisol, prior to the start of surgery; 1st ovary out, after the first ovary was removed; 2nd ovary out, after the second ovary was removed; 8 hours postoperatively; and 24 hours postoperatively. The data points represent serum cortisol concentration (μg/dL) for each horse at each time point, and the bars represent the median

addition to systemic opioids does not change frequency or intensity of signs of pain during ovariectomy and appears to provide analgesia equivalent to that of repeated opioid treatment in the postoperative period. The lack of difference between groups is likely due to achievement of adequate analgesia using our standard pain management protocol.

It is difficult to determine the amount of pain mitigation directly attributable to either epidural or opioid treatment during surgery or in the postoperative period in the absence of an untreated control group. However, our experience with this procedure (over 50 ovariectomies via colpotomy by KH) is that ovariectomy is a notably painful procedure and that mares show extreme discomfort in the first 24 hours postoperatively if analgesia is not administered. Thus, for ethical reasons, a control group that did not receive intraoperative sedation and analgesia or that was left untreated in the postoperative period was not used. This is a limitation of this study.

Pain is difficult to measure objectively in the horse.[15,16] One objective measure to assess pain is serum cortisol, which increases in the horse secondary to stress and pain and can be used as a comparative measure of pain response between individuals and over time.[17,18] That cortisol increased significantly at 8 hours but not intraoperatively was not surprising because systemic cortisol concentration peaks 2 hours after stimulus.[19] In addition, systemic administration of detomidine during the surgical procedure likely resulted in downregulation of sympathoadrenal activity, causing a temporary decrease in serum cortisol.[19,20] At 8 hours postoperatively, the control group had already received a dose of systemic butorphanol; lack of difference between groups at this time suggests that epidural detomidine and morphine were as effective as systemic butorphanol for postsurgical analgesia.

As another measure of pain, we used the recently reported HGS. We chose to use this system because it is rapid to perform, observers can be trained quickly to score with good inter-observer repeatability, and it has been shown to be effective and reliable for assessing pain in horses.[14,21] The significantly reduced HGS scores postoperatively at 20 hours compared with 16 hours in both groups may have been associated with phenylbutazone administration at 18 hours, which is our normal protocol after ovariectomy via colpotomy.[22] Lack of difference in heart rate postoperatively at 20 hours compared with 16 hours suggests that the HGS may have improved sensitivity compared with heart rate for the detection of a change in mild pain in horses.

We had hypothesized that addition of epidural analgesia to the standard sedation and analgesic regimen used during ovariectomy would decrease the pain responses noted and the requirement for additional sedative administration; however, it did not. Preparation for the surgery was started immediately after epidural administration, so it is possible that the epidural analgesia had not reached maximum efficacy during surgery. Time to onset of analgesia after administration of epidural morphine has been reported to be from 20 minutes to 6 hours; however, when morphine was administered in combination with detomidine, onset of action was more rapid (as short as 10 minutes after administration), and duration of action was potentiated for as long as 24 hours.[7,23,24] We used a relatively low detomidine dose in the epidural; it is possible that a higher dose may have produced a greater intraoperative effect. It is also possible that the presence of systemically administered butorphanol (κ-agonist and a partial μ-antagonist) may have antagonized the epidural morphine (μ-agonist) during surgery because opioids are known to interact when administered concurrently, regardless of the route of administration.[25,26] However, the extent to which this may occur has not been proven and may not be marked enough to alter the effect of the epidural morphine, which is highly conserved in the epidural space.[11]

The effect of the epidural on intraoperative pain would have been clearer had this been the sole analgesic during the surgery. However, because we were unsure of the level of analgesia afforded by the epidural alone, we hesitated to include a control or epidural group that did not receive systemic analgesics. In addition, administration of sedation before and during surgery maintained blinding to treatment group by the surgeons and the person noting pain responses during the procedure. The additional intraoperative sedation was not standardized in the dose or drug used, which is a potential limitation of the study. The operating clinician,

who was blind to the mare group, chose the drug and dose based on the level of the mare's sedation and the amount of time until the end of surgery. If the colpotomy incision had already been made, xylazine was typically used because of the shorter duration of action. One factor that may relate to the lack of difference in sedative administration between groups is that horse head height and reaction to environmental stimulus, rather than level of analgesia, was largely used by the operating clinician; these parameters would have been minimally affected by epidural administration of detomidine and morphine.

The doses of butorphanol used in the postoperative period of this study were low compared with some older reports but were similar to previously reported doses of butorphanol used during ovariectomy.[27,28] We administered the butorphanol at the interval recommended by the manufacturer (every 4 hours) because analgesic effects have been shown to last over this period. Using our current clinical practice of walk-by monitoring every hour, we verified that none of the horses in either group showed the signs that we had designated for rescue analgesia.

We limited the number of horses in the study to 9 (4 in the control group, 5 in the epidural group) because this study was performed concomitantly with a study for which the ovaries were being removed for examination. We believed that performing additional ovariectomies for the sake of validating a measure of pain control would be unethical.

In conclusion, our findings indicate that caudal epidural analgesia with detomidine and morphine do not provide additional analgesia during surgery in mares also given the standard sedative/analgesic regimen but that they do provide analgesia equivalent to that of systemic butorphanol administration in the postoperative period. Although administration of a caudal epidural is technically more challenging than administration of systemic butorphanol, it significantly decreases the requirement for postoperative handling and repeated IV or IM injections and, thus, may be especially applicable in situations such as sterilization of feral or wild equids in which repeated handling is problematic. The HGS proved easy to apply and, because handling is not required to evaluate HGS, this may also be applicable for assessment of feral equids. Our results lead us to conclude that use of caudal epidural analgesia should be considered by the practitioner when performing ovariectomy via colpotomy.

Pattern of focal γ-bursts in chess players

Grandmasters call on regions of the brain not used so much by less skilled amateurs.

The brain's medial temporal lobe structures are thought to be important for the initial formation of long-term memory[1,2], and active memory is indicated by bursts of γ-band activity in these and other areas of the association cortex[3,4]. Here we use a new technique of magnetic imaging to compare focal bursts of γ-band activity in amateur and professional chess players during matches. We find that this activity is most evident in the medial temporal lobe in amateur players, which is consistent with the interpretation that their mental acuity is focused on analysing unusual new moves during the game. In contrast, highly skilled chess grandmasters have more γ-bursts in the frontal and parietal cortices, indicating that they are retrieving chunks from expert memory by recruiting circuits outside the medial temporal lobe.

The 'chunking' theory of chess playing[5] suggests that expert memory is based on a large database of chunks in long-term memory. A chess grandmaster studies and practises for at least 10 years to learn more than 100,000 patterns (memory chunks). Consequently, grandmasters can 'recognize' the key elements in a problem situation much more rapidly than amateur players. Experts differ not only in the extent of their knowledge, but also in its organization. High-level processing elements, such as structuring knowledge and planning, assist in accessing the respective chunks[6].

We tested 20 male players (aged 42 ± 14 years), each with more than 10 years of tournament and training practice. Ten professional grandmasters scored between 2,400 and 2,600 on Elo's chess-skill rating scale[5]; amateur players ranked 1,700 and above. Magnetoencephalographic recordings were made while subjects played against a computer and were scanned in the 5 seconds after each move by the computer program for focal γ-bursts (20–40 Hz; Fig. 1a). Examination of single slices indicates pronounced activity in the region of the perirhinal and entorhinal cortex, hippocampus and related structures in amateur players, but not in grandmasters.

There was a strong negative correlation ($r = -0.84$) between the relative share of dipoles in these structures and Elo chess skill (Fig. 1b). The correlation was also significant when only the 12 players who had lost in the game were included in the analysis (draws and wins were achieved only by grandmasters). There was no relationship between the length or complexity of the game and the Elo score.

These marked differences in the distribution of focal brain activity during chess playing point to differences in the mechanisms of brain processing and functional brain organization between grandmasters and amateurs. Lesions in structures that are activated in amateur players impair recent memory while leaving remote memory intact[2]. Grandmasters seem to rely more on remote than on recent memory.

High-level processing elements[6] may also have contributed to the observed differences. The chunking theory of memory states that the number and nature of chunks that chess experts can hold in long-term memory can be used to predict chess performance[6]. Our results indicate that the activation of expert memory chunks produces focal γ-band activity in the neocortex, whereas amateur players primarily encode and analyse new information, tasks that activate the medial temporal lobe and the hippocampus. It is possible that these structures play only a transitional role during the establishment of expert memory in the neocortex.

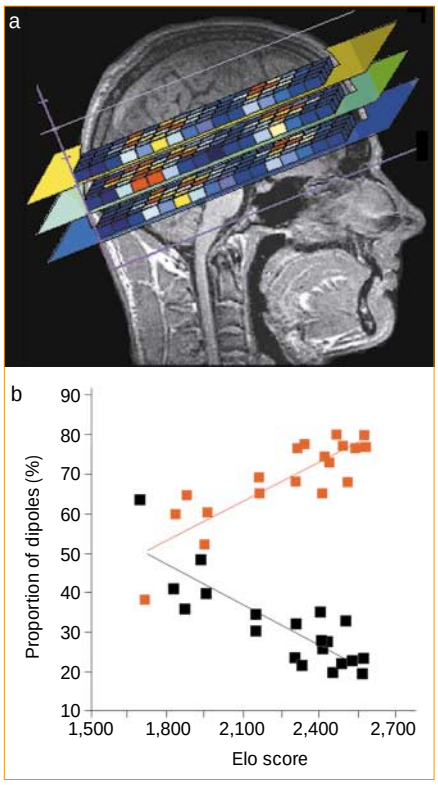

Figure 1 Focal γ-band activity in the brains of chess players. **a,** Determination of equivalent-current dipole density for inferior 'slices' through the hippocampus and medial temporal areas in an amateur player's brain. Increasing dipole density is indicated by a colour scale from dark to light blue, to yellow, to red. **b,** Relationship between chess-playing skill (Elo rating scale) and the relative share of dipoles located in medial temporal lobe structures (black) and in the frontal and parietal cortices (red). Amateur players show more focal γ-bursts in the medial temporal lobe than grandmasters, who show more activity in the frontal and parietal cortices.

Anabolism

Low mechanical signals strengthen long bones

Although the skeleton's adaptability to load-bearing has been recognized for over a century[1], the specific mechanical components responsible for strengthening it have not been identified. Here we show that after mechanically stimulating the hindlimbs of adult sheep on a daily basis for a year with 20-minute bursts of very-low-magnitude, high-frequency vibration, the density of the spongy (trabecular) bone in the proximal femur is significantly increased (by 34.2%) compared to controls. As the strain levels generated by this treatment are three orders of magnitude below those that damage bone tissue, this anabolic, non-invasive stimulus may have potential for treating skeletal conditions such as osteoporosis.

A common perception of bone adaptation is that mechanical signals must be large to influence morphology[2]. The peak signals that result from natural vigorous activity cause microdamage to bone material and require repair[3]. For example, peak strains of 2,000–3,000 microstrain are typically induced during locomotion[4], stimulating osteoclasts and osteoblasts to remove and then replace damaged tissue[5].

We have departed from this repair-mediated hypothesis by proposing that extremely small strains (for example, those that arise from muscle contraction during less vigorous but more frequent activities such as maintaining posture) are strong determinants of bone morphology[6].

© 2001 Macmillan Magazines Ltd

We examined the regulatory potential of extremely small (0.3*g*, where *g* is the Earth's gravitational field), high-frequency (30 Hz) mechanical accelerations by subjecting the hindlimbs of adult (6–8-year-old) female sheep (Warhill, intact ewes) to a ground-based vertical oscillation[7] for 20 min per day for 5 days a week. When the animals were not being treated, they joined the controls to roam freely over a pasture area. We used strain gauges attached to the animals' tibia bone to calibrate the device: these showed that the peak-to-peak amplitude of the strain generated was about 5 microstrain, which is 0.1% of the strain magnitude that is known to cause yield-failure in bone[8].

After 1 year of this mechanical-stimulation regime, the density of trabecular bone in the proximal femur, as quantified by computer tomography, was 34.2% greater in experimental sheep than in controls ($P < 0.01$; Table 1). This strong anabolic response was substantiated by undecalcified bone histology of the same region, which revealed a 32% increase in trabecular bone volume, a 45% increase in trabecular mesh number (Fig. 1) and a 36% reduction in mesh spacing, indicating an increase in the mean width of each trabecular element and the addition of new trabeculae.

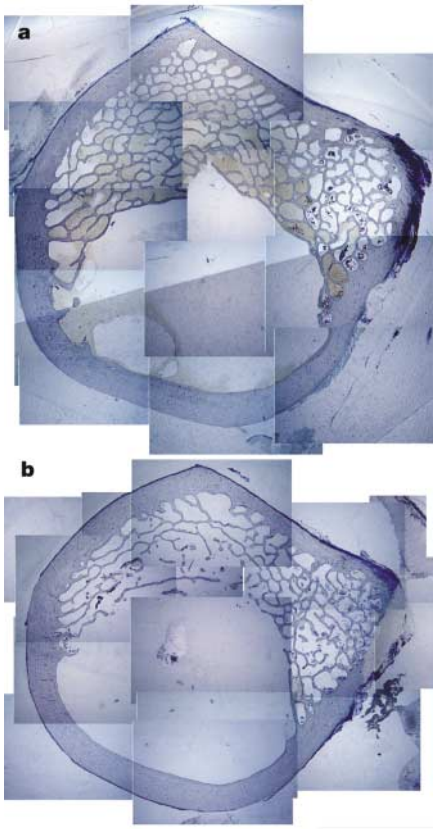

Figure 1 Montages of photomicrographs of the proximal sheep femur used for static histomorphometric evaluation after 1 year of exposure (20 min per day) to a 0.3*g*, 30-Hz mechanical stimulus. **a, b,** There is 32% more trabecular bone in the proximal femur of experimental animals (**a**) compared with age-matched controls (**b**) ($P < 0.04$).

Table 1 Proximal-femur parameters of control and stimulated sheep

	Control	Experimental	Difference	P
Animal mass (kg)	71.1 ± 7.1	70.3 ± 9.4	−1.1%	n.s.
Total density (gm cm^{-3})	466 ± 60	496 ± 53	+6.5%	< 0.1
Trabecular density (gm cm^{-3})	169 ± 37	227 ± 56	+34.2%	< 0.01
Bone volume/total volume (%)	15.2 ± 4.1	20.1 ± 4.8	+32%	< 0.04
Trabecular spacing (μm)	1,170 ± 124	756 ± 97	−36%	< 0.02
Trabecular number (trabeculae mm^{-2})	0.82 ± 0.16	1.19 ± 0.18	+45%	< 0.01
Bone-formation rate (μm^2 mm^{-1})	8.4 ± 12.7	17.9 ± 16.3	+113%	< 0.2
Mineralizing surface (%)	2.6 ± 0.16	6.34 ± 5.14	+144%	< 0.1

Animal mass and envelope-specific bone density (determined by quantitative computer tomography) of the proximal femur after 12 months of low-level mechanical stimulation. Also shown are indices of static and dynamic histomorphometry of the proximal femur. Although 'whole-bone' parameters of the proximal femur show only a limited tendency to be influenced by mechanical stimuli ($P = 0.1$), the increase in treated animals compared with controls is over 30% for trabecular bone alone ($P < 0.01$). One control was lost over the course of study for reasons not associated with the protocol. Nine animals were evaluated in the experimental group, with eight controls. All evaluations were made without knowledge of whether the animals were control or experimental.

We found that this low-level mechanical stimulation increased the rate of bone formation 2.1-fold ($P < 0.2$) and the mineralizing surface 2.4-fold ($P < 0.1$). This anabolic effect was highly specific to cancellous (porous) bone, as there was no significant histomorphometric change in any of the cortical bone parameters. We detected no difference in any bone index in the radius of either control or experimental animals (for example, mineral density was 0.6% less than controls; not statistically significant), indicating that the anabolic effect was specific to the region of the skeleton that was subjected to the mechanical signal.

Mechanical strain in the skeleton is a product of functional load-bearing — as seen, for example, in the mandible of the macaque[9] and the tibia of the alligator[10]. In addition to the large-amplitude strains typically associated with functional activity, a strain signal, much less than 5 microstrain in amplitude, arises through muscular activity in the frequency band 10–50 Hz (ref. 11). Generation of this small-amplitude, high-frequency muscle 'vibration' persists through even such passive activities as standing.

Skeletal morphology may therefore be sculpted by omnipresent, low-level muscle activity as well as by the peak impacts inherent in load-bearing. In terms of clinical relevance, the strong bone-generating capacity of these small signals suggests that biomechanical intervention might help to strengthen bone in osteoporosis sufferers without the side-effects associated with pharmacological treatment. In addition to being non-invasive and inducing a therapeutic response from the bone tissue itself, low-intensity mechanical signals incorporate all aspects of a complex remodelling cycle[12] and ultimately stimulate formation of lamellar bone[13] to improve bone quantity and quality.

Vision

Realignment of cones after cataract removal

Through unique observations of an adult case of bilateral congenital cataract removal[1], we have found evidence that retinal photoreceptors will swiftly realign towards the brightest regions in the pupils of the eye. Cones may be phototropic, actively orientating themselves towards light like sunflowers in a field.

For 40 years, one of us (P.D.) lived with an unusual pupil configuration caused by congenital bilateral cataracts, first diagnosed at three years of age. The cataracts were managed by using a twice-weekly application of atropine, which dilated P.D.'s pupils to produce roughly annular (ring-shaped), clear regions around the dense nuclear cataracts. Because his optics were so poor (he was far-sighted, astigmatic and incapable of accommodation), P.D. squinted continuously as an adaptation, particularly for close work. His eyelids thus horizontally cropped each annulus at the top and bottom, leaving two clear entry points for light

Abstract

Context. At some sites, wild horse populations have been effectively and non-invasively regulated using remote darting with porcine zona pellucida (PZP) immunocontraceptive vaccines. However, this model has not been widely applied to wild horse herds in western USA, many of which are difficult to access because they roam large areas and are wary of people. Single-treatment, multi-year contraceptive vaccines would significantly broaden the scope for successful contraceptive management.

Aims. The aims of the present field studies were to (1) test the contraceptive effectiveness and longevity of primers incorporating PZP–adjuvant emulsions plus PZP and adjuvant in controlled-release pellets ('PZP-22'); and (2) compare the contraceptive effectiveness and duration of PZP–adjuvant emulsion-only boosters with those of PZP-22 boosters when administered by hand or remote darting to PZP-22-primed mares.

Methods. Wild horses in herd management areas in Colorado and Utah, USA, were rounded up in 2008 and in Utah again in 2012. Previously untreated females received a single hand-injection of PZP–emulsion plus controlled-release PZP pellets ('PZP-22' vaccine) and were then released. In Autumn 2010, 50 Colorado females treated in 2008 were booster-darted with either the PZP-22 vaccine or the PZP emulsion alone. In Utah, 57 previously treated females rounded up in 2012 received hand-injections of either the PZP emulsion–pellet vaccine or the PZP emulsion alone. Maternity was established through field observation of nursing and other close associations.

Key results. Effectiveness of initial controlled-release PZP treatments over 2 years was low relative to previous trials. However, boosters delivered by dart or by hand to PZP-22-primed mares yielded high levels of contraceptive effectiveness for 3 years, with no consistent difference between simple PZP-emulsion boosters and boosters incorporating controlled-release pellets.

Conclusions. Priming mares with PZP-22 extends the efficacy of a subsequent PZP booster to at least 3 consecutive years.

Implications. Regulation of wild horse populations may be achieved with existing contraceptive agents by developing models and management plans that account for the increased longevity of repeated contraceptive treatments.

Additional keywords: feral horse, immunocontraception, porcine zona pellucida, remote delivery.

Introduction

The 1971 *Wild Free Roaming Horse and Burro Act* (P.L. 92-195) assigned primary responsibility for managing wild horses and burros occupying public lands to the US Bureau of Land Management (BLM), with secondary responsibilities to the US Forest Service (USFS) for managing the species on USFS lands. In 1978, prompted by growth of the herds subsequent to passage of the *Act*, Congress authorised the BLM and USFS to gather, remove and make available for adoption by the public wild horses and burros deemed excess relative to appropriate management levels set by public land use planning processes (*Public Lands Improvement Act*, P.L. 95-514).

Through the fiscal year (FY) 2015, the BLM had adopted out more than 239 000 wild horses and burros to the public (BLM 2016*a*). However, the rate at which horses have been adopted has failed to keep up with the number of horses removed from the range, especially since FY2001, resulting in increases in wild horse numbers in captive-holding facilities and on the range. As of March 2015, more than 45 000 formerly free-roaming wild horses were being maintained in short- and long-term holding facilities at a budgeted cost of US$62 million for FY 2016 (BLM 2016*b*). In addition, the 67 027 wild horses and burros estimated to be living on the range as of 1 March 2016 significantly exceeds BLM estimates of a system-wide

Journal compilation © CSIRO 2017

appropriate management level (AML, the number of horses and burros defined by the BLM as the number that can thrive in balance with other public-land resources and uses) of 26 715 (BLM 2016*b*). While BLM estimates of AML can be challenged, it is clear that the system is unsustainable as currently being operated.

Both BLM documents and outside reviews have repeatedly identified on-the-range fertility control as a plausible option for reducing the rate of growth of wild-horse herds, thereby reducing pressure on the system of removal and adoption as well as the range itself. In response, BLM has been funding research into practical, safe, and effective wild-horse contraception since the 1970s (Turner and Kirkpatrick 1982; Plotka *et al*. 1988, 1992; Turner *et al*. 1997, 2007; National Research Council 2013). Several potentially suitable immunocontraceptive agents have emerged from BLM-funded research, including porcine zona pellucida (PZP) and GnRH vaccines (Killian *et al*. 2008; National Research Council 2013). Porcine zona pellucida has the deepest research history, having been previously tested and applied for several years at Assateague Island National Seashore, MD, and elsewhere (Kirkpatrick *et al*. 1990; Kirkpatrick and Turner 2002, 2003, 2008; Ransom *et al*. 2011; National Research Council 2013).

In a minority of BLM herd management areas (HMAs), wild horses are approachable enough so that contraceptive vaccines can be delivered directly by dart (Ransom *et al*. 2011; Naugle and Grams 2013). However, in others, horses are too wary to approach closely enough for darting, and are thinly dispersed over wide areas (Naugle and Grams 2013). In these areas, either gathers or trapping must be used to make horses accessible for treatment. Where accessing horses for treatment is challenging, the availability of a multi-year, single-treatment contraceptive vaccine would be enormously helpful in effectively and substantially reducing foaling rates and, consequently, rates of population growth.

Evidence for multi-year effectiveness of contraceptive vaccines is mixed. Killian *et al*. (2008) showed that single doses of SpayVac® (Immunovaccine Technologies, Halifax, NS, Canada) and GonaCon™ (USDA/NWRC, Fort Collins, CO, USA) significantly reduced fertility in a small sample of captive horses for up to 4 years. Gray *et al*. (2010) showed that GonaCon-B™ and a formulation of PZP with Adjuvac™ (USDA/NWRC, Fort Collins, CO, USA) reduced fertility in free-roaming Nevada mares for 3 years, although efficacy was modest for both vaccines (reducing fertility from control levels by 25–59%). Turner *et al*. (2001) showed that a single dose of native PZP plus PZP prepared in controlled-release microspheres produced a 1-year reduction in fertility comparable to that of two doses of native PZP administered 3 weeks apart. However, the microspheres tended to clump in the syringe and proved difficult to handle under field conditions (Turner *et al*. 2002). In a subsequent field trial at Clan Alpine HMA, NV, a single injection of 65 µg PZP emulsified in Freund's complete adjuvant (FCA) plus 410 µg PZP and 875 µg QA-21 adjuvant in controlled-release pellets reduced fertility in treated mares by 91%, 73%, and 38% from control levels in Years 1–3 after treatment (Turner *et al*. 2007).

On the basis of the results of the Turner *et al*. (2007) trial and supporting data on captive and non-captive mares (Turner *et al*. 2002; Liu *et al*. 2005), BLM initiated wider use of the PZP emulsion plus PZP/QA-21 pellet vaccine (dubbed 'PZP-22,' based on antibody titer concentrations displayed in Liu *et al*. 2005; National Research Council 2013), treating between 500 and 1000 mares annually between 2007 and 2013. However, the Clan Alpine study was not replicated, and information on the efficacy of BLM administrations at both the individual and population levels was anecdotal. Also lacking are any studies of the effectiveness and longevity of PZP boosters administered to mares primed with PZP-22.

As a part of a larger study to further evaluate the individual- and population-level effectiveness of PZP-22, and to establish the effectiveness and longevity of PZP boosters administered to mares that had previously been primed with PZP-22, we conducted field studies in two BLM herd management areas.

Materials and methods

Study areas

Sand Wash Basin Herd Management Area, Colorado

The Sand Wash Basin (SWB) HMA comprises ~638 km^2 located ~72 km west of Craig, CO, USA. Elevation ranges from 1900 to 2660 m. SWB receives 18–30 cm of annual precipitation, and the climate is typical of the cold deserts of the Rocky Mountain Region, with warm summers and very cold winters. Vegetation types within the HMA include sagebrush (*Artemesia spp*), bunchgrasses, saltbush (*Atriplex* spp.), and pinyon–juniper woodlands. Horses, livestock and wildlife at SWB rely for water on a combination of developed wells, undeveloped springs and seeps and artificial reservoirs.

According to BLM aerial-survey estimates, there were ~463 wild horses on the SWB HMA and 50 wild horses off HMA. Our initial ground inventory after the BLM gather in October 2008 indicated the presence of 194 horses (K. Grams and A. Rutberg, unpubl. data). The appropriate management level at SWB is 163–362 (BLM 2017).

Cedar Mountains Herd Management Area

The Cedar Mountains (CM) HMA comprises 727 km^2 and is located ~80 km west of Salt Lake City, UT, USA. Approximately 425 km^2 within the HMA is part of a congressionally designated candidate wilderness area; vehicles and permanent structures are not permitted within the designated wilderness area. Elevations vary from 1400 to 2460 m. Annual rainfall in the lower elevations averages 20–25 cm, and 25–38 cm of rainfall is received in the upper elevations. Desert shrubs and bunchgrasses are common in the lowlands, with sagebrush and juniper woodlands dominating higher elevations. Water is seasonally scarce, and is concentrated in dry summer months at cattle troughs and a few natural springs.

Our ground-based population inventory indicated that there were at least 608 horses on CM when the study began in 2008, with additional horses on adjacent military lands that had not yet been documented. Initial estimates by BLM based on their aerial survey indicated that 191 remained after the December 2008 BLM gather, although subsequent ground-based population inventories indicated that there were at least 265 horses present post-gather. The appropriate management level for CM is set by the BLM at 190–390 (BLM 2017).

Horse identification

Beginning in 2008, information was documented in the field and then entered into a database. This working document included sex, colour, face and leg markings, unique descriptions, mane and tail description, year of birth and the subpopulation in which the horses lived. Each horse was assigned an ID number to establish individual identity. Horses, including bachelors, were grouped by band in the areas in which they were most recently found. The horse list was updated weekly to reflect any changes or additions and was used in the field to help identify horses. Horses were individually recorded in the Wild Horse Identification Management System (WHIMS, US Geological Survey, Fort Collins, CO, USA). Information from the horse list was placed into this database along with individual pictures of each horse. A photo catalogue allowed for viewing each horse, with the pertinent information to that horse.

Horses that were identified during the study but were not observed within the HMA were excluded from the analysis.

PZP treatments

Wild-horse mares were gathered by the BLM and restrained in squeeze chutes for PZP treatments at Sand Wash Basin on 23 October 2008, and at Cedar Mountains on 17 December 2008 and 25–28 February 2012. Porcine zona pellucida treatments were also administered remotely by dart at SWB from 11 September to 17 November 2010. Thus, boosters were administered at SWB 2 years after the initial treatment, and at CM 3.2 years after the initial treatment.

Hand-injections

In October 2008 and December 2008 respectively, 62 mares (2+ years old) at SWB and 70 mares (2+ years old) at CM were gathered and treated with hand-injections of PZP-22, consisting of one priming injection of 100 µg PZP in 0.5-mL phosphate buffer solution (PBS) emulsified in 0.5 mL of modified FCA (mFCA, Calbiochem, LaJolla, CA, USA) (following Kirkpatrick *et al*. 1990), and a second injection of three heat-extruded lactide–glycolide polymer pellets (polymers from Lactel/Durect, Pelham, AL, USA) containing a total of 450 µg of PZP and 900 µg of QA-21 (Antigenics, Lexington, MA, USA), a saponin adjuvant, engineered to release at 1, 3 and 12 months (Turner *et al*. 2008). The 1- and 3-month pellets each contained 100 µg of PZP and 200 µg QA-21, and the 12-month pellet contained 250 µg PZP and 500 µg of QA-21. Both injections were delivered intra-muscularly into the hip, the PZP–mFCA emulsion with a hand-held syringe fitted with an 18-gauge needle, and the pellets with a trocar fitted with a 14-gauge needle. In the squeeze chute, the horses were also freeze-branded on the hip with a marking that identified them as PZP-treated mares. In February 2012, 85 previously untreated mares at CM were similarly treated and released. Of these mares, 23 were 2 years old, and 62 were ≥3 years old.

Booster trials

To examine the relative effectiveness of the PZP-22 booster when hand-injected, 58 mares that had been treated at CM in 2008 and recaptured for treatment in February 2012 received a hand-injection of either PZP-22 (with Freund's incomplete adjuvant (FIA, Calbiochem, LaJolla, CA, USA) substituted for mFCA, 'PZP-22–FIA'; $n = 39$) or the PZP–FIA booster alone ($n = 19$).

A parallel test of the PZP-22 booster when delivered remotely, by dart, was conducted at SWB. From 11 September to 17 November 2010, 34 mares received PZP-22–FIA delivered in a Pneu-dart® (Williamsport, PA, USA) dart designed with a rod within the 1.5-inch needle, to simultaneously inject both the emulsion and the dart (see Walter *et al*. 2012 for a similar device). Another 16 mares received only the PZP–FIA emulsion by dart (Kirkpatrick *et al*. 1990). Two dart projectors were utilised for short and longer distances. The Dan-Inject CO2 pistol (Børkop. Denmark) projected darts at a distance of 10–18 m. The Pneu-Dart X-Caliber Gauged CO2 projector rifle projected darts at a distance of 17–45 m. Depending on the tractability of the animal, the Dan-Inject was primarily used for close range.

Observations

Observational data were collected beginning in 2008, focusing on the months from June to October in SWB and April through to December at CM. Observations were conducted from the ground, usually by one but sometimes by two observers. Depending on distance, observations were made through binoculars or 20–60 × 80 spotting scope.

For each band encountered, observers identified all known horses present, described any new horses in the band that had not previously been described, tabulated the age–sex composition of the group, and, using maps and field notes, noted the location of the band. Mares were matched with foals within 2 weeks of birth, as indicated by persistent proximity and nursing. Within limits of visibility and accessibility, the observer also estimated and recorded body condition scores on a 1–5 scale (after Rudman and Keiper 1991) and noted any apparent injuries, lameness, abscesses and other injection-site reactions, or other signs of ill health, for each band member, as well as any reproductive activity or mortalities that occurred.

Data analysis

Foaling data inferred from observations of foal–mare associations and behaviour were compiled by mare age (when age data were available) and PZP treatment status. The relationship between age and foaling rates was examined using the linear regression function of IBM SPSS®-22, using study site, age and age squared as independent variables (modified from Ransom *et al*. 2011). Foaling rates were compared among treatment groups and between treatment groups and untreated mares by year after treatment, using Pearson's chi-square tests or, if sample sizes were too small, by two-tailed Fisher's exact tests. Sham controls were not used, because Turner *et al*. (1997) had previously demonstrated that fertility rates among sham controls and untreated controls were virtually identical.

The proportions of untreated and pretreatment mares of known age that foaled in a given year were calculated for each site. Foaling data comprised 170 foals born to mares of known age (2–17 years old) in 311 mare-foaling opportunities at SWB between 2008 and 2014, and 193 foals born to mares of known age (2–24 years old) in 376 mare-foaling opportunities at CM

between 2008 and 2015. Because fewer records existed for older mares, ages were consolidated into groups of at least 10 mares in each age category, assigning the median age to each group. Sample size per age group ranged from 12 to 154.

Because of uniformly low foaling rates among untreated 2-year-old females (see below), all comparisons between treatment groups and untreated controls were performed using mares 3 years old and older at the time of foaling. The criterion for rejecting null hypotheses was set at $\alpha = 0.05$.

Results

Effects of age on likelihood of foaling

In both study sites, 2-year-old females were less likely to foal, then older females (Fig. 1). Site, as an independent variable, was not a significant predictor of foaling rate ($P = 0.824$), and was eliminated from the analysis. Because the form of the relationship between age and fertility appeared to differ at both sites, each site was analysed separately. At CM, the probability of foaling followed a fairly strong parabolic relationship with age ($R^2 = 0.817$, $F_{2,5} = 11.14$, $P = 0.014$; Fig. 1*a*). However, at SWB, the age–foaling relationship was flat for mares older than 2 years old relative to CM, and the parabolic relationship was not significant ($R^2 = 0.580$, $F_{2,5} = 3.46$, $P = 0.114$; Fig. 1*b*).

Initial treatments with PZP emulsion and controlled-release pellets

Sample sizes for observation of foaling in treatment groups showed only slight attrition during the study, whereas samples of untreated controls observed for foaling generally grew from year to year as new individuals in the population were identified or were recruited as foals born into the herd during the study aged into the 3+ years age group (Table 1).

In all three priming treatments (CM 2008 and 2012 and SWB in 2008), foaling rates were statistically indistinguishable between treated and untreated mares during the foaling period immediately after treatment, defined as Year 0 (reflecting pretreatment pregnancy rates; Fig. 2). Significantly lower foaling rates were found among mares ≥3 years old in treated mares in Year 1 at CM in the 2008 ($\chi_1^2 = 29.04$, $P < 0.0001$; Fig. 2*a*) and 2012 ($\chi_1^2 = 24.99$, $P < 0.0001$; Fig. 2*b*) treatments, but not in the 2008 SWB treatments ($\chi_1^2 = 3.4$, $P = 0.065$; Fig. 2*c*), relative to untreated controls. In Year 2, foaling rates in treated mares were significantly lower than those in untreated mares for both the 2008 and 2012 CM treatments ($\chi_1^2 = 5.94$, $P = 0.015$; $\chi_1^2 = 5.57$, $P = 0.018$) and the SWB treatments ($\chi_1^2 = 6.2$, $P = 0.013$). Summed over the two post-treatment years, foaling

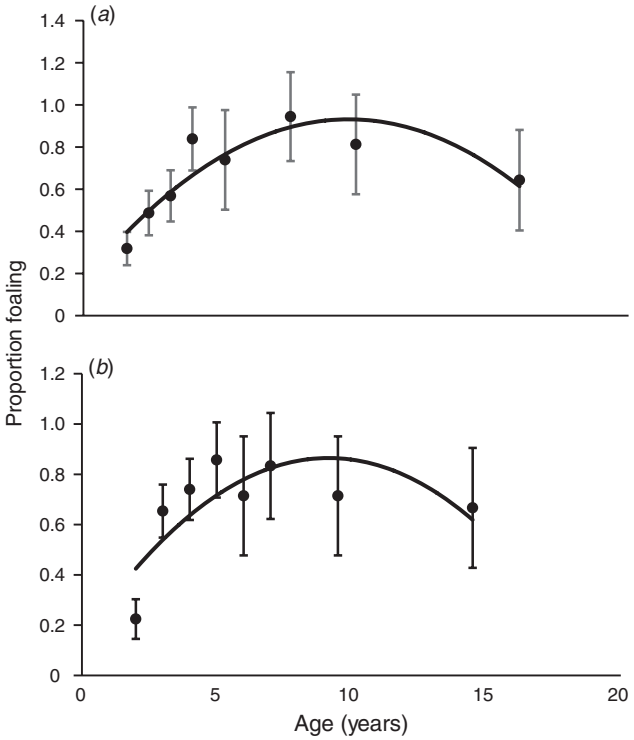

Fig. 1. Proportion of untreated and pretreated mares foaling by age. $N > 10$ for each age category. Error bars represent 95% CI. (*a*) Cedar Mountains, UT, USA, 2008–15 ($Y = -0.005X^2 + 0.126X + 0.165$, $R^2 = 0.817$, $F = 11.14$, d.f. = 2,5, $P = 0.014$). (*b*) Sand Wash Basin, CO, USA, 2008–14 ($Y = -0.009X^2 + 0.157X + 0.144$, $R^2 = 0.580$, $F = 3.46$, d.f. = 2,5, $P = 0.114$).

Table 1. Number of mares 3+ years old for which foaling data were obtained in each treatment group at Cedar Mountains (CM) Herd Management Area, Utah, USA, and Sand Wash Basin (SWB) Herd Management Area, Colorado, USA

At CM, 39 mares received PZP-22–FIA boosters and 19 received PZP–FIA boosters. At SWB, 34 mares received PZP-22–FIA boosters, and 16 received PZP–FIA boosters

Year	Cedar Mountain HMA			Sand Wash Basin HMA		
	PZP-22 primer	PZP boosters (total)	Untreated control	PZP-22 primer	PZP booster (total)	Untreated control
2008	70 hand-treated	–	–	62 hand-treated	–	–
2009	69	–	61	62	–	15
2010	69	–	63	61	50 dart-treated	18
2011	68	–	73	61	50	22
2012	85[A] hand-treated	58 hand-treated	38	–	50	52
2013	83	57	44	–	49	68
2014	80	56	56	–	28[B]	107
2015	–	55	94	–	–	–

[A]Twenty-three (23) mares that were 2 years old at the time of treatment were not included in Year 0 (2012) foaling-rate calculations.

[B]Twenty-one (21) mares were lost to the study because they received additional PZP treatments in 2013. Of the 28 remaining in the study, 17 had received PZP-22 boosters and 11 had received PZP emulsion only.

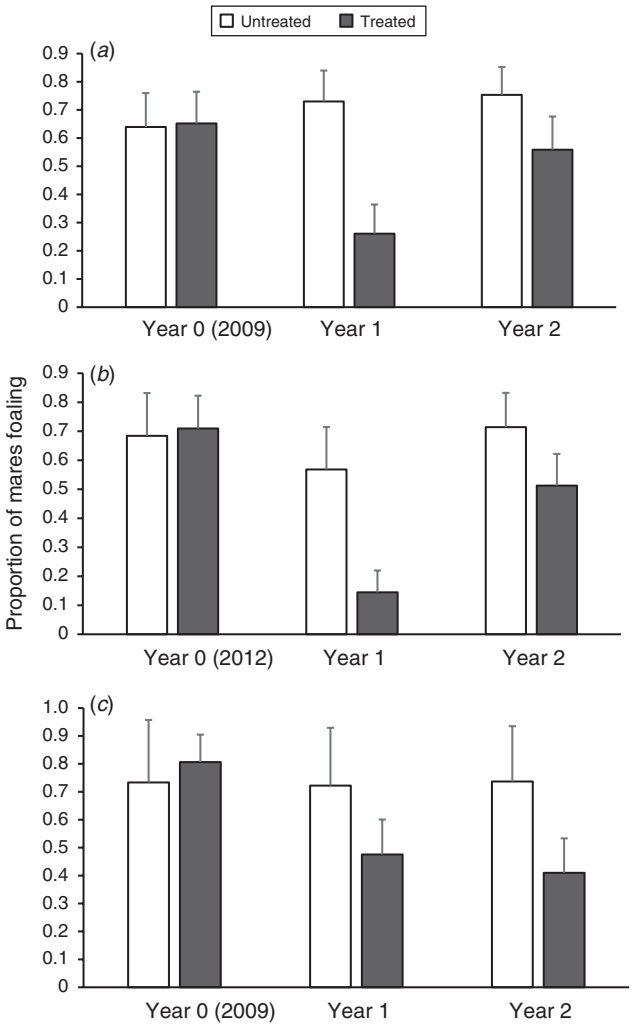

Fig. 2. Foaling rates in mares ≥3 years old. Error bars represent 95% CI. (*a*) Cedar Mountains herd-management area (HMA), UT, USA, following December 2008 administration of porcine zona pellucida (PZP)-22 primers by hand. Year 0 = 2009. (*b*) Cedar Mountains HMA, UT, USA, following February 2012 administration of PZP-22 primers by hand. Year 0 = 2012. Twenty-three PZP-22-treated females that were 2 years old in 2012 were excluded from the Year 0 analysis. (*c*) Sand Wash Basin HMA, CO, USA, following October 2008 administration of PZP-22 primers by hand. Year 0 = 2009.

rates among treated mares were reduced by 39% at SWB in 2008, by 45% at CM in 2008, and by 50% at CM in 2012.

No injection-site reactions were observed in mares after priming via hand-injection.

PZP booster treatments

At both SWB and CM, PZP boosters were associated with significant reductions in foaling rates among mares ≥3 years old every year for 3 years after treatment (Fig. 3).

At SWB, foaling rates in mares boosted with PZP by remote darting averaged 25.2% over 3 years (range 22.0–32.1%) versus 74.9% (65.4–79.4%) in untreated mares (Fig. 3*b*), i.e. foaling rates in booster-treated mares were reduced by 66% relative to those of untreated mares. In each year, foaling rates were significantly lower in treated mares than in untreated mares (Year 1, $\chi_1^2 = 19.46$, $P < 0.0001$; Year 2, $\chi_1^2 = 34.94$, $P < 0.0001$; Year 3, $\chi_1^2 = 20.00$, $P < 0.0001$). Mares darted with PZP-22–FIA showed lower foaling rates (averaging 17.8% across 3 years) than did mares darted with PZP–FIA emulsions alone (averaging 39.5% across 3 years), but there were no significant differences in foaling rates between the two treatment groups in any year.

Injection-site reactions were seen in 32 of 47 darted SWB horses (68.1%) observed in the weeks following darting. Of these reactions, 5–8 were draining abscesses (uncertainty owing to observation quality), of which at least five had resolved by the last time the horse was observed in the 2010 field season (15–52 days after darting). The remainder were swellings and granulomas averaging 2.75 cm (s.d. = 0.87 cm) in diameter. The two treatment types did not differ from one another in either the frequency of swellings and granulomas or in the frequency of draining abscesses.

At CM, hand-injected PZP boosters were also highly effective, with foaling rates of treated mares across 3 years averaging 14.9% (ranging from 7.0% to 20.0%) versus 67.5% (range 56.8–71.4%) for untreated females ≥3 years old, i.e. foaling rates in booster-treated mares were reduced by 78% relative to those of untreated mares (Fig. 3*a*). Treated mares had significantly lower foaling rates than did untreated controls in all years (Year 1, $\chi_1^2 = 30.09$, $P < 0.0001$; Year 2, $\chi_1^2 = 30.38$, $P < 0.0001$; Year 3, $\chi_1^2 = 35.03$, $P < 0.0001$). At CM, no consistent differences in efficacy emerged between the two treatment groups, and there was no significant difference in foaling rates between the PZP-22–FIA and the PZP–FIA-only group in any treatment year. No injection-site reactions were observed in hand-boosted mares.

Discussion

Mares hand-injected with PZP-22 primers generally demonstrated lower foaling rates than did untreated control mares. However, the effectiveness and longevity of PZP-22 were much lower at both CM and SWB than was reported in Turner *et al*. (2007) for wild horses in Clan Alpine. Several differences in manufacturing and protocol may account entirely or in part for the differences.

(1) *Treatment month of administration.* The 1-, 3- and 12-month pellet-release times were engineered to optimise effectiveness of vaccines delivered December to February. The highest 2-year efficacy of primers in the present study occurred when vaccinations were delivered in February (CM 2012), followed by vaccinations delivered in December (CM 2008), with those delivered in October (SWB 2008) being least effective. However, even with optimal administration timing, the efficacy levels observed in these trials following Year 1 did not match those observed at Clan Alpine, suggesting that timing alone is not a sufficient explanation for the differences.

(2) *Differences in timing of antigen release*. Subsequent *in vitro* testing of the heat-extruded controlled-release pellets of batches used in this trial was undertaken to ascertain whether changes in pellet-release characteristics originally described in Turner *et al*. (2007) and Turner *et al*. (2008)

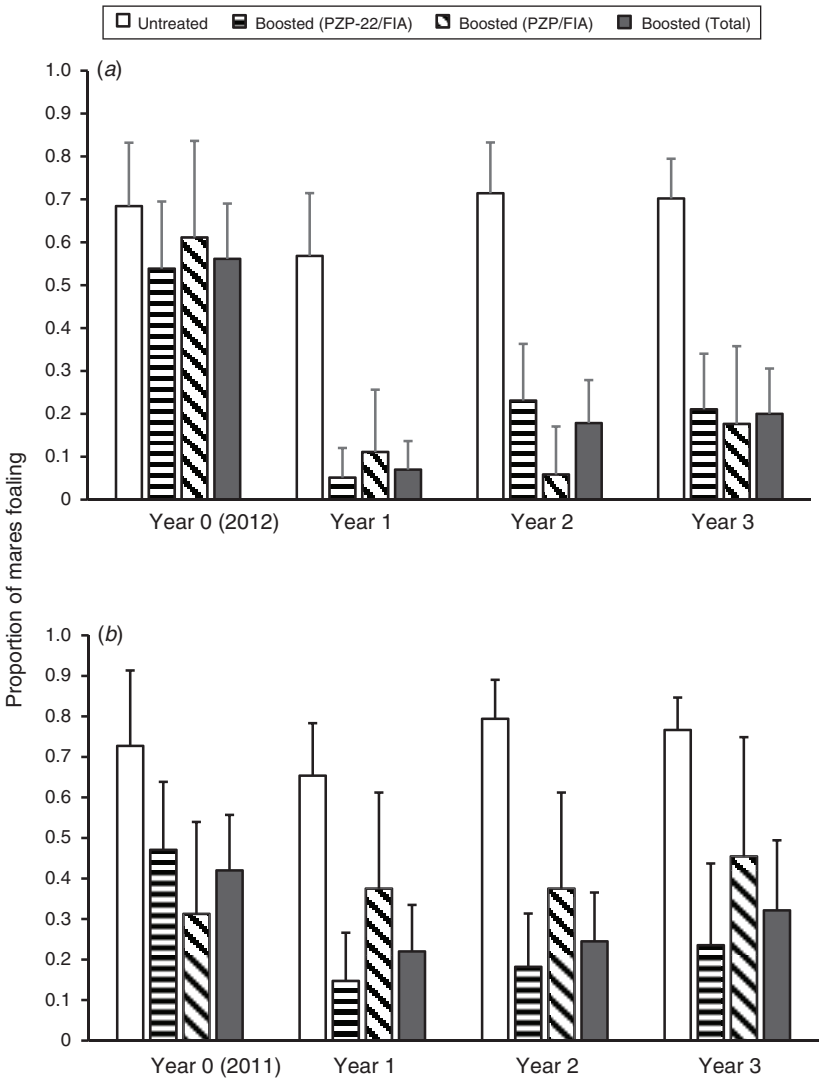

Fig. 3. Foaling rates in mares ≥3 years old. Error bars represent 95% CI. (*a*) Cedar Mountains herd-management area (HMA), UT, USA, following February 2012 administration of PZP-22–FIA or PZP–/FIA boosters by hand. Year 0 = 2012. (*b*) Sand Wash Basin HMA, CO, USA, following Autumn 2010 administration of PZP-22–FIA or PZP–FIA boosters by dart. Year 0 = 2011. Note that the Year 0 (2011) foaling rates for treated mares are the same as those for Year 2 in Fig. 2*c*.

contributed to suboptimal PZP-22 performance. Comparison of release characteristics of pellets produced before and after 2007 revealed that post-2007 pellets of the 12-month delay type released prematurely and more gradually than was expected (J. W. Turner, unpubl. data). Possible contribution of polymer-batch and pellet-manufacture variations to this circumstance are under investigation.

(3) *Method of injection.* PZP-22 at Clan Alpine was delivered by jab stick, and both the emulsion and pellet components were delivered together at the same injection site, whereas emulsion and pellets were delivered by two separate injections in all hand-injection protocols of PZP-22 followed in the present study. Although being an implausible explanation for the differences, this hypothesis also receives weak support from the improved PZP-22 efficacy relative to the PZP–FIA emulsion associated with dart delivery in booster trials (described below).

(4) *Difference in adjuvant.* PZP vaccine prepared before 2005 utilised FCA, and, thereafter, mFCA was used. Similar anti-PZP titer responses to primer-dose PZP treatment with these two adjuvants have been reported (Lyda *et al*. 2005). However, contraceptive efficacy was not determined, and it is possible that the antibody type and quality generated by these two adjuvants differed sufficiently to influence the immune memory generated by pellet-based boosters (M. Wooten, pers. comm.). In light of the limited future for FCA (related to tissue reactions and false-positive TB tests) and the promise of alternative multi-target adjuvants (e.g. Lu *et al*. 2015), comparison of mFCA with such novel adjuvants to address the above issue may be warranted.

Although the initial PZP-22 treatments tested in the present study showed disappointing effectiveness, a single PZP booster (either the PZP–FIA emulsion or PZP-22–FIA) effectively reduced fertility across three consecutive years. Whether delivered by dart, as at SWB in 2010, or by hand, as at CM in 2012, PZP boosters reduced foaling rates in treated mares by roughly 65–72% relative to untreated control mares over the 3 years. We do not know, because the studies had to be ended 3 years after boosting, whether some contraceptive effectiveness might persist into a 4th year.

Most previous research on PZP in western wild horses has presented data only on the effectiveness and longevity of the initial treatment (Turner *et al.* 1997, 2001, 2007). Working on wild horses at Little Book Cliffs Wild Horse Range, CO, USA, and the Pryor Mountain Wild Horse Range, MT, USA, Ransom *et al*. (2011) examined the relationship between the number of consecutive years of treatment (up to 4 years) with PZP emulsion boosters and the interval between the last booster and the first foaling. This interval ranged from 7 to 18 months, with some trend towards longer intervals as the number of consecutive years of treatment increased, although the sample size for 3 and 4 consecutive years of treatment was very small and the trend was not significant. In their study of reversibility of PZP treatments of wild horses at Assateague Island National Seashore, MD, USA, Kirkpatrick and Turner (2002) showed that most mares receiving two initial injections and up to one subsequent annual booster returned to fertility within 1 year, whereas mares receiving three or four consecutive years of treatment experienced delays of 3–4 years in return to foaling. Although our measures of the longevity of vaccine effectiveness differ from those used in other studies, namely annual foaling rates of treated mares relative to those of controls, rather than interval between last booster and first foaling, as used by Ransom *et al*. (2011) and Kirkpatrick and Turner (2002), our results appear to parallel those for Assateague mares receiving three or more consecutive years of treatment. Thus, even if the initial effectiveness of PZP-22 was low relative to previous studies, the combination of a PZP-22 primer and a single PZP booster appears to have yielded effectiveness comparable to three or more years of consecutive treatments (i.e. 4+ injections) of Assateague mares initially treated with the PZP–mFCA emulsion primer.

Our study failed to show that the addition of the controlled-release pellets to the PZP emulsion increased the efficacy and longevity of the booster. At CM, addition of pellets in hand-administration did not increase the efficacy or longevity of the PZP emulsion over the 3 years of the study. Dart delivery of the booster was associated with a doubling of efficacy across all 3 years at SWB, but because the sample is small, this test warrants replication.

Conclusions

Long-term management of wild horse populations with a non-invasive reversible contraceptive will require repeated treatments over the life of the wild mare. Thus, we believe that the research emphasis placed on the effectiveness and longevity of the primer vaccination may be misguided. The data presented here, as well as in Kirkpatrick and Turner (2008), suggest that population models should be constructed that allow for increased longevity of vaccine effectiveness with successive boosters. In practice, the initial application of contraceptives to a wild horse herd may produce only a modest reduction in population foaling rates, but sustained contraceptive applications over time could result in a much greater reduction in population foaling rates, even with current technology.

At Assateague, the initial management step was to treat every mare with a single primer of PZP–FCA emulsion (Kirkpatrick and Turner 2008). Although the primer alone was only somewhat effective as a contraceptive, subsequent boosting yielded increased effectiveness, and, ultimately, a reduction in herd numbers. This lesson needs to be applied in Western herds.

Also encouraging is the demonstration of management flexibility in PZP-22 application. First, the data suggest that the interval between initial and booster treatments, i.e. 2 years at SWB, and 3.2 years at CM, does not obviously influence effectiveness or longevity of the booster over the range of times tested. Second, the SWB data indicate that PZP-22–FIA can be effectively delivered remotely, at least matching the effectiveness of the PZP–FIA emulsion. However, until technical improvements and additional tests show that the controlled-release pellets significantly increase booster efficacy, managers can employ the much less costly PZP–FIA emulsion as a booster following administration of the PZP-22 primer.

Continuing to improve vaccine longevity is essential. The more individual mares are darted, the more difficult they become to re-treat (Kirkpatrick and Turner 2008; Naugle and Grams 2013). As the controlled-released pellets are refined, re-darting can be performed less frequently, making contraceptive control more cost effective.

Acknowledgements

The authors thank Amanda Conner, Kira Donnelly, Katie Guntly and Josh Irving for their work with darting and data collection at Sand Wash Basin; Aleta Wagner and Great Escape Mustang Sanctuary for corroborating foaling and identification data at SWB in 2014; and Ron Osborn of Wildwise Solutions for assistance applying WHIMS. Rick Naugle of HSUS and Pneudart® developed and tested the dart used to deliver the emulsion/pellet vaccine. The Science and Conservation Center, Billings, Montana, and Dr I. K. M. Liu supplied PZP for the study; preparation of the controlled-release pellets was conducted under the supervision of Dr D. R. Flanagan, University of Iowa, Iowa City, Iowa. We especially thank Gus Warr, Kathy McKinstry, Jerome Fox and the BLM Salt Lake and Little Snake field offices, and the Resource Management Division of the USA Army's Dugway Proving Ground. This study was conducted under the auspices of Tufts University IACUC protocols G949-08 and G2011-65, and was principally funded by a generous gift from the Annenberg Foundation to The Humane Society of the United States.

Range Relationships of Feral Horses with Wild Ungulates and Cattle in Western Alberta

R.E. SALTER AND R.J. HUDSON

Abstract

Spatial and foraging relationships between feral horses and coexisting ungulates were studied in the foothills of western Alberta. Distribution patterns of horses were compared to those of cattle, elk *(Cervus elaphus)*, deer *(Odocoileus hemionus* and *O. virginianus)*, and moose *(Alces alces)* using indices of spatial and habitat use overlap. Horses were more ubiquitous in their distribution than any other ungulate and utilized sites also used by other species. Lack of behavioural interactions and dietary differences suggested ecological separation of horses from deer and moose. Although horses and elk both used dry grasslands during winter and spring, competition for forage was minimal due to the low number of elk present. During spring horses occupied some areas later preferred by cattle but range use was not excessive prior to the turn-out of cattle. There was little contemporaneous spatial overlap of horses and cattle even though their summer diets showed 66% overlap. Potential for competition appeared highest between horses and cattle but grazing relationships were complex.

The growing body of knowledge concerning the ecology of feral horses includes several comparative studies on diets of horses, domestic stock and native ungulates (Hubbard and Hansen 1976; Hansen and Clark 1977; Hansen et al. 1977; Olsen and Hansen 1977). A commonly expressed rationale is the need to determine carrying capacities for various combinations of herbivores. However, dietary overlap is important only if accompanied by spatial overlap, if shared foods are in short supply, or if one herbivore limits access of another to a preferred food source. We report here results of a study to determine the extent of spatial, habitat use and dietary overlap between feral horses and other ungulates in western Alberta, and to determine levels of range utilization.

Authors are graduate student and associate professor, Dept. of Animal Science, University of Alberta, Edmonton, Alberta, T6G 2E3.

Financial support was through the Forest Development Research Trust Fund, Alberta Forest Service. The authors thank G. Erickson for field assistance during the initial phases of the study.

Manuscript received January 10, 1979.

Study Area

The study was conducted within 200 km^2 of the outer foothills of the Rocky Mountains approximately 30 km west of Sundre, Alberta. The predominant topographical feature was a series of roughly parallel, forested ridges rising to a maximum altitude of 1,900 m ASL. Lodgepole pine *(Pinus contorta)* dominated the forest cover. Meadow and shrub vegetation on a moisture gradient from flooded to dry covered approximately 20% of the study area, primarily in the valley bottoms and on south-facing slopes. Nine forested habitats, seven meadow/shrub habitats, and one miscellaneous (disturbed) habitat were identified (Salter 1978).

The area supported over 200 resident feral horses during the study. Harvestable populations of white-tailed deer, mule deer, and moose also were present year-round, although no estimates of numbers are available. A primarily cow-calf elk population estimated at approximately 50 animals used the area as winter-spring range. Cattle were present between June 15 and October 15 at a permitted stocking rate of 1,500 AUM.

Methods

Study Design

We considered late winter to be the critical period for survival of ungulates in this area (Salter and Hudson 1979), and thus focused on this period when determining spatial relationships.

Supplementary data on year-long distribution patterns of horses and native ungulates were obtained in summer, concurrent with data on cattle distribution. Literature available at the time of the study suggested forage competition would be most likely among the grazing ungulates (horses, cattle and elk) and thus only these species were included in dietary determinations. All quantitative data were obtained within two areas (total 30 km^2) considered representative of the study area as a whole.

Occupational Patterns

Occupational patterns were delineated by inspection of 983 temporary macroplots, each 15 m in diameter and spaced at 100-m intervals along straight line transects. Transects were located to provide representative coverage of major habitat types. Approximately one half of the plots were examined during January-March 1976, providing information on winter distribution of native ungulates and horses, while the remainder were examined from July-August 1976 for data on distribution of horses and cattle. Habitat type and presence/absence of sign of each species were recorded. Horse pellet groups were aged as spring type (amorphous, bleached and insect-riddled), fresh (moist, green), or unknown during the July-August surveys.

Food Habits

Diets were determined through analysis of fecal fragments. Fifty horse fecal samples were collected each month during 1976. Seventy-five fresh elk fecal samples were obtained during January-March (25 each month). Two hundred samples of cattle feces, representing deposition from mid-June to the date of sampling, were obtained in October. Each sample consisted of approximately 10 g of material. Composited samples were analyzed by the Composition Analysis Laboratory, Colorado State University.

Range use

An extensive survey method (Anderson and Currier 1973) was used to examine zones of utilization on all meadows within the areas covered by the macroplot surveys.

During October 1976 each meadow was traversed on foot in a zig-zag fashion, with sufficient coverage to determine the gross pattern of utilization. Use zones representing five classes of herbage utilization were mapped on enlarged aerial photographs and levels of use, stubble heights, and plant community types were recorded for each zone. A 70 ha area that constituted an important winter-spring range for elk and feral horses and a summer range for cattle was re-mapped on June 1, 1977, to establish level of use by feral horses and native ungulates during spring; remaining meadow areas also were re-examined (without mapping) during late May-early June, 1977.

Statistical Analysis

Distribution of sign on the macroplots was used as a measure of habitat occupancy. All analyses were based on presence/absence of sign (as opposed to absolute abundance) to avoid the assumptions of equal visibility and equal rates of disappearance among habitats and among species. Distribution in relation to habitat availability was examined using chi-square tests. A coincidence index and an association index (Dice 1945), and a coefficient of association (C_8: Hurlbert 1969), were used to evaluate the extent of mutual use of plots by horses and each other herbivore. Coincidence indices provide a measure of how much of the combined area used by two species sustained mutual use (i.e., what proportion of sites used by either species a or b were used by both). Association indices indicate the degree of overlap (i.e., what proportion of sites used by a were used by b, and vice-versa). C8 values provide a frequency independent measure of association.

Diets of horses were compared to those of cattle and elk using Kulcyznski's similarity index (Oosting 1956), which indicated what percentage of a pair of diets was identical, and Spearman's rank order correlation coefficient (Nie et al. 1975), which indicated to what degree forages were chosen in the same order by a pair of herbivores. One or both of these procedures have been used in previous studies of the interactions of feral horses with other ungulates (Hubbard and Hansen 1976; Hansen and Clark 1977; Hansen et. al. 1977; Olsen and Hansen 1977) and thus provide a standard means of comparison.

Results

Horse-Deer Relationships

On a year-long basis horses used 87% of sites used by deer (primarily mule deer, although some white-tailed deer were present), while deer used 33% of sites sustaining use by horses (Fig. 1). However, during winter horse sign occurred on only 25% of sites used by deer. Deer sign occurred on plots in white spruce woods much more frequently than expected, and in dry grasslands and mixed shrub and dwarf birch meadows much less frequently than expected, contrasting with the pattern of winter habitat selection by horses, which avoided white spruce woods and used meadow habitats in proportion to availability (Table 1).

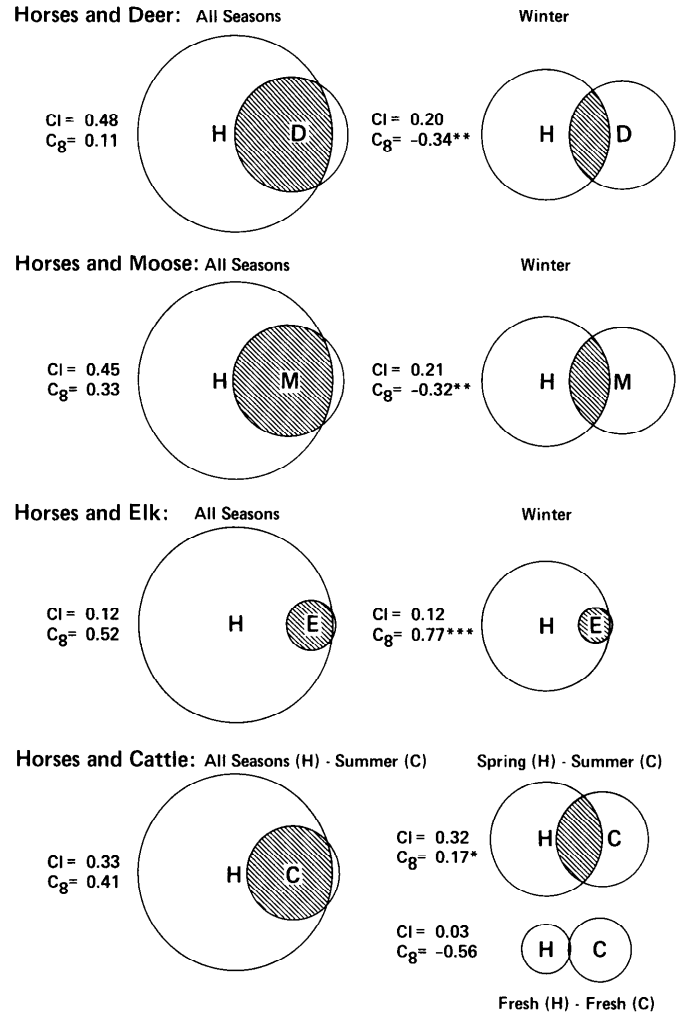

Fig. 1. *Diagramatic representation of spatial overlap of feral horses with native ungulates and cattle. Circles are drawn to scale based on frequency of occurrence of sign in macroplots examined during January-March and July-August, 1976. Proportions of plots receiving mutual use (calculated as association and coincidence (CI) indices) are represented by cross-hatched areas. Each C_8 value provides a frequency indepdent measure of association that was evaluated by chi-square probability of obtaining a greater x^2 value give as: *0.05≥p>0.01; **0.01≥p>0.005; ***p≤0.005). C_8 can vary from -1 to +1, a zero value indicating that two species are associated as expected by chance. Coincidence and association indices can vary from 0, representing no association, to +1, representing complete overlap.*

Table 1. Distribution of feral horse and native ungulate winter sign by habitat type.[1]

Habitat type	Percent of sampled plots in habitat type (n=490)[2]	Percent of plots containing sign in habitat type			
		Deer (n=126)	Moose (n=126)	Elk (n=14)	Horse (n=185)
Dwarf birch meadow	5.3	0.0⁻	7.1	14.3	6.5
Mixed shrub meadow	8.5	2.4⁻	18.2⁺	0.0	11.4
Willow thicket	2.6	0.8	6.3⁺	0.0	3.8
Dry grassland	7.5	0.8⁻	5.6	50.0⁺	9.7
Dwarf birch thicket	3.2	0.8	7.9⁺	0.0	4.3
Mesic pine woods	1.2	2.4	0.0	0.0	0.5
Dry pine woods	14.4	15.1	19.0	7.1	6.0⁻
Black spruce woods	3.0	1.6	2.4	0.0	3.8
White spruce woods	7.1	18.2⁺	4.0	0.0	2.2⁻
Poplar woods	4.2	3.2	0.8	14.3	7.6⁺
Mixed woods	12.8	15.9	12.7	14.3	14.0
Alder thicket	26.8	35.7	15.1⁻	0.0	27.0
Forested watercourse	1.8	1.6	0.0	0.0	2.7
Total χ^2		54.6	53.0	44.5	29.0

[1]Based on presence/absence of tracks or pellet groups in plots examined during January-March 1976. Habitat types contributing 10% or more to significant total x^2 values are underlined and marked ⁺ or ⁻ to signify preference or avoidance by each species. Value of χ^2 at p=0.05 is 26.3.
[2]Other habitats each comprising less than 0.5% of the total sample were sedge meadow, silver-berry thicket, alpine fir woods and disturbed sites.

Dietary overlap of horses and mule deer was not determined during this study, but reports from other areas indicate that little similarity would be expected. In three studies conducted in Colorado, annual diet similarity ranged from one to 11% and was usually less than 5% (Hubbard and Hansen 1976; Hansen and Clark 1977; Hansen et al. 1977).

Horse-Moose Relationships

On a year-long basis horses used 90% of sites used by moose, but overlap during late winter decreased to 25% (Fig. 1).

Although moose preferred mixed shrub meadows, dwarf birch thickets and willow thickets—habitats also frequented by horses (Table 1)—observations suggest separation of the two species on the basis of food selection. Moose were most commonly observed in February, when they browsed during morning in extensive shrubby meadows. Although meadow areas also were utilized for winter feeding by horses, different foods were chosen. The lack of direct evidence of browsing by horses was confirmed by fecal fragments analysis, sedges and grasses proving to be the most important dietary constituents (Table 2). An observation on February 12, 1976, of an adult moose and five horses feeding within 25 m of each other in a mixed shrub meadow—the moose on shrubs protruding above the snow and the horses pawing for sedges and grasses—suggests ecological separation of these two species during winter even in shared habitats.

Moose rely primarily on browse throughout the year, although grasses occur in the spring and summer diet (Banfield 1974). No comparative studies of horse and moose diets have been reported, but Storrar et al. (1977) found significant ecological separation of the two species in central British Columbia and believed that this was due primarily to differing food habits.

Horse-Elk Relationships

Horses used 93% of sites occupied by elk, whereas elk utilized only 6% of sites used by horses (Fig. 1), reflecting the wider dispersion and greater numbers of the latter within the study area. A similar situation occurred in winter, when there was a highly significant association between the two

Table 2. Percentages of plants in seasonal diets of feral horses, elk, and cattle.

Forage category	Late winter diets (Jan.-Mar.)		Summer diets (June-Oct.)	
	Horse	Elk	Horse	Cattle
Timber oat grass *(Danthonia intermedia)*	1	1	3	5
Tufted hair grass *(Deschampsia caespitosa)*	1	–	2	7
Hairy wild rye *(Elymus innovatus)*	28	19	26	7
Fescue *(Festuca* spp.)	15	21	23	41
Bluegrass (*Poa* spp.)	1	–	4	2
Sedge (*Carex* spp.)	35	9	34	27
Wire rush (*Juncus balticus*)	4	–	2	<1
Cinquefoil-avens (*Potentilla-Geum* spp.)	<1	2	<1	3
Lodgepole pine (*Pinus contorta*)	5	22	1	<1
Willow (*Salix* spp.)	<1	19	–	<1
Horsetail (*Equisetum* spp.)	3	<1	<1	–
Moss	3	–	<1	2

Other foods (<3%) in horse, elk and cattle diets were *Koeleria cristata* and *Schizachne purpurascens;* in horse and elk diets *Astragalus frigidus, Picea* spp., *Shepherdia canadensis-Elaeagnus commutata* and lichen; and horse and cattle diets *Agrostis scabra, Agropyron* spp., *Bromus* spp., *Calamagrostis* spp., *Stipa* spp. and *Vicia americana.*

Table 3. Percentages similarities and rank correlations of seasonal herbivore diets.

Diets	Percentage similarity	RHO values	p values[1]
Horse winter–elk winter	51	+0.38	0.011
Horse spring–cattle summer	67	+0.57	0.001
Horse summer–cattle summer	66	+0.57	0.001

[1]Two-tailed test.

species. During this time elk exhibited a preference for dry grassland habitat, as shown by a higher than expected frequency of sign (Table 1) and by observational data. Nine sightings of elk involving some 84 animals were made during February and March, all but two of these of herds feeding on south-facing grassland slopes. Horses were observed feeding on the same slopes at this time (22 sightings, January-March). Evidence of mutual use of winter habitat also was found in two small dwarf birch meadows, where it appeared that elk had followed horses into the area to feed in the same craters. Due to the paucity of elk sign in the study area as a whole, it was not possible to determine the extent of this relationship, or whether it represented commensalism or competition. Winter diets of the two species had some similarity (Tables 2, 3). Hairy wild rye *(Elymus innovatus),* fescues (*Festuca* spp.), and sedges (*Carex* spp.) were important shared constituents. Both coniferous and deciduous browse were important in elk diets but were little used by horses.

The level of dietary overlap between horses and elk was comparable to that occurring in other areas. In Wyoming, horse diets overlapped with those of elk by 52% in winter, 26% in spring, 14% in summer and 70% in fall (Olsen and Hansen 1977), while in northwestern Colorado dietary overlap of the two species averaged 42% on an annual basis (Hansen and Clark 1977).

Horse-Cattle Relationships

Over 90% of sites utilized by cattle in summer had received prior use by horses (Fig. 1). About 40% of these sites were used by horses in spring; the remaining 50% were used in winter or during an undetermined season. However, there was little overlap during the time when cattle were actually present, the coincidence and association indices being low and the C_8 value negative (although not statistically significant) when only fresh feces were considered.

Cattle utilized the dwarf birch thicket, willow thicket and dry grassland habitat types more frequently than expected, and the alder thicket types less frequently than expected from their availability within the study area (Table 4). All habitats except dwarf birch meadow were used to some extent. The general pattern of avoidance of the wettest habitats and concentration on dry, open sites, including roadsides, was confirmed by direct observation of cattle.

Horse and cattle diets during the period of cattle occupancy overlapped by nearly 70% (Table 3). Fescues and sedges together constituted over 50% of the horse diet and nearly 70% of the cattle diet during this time; the two diets differed chiefly in that horses ate more hairy wild rye (Table 3), indicating a greater use of forested habitats. However, open habitats—chiefly mixed shrub meadows—appeared to supply most of the forage utilized by horses throughout the summer.

In order to determine whether horses ate preferred cattle foods in spring, prior to arrival of cattle on the study area, comparisons were made between the April-May diet of horses (Salter and Hudson 1979) and the late June-early October diet of cattle. This pair of diets was 67% identical, although the order of the two most important forages was reversed—sedges being most important in the horse diet and fescues being most heavily utilized by cattle.

The high levels of similarity between the diets of horses and cattle agree with results of other studies of these two species (Hubbard and Hansen 1976; Hansen and Clark 1977; Hansen et al. 1977; Olsen and Hansen 1977).

Effects of Combined Range Use

By late summer 75% of nonforested habitat was used at a safe or lower level, most of the remaining 25% receiving heavy utilization (Table 5). This pattern varied according to habitat type. Dry grassland clearly received the heaviest use

Table 4. Distribution of feral horse and cattle pellet groups by habitat type.[1]

Habitat type	Percent of sampled plots in habitat type (n=493)	Percent of plots containing all age pellet groups in habitat type	
		Cattle (n=92)	Horse (n=417)
Dwarf birch meadow	2.4	0.0	2.4
Mixed shrub meadow	6.3	9.8	7.0
Willow thicket	1.6	8.7$^+$	1.0
Dry grassland	4.1	15.2$^+$	4.8
Dwarf birch thicket	2.2	12.0$^+$	2.6
Dry pine woods	20.4	15.2	19.2
Black spruce woods	2.4	2.2	2.9
White spruce woods	4.3	3.3	3.8
Poplar woods	3.9	6.5	4.3
Mixed woods	16.9	16.3	18.4
Alder thicket	32.9	5.4$^-$	31.4
Disturbed sites	1.0	4.4	0.7
Forested watercourse	1.4	1.1	1.4
Total χ^2		150.5	5.0

[1]Based on presence/absence of pellet groups in plots examined during July-August 1976. Habitat types contributing 10% or more to significant total χ^2 values are underlined and marked $^+$ or $^-$ to signify preference or avoidance by each species. Value of χ^2 at $p = 0.05$ is 21.0.

Table 5. Degree of grazing utilization on nonforested habitats, mid-October, 1976.

Habitat type	*Percent of habitat in use class*[1] None-very light	Light	Safe	Heavy	Severe	Habitat area (ha)	Percent of total
Dwarf birch meadow	73.3	20.8	3.9	2.0	0	68.9	17.5
Sedge meadow	34.7	38.8	22.4	4.1	0	4.9	1.2

Miscellaneous	0	0	0	83.3	16.7	0.6	0.2
Total area (ha)	71.4	109.3	117.2	88.7	7.3	393.9	100.0
Percent of total	18.1	27.7	29.8	22.5	1.8	99.9	

[1]None-very light: 0-15% of herbage biomass removed; light: 16-35% removed; safe: 36-65% removed; heavy: 66-80% removed; severe: >80% removed, plants grubbed, trampling damage evident.

and dwarf birch meadows the lightest, although grazing occurred in all habitats. Combined grazing by horses and cattle caused localized damage along stream courses and around both natural and artificial salt licks (category Miscellaneous, Table 5).

With the exception of some stream courses, wet and mesic habitats generally received limited utilization in summer, in direct contrast to the situation for dry grasslands, dwarf birch thickets and willow thickets—all preferred cattle habitats—which together received the heaviest grazing use. At the end of the summer grazing season, nearly half of the dry grasslands were heavily grazed and nearly all had received some degree of use. Although residual biomass was not measured, stubble heights (usually less than 5 cm) indicated that forage available on these areas over winter had been severely reduced. This also was true to a lesser extent for the closely associated dwarf birch thicket type.

In contrast, intensive examination of an important winter-spring range (and cattle summer range) showed that utilization of new growth was none to very light over 95% of the 70 ha area just prior to the cattle turn-out date. Concentration of foraging activity in other areas resulted in localized grazing and trampling damage (primarily in wet habitats) during spring, but evidence of spring grazing was found on less than 5% of total meadow habitat.

Discussion

A primarily descriptive approach was adopted in this study toward determination of spatial, habitat use and dietary relationships of feral horses with coexisting herbivores. It is recognized that when viewed superficially indications of spatial and food habits overlap may be taken as evidence either for or against competition (Sale 1974; Hudson et al. 1976). Overlap may be functionally synergistic, at least in some grazing systems (Bell 1971). Although measures of resource use overlap can only indicate the degree of similarity between species, and do not measure competition directly, the degree of competition and the amount of overlap are directly related when food is in short supply (Sale 1974). Thus, the extent of actual or potential competition can only be inferred when the use of food and space, the level of range utilization and the behaviour and physical condition of the animals are considered together rather than in isolation (e.g., Wilkinson et al. 1976). In the present study, evidence of competition was sought from the condition of the range and from behavioural interactions, interpreted in light of knowledge of spatial and dietary relationships.

Association and coincidence indices revealed the basic spatial relationships between feral horses and other ungulates. Perhaps the most interesting finding was the high frequency of occurrence of multi-season horse pellet groups as compared to those of other species. This may indicate a broad niche and non-specialist strategy of habitat occupation by horses, although their seasonal distribution was decidedly non-random. Diagrammatic representation of spatial relations showed that, on a year-long basis, horses overlapped extensively onto the areas used by all other species. However, consideration of seasonal distribution indicated that much of this overlap was noncontemporaneous.

Strongly expressed competitive interference (i.e., one species blocking another's access to a limited resource) or exploitation (depletion of the food resource by one species) would influence the interpretation of spatial relationships. Behavioural observations provided little evidence for competition through interference in this grazing system (cattle, mule deer, elk and moose all were observed feeding in proximity to feral horses without interaction), but dietary similarities and spatial overlap indicated the potential for exploitation of elk and cattle foods by horses. In contrast, feral horses would be not expected to exploit the food resource of browsing herbivores (moose, mule deer and white-tailed deer), which utilize herbage primarily during early growth stages in spring and summer (Banfield 1974).

The ability of elk to subsist on browse (Kufeld 1973) makes the importance of forage competition between elk and horses difficult to evaluate. Some shared winter foods (hairy wild rye, sedges) were abundant within extensive habitats (Salter 1978). Horses and elk both also used fescues during winter, but although these grasses were in short supply due to previous heavy grazing the extent of competition for them was minimized by the low numbers of elk present. Elk and horses (and to a lesser extent mule deer, white-tailed deer, and moose) utilized succulent green herbage during April-May, but the low incidence of grazing in nonforested habitats indicated that food was being produced more rapidly than it was consumed; in this situation no competition for food occurs (Sale 1974).

Similarly, spring grazing by horses did not deplete ranges preferred later in the season by cattle, but certain common use areas (primarily dry grasslands and dwarf birch thickets) were overgrazed by autumn. Heavy use of these habitats indicated that competition for some forages may have occurred late in the cattle grazing season.

Fescues were likely the key species in competitive

relationships; of the major shared forages they were the only ones confined largely to the heavily used dry grassland and dwarf birch thicket habitats. Their depletion also may have affected subsequent (winter) distribution and food selection by both horses and elk, but whether there was any effect on population productivity could not be determined. All other shared forage species were widespread and were not overutilized during any season of the year.

While these conclusions are valid for the patterns of resource use documented during the study, the complex and labile nature of range relationships needs to be emphasized. For example, the use of previously grazed areas by several species in spring illustrated a feedback effect of previous grazing resulting in increased availability of succulent forage early in the next growing season. Conversely, large areas of meadow habitat of apparently similar species composition were ungrazed throughout the year. The stability of this grazing pattern (i.e., the period over which certain areas are heavily grazed, while others remain ungrazed) could not be determined from the information available. This would be influenced by extrinsic factors such as location of artificial salt licks, alterations in cattle distribution through increased management, and control of feral horse numbers.

MAKE YOUR IMPACT STUDIES MORE IMPRESSIVE THAN EVER.

With aerial photographs and a Bausch & Lomb ZOOM TRANSFER SCOPE™ instrument, you can map and plan land use studies quickly, economically, simply.

The Z.T.S.® instrument optically mixes aerial photographs and data base without projection, without expensive darkroom equipment.

It compensates for distortion.

It is compact, lightweight, simple to operate. And much more.

We'll be happy to recommend the instrument that's best for your needs. Call us at (716) 338-6000. Or send coupon for illustrated brochure.
